There is uncertainty regarding the role of surgery. CT- or MR-based stereotactic biopsies are performed in many-centers. Tertiary neurosurgical hospitals advocate complete tumor resection. Radiation therapy to the pineal region and the craniospinal axis is provided to patients with high-grade neoplasms, residual tumor after surgery, and subarachnoid dissemination. Chemotherapy is used in the setting of pineoblastoma or parenchyma) tumors that are disseminated at onset or at recurrence. Commonly, preirradiation chemotherapy reduces tumor size. As with other neuroblasts tumors (esthesioneuroblastoma, mcdullobla stoma, PNET), platinum-based compounds are used, usually in combination with etoposide, alkylating agents (CCNU, PCZ, cyclophosphamide), or vincristine. Long-term responders are reported, but estimates of survival are based on literature reviews or small retrospective institutional series.

Peripheral Neuroblastic Tumors

Esthesioneuroblastoma

Esthesioneuroblastoma arises from the neuroepithelium of the upper nasal cavity. From there it invades the neurocramum through the cribriform plate, compresses the frontal lobes of the brain, and may infiltrate the brain parenchyma or subarachnoid spaces. A standardized therapeutic approach has not been established. Frequently, gross total resection via a craniofacial approach is followed by

adjuvant external beam radiation therapy unless the tumor is excised completely or is low grade (Eich ct a I. 2001). Because gratifying responses are seen with chemotherapy, patients with disseminated or recurrent disease and those with high-grade tumors are treated with combinations such as cisplatin-etoposide, cyclophosphamide-vincristine-doxorubicin, or alternating cycles of cisplatin-etoposide and cyclophosphamide-vincristine (McElroy et al. 1998). Advocates of radiation and chemotherapy prior to surgery cite decreased tumor burden and facilitation of gross total removal with decreased morbidity as benefits of this approach. Others recommend chemotherapy with cisplatin and etoposide after biopsy, followed by radiosurgery and postradiation chemotherapy.

Patients with low-grade tumors have progression-free survival exceeding 10 years, in comparison with less than 3 years for those with more aggressive tumors. Not uncommon are late local recurrences or metastases to cervical lymph nodes. When the tumor invades through the dura into the subarachnoid space, intrathecal methotrexate, cytosine-arabinosidc, or thio-TEPA may be used. Radiation is administered to symptomatic or nodular leptomeningeal recurrences,

Embryonal Tumors

Medulloblastoma

Medulloblastomas in adults are rare neoplasms. The majority of patients present before 40 years of age. Unlike childhood tumors, these are prone to the cerebellar hemispheres, less commonly in contiguity with the fourth ventricle. As a result, dissemination into the CSF is seen in fewer than one third of cases. In general, the natural history is less aggressive: Extraneural metastases have been reported in fewer than 150 patients, and then most frequently to bone (Chan et al. 2000). Multidisciplinary management is critical for the successful treatment of these tumors. Resection, craniospinal radiation, and adjuvant chemotherapy results in 10-year survival rates of *56%.* Obstructive hydrocephalus is a frequent complication of medulloblastoma. Ventrieulo-pcritoncal shunting is provided to symptomatic patients with occlusion of the fourth ventricle and dilatation of lateral ventricles. Often a filter is placed into the distal end of the shunt tubing to reduce the risk of peritoneal dissemination of tumor. Resection is followed by evaluation of CSF and lumbar spine for tumor spread, and craniospinal irradiation (posterior fossa 56 Gy, whole-brain 36 Gy, and spine 30-36 Gy). Chemotherapy benefits high-risk patients with significant residual tumor, brainstem infiltration, or leptomeningeal metastasis. Commonly used drugs cither prior to or following irradiation include cisplatin, cyclophosphamide, nitrosoureas, and etoposide. The Pediatric Oncology Group pioneered the use of alternating cycles of cisplatin (90 mg/m^2 on day 1 or 20 mg/m on days 1-5) and etoposide (100 mg/m on days 1-5) with cyclophosphamide (between 450 and 1580 mg/m on days 1 and 2) and vincristine (1.5 mg/m day 1). Rational administration of these drugs provides for their use before irradiation because craniospinal irradiation limits bone marrow reserve and the incidence of leukoencephalopathic complications is higher when chemotherapy follows radiation. However, radiation therapy should not be delayed by extended periods of myclosuppression from chemotherapy. Whether to offer prophylactic chemotherapy to low-risk patients is uncertain. Ultimately this issue will he addressed by formal study, but drugs are easily provided at diagnosis, and even "low-risk" patients are **seldom** cured, with relapse occurring years after initial diagnosis. Treatment of tumor recurrence after multimodality therapy is extremely difficult. Re-resection or SRS may be offered to selected patients. Alkylating agents are effective, and high-dose chemotherapy followed by stem cell rescue may benefit young patients.

Supratentorial Primitive Neuroectodermal Tumors

Supratentorial PNETs arc rarer than medulloblastomas. Well-delineated tumors with minimal residual tumor after surgery have a favorable prognosis. Surgical resection establishes the diagnosis and reduces the tumor burden. Adjuvant therapy consists of fractionated external beam radiation to the primary site and the craniospinal axis. However, because many of these masses are sensitive to chemotherapy, many centers have begun to treat high-risk patients with low-dose radiation in conjunction with chemotherapy. Drugs used include the PCV combination, cisplatin-etoposide alone, or alternating with cyclophosphamide-vincristine. Toxicity to bone marrow, gastrointestinal tract, and kidney accompanies the latter regimen, and thus these agents are provided prior to radiation therapy. Survival may exceed 5 years, but many patients succumb to their disease within a few years. Whether intrathecal chemotherapy with ara-C, methotrexate, or thio-TEPA confers any benefit to the patient with leptomcninge.il spread is uncertain. Treatment failure usually occurs locally. At recurrence, re-resection and salvage chemotherapy can be offered.

Tumors of Cranial and Peripheral Nerves

Schwannoma and Neurofibroma

Schwannomas and neurofibromas are benign tumors of the peripheral nerve sheath. Intracranial schwannomas arise commonly from the sensory branches of cranial nerves such as the acoustic or trigeminal nerves. However, these rarely occur within the parenchyma of cortex or medulla. Schwannomas most commonly affect the vestibular division of the eighth cranial nerve and may result in hearing

loss, vertigo, and facial numbness. However, the majority arc without symptoms and thus arc undetected. Small and stable asymptomatic tumors arc commonly followed with serial MRI scans on an annual basis. Symptomatic tumors are treated with microsurgical resection or SRS. Surgical risks include postoperative CSF leak, facial and trigeminal neuropathy, and deafness. These risks are directly related to tumor size (Kaylie et al. 2001}. The use of proton radiosurgery or fractionated SRT achieves tumor "control" without disappearance in more than 90% of patients, with hearing complications in approximately 20% (Harsh et al. 2002). Only a small fraction of schwannomas undergo malignant degeneration.

Malignant Peripheral Nerve Sheath Tumor

Malignant peripheral nerve sheath tumor (MPNST) is a rare neoplasm of peripheral nerves, including cranial nerves. Wide surgical excision is the treatment of choice, Average extent of resection depends on tumor location and ranges from 20% in paraspinal nerve root and plexus masses to nearly 100% in tumors of the distal extremities. Radiation therapy is provided for residua! disease in the form of external beam radiation alone or in combination with brachytherapy (iridium-192) or intraoperative high energy electron irradiation. Although amputation has been historically offered, these approaches have improved limb-sparing control. Twenty to forty percent of patients are treated with adjuvant chemotherapy at diagnosis (MESNA, doxorubicin [Adriamycin], ifosfamide, and dacarbazine, or single-drug regimens such as high-dose methotrexate). No • link/.! trials have been published and chemotherapy does not have a role in the initial treatment of completely resected MPNST.

Treatment failure in half the patients is local within 3 years, but late local recurrences at 25 years have been described. The median survival exceeds 2-5 years. Tumor size, extent of surgery, and age at diagnosis are predictors of survival.

Meningeal Tumors

Meningioma

Meningiomas are the most common nonglial intracranial tumors. These tumors have been found incidentally in 20% of autopsy series and affect women more than men. Management depends on location, coexistent motbidities, and the patient's age and health (Chamberlain 2001). Incidentally found asymptomatic meningiomas lacking mass effect or compression of a venous sinus can be followed conservatively with serial MRI evaluations. Many meningiomas will not grow over years, sparing older adult patients the need for craniotomy (Black et al. 1998). However, when seizures occur (20% risk), tumors grow (approximately one third of patients), or focal signs emerge, surgical resection can be curative, especially in meningiomas overlying the hemispheres. Although highly vascularized, preoperative embolization is usually not necessary. Technically more challenging are tumors invading dural venous sinuses, tumors arising from the dura overlying the medial portions of the sphenoid bone or other parts of the skull base, meningioma en plaque, posterior fossa meningiomas, and the rare intraventricular meningiomas. Complete surgical removal may not be possible in these situations and may be complicated by infection, CSF leakage, cerebral venous thrombosis, or cranial neuropathies. Less aggressive surgery in association with stereotactic radiation reduces treatment morbidity and may improve progress ion-free survival (Villavicencio et al. 2001). At recurrence or tumor progression, conventional external beam irradiation or SRS are the major treatment options.

Atypical (6%) and malignant meningiomas (2%) account for a small fraction of all meningiomas, but these tumors recur in spite of surgical resection and irradiation. Although meningiomas express estrogen and progesterone receptors, clinical trials with tamoxifen or progesterone receptor antagonists such as mifepristone (RU-486) have been disappointing. Some authors have reported partial responses or stable disease in patients with recurrent or malignant meningioma who receive hydroxyurea, alpha interferon, or drug regimens such as cyclophosphamide/ doxorubicin vincristine, ifosfamide/MESNA, or doxorubicin dacarbazine.

Hemangiopericytoma

Intracranial hemangiopericytoma, often confused **with** meningioma on imaging studies, is a rare meningeal neoplasm. Its high rate of local recurrence and predisposition to metastases to bone and liver make it unique in mcningeal-based neoplasms. Leptomcningeal spread has been described as have recurrences beyond 5 years of diagnosis. Gross total resection emphasizes removal of surrounding normal dura or brain. Radiation therapy (fractionated to 48-60 Gy) reduces the local recurrence rate and prolongs the progression-free and overall survival (Rastin et al. 1992). Unfortunately, as with meningioma and schwannoma, tumor shrinkage cannot be expected until years after therapy.

At tumor recurrence, options include surgical resection, conventional external beam radiation, and SRS. Chemotherapy may benefit the patient with systemic metastases or local therapy-refractory disease, but data are not available (Galams et al. 1998). Most protocols use doxorubicin in combination with cyclophosphamide, ifosfamide, cisplatin, and/or dacarbazine. Partial responses or stable disease for several months have been observed with these regimens. Up to 90% of tumors recur locally or systcmically within 9 years of initial manifestation.

Extraneural recurrence is predictive of worsened prognosis. Median survival after first tecurrcnce is between 4 and 5 years, but with aggressive management, long-term survival is possible.

Ncuraxis Tumors Derived from the Hematopoietic System

I'rimary Central Nervous System Lymphoma

Non-AIDS Related Disease. PCNSI, is a highly aggressive tumor. Left untreated, most patients succumb within *6* months. As with most brain malignancies, young age (younger than 60) conveys improved prognosis. Unfavorable prognostic factors include older age, low performance status, multiple brain lesions, evidence of leptomeningeal dissemination, lack of radiographic complete response to treatment, and elevated serum lactate dehydrogenase level. Methotrexate-based chemotherapy given in high doses (above 3.5 g/m^1) followed by leucovorin rescue has been shown to be the single most effective treatment for PCNSI,. Its introduction, either alone or in combination before radiation therapy, has resulted in response rates of 70-95% and survival durations in excess of 3 years. The treatment produces no alopecia, minimal to modest myelotoxicity, and is compatible with normal cognitive function. Other potentially efficacious agents include ara-C, rhio-TEPA, cyclophosphamide, ifosfamide, BCNU, PCV, CCNU, PCZ, temozolomide, and topotecan. Polychemotherapy tcgimens include inelkolitwalc. K.Z-, .i:id vn\ i ist ire with radiation therapy, and postradiation ara-C. Virtually all regimens share response rates and durations of response that are comparable to those provided by methotrexate monotherapy. However, combination regimens are associated with highet tisks of myelotoxicity and radiation-containing regimens increase the likelihood of clinically significant neurotoxicity, especially in older adult patients. Intraarterial administration of chemotherapy preceded by disruption of the BBB with manmtol is effective, but requires two-vessel angiography and general anesthesia with each treatment. The administration of intrathecal or intraocular chemotherapy is of uncettain benefit. High-dose intravenous methotrexate results in cytotoxic drug levels within the CSF and in the aqueous and vitteous humor of the eyes. However, high tumor burden within CSF may be associated with methotrexate resistance and thus intrathecal chemotherapy may postpone the need for craniospinal irradiation.

WBRT is now commonly deferred until the time of recurrence, given the high incidence of neurotoxicity, especially in patients older than the age of 60. Above doses of 35-45 Gy, escalation provides no survival benefit. Failures of radiation therapy occur within months and within the radiation field. Similarly, surgical resection provides no survival benefit and thus only biopsy is performed to establish the diagnosis.

In spite of major progress, there is still a need for refinement of therapy. This reflects several noteworthy features of the current natutal histoty: Most patients relapse, systemic dissemination is encountered in up to 8%, and the underlying hematogenous origin of the tumor is uncertain. At the time of recurrence there is likely benefit for retreatment. We have successfully used methotrexate at the time of relapse even in prior methotrexate recipients. Anecdotal responses at the time of relapse have also been reported with the use ci topotecan, NIU\II:LI1> (a chimerit antibody targeting CD20), temozolomide, PCV, or cytosine-arabinoside/etoposide, as well as intensive chemotherapy supported by autologous or allogeneic peripheral blood stem cell transplantation, WBRT is an option for patients who either fail or are not candidates for salvage chemothctapy. Meningeal or ocular relapse can be treated with radiation and chemotherapy (intrathecal or intravitreal).

AIDS-Related PCNSL. Patients with the acquited immunodeficiency syndrome (AIDS) develop PCNSL in the advanced stage of their disease. A severely compromised immune system and concomitant opportunistic infections frequently preclude chemotherapy. Thus WBRT has been the standard treatment for PCNSI. in AIDS patients. This approach has been associated with poor and nondurable responses. A subset of patients with low HIV burden and high CD4 T-cell counts are eligible to receive chemotherapy, The introduction of highly aggressive antiretroviral therapy has increased the patients in this category while reducing the incidence ot brain lymphoma.

Germ Cell Tumors

Germ cell tumors of the CNS are rare adult tumors (less than 0.1% of primary brain tumors) occurring commonly before the age ol 20 years. Nine times more common in Asia, the most common germ cell tumor occurring within the CNS is germinoma, which shares a common histology with testicular seminoma and ovarian dysgerminoma. Less common are nongerminomatous germ cell tumors (teratoma, embtyonal carcinoma, yolk sac tumor [endodermal sinus tumorl, choriocarcinoma, and mixed germ cell tumors). The entire group has a proclivity for the sellar and suprasellar region, walls of the third ventricle, and the pineal gland. Surgical access u difficult and often limits intervention to biopsy or empiric radiation/chemotherapy. The latter approach is usually avoided, given the high incidence of mixed neoplasms. Treatment planning depends on careful analysis of resected tissue, often with evaluation of serologic and CSF levels of ,8-human chorionic gonadotropin, a-fetoprotein and placental alkaline phosphatase. The major determinants of outcome are local tumor control and histological subtype. Treatment schedules are still being optimized.

Germinoma

Germinomas are infiltrative tumors with a tendency to subependymal and leptomeningeal spread. Traditionally, treatment has included surgical resection or biopsy followed by radiation therapy. The radiation is provided to the ventricular system, with craniospinal irradiation reserved for patients with cy to pathological or radiographic evidence of leptomeningeal spread. Preirradiation chemotherapy is given to high-risk patiencs to achieve complete responses and allows significant reduction of radiation dose (Matsutani et al, 1998; Sawamura et a I. 1998). The most commonly used agents are cisplatin, etoposide, and cyclophosphamide. Long-term survivors of radiation exceed 15 years with hypothalamic/pituitary neuroendocrine morbidities.

Nongerminomatous Germ Ceil Tumors

Gtoss total resection prolongs survival but is achieved in less than half the cases. Each of the nongerminomatous germ cell tumors is approached differently (Schild et al. 1996). Mature or immature teratomas are operated on and then uu'iu' invu!u'd held i.iLh.Ltic i:i ihcrap\ v, n:i *i.\<.ind* control, If the teratoma has undergone transformation to malignancy, there is an increased risk of leptomeningeal metastases. This argues strongly for prophylactic whole-brain or craniospinal irradiation. Other nonteratoma, nongerminomatous germ cell tumors are provided adjuvant radiation therapy (above 50 Gy) and cisplatin-based polychemothcrapy. The radiation therapy fields include the whole brain followed by a "boost" to the tumor bed. These approaches are associated with complications of anterior pituitary dysfunction and intellectual decline—changes that have spurred the use of localized, lower doses or hyper fraction a ted radiation in the setting of polychemothcrapy (cisplatin + etoposide; cisplatin + etoposide + ifosfamide). Prognosis for mature teratomas is excellent, Only 10-15% of patients with embryonal carcinoma, yolk sac tumor {endodermal sinus tumor), or choriocarcinoma survive 3 years a her diagnosis. Mixed germ cell tumors and immature teratomas fall in between these two extremes.

Tumors of the Scllar Region

Craniop baryngioma

Craniopharyngioma is a tumor derived from Rathke's pouch epithelium, which may be present both within the sella turcica as well as other skull base locations. Microsurgical resection via a frontoptetional or transsphenoidal approach is the primary treatment in symptomatic cases. External beam radiation therapy may extend progression-free survival after incomplete resection, although long-term survival can be accomplished with surgery alone. Masses may infiltrate the hypothalamus and multistage operative interventions are provided (van Effenterre et al. 2002).

Pituitary Adenoma

Surgical resection is the treatment of choice for pituitary adenomas larger than 1 cm in diameter, or those with compression of the optic chiasm, erosion of bone, or extension into the walls of the sella. The transsphenoidal approach (Hardy's procedure), preferable to the transcranial route (most often fight pterional craniotomy}, achieves gross total resection in one third of patients. Postoperative complications include diabetes insipidus, meningitis, hemorrhage, and persistent leak of CSt\ Improvement in microsurgical technique and imaging has reduced mortality to below 2%.

Radiation therapy is provided as primary treatment to older adult patients, those who are not surgical candidates, and following partial resection (Sasaki et al. 2000). Tumor shrinkage is seen only years after treatment. Adverse effects are infrequent and include necrosis of the adjacent portions of the temporal lobe, hearing loss, optic neutopathy, and radiation-induced sarcomas. Multiple field techniques and radiosurgery have reduced the incidence of these complications. However, the majority of patients treated with surgery and radiation require replacement of pituitary gland-dependent hormones. For recurrent adenomas, SRS or SRT have been used. Local control rates are higher than 80% for patients with nonsecreting pituitary adenomas. Prognosis for secreting adenomas is slightly worse.

Dopamine agonists such as bromocriptine, cabergoline, quinagolide, and pergolide can lead to a reduction in tumor size, improvement of symptoms, and normalization of prolactin levels in microprolactinomas as well as macroprolactinomas (Pinzone et al. 2000).

CONCLUSION

Management of patients with primary brain tumors is an interdisciplinary effort that includes neurosurgeons, neurologists, radiation oncologists, medical oncologists, neuroradiologists, and neuropathologists. Neurologists are involved in the clinical diagnosis of primary brain tumors and their neurological complications such as seizures and intracranial hypertension. An increasing number of neurologists treat brain tumors with chemotherapeutic agents or new medical strategies.

Progress has been made in diagnostic procedures, monitoring of therapeutic efficacy, understanding the pathogenesis of primary brain tumors, optimizing standard treatments for selected tumor subtypes, and developing new treatment concepts.

However, the outcome in the majority of primary brain tumors—the malignant gliomas—remains poor. A large number of new treatment strategies awaits further study. Clinical testing has been facilitated by multispceialty neuro-oncology centers and national brain tumor consortia, raising hope for an imminent breakthrough in the treatment of this tumor type.

Chapter 58
Cancer and the Nervous System

F. MANAGEMENT OF PRIMARY NERVOUS SYSTEM TUMORS IN INFANTS AND CHILDREN

Alfredo D. Voloschin, Tracy T. Batchelor, and Jeffrey C. Allen

Primary brain tumors are the most common solid tumors of childhood, representing 20% of all childhood cancers in the United States. They are second only to leukemia in frequency among all childhood cancers (Swensen and Bushhouse 1998). Approximately 85% of primary brain tumors in children 2 years to 12 years of age arc located in the posterior fossa. Most primary brain tumors are located in the supratentorial compartment in children younger than 2 years and older than 12 years. Seventy percent of primary brain tumors are gliomas and only 5% of central nervous

system (CNS) tumors arise from the spinal cord. No geographical or ethnic predominance exists.

PRIMITIVE NEUROECTODERMAL TUMORS (MEDULLOBLASTOMAS, SUPRATENTORIAL PNETS, PINEOBI.ASTOMAS, AND EPENDYMOBLASTOMAS)

Background

Although original reports (Harvey Cushing, 1930) suggested that mcdulioblastomas originated from multipotential medulloblasts, the term *meduWoblastoma* is now a synonym for a primitive neuroectodermal tumor (PNET) of the posterior fossa. These tumors represent approximately 20% of all pediatric brain tumors. The incidence in boys is twice that of girls, and median age at diagnosis is 5 to 7 years. Supratentorial PNETs represent only 3% of all pediatric brain tumors. Eighty percent are diagnosed before 10 years of age. Although a slight male predilection exists, it is less than for mcdulioblastomas.

Etiology

No clear causc-and-effect association with dietary or environmental factors lias been found, but a genetic predisposition exists in rare syndromes such as Turcot's (associated with mutations in the APC gene on chromosome 5), Gorlin's (or nevoid basal cell carcinoma associated with abnormalities on chromosome 9q), and Ei-Fraumeni's.

Although most medulloblastomas are sporadic, familial cases, unrelated to the previously mentioned syndromes, are reported (von Koch et al. 2002). *Trilateral retinoblastoma* refers to a peculiar familial syndrome with bilateral retinoblastomas and a pineoblastoma with retinoblastic features (Finelli et al. 1995).

Clinical Presentation

Several of the clinical manifestations are the result of increased intracranial pressure (ICP). Headache is the most common symptom at presenrarion and usually precedes diagnosis by 4 to 8 weeks. Personality- changes, namely irritability, arc an early feature, but are difficult to recognize as a sign of a brain tumor. The features that most often lead to diagnosis arc morning nausea and vomiting, lethargy, diplopia, head tilt, and ataxia. The common signs on physical examination are papilledema, ataxia, dysmetna, and cranial nerve involvement. Clinically significant brainstem invasion at diagnosis is unusual. Abduccns nerve palsy secondary to raised ICP is a cause of diplopia and head tilt. Torticollis is a sign of cerebellar tonsillar herniation. Although magnetic resonance imaging (MRI) visualizes leptomeningeal metastases in 20-30% of children with PNETs at the time of diagnosis, clinical manifestations are uncommon. Back pain and radicular pain indicate the rare complication of spinal canal dissemination.

Among infants with posterior fossa tumors, the important features are changes in mood and personality as well as macrocephaly. Delay in milestone achievement or loss of previous!! achieved milestones and failure ic ilime uncharacteristic. Less commonly, intratumoral hemorrhage may lead to an apoplectic presentation.

The presenting features of supratentorial PNETs are progressive headache, nausea, vomiting, and lethargy secondary to increased ICP. Children with pineoblastomas often present with Parinaud's syndrome. The enhanced MRI of the brain typically shows a hctcrogcncously enhancing mass within the fourth ventricle, cerebellum, pineal region, or cerebrum. Obstructive hydrocephalus and, occasionally, intratumoral calcifications, hemorrhage or necrotic cysts, are often associated (Figure 58F.1).

The differential diagnosis relates to tumor site and age at diagnosis, and includes high-grade glioma, choroid plexus carcinoma, ependymoma, desmoplastic infantile ganglioglioma, neurocytoma, and germ cell tumors (when located in the pineal region).

Management

A high level of clinical suspicion is critical to make an early diagnosis. Neuroimaging is usually the first step. A computed tomography (CT) scan of the brain is usually obtained in the acute setting, but MRI of the brain and spine should be performed shortly thereafter in all children in whom the diagnosis of mcdulloblastoma is suspected. A contrast-en ha need brain MRI typically shows a heterogeneously enhancing mass in the fourth ventricle with obstructive hydrocephalus. Tumors that arise in the cerebellar hemispheres may not cause hydrocephalus as frequently. Spinal MRI is required in all cases to exclude leptomeningeal metastases. The differential diagnosis of a posterior fossa tumor in children includes inedulloblastoma, cerebellar astrocytoma, ependymoma, dorsally exophytic brain stem glioma, and choroid plexus carcinoma. The brain MRI in supratentorial or pineal region PNETs frequently shows a large heterogeneously enhancing mass. The differential diagnosis of such a pineal region mass includes a glioma such as an astrocytoma or ependymoma, as well as a germ cell tumor. Cerebrospinal fluid (CSF) obtained at the time of surgery or after resection is an important part of the staging evaluation. However, if the tumor is small and without significant mass effect, lumbar puncture to obtain a CSF sample for cytology and routine analysis before resection is recommended. The treatment consists of surgery, radiation therapy, and chemotherapy,

The gnuU of siirgen are to control IC P, achieve a gross total resection (if feasible), and prevent recurrence of

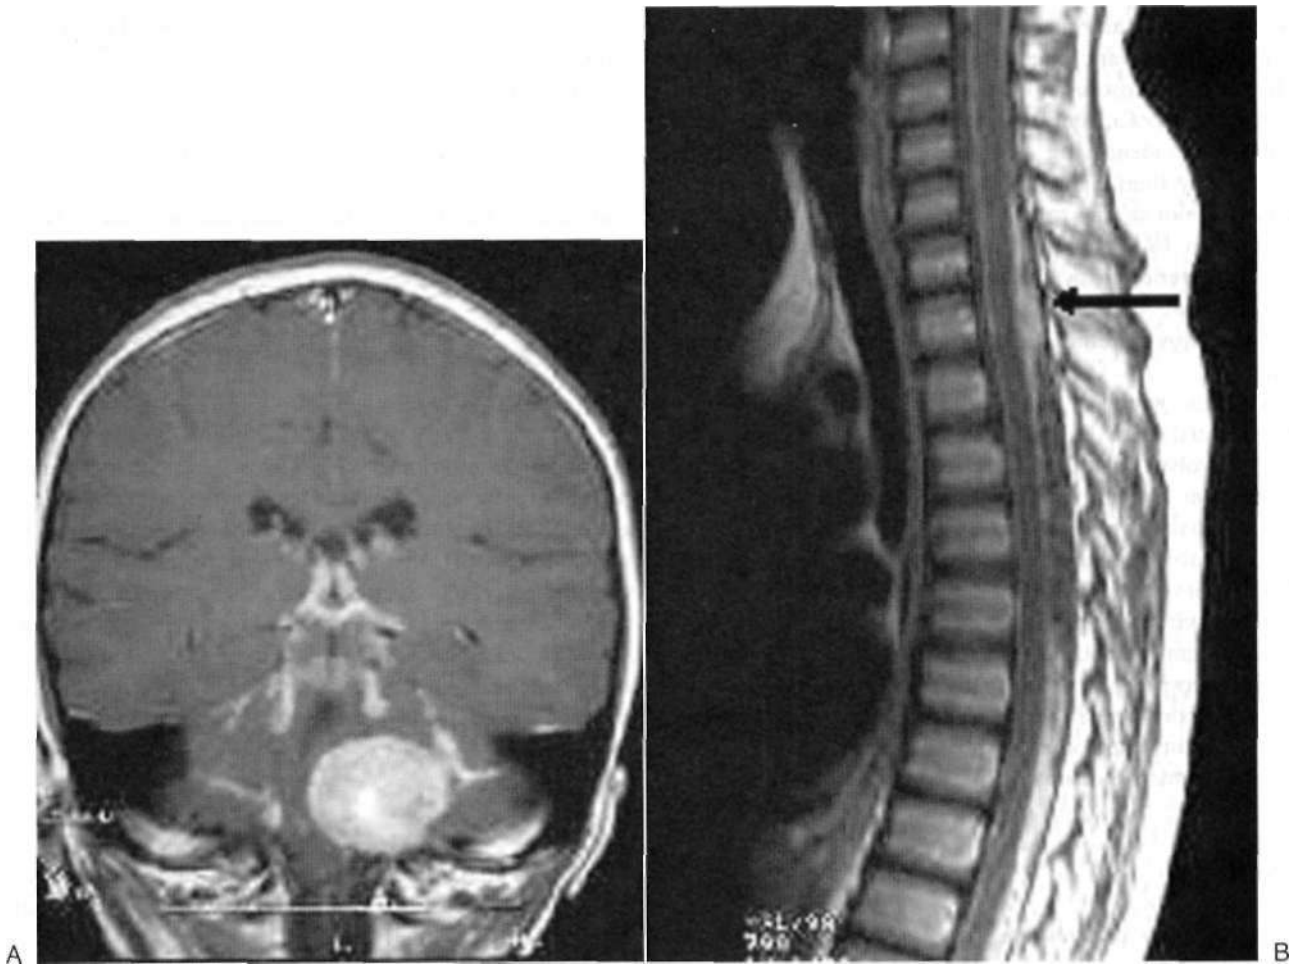

FIGURE 58F.1 Posterior fossa medul I obi a stoma with dissemination. This 7-year-old girl presented with a 6-week history of morning nausea and vomiting, left-sided hearing impairment, diplopia, dysphagia, ataxia, and back pain. Contrast-enhanced magnetic resonance imaging (MRl) (A) shows a large fourth-ventricle enhancing mass that extends laterally into the left cerebellopontine angle. There is diffuse leptomcningeal spread and extension into the left internal auditory canal (IAC). The contrast-enhanced, sagittal spine MRl (B) shows diffuse leptomeningeal metastases *Lunitf).*

obstructive hydrocephalus. A vemriculoperitoneal (VP) shunt may be necessary after surgery. Potential complications of posterior fossa surgery include cerebellar mutism, mainly seen with section of the vetmis, and aseptic meningitis. The posterior fossa or *cerebellar mutism syndrome* occurs in approximately 10-20 % of cases. The characteristics are reduced speech output or mutism, personality changes, hypotonia, ataxia, and reduced oral intake. Symptoms typically appear 1 or 2 days after surgery and may last for a few months with varying degrees of recovery.

Following the completion of the staging evaluation (MRl of brain and spine, CSF cytology), the patient is assigned to cither a high- or average-risk prognostic group. The major determinants of this risk categorization are age at diagnosis, metastasis or "M-stage," primary tumor site, and volume of residual postoperative disease. Distinction is made between age younger than 3 years versus older than 3 years, MO versus M+, cerebellar versus noncerebcllar primary-tumor, and postoperative residual tumors smaller than 1.5 cm^2 versus larger than 1.5 cm" (Table 58F. 1).

Adjuvant therapy depends on the age at diagnosis and risk group. Standard risk patients arc older than 3 years at diagnosis, have residual disease smaller than 1.5 cm , have a primary tumor in the cerebellum, and no evidence of metastasis (MO). Present treatment recommendations include craniospinal irradiation (24 Gy) with a boost to the primary tumor {54 Gy). Vincristine may be given

Table 58F.1: Staging

MO	No dissemination
Ml	Positive cytology on CSF
M2	Nodular seeding into cerebellum, cerebral subarachnoid space, or intraventricular cavity
M3	Nodular seeding into spinal subarachnoid space
M4	Extraneu ral metastases; rare, except in infants and young children

weekly during radiotherapy. Following radiotherapy, eight cycles of adjuvant chemotherapy (cisplatin, cyclohexyl-chloroethy I nitrosourea [CCNU], and vincristine) is usually administered. Current research in this group of patients consists of identifying adjuvant chemotherapy with less ototoxicity than cisplatin and less myelosuppression than CCNU. Pilot studies to lower the dose of craniospinal irradiation to 18 Gy and reduce the boost volume from the entire posterior fossa to the postoperative volume are also in ptogrcss. The use of protons rather photons for the radiotherapy minimizes the exposure of normal tissue to radiation.

Patients younger than 3 years of age at diagnosis are treated with chemotherapy alone or chemotherapy with involved field radiotherapy. Whether conventional multiagent chemotherapy or high-dose submyeloablative or myeloablative chemotherapy with stem cell support is preferable is under investigation (Dunkel and Finlay 2002). Several experimental protocols exist for older patients with high-risk disease (M+, residual tumor larger than 1.5 cm^2). Concepts under study include preirradiation chemotherapy, hyperfractionated radiorherapy (more than one fraction per day), reduced-dose radiotherapy with concomitant chemotherapy (Packer et al. 1999), and submyeloablative or myeloablative chemotherapy.

Prognosis

Standard risk patients have a 5-year survival between 60-70%; 5-year survival in high-risk patients is between 30-40%. Most initial recurrences occur at the primary site. Retrieval therapy is rarely curative, but long-term disease control may occur with high dose myeloablative chemotherapy. One histological variant, *anaplastic large cell medal lu-blastoma,* carries a poorer prognosis because of a higher risk for early metastatic involvement and recurrence (Ebcrhart 2002). The presence of dissemination is the single most important factor that correlates with outcome (Helton et al. 2002}.

Radiotherapy can cause significant adverse late effects in cognitive development (Mulhern et al. 1999), growth, and endocrine function. Repeated surveillance imaging is ret]uired throughout the patient's life time in anticipation of radiation-induced secondary malignancies such as an atypical meningioma.

ATYPICAL TERATOID/RHABDOID TUMOR

Background

Atypical teratoid/rhabdoid tumor is an uncommon tumor seen primarily in infants and young children (Bambakidts et al. 2002). Because only 150 cases have been reported, the true incidence is unknown. These tumors may arise anywhere in the body, but are most common in the kidney and CNS, primarily in the posterior fossa, either in isolation or in association with a renal tumor. The tumor is very aggressive and tends to present with high M stage. It rarely responds to adjuvant therapy and is uniformly fatal.

ASTROCYTOMAS

Low-grade glial and neuronal tumors include localized and diffuse subtypes (Table 58F.2). Their clinical features arc different (Table 58F.3).

JUVENILE PILOCYTIC ASTROCYTOMA

Background

Juvenile pilocytic astrocytomas (JPAs) are well-circum-scribed tumors, classified as grade 1 by the World Health

Table S8F.2: Low-grade glial and/or neuronal tumors

Gliomas	*Mixed glioneurona! tumors*	*Neuronal tumors*	*Miscellaneous*
JPA	DNET	Central neurocytoma	Dysplastic gangliocytoma of the cerebellum (Lliermittc-Ducios's syndrome)
PXA	GG	Gangliocytoma	
SEGCA	DIG		
DCAI			
Diffuse Tumors			
Grade '4 (Circumscribed, benign tumors, typically, pilocytic astrocytoma)			
Grade % (Low grade astrocytoma)			
Grade % (Anaplastic astrocytoma)			
Grade % (GEM)			

DCAI = desmoplastic cerebral astrocytoma of infancy; DIG = desmoplastic infantile ganglioglioma; DNET = dysembryoplastic neuroepithelial tumor; GBM = glioblastoma multiforme; GG = ganglioglioma; JPA = juvenile pilocytic astrocytoma; PXA = pleomorphic xanthoastrocytoma; SEGCA = subependymal giant cell astrocytoma.

Tahle 58F.3: Clinical findings with pediatric brain stem tumors

Clinical findings	*Diffuse tumors (60-80%)*	*Focal tumors*	*Dor sally exophytic (20%)*	*Cervicomedu ila ry*
Cranial nerves	Bilateral, asymmetric; sixth and seventh most often	Unilateral; depends on location in the brainstem	R.IIV	Lower cranial nerves -» dysphonia, dysphagia
Brainstem symptoms	Progressive gait ataxia, weakness, and long-tract signs	Usually spared	Nausea and vomiting; long-tract signs are rare	Chronic nausea, vomiting
Duration of symptoms before diagnosis	Short (6 weeks) because of aggressive behavior	Longer duration; more indolent course; chronic course	Gradual and chronic course	Chronic course
Anatomical location	Almost always in the pons	Anywhere in the brainstem, but usually midbrain	Floor of the fourth ventricle	Cervicomedu] hi in-junction
Pathology	Often malignant	Usually low-grade; solid or cystic	Usually low-grade	Usually low-grade
Imaging	Infiltrative lesion in the pons with rare enhancement	Occasional enhancement	Exophytic component strongly enhances on CT and MRI	May show homogeneous or heterogeneous enhancement
Other signs and symptoms	Spastic qu.idriparcsis	Contralateral hemiparesis; tectal tumors cause obstructive hydrocephalus	larly obstructive hydrocephalus, papilledema, ataxia and torticollis	Intractable neck pain, torticollis; hydrocephalus
Treatment	Palliative: radiation therapy (54Gy); chemotherapy: platinum-based, but no clear role as of yet	Aggressive resection; may need shunt; RT if progressive or malignant component	Resection of exophytic component; reoperation if recurrence; RT if malignant	Resection
Prognosis	Most die within IS months	Relatively good; chronic course.	Relatively good	Relatively good

CT = computed tomography; MRI - magnetic resonance imaging; RT = radiation therapy.

Organization (WHO). These tumors represent approximately 20% of all childhood brain tumors, without clear gender predominance. Neurofibromatosis (NF) type I is the best example of a condition associated with an increased risk of JPA. No other definite predisposing factors are known.

Clinical Presentation

JPAs commonly arise in the optic pathways, cerebellum, hypothalamus, basal ganglia, or cerebral hemispheres, but also occur in the brain stem and spinal cord. Therefore the spectrum of clinical manifestations depends on the structures involved, and may include visual deficits, obstructive hydrocephalus, ataxia, endocrine dysfunction, focal neurological deficits, seizures, long-tract signs, arid cranial nerve dysfunction.

Diagnosis

The diagnosis should be suspected when any of the previously noted features are found in a young patient. The history of illness is usually long and other signs of chronicity, such as bone remodeling, scoliosis, or hemihypotropby, are present depending on primary tumor location. The typical MRI appearance is an intensely homogeneously enhancing lesion with only minimal, associated edema. Intratumoral cysts are common, depending on location (i.e., cerebellum, cerebrum, midbrain, and spinal cord). Histological examination reveals both a compact and loose cellular array. The pathological hallmarks for diagnosis are Rosenthal's fibers and eosinophilic granular bodies. JPAs are glial fibrillary acid protein (OFAP)-positivc. Invasion of the overlying meninges is common, but is uol *A* negative prognostic factor. Mitoses are ran- and the MIB-1 labeling index is usually less than 4% (Dirven et al. 1998).

Management

Treatment consists mainly of surgery. Gross total resection is considered curative and radiation and chemotherapy are not required. Recurrent, progressive, or unresectable tumors may require adjuvant treatment such as chemotherapy for younger patients and radiation therapy for older patients.

Chemotherapy is assuming an increasingly important role in the management of recurrent and unresectable tumors, and various regimens such as cisplatin and vincristine or procarbazine, CCNU, and vincristine have produced consistent, durable responses. Surgery is contraindicatcd in typical optic pathway gliomas (OPGs) with expansion of the chiasm, with or without involvement of the proximal optic nerves, contiguous optic tracts, hypothalamus, or optic radiations.

Prognosis

The prognosis is excellent; 5-year survival is 100% after gross total resection. The main limitation is the anatomical location of the tumor. Complete resections are most difficult for tumors located in the brain stem, spinal cord, and hypothalamus. The quality of survival depends on multiple factors, including the tumor location and the side effects of surgery, chemotherapy, and radiotherapy.

PLEOMORPHIC XANTHO ASTROCYTOMA

Background

Pleomorphic xanthoastrocytomas (PXAs) are cortical tumors that mainly occur in children. The median age at the time of diagnosis is 14 years,

Clinical Presentation

PXAs are typically very large and superficially located. Seizures are the most common initial feature. Contrast-enhanced cranial MR! typically shows a large, enhancing tumor with occasional cystic components and calcification. The typical pathological findings are pleomorphism with significant cellular ntypia and bizarre multinucleated giant cells with intracellular lipid accumulation. The proliferative indices are usually low, although necrosis, endothelial proliferation, and mitoses are described, PXA can be confused with glioblastoma multiforme (GBM) because of the presence of multinucleated cells and occasional foci of necrosis (Giannini et al. 1999).

Diagnosis and Management

The clinical diagnosis of PXA should be suspected in children who present with new onset seizures, focal deficits, and a large, enhancing cortical mass on brain imaging. The goal of surgery is to achieve a gross total resection, which may be curative. Adjuvant therapy can be deferred while the patient is followed expectantly.

Prognosis

Several scries report a 5-year progress ion-free survival of greater than 70%. However, the presence of mitoses, endothelial proliferation, or necrosis on the pathological specimen, although very rare, may significantly alter the clinical behavior and prognosis (Sugira et al. 2000). Radiation therapy does not alter the poor outcome in these cases.

SUBEPENDYMAL GIANT CELL ASTROCYTOMA

Background

Subependymal giant cell astrocytomas (SEGCAs) usually originare in rhe ependymal walls of the lateral ventricles and are associated almost exclusively with tuberous sclerosis (TS). Sporadic cases are rare.

Clinical Manifestations

SEGC A is sometimes the presenting feature of TS in patients without the typical physical stigmata of rhe syndrome. These tumors tend to grow toward the foramen of Monro, leading to obstructive hydrocephalus, headaches, vomiting, and visual deficits. On physical examination, papilledema is common, as are focal neurological deficits such as hemiparesis. Other findings, related to TS, arc skin and retinal abnormalities. Small, subependymal calcified lesions as well as areas of gliosis, cortical tubers, and heterotopias are often associated with SEGCA in TS. Therefore both CT and MRI are essential for early and accurate diagnosis. Although the former is better for detecting small, calcified lesions, MRI is superior to CT in identifying areas of gliosis, heterotopia, and SEGCA, which gives the typical radiographic appearance of "candle dripping,"

Management

SEGCAs typically show diffuse contrast enhancement on both CT and MRI studies. Total gross resection is the treatment of choice for SEGCAs that are large, progressive, and cause obstructive hydrocephalus. The major risk is injury to the forniceal columns. Alternatively, a VP shunt can provide symptomatic relief. The benign behavior of these tumors warrants reoperation in the case of recurrence or progression, after subtotal resection.

Prognosis

SEGCAs are essentially benign tumors. Gross total resection should be curative. However, in some patients with TS,

multiple tumors may be present. The overall prognosis for patients with TS is good, despite an increased susceptibility to other tumors types, including rhabdomyomas of the myocardium and angiomyomas of the kidney, liver, adrenals, and pancreas.

DESMOPLASTIC CEREBRAL ASTROCYTOMA OE INFANCY

Desmoplastic cerebral astrocytomas of infancy (DCAI) are characterized by their large size and superficial/cortical location. These tumors may involve an entire hemisphere. The usual initial presentation is a seizure, although progressive focal deficits may be the first manifestation. The tumor is contrast-enhancing on MRI and usually has a large cystic component. Lepto meningeal invasion is common in patients with DCAI, classified as a grade 1 tumor by the WHO. Despite the malignant features, patients with DCAI have a good prognosis after gross total resection.

DYSEMBRYOPLASTIC NEUROEPITHELIAL TUMOR

Background

Dysembryoplastic neuroepithelial tumors (DNETs) represent 1% of all brain tumors in patients younger than 20 years of age. The wide variation in the reported incidence of DNET is perhaps due to the different criteria used for diagnosis. Two thirds of DNET are located in the temporal lobe and DNET are found in 5-15% of temporal lobe resections for intractable epilepsy. These lesions are classified as WHO grade 1 tumors.

Clinical Presentation

These tumors typically present with a long history of complex partial seizures. The average age at onset is 9 years. The superficial, cortical location of DNET may account for the high risk of seizures. Contrast-enhanced cranial MRI shows absence of edema and only minimal, if any, enhancement. The diagnosis of DNET is a consideration in children and young adults with either new-onset seizures or a long history of epilepsy. The pathological findings include a specific glioneuronal element manifested by GFAP-negative oligodendroglia-like cells and neurons in a mucinous eosinophilic background that give the appearance of "floating neurons." In addition, oligodendrocytes, astrocytes, or both, are found. The pathological differential diagnosis includes oligodendroglioma, mixed oligoastrocytoma, and ganglioglioma.

Management

These tumors have a benign course and gross total resection is often curative. Radiation and chemotherapy are not recommended.

Prognosis

The stable behavior of these tumors over time results in an excellent prognosis after either gross total or partial resection.

GANGLIOGLIOMA

Gangliogliomas represent 4-8% of primary brain tumors in children and 80% occur before age 30 years.

Clinical Presentation

Seizures are the first manifestation in half of the cases. Complex partial seizures are common because the typical tumor location is in the temporal lobe. Contrast-enhanced, cranial MRI shows a supratentorial cystic mass with an enhancing mural nodule. This appearance is similar to JPA and PXA. An infantile variant of ganglioglioma, desmoplastic infantile ganglioglioma (DIG), is characterized by a large size and a supratentorial location. Pathological studies show a synaptophysin positive ganglion cell component as well as a GFAP-positive astrocytic component (De Munnynck et al. 2002).

Management

Gross total resection is the treatment of choice. Recurrent or unresectable tumors are irradiated (Johnson et al. 1997). Ganglioglioma may be WHO grade 1 or 2. Some tumors show anaplastic features in the glial component. This tumor variant has responded to chemotherapy in clinical trials.

Prognosis

Gross total resection is usually curative. Thus location and extent of resection are the most important prognostic factors.

CENTRAL NEUROCYTOMA

Background

Central neurocytoma is a rare tumor of neural origin that usually has an intraventricular location. Obstructive

hydrocephalus or focal deficits are common presentations. MRI of the brain shows an isointense mass with minimal enhancement. On pathological study the presence of perinuclear halos on light microscopy may lead to a mistaken diagnosis of oligodendroglioma. The diagnosis is a consideration in every young patient with an intraventricular mass. Synaptophysin, a neuronal stain, positive in neurocytoma but negative in oligodendroglioma, is crucial to make the correct diagnosis. Very rare atypical forms with mitoses, necrosis, and endothelial pro I i (era t ion are reported (Soyletnezoglu et al. 1997). A MIB-1 labeling index is useful for prognostic purposes. Patients with a MIB-1 labeling index greater than 2% have a worse prognosis.

Management

Gross total resection can be curative for central neurocytomas. Radiation and chemotherapy are not necessary in typical cases. This emphasizes the importance of differentiating central neurocytoma from oligodendroglioma, a tumor that may require adjuvant radiation and chemotherapy. Radiotherapy is a consideration only for atypical forms with a high MIR-1 Libeling index and for recurrent, unresectable tumors.

Prognosis

Gross total resection of typical central neurocytoma is often curative. The outcome in atypical central neurocytomas is difficult to predict accurately because of the rarity of the tumor. Data is not available on response to chemotherapy or radiation therapy.

COLLOID CYST OF THE THIRD VLNTRICLL

Colloid cysts are typically located in the third ventricle. Less than 50 pediatric cases arc reported. The mean age at presentation in children is 11 years.

Clinical Presentation

A colloid cyst of the third ventricle may obstruct the foramen of Monro and result in acute obstructive hydrocephalus and sudden death. Headache, nausea, and vomiting may occut. Drop attacks and transient loss of consciousness is reported in adults. Mortality is higher in children than in adults. Contrast-enhanced cranial MRI typically shows an isointense or hyperintense lesion with a variable degree of enhancement. Viscous fluid within the cyst results in a hyperdense appearance on CT. The very slow tumor growth over time may explain the very low incidence in children.

Surgery is the treatment of choice. Several surgical approaches are possible (i.e., transcortical, transventricular, and endoscopic transcallosal). The latter is associated with less morbidity. Total resection is curative. Disconnection syndromes may occur after the transcallosal approach.

LOW-GRADE FIBRILLARY ASTROCYTOMA

Background

Low-grade astrocytomas (LGA) localized to the posterior fossa represent 12-18% of all pediatric intracranial tumors. Focal LGA represents 20-40% of all brainstem tumors. No gender predilection exists, and the peak age at diagnosis is 6—10 years. In contrast to the adult population, LGA are more common than high-grade astrocytomas (HGA) in children.

The incidence of LGA has increased over the past several years without an identified reason. A potential association of paternal exposure to chemical and electrical industries and tumor occurrence is reported (McKean-Cowdin et al. 1998).

Presentation

The initial symptoms vary depending on the location of the tumor. The prodrome is months to years.

LGAs in the brain stem are usually "focal" rather than diffuse. They tend to arise in the midbrain, cerebellar peduncles, medulla, or cervicomeduUary region. Diffuse pontine astrocytomas have a different clinical course and often undergo malignant transformation within months. This is much less likely in other locations.

Patients with medullary tumors may present with a long history of dysphagia, hoarseness, ataxia, and hemiparesis. CervicomeduUary tumors may cause medullary or upper cervical symptoms such as neck discomfort, weakness or numbness of the hands, and an asymmetric quadriparesis. Patients with midbrain tumors such as a tectal glioma often present with signs and symptoms of raised ICP. Other symptoms include diplopia and hemiparesis. In children with dorsally exophytic brainstem glioma, a component of the tumor arises in the medulla and grows exophytically in a dorsal direction resulting in noncommunicating hydrocephalus. Low-grade fibrillary astrocytomas car also arise in tile brain hut the clinical course may be more aggressive, especially when the thalamus is involved.

Most low-grade fibrillary astrocytomas appear isodense on CT without significant contrast enhancement. The tumor is hypointense on Tl-weighted MRI and hyperintense on T2-wcighted MRI, with minimal or no gadolinium enhancement with the exception of dorsally

exophytic brainstem tumors. Pathological examination may demonstrate some cellular plcomorphism but no mitoses, necrosis, or endothelial proliferation (i.e., histologic features of malignancy) (Table 58F.3).

Management

Management depends on the clinical prodrome and location of the primary tumor (F.rnestus et al. 1996). A rapidly evolving prodrome with an operable tumor usually warrants prompt neurosurgical intervention. The management of a tumor with a long history of indolent and mild symptoms is often done with close MRI and clinical surveillance. Patients with progressive neurological symptoms and MRI studies suggesting tumor growth tequire therapeutic intervention (Jallo et al, 2001). The likelihood of total resection of a diffuse fibrillary astrocytoma is minimal, especially when the tumor is located in the tectum or medulla. However, radical resection can often confer a long symptom-free outcome, especially in patients with suprarcntorial and dorsally exophytic brainstem tumors. If resection is not feasible, chemotherapy or radiotherapy may he indicated. Chemotherapy is reserved primarily for younger patients (Allen and Siffcrt 1996), and radiotherapy may be instituted in younger patients whose tumors progress during chemotherapy (Pollack et al, 1995). Radiotherapy may be used more liberally in older children.

Prognosis

The 10-year survival rate for completely resected supratcntorial LGA is excellent (higher than 90%). The prognosis for gemistocytic astrocytomas is less predictable because of the propensity of these tumors to rapidly degenerate into HGA. The prognosis for focal midbrain tumors is also favorable, in spite of the fact that complete resection is impossible.

OPTIC PATHWAYS GLIOMAS

Background

OPGs represent approximately 4% of all primary pediatric brain tumors. These rumors may involve various parts of the optic pathway such as the optic nerves, chiasm, optic tract, and optic radiations. The tumor may also infiltrate the adjacent hypothalamus and temporal lobes. Optic nerve gliomas are strongly associated with NF1. OPG in NF1 patients may have a more indolent course than those arising in patients without NF1 (Deliganis et al. 1996).

Clinical Presentation

Most OPGs are LGAs; 60% are pilocytic astrocytomas and 407o are fibrillary astrocytomas. Although most optic nerve and chiasm gliomas are LGAs, their clinical course may be aggressive when the optic pathways and hypothalamus are invaded. Age is an important prognostic factor; children younger than 5 years of age have a more aggressive course. Unilateral optic nerve gliomas present with the classic triad of visual loss, proptosis, and optic atrophy. Chiasmatic involvement may lead to visual loss, a bitemporal field defect, as well as to obstructive hydrocephalus as the tumor grows dorsally to obstruct CSF flow in the third ventricle. Further invasion into brain parenchyma may result in hemiparesis and seizures. t liinMLi.iiu- minors in infants prcscnl as ver\ large suprasellar masses that may also extend into the hypothalamus and third ventricle, producing hydrocephalus and endocrine abnormalities. The diencephalic syndrome consists of irritability, failure to thrive, nystagmus with visual loss, and hydrocephalus.

Management

The clinical diagnosis of an OPG is suspected when a child presents with visual impairment associated with nystagmus and optic atrophy. Contrast-enhanced cranial or orbital MRI typically shows a solid, cystic, or mixed type of tumor with gadolinium enhancement. MRI studies and clinical presentation may distinguish an OPG from other childhood tumors that arise in the suprasellar location such as a germ cell tumor or craniopharyngioma. The unpredictable clinical course of patients with OPGs has led to controversy regarding the optimal management of these tumors. The clinical course, age i>r onset, severity ot symptoms, size .rid extent of the tumor, and the presence of NF1 may all affect management decisions. Early treatment is started in younger patients, patients with progressive symptoms, and those with more extensive CNS involvement. The initial treatment of choice is chemotherapy, which may cause stabilization or regression (Silva et al. 2000), Combination therapy with cither cisplatin and vincristine (Kato et al. 1998) or thioguanine, procarbazine, CCNU, and vincristine have had comparable beneficial effects. Oral temn/nlonnde or etoposide may also be effective. Radiotherapy is reserved for older children or for those whose tumors progress after multiple chemotherapy regimens.

Prognosis

Although optic nerve gliomas are almost always low-grade histologically, their location often results in devastating morbidity. The growth rate, however, often slows in older

children and young adults. Patients with NFl-associated optic nerve gliomas may remain stable for several years, Close observation and symptomatic management are recommended.

HIGH-GRADE ASTROCYTOMAS

Background

HGAs are much less common in children than adults. These tumors consist of either anaplastic astrocytoma (III/1V) or GBM (1V/IV). The tumors arise in the brainstem, thalamus, and, less commonly, in the cerebrum. Hemispheric tumors account for 15-20% of all HGAs. Certain genetic syndromes, such as hereditary nonpolyposis colorectal carcinoma, are associated with HGAs. NFl is most frequently associated with pilocytic astrocytomas (Rodriguez et al. *1996).* Li-Fraumeni syndrome (P53 mutation), has also been associated with gliomas of different grades (LGA, anaplastic astrocytoma [AA], GBM), medulloblastoma, choroid plexus carcinoma, and supratentorial PNFT.

Clinical Presentation

The clinical manifestations of HGA depend on the anatomical location as well as the age of the patient. The clinical prodromes are usually short and rapidly evolving, although in some cases an HGA may arise in the setting of prolonged symptoms from a low-grade fibrillary astrocytoma.

Management

The diagnosis of an HGA should be suspected based on the clinical presentation, tumor location, and the MRI that shows combinadons of diffuse, nonenhancing signal abnormalities and focal, enhancing solid lesions. Intratumoral cysts often correlate with spontaneous necrosis. The T2 signal is often more diffuse, consistent with both infiltrative tumor and edema. Significant mass effect, hydrocephalus, and intratumoral hemorrhage may be present. Malignant features on pathological studies include nuclear pleomorphism, mitoses, necrosis, endothelial proliferation, and a high MIB-1 labeling index.

Gross total resection is the initial treatment goal (Pollack 1999). This facilitates a more accurate diagnosis and makes subsequent radiotherapy more tolerable. Chemotherapy has .in ; nuTi'.ir,;'. bin k'ss drilled role *:i:* pivsrnl. The prognosis for children with HGA is poor, but better than in adults. A report from the Children's Cancer Group (Wisoff et al. 1998) showed that the 5-year progress ion-free survival (PFS) rates for anaplastic astrocytoma were 44% ± 11% and 22% ± 6% for children who underwent radical resection versus other types of surgery, respectively. The 5-year PFS rates for GBM were 26% ± 9% and 4% ± 3% for children who underwent radical resection versus other types of surgery, respectively. Radical resection and the absence of P53 immunostaining are favorable risk factors. Thus patients with diffuse thalamic and pontine tumors have the worst prognosis (Reardon et al. 1998). Several studies have shown that chemotherapy may have a clinically beneficial role in children with HGA. The overall 5-year survival of children with supratentorial HGA treated with chemotherapy and radiation is approximately 43%, versus 18% for radiation alone. Prcirradialion chemotherapy has been studied with the goal of delaying radiation. This approach is especially important for children younger than 3 years of age. Treatment with high-dose chemotherapy and autologous bone marrow support has been conducted in children with HGA (Dunkel and Finlay 2002). The risk/benefit ratio is still under investigation, with initial reports of 23% overall response but a mortality rare of 16% (Finlay et al. 1996). Diffuse, infiltrating brainstem tumors have been treated with high dose chemotherapy (CCNU, vincristine, and prednisone, as well as platinum-based agents) and stem cell rescue, with disappointing results.

Prognosis

The extent of surgical resection contributes to prolonged progression-free survival (Campbell et al. 1996). Patients with anaplastic astrocytoma have a more favorable prognosis than those with GBM. New treatment approaches include radiosurgical boost to the postoperative tesidual tumor following external beam radiotherapy, radiosensitizing agents, and new adjuvant chemotherapy agents such as temozoiomidc (Friedman et al. 2000).

EPENDYMOMAS

Background

Ependymomas represent approximately 10% of all childhood intracranial neoplasms, constituting the third most common pediatric brain tumor, after medulloblastoma and astrocytoma. Ninety percent of pediatric ependymomas are intracranial and 75% arise in the posterior fossa. Most supratentorial ependymomas are located in the brain parenchyma away from the ependymal surface, in contrast to infratentorial ependymomas. Ependymomas represent less than 10% of pediatric intramedullary spinal cord tumors. In contrast, ependymomas represent more than 50% of intramedullary spinal cord tumors in adults. The association of intramedullary spinal cord ependymomas and NF2 are clear. In fact, ependymomas account for almost all spinal cord gliomas in NF2.

Clinical Presentation

The presenting symptoms of infra tentorial ependymomas relate to their origin from ependymal tissue lining the fourth ventricle. Hydrocephalus results when the tumor fills the fourth ventricle, causing headache, irritability, nausea, vomiting, ataxia, and papilledema. Tumors that extend out one of the foramens of Luschka compromise unilateral lower cranial nerves and cause hoarseness and dysphagia. If the tumor extends through the foramen of Magendie, the patient may complain of neck discomfort and have torticollis. The initial feature of the tumor in infants is increased head circumference. Other, less frequent, features include low back pain and leg weakness resulting from dissemination along the spine.

Spinal cord ependymomas are typically located in the cervical region. The most common presenting symptom is localized pain at the level of the lesion. The pain is worst' at night, presumably because of congestion of the spinal venous plexus in the recumbent position. The second most common symptom is radicular dysesthesias and a late manifestation is progressive spastic quadriparesis. Thoracic ependymomas are associated with scoliosis. Myxopapillary ependymomas of the conus medullaris and filum terminate may present with low back pain, radicular pain, saddle anesthesia, and sphincter dysfunction. A typical MRI appearance of a fourth ventricular ependymoma is that of a homogeneously enhancing solid mass extending out one of the foramens of Luschka or Magendie with obstructive hydrocephalus (Figure 58F.2). The characteristic microscopic feature of an ependymoma is dense eellularity with pen vascular pseudorosctrcs; a minority express true ependymal rosettes. The presence of mitoses, necrosis, and vascular proliferation is observed in malignant variants. GFAP is usually positive in most ependymomas and epithelial membrane antigen stains are positive in anaplastic variants. Myxopapillary ependymomas have a mucinous appearance and arise exclusively in the eauda equina. Malignant ependymomas are very rare in the spinal cord. Intracranial ependymoblastomas, a type of PNET, are malignant and arc similar to medulloblastoma, retinoblastoma and pineoblastoma in their clinical course.

Management

The first line of treatment is surgery with a goal of curative gross total resection. Complete resection of spinal cord and supratentorial ependymomas is common. Technological advances such as the operating microscope, Cavitron ultrasonic aspirator, intraoperative ultrasound, and MRI, as well as electrophysiological monitoring, have reduced operative morbidity of spinal cord surgery. Overall, spinal cord ependymomas are more easily resectable than astrocytomas because of the presence of a better demarcated "cleavage plane."

The role of radiation therapy remains controversial and is reserved for patients in whom a gross total resection is not possible. Several studies suggest that radiotherapy-prolongs progression-free survival after subtotal resection of an ependymoma (McLaughlin et al. 1998). The usual dose of radiation is 5400 cGy to the posterior fossa. The role of radiotherapy for partially resected myxopapillary ependymomas is less clear.

Approximately 10-15% of fourth ventricular ependymomas present with subarachnoid metastases. Presently, no established role exists for chemotherapy in the management of ependymomas (Siffert and Allen 1998). Several small series in newly diagnosed and recurrent disease have shown objective responses to the following drugs: carboplatin, cisplatin, ifosfamide, and etoposidc. Chemotherapy is used for infants and younger children with incompletely resected or disseminated disease (Duffner et al. 1998).

Prognosis

The most important prognostic factors for both intracranial and spinal cord ependymoma are age and extent of surgical resection (Paulino er al. 2002; Pollack et ai. 1995b). The 5-year progress ion-free and overall survival for patients with subtotal versus total resections of posterior fossa ependymomas is 25% and 66%, respectively. Consequently, the prognosis of patients with disseminated disease is much worse (Finestus et al. 1996). Local radiation therapy improves survival as well (McLaughlin eral. 1998).

CHOROID PLEXUS TUMORS

Background

Although tumors of the choroid plexus represent only 1-2 % of all pediatric hrain tumors, more than ""()% of choroid plexus tumors occur in pediatric patients and half occur in children younger than 2 years of age. Seventy-five percent arise in the lateral ventricles and the remainder in the fourth ventricle.

Clinical Presentation

Initial symptoms are usually secondary to elevated ICP and hydrocephalus, and include headaches, nausea, and vomiting. Other possible manifestations include lethargy, seizures, and failure to thrive. On physical examination, papilledema is often present. Infants may show irritability, lethargy, vomiting, a tense fontanelle, and macrocephaly with splayed sutures. Diagnosis is suspected when a large enhancing tumor in the lateral ventricle is visualized on gadolinium-enhanced MRI, Multilobular, calcified, contrast-enhancing intraventricular masses are characteristic of choroid plexus tumors. Two histological types of tumors are recognized: choroid plexus papilloma, a low-grade variant, and choroid plexus carcinoma, a malignant variant that has a higher mitotic index and is more invasive (Pencalet ct al, 1998).

Management

The clinical diagnosis of a choroid plexus tumor is considered in a young child with features suggestive of hydrocephalus and increased ICP. Macrocephaly and lethargy indicate the need for a contrast-enhanced cranial MRI. Intraventricular enhancing masses with a peculiar "cauliflower" shape on MRI arc characteristic of choroid plexus tumors.

A major obstacle to the surgical removal of choroid plexus tumors is the rich vascular network within these tumors. The choroid plexus receives its blood supply from the anterior and posterior choroidal arteries, branches of the internal carotid artery and the posterior cerebral artery. The exrent of surgical resection is the single most important factor that determines the prognosis of choroid plexus papilloma.

The primary treatment objective for both low-grade and high-grade choroid plexus tumors is gross total resection. For choroid plexus papilloma, this is a curative procedure, For choroid plexus carcinoma, adjuvant therapy is often necessary. Because the majority of children diagnosed with choroid plexus carcinoma are younger than the age of 3 years, chemotherapy is the treatment of choice (Duffner et al. 1995), A variety of multiagent regimens have been explored, and preliminary evidence suggests that choroid plexus carcinomas are chemosenskive tumors. The role of adjuvant radiotherapy is controversial. Radiation is reserved for children older than 3 years who have had a subtotal resection, malignant features within the tumor, or dissemination of the tumor along the neuraxis.

Prognosis

Gross total resection is curative for papillomas. The prognosis in significantly worse for carcinomas and several adjuvant therapies are being investigated.

CRANIOPHARYNGIOMA

Background

Craniopharyngiomas are the most common nonglial tumors in children and account for 3-5% of all pediatric brain tumors. The peak age range for diagnosis of this tumor is 6-14 years,

Clinical Presentation

The typical onset is insidious and a 1- to 2-ycar history of slowly progressive symptoms is common. These symptoms may include progressive visual loss, delay in sexual maturation, growth failure, weight gain, and diabetes insipidus. Eventually, extension of the tumor into the hypothalamus, third ventricle, and limbic system produces endocrine dysfunction. More than 70% of children at time of diagnosis present with growth hormone deficiency, obstructive hydrocephalus, short-term memory deficits, and psychomotor slowing. The presenting feature in young adults is hypopituitarism, galactorrhea-amenorrhca syndrome in females, and impotence in males. Craniopharyngiomas arc subdivided into adamantinomatous and papillary types. The first gtoup is the more common and occurs in children and adults. Adamantinomatous craniopharyngiomas typically have cystic and solid areas with calcifications. Papillary tumors, seen almost exclusively in adults, arc predominantly solid without calcification and ate less infiltrative. MRI features include a multicystic and solid enhancing suprasellar mass, which, if large enough, causes hydrocephalus and stretching of the optic nerves and chiasm (Brunei et al. 2002). The CT usually reveals intratumoral calcifications (Figure 58F.3).

Management

Surgical removal of the tumor is the most effective treatment. Complete microsurgical resection is the treatment of choice for newly diagnosed craniopharyngiomas. Transcranial or transsphenoidal surgical approaches are commonly used.

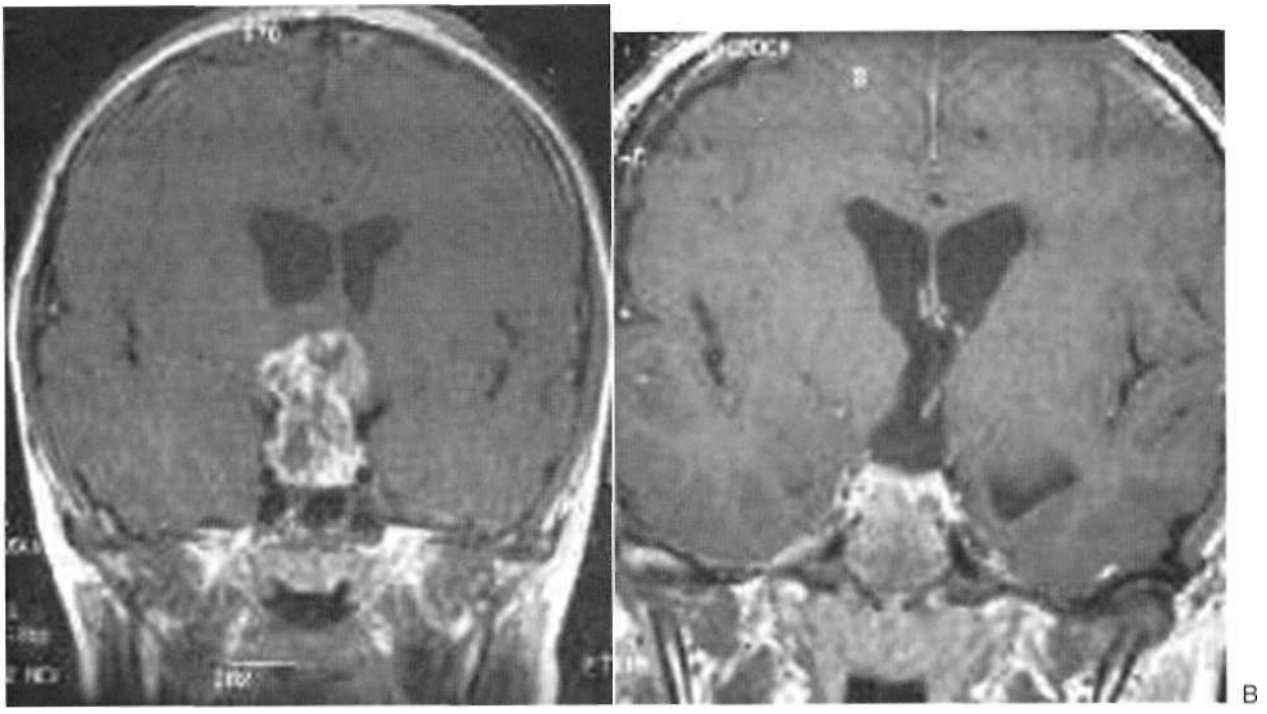

FIGURE 58F.3 Suprasellar craniopharyngioma. This 8-year-old girl presented with short stature, bitemporal field cuts, and headaches. The preoperative magnetic resonance imaging (MRI) (A) scan shows a cystic, enhancing suprasellar mass. Following ;i trnnssphenoid.il resection, the postoperative MRI (B) shows a gross total resection.

Transsphenoidal resection is the preferred method for tumors in a subdiaphragmatic location and is associated with a tower incidence of postoperative diabetes insipidus.

Radiosurgical techniques are in use for surgically unresectable or recurrent tumors. Long-term complications of radiation include secondary malignancies, optic neuropa thy and vascular injury leading to moyamoya disease, Intracavitary irradiation is also an option. ^{i2}P is the preferred agent because of less penetration of normal tissue and a longer half-life.

Recurrent craniopharyngiomas are treated with rcopcration, radiation, or chemotherapy. Intracavitary bleomycin is used for recurrent tumors. This form of local chemotherapy may also be beneficial as a supplement to surgery by thickening the cyst wall, making it resistant to tearing, and, in turn, facilitating resection.

Prognosis

The most important factors that correlate with PHS are the extent of resection and postoperative radiation. In fact, recurrence occurs in 30% of cases after total resection and in 57% cases aftet subtotal resection. The recurrence rate drops to 30% when subtotal resection is followed by radiation. Unfortunately, most long-tetm survivors experience significant morbidity related to panhypopituitarism, cognitive impairment, and obesity.

GpRMC£LL ANQ NONGERM CEL, TUMORS

Background

Tumors of the pineal region represent 3-5% of all pediatric brain tumors. Germ cell tumors include gcrminomas, which compose 60-70% of all pediatric germ cell tumors, and nongerminomatous germ cell tumors (NGGCT), NGGCT include embryonal cell carcinoma, teratomas, endodermal sinus tumor, choriocarcinoma, and mixed germ cell tumors such as teratocarcinoma. These tumors typically arise in midline locations such as the pineal or suprasellar regions. Germinomas are the most common tumors of the pineal region, but NGGCTs and germinomas arise with equal frequency in the suprasellar region. Intracranial germ cell tumors arise typically in the second and third decades of life. A male excess occurs in pineal region tumors, and both genders are equally affected in the suprasellar region. People of Japanese descent have a higher incidence of intracranial germ cell tumors. Other malignant tumors arising in this location include pincoblnstoma and pineocytoma. Pineoblastoma represents an aggressive tumor that resembles a PNET in terms of age at diagnosis and propensity to disseminate into the subatachnoid space. Pineoblastoma can also present as a component of the familial syndrome termed *trilateral retinoblastoma,* which includes bilateral retinoblastomas and a pineoblastoma with retinoblastic features {Finelli et al. *1995).* Pineocytoma usually presents during

Table 58F.4: Subtypes of germ cell and nongerm cell tumors

adolescence and has a much less aggressive course (Table 58F.4).

Gliomas, low-grade and high-grade, are the second most common tumor type in the pineal region. Benign cystic lesions of the pineal region should be differentiated from low-grade cystic astrocytomas. The former should demonstrate no progression on serial ncuroimaging studies over time.

Clinical Presentation

The typical presentation of a patient with a suprasellar germ cell tumor, such as a germinoma, is a months-to-years long history of endocrine dysfunction: hypopituitarism manifested by polyuria, polydipsia, growth impairment, precocious puberty, and hypothyroidism. Visual loss may result from dorsal extension of the suprasellar tumors. Tumors arising in the pineal region may produce headache, nausea, and vomiting caused by obstructive hydrocephalus. Limitation of vertical gaze, convergence nystagmus, impaired pupillary reflexes, and double vision may occur as a result of compression of periaqueductal structures (Parinaud's syndrome), Papilledema is often present secondary to increased 1CP caused by obstructive hydrocephalus. Germ cell tumors can cause precocious puberty as a result of result of /{-human chorionic gonadotropin (/i-HCG).

Management

The classical presentation of a pineal-region tumor is a patient with signs and symptoms of increased ICP in association with Parinaud's syndrome. Because the differential diagnosis of tumors in this location is large, every patient should have some type of histological or chemical confirmation of a specific tumor type. Histological confirmation may not be necessary in patients with elevated CSF concentrations of tumor markers (o?-fetoprotein fAFPl, HCG) consistent with a NGGCT (Seregni et al. 2002).

Germ cell tumors typically show homogeneous enhancement with peripheral calcification on contrast-enhanced cranial MRI, in contrast to the intratumotal calcification typically seen in pineocytomas.

Tumor markers in CSF and serum may suggest the specific type of underlying tumor and are useful as parameters to follow during the course of therapy (Table 58F.5). Elevation of AFP occurs with endodermal sinus tumors and embryonal carcinomas, whereas a high level of /J-HCG suggests choriocarcinoma. Pure germinomas may have modest elevations of CSF HCG up to 50 mlU/ml. Lactate dehydrogenase isoenzymes and placental alkaline phosphatase are also detectable in CSF in germinoma patients. The current standard of care for pineal region tumors includes biopsy for tissue diagnosis, and possible resection, depending on rhe specific tumor type. Resection is not indicated for germinomas because of the extreme sensitivity of this tumor to radiation and chemotherapy. Preoperative evaluation should include contrast-enhanced cranial and spinal MRl, serum and CSF tumor markers (if lumbar puncture can be safely performed), CSF cytology, assessment of pituitary and endocrine function, and visual field assessment. In cases of obstructive hydrocephalus, preoperative third ventriculostomy eliminates the need for a VP shunt, which would carry a risk of in tec n on as well as peritoneal dissemination of the tumor. Furthermore, endoscopic biopsy of the tumor may be achieved during the third ventriculostomy,

Resection is the procedure of choice for nongerininomatous pineal region tumors once the diagnosis is established. It may be curative for benign lesions such as a pure teratoma and may improve prognosis for patients with malignant tumors. In addition, resection provides ample tissue to avoid potential diagnostic mistakes caused by sampling error, especially for mixed tumots. Spinal MRI, to rule out CSF dissemination, should be obtained either prior to surgery or 2 weeks after surgery. In contrast, a postopetative, contrast-enhanced cranial MRI should be obtained within 48 hours of surgery to assess the extent of resection. The most common complications of pineal gland surgery are ocular dysmotility, ataxia, and altered mental status. Other, less common complications include seizures, hemiparesis, visual field defects, aseptic meningitis, and intratumoral hemorrhage.

Sensitivity to radiation and outcome depend on histology. Germinomas are the most radiosensitive, with a 90% PFS at 5 years, whereas nongerminomatous malignant germ cell rumors have a 5-year survival rate of .30-40%.

Table 58.5: Tumor markers for germ cell tumors

Tumor	*AH}*	*0-HCG*	*LDH*	*PLAP*

Several treatment alternatives exist regarding the management of intracranial germinomas. Radiotherapy alone is usually administered in relatively high doses and large volumes {whole ventricular or craniospinal) even for localized disease. Although the 10-year survival proportion ranges from 80-90%, children often suffer from the late consequences of radiotherapy. Alternatively, the use of chemotherapy followed by response-based radiotherapy permits a selective reduction in not only dose, but also volume of radiotherapy in patients whose tumors completely disappear after 2-4 courses of chemotherapy. For NGGCT, more aggressive chemotherapy (Kellie et al. 2002) and high dose/volume radiotherapy is required to improve survival. Patients with pineoblasromas are treated on protocols designed for patient with PNETs.

Prognosis

The prognosis for patients with pineal region tumors depends on the histology. Surgical resection may be curative for pineocytomas and ependymomas. Patients with anaplastic pineocytomas and pincoblastomas have a much worse prognosis. Germinomas have an excellent prognosis because of their sensitivity to radiation and chemotherapy. NGGCTs, however, tend to have a poor prognosis. Recurrent germ cell tumors may respond to salvage chemotherapy or radiation.

LATE EFFECTS OF THERAPY

Late effects of therapy sinmId be considered before deciding on a particular modality of treatment for an infant or child with a tumor of the nervous system. Indeed, it is often the profile of the potential late effects of one therapy versus another that determines which modality to apply. The particular importance of this concept in pediatric ncuro-oncology is twofold. (1) The developing nervous system is particularly vulnerable to the toxic effects of chemotherapy and radiation compared with adults, (2) The long-term survival of several types of pediatric brain tumors permits the development of some late effects (e.g., secondary malignancies) and has implications for the quality of life for these patients. The late effects of specific treatment modalities are reviewed below.

Surgery

Although gross total resection is the goal of sutgery for most U;H-S i'l brair Uin-ors, Lii:nplic;:lioii\, iikhkluig local injur) to eloquent neural tissue and postoperative complications such as infection, may result in greater neurological injury. Specific neurological syndromes such as cerebellar mutism are common after surgery for posterior fossa tumors. In addition, VP shunts are subject to infection and malfunction, which may require additional interventions.

Radiation

Radiation therapy may produce subacute and late effects on the CNS. The subacute effects include the radiation somnolence syndrome (RSS) and Lhermitte's syndrome. The RSS typically follows within 1-2 months of large-volume cerebral irradiation. Patients typically become lethargic and anorexic, and may develop symptoms that recapitulate the symptoms of the initial tumor. The syndrome spontaneously resolves within 3 months in most cases, but occasionally low-dose corticosteroids are required (Ryan 2000). Lhermitte's sign, electric shocks traveling down the spine on neck flexion, usually arises within several months of cervicothoracic spinal irradiation (Lewanski et al. 2000). This usually resolves spontaneously within months.

Late consequences may include subtle, progressive cognitive deficiencies such as memory impairment or learning disabilities (Mulhern et al. 1999). A leukoencephalopathy has been described in children with acute lymphoblastic leukemia who received intrathecal and intravenous methotrexate (Lovblad et al. 1998} and whole-brain irradiation (Hcrtzberg et al. *1997).* Patients develop subtle but progressive cognitive decline as well as seizures. Similar findings are reported with high dose cytosine arabinoside. In its severe form, the child becomes demented and incapacitated. The MRI and CT show a diffuse periventricular Icukomalacia with patchy necrosis and calcification. The administration of high-dose intravenous methotrexate following radiation therapy results in an especially high risk of leukoencephalopathy, and this sequence of treatments should be avoided. Radiation necrosis may occur after radiation delivery to the tumor and surrounding brain. The necrosis is characterized by necrotic brain and tumor tissue that can cause mass effect, edema, and contrast enhancement on MRI. This complication of radiation may be indistinguishable trom progressive or recurrent tumor on conventional neuroimaging studies.

In fact, cerebral radionccrosis can produce symptoms identical to that of an expanding tumor including progressive focal neurological deficits, seizures, and increased ICP. Treatment of cerebral radionecrosis with corticosteroids may result in improvement of clinical symptoms and reduction in contrast enhancement on CT or MRI studies. However, surgical debulking is often necessary to reduce mass effect and increased ICP. Involvement of small cerebral blood vessels may lead to ischemic strokes. Eventually, the development of multiple small collateral vessels may result in a moyamoya pattern of vascular abnormality that, in turn, increases the risk for stroke or cerebral hemorrhage.

Secondary malignancies, including high-grade gliomas, atypical meningiomas (Santoro et ah 2002), and schwannomas, have been observed within the treatment field several years after the completion of radiation therapy. Patients with Turcot's syndrome, Gorlin's syndrome and NF1 are more likely to develop a secondary malignant glioma after radiation therapy compared with patients without these conditions. This ptovides additional rationale to defer, when possible, radiation therapy for low-grade gliomas. Growth tetardation in children with brain tumors is usually multifactorial. Radiation involving the pituitary gland may affect the production and release of growth hormone. In addition, spinal radiation (as part of craniospinal treatment) affects the growth of the vertebral bones. Pituitary function may also be impaired by direct invasion of the gland by adjacent tumor.

Chemotherapy

Bone marrow suppression is the most common hematological side effect of chemotherapy. Although this toxicity is usually reversible after stopping chemotherapy, some patients develop prolonged cytopenias. These patients are at risk for recurrent and opportunistic infections caused by neutropenia; risks of hemorrhage, resulting from thrombocytopenia as well as fatigue; syncope; and risk for cerebral and cardiac ischemia caused by anemia.

Secondary malignancies are also a potential late effect of chemotherapy. In children, acute myelogenous leukemia is the most common type of secondary malignancy induced by chemotherapy. Alkylating agents, platinum-based drugs, and etoposide are most commonly involved.

Peripheral neuropathy is a common late effect of several chemotherapies (Quasthoff and Hartung 2002). Cisplatin mainly affects proprioception and spares pain and temperature sensation. The usual presenting symptoms are painful dysesthesias and tingling sensations in the roes and later in the fingers. Motor fibers are spared. In contrast, vincristine produces a sensorimotor neuropathy. The first symptoms are usually tingling in the toes and fingers. Loss of ankle jerks is typically the first objective sign. Continued use leads to areflexia and motor weakness involving the dorsiflexors of the feet. Patients with pre-existing neuropathies may become quadriparetic after treatment with vincristine. Cerebellar syndromes of acute onset may be seen with high-dose eytarabine and occasionally with 5-fluorouracih These complications are usually reversible within 2 weeks, but severe irreversible damage to Purkinje cells may occur if the drug is given for several months or if the drug is reintroduced (Friedman and Shetty 2001).

Transverse myelopathy may be seen with prolonged treatments with intrathecal methotrexate or eytarabine. The risk is higher when combined with spinal irradiation.

CONCLUSION

Pediatric brain tumors arc a distinct group of neoplasms with unique characteristics with respect to clinical presentation and management. In contrast to the location of primary brain tumors in adults, posterior fossa tumors predominate in children. Pediatric brain tumors present with a variety of symptoms, usually involving changes in personality, nausea, vomiting, :\]\t.\ morning headaches. Neurological deficits may not become evident until a month or two after the onset of symptoms.

An accurate pathological diagnosis is critical for the management of pediatric brain tumors. Indeed, certain neoplasms have a benign course and good prognosis after gross total resection, despite a malignant appearance on MRI and pathological examination (e.g., PXA). Likewise, other tumors such as a DNET or a centtal neurocytoma may be mistaken for oligodendrogliomas. Because of the potentially severe side effects of adjuvant radiation and chemotherapy, these modalities of treatment should be reserved for truly malignant tumors that carry a poor prognosis. The prognosis and management of pediatric brain tumors is determined by such factors as histopathology, extent of resection, age of the patient and the presence or absence of metastases. Chemotherapy is assuming an iiKTC.iMngK impoi Mill role Il'. the management oi many types of malignant tumors in children. In many cases, chemotherapy may improve survival and reduce rhe chances of neurotoxicity by delaying the need for radiation therapy in young children.

Chapter 58
Cancer and the Nervous System

G. NERVOUS SYSTEM METASTASES

David Schiff and Patrick Wen

BRAIN METASTASES

Epidemiology

Parenchymal brain metastases are the most common direct neurological complication of systemic cancer. Their precise incidence is unknown; autopsy studies dating hack several decades suggested that brain metastases occurred in 15% of patients dying with cancer. Current estimates range from 20 to 40% (Posner 1995). Based on the greater than 500,000 cancer deaths yearly in the United States, these figures suggest a range of 75,000 to 200,000 new cases of brain metastases each year. For comparison, 35,000 new patients with primary brain tumors are diagnosed each year in the United States.

The incidence of brain metastases varies with the tumor type. For example, the chance of developing brain metastases is 1% in men with prostate cancer, whereas the figure is 3% in women with ovarian cancer. In contrast, the likelihood of developing brain metastases with melanoma ranges from 18-90%, whereas corresponding figures for lung cancer are 18-63% and for breast cancer 20-30%. Overall, lung cancer accounts for 40-50% of all patients with brain metastases and breast cancer accounts for 15-20% (Figure 58G.1). Melanoma, renal cell carcinoma, and gastrointestinal tumors each account for an additional 5-10% of cases (Lassman and DcAngelis 2003).

Brain metastases can arise anywhere in the brain, and their frequency in various locations reflects the relative proportion of cerebral blood flow. Thus 80% of metastases arise in the supratcntorial compartment. For unclear reasons, pelvic and gastrointestinal primary tumors are more likely to metastasize to the posterior fossa than to the supratcntorial region.

Although most patients develop brain metastases in the setting of known cancer, brain metastases are the initial manifestation of the underlying primary tumor in 10-30% of cases. Less than one fourth of these have clinical features pointing to the location of the primary tumor. Nonetheless, 80% will eventually have the primary site of tumor identified during their lifetime. Lung cancer is the most common cause of brain metastases presenting without a known primary, accounting for two thirds of cases. Among lung tumor metastases, two thirds are from non-small cell lung cancer (NSCLC) (Lc Chevalier et al. 1985). Gastrointestinal primaries account for an additional 10%. The high likelihood of a lung primary, and the fact that many patients with other primary tumors have lung

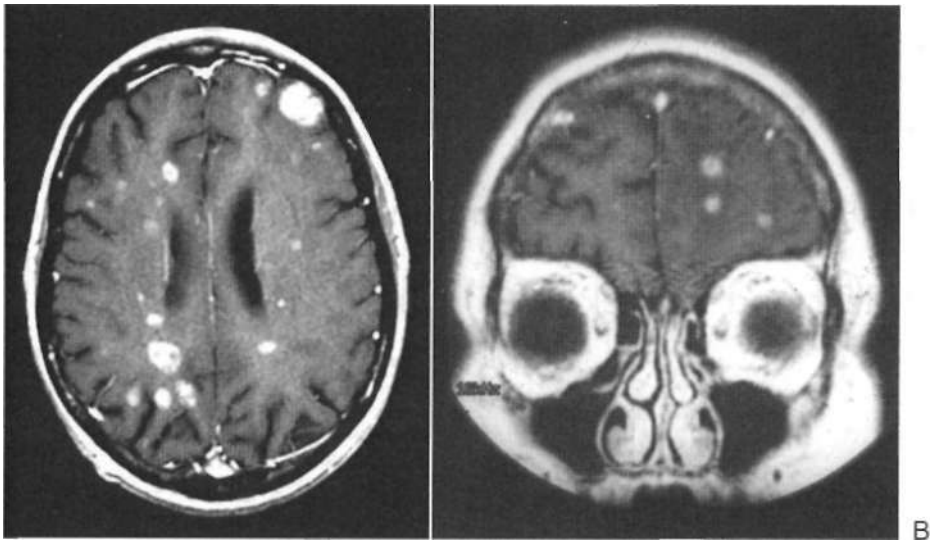

FIGURE 58G.1 (A) Axial and (B) coronal Tl-weighted, contrast-enhanced magnetic resonance image of the brain of a 58-year-old woman with breast cancer treated 1 year previously with whole-brain radiation therapy for brain metastases who presents with multiple recurrent lesions. The treatment options are limited to chemotherapy or reirradiation,

metastases by the time they develop brain metastases, makes restricting initial radiological studies to the chest the more cost-effective approach. Because most brain metastases are multiple, and most patients with brain metastases have a known cancer, only 15% of solitary intracranial masses in patients not known to have cancer turn out to be metastatic tumors (Voorhies et al. 1980).

Pathophysiology and Pathology

Parenchymal brain metastases generally arise from hematogenous spread, typically through the arterial circulation. Tumor emboli, like all emboli, tend to lodge at the gray-white junction because the caliber of blood vessels narrows at this site. These small emboli enlarge in a spherical fashion, eventually developing central necrosis as they outgrow theit blood supply. They are usually associated with substantial surrounding vasogenic edema and are well demarcated from the adjacent brain. The surrounding, normally functioning brain tissue is displaced, and herniation occurs if the displacement is not successfully treated.

The histopathology of brain metastases usually closely resembles that of the underlying systemic tumor. Brain metastases may have a highei labeling index (percentage of cells going through the cell cycle) than the corresponding systemic tumor, suggesting that their growth rate is faster.

Metastases from certain primary tumors (melanoma, choriocarcinoma, and renal cell carcinoma) have a tendency for intratumotal hemorrhage. This may be attributable to a tendency for neovascularization or because they invade blood vessels. Brain metastases from NSCLC also occasionally hemorrhage.

Clinical Presentations

Symptoms of brain metastases may arise as long as 20 years after discovery of the primary tumor, or may even antedate discovery of the underlying systemic cancer. The latter is common with lung cancer, whereas patients with systemic breast cancer and melanoma may enjoy years of apparent freedom from systemic cancer prior to discovery of cerebral metastasis (Henson and Urich 1982).

The presenting features are usually progressive over days to weeks, although occasional patients present acutely with seizures or intratumoral hemorrhage. I lalf of all patients complain of headache, and one third have mental status changes. Most headaches are indistinguishable from tension headache (Husain and Forsyth 2002). The "classic" brain tumor headache, which is worse in the mornings or awakens the patient from sleep, is uncommon, and its absence does not preclude the diagnosis of a brain tumor, Headache in the absence of other symptoms is more likely to be due to multiple metastases than a single metastasis, Over time, headache from brain metastasis becomes progressively more severe and may be accompanied by nausea, vomiting, and drowsiness. Unilateral weakness and gait disturbances are other common presenting complaints. Seizures are present at diagnosis in 18% of patients with brain metastases (Cohen et al. 1988).

Mental status changes and hemiparesis are the most common findings on neurological examination; each is present in approximately 60% of patients (Posner 1995),

Despite the frequent occurrence of increased intracranial pressure, papilledema is detected in only 10% of patients.

Differential Diagnosis

Several neurological conditions may mimic brain metastases both clinically and radiographically. A primary brain tumor must be considered, especially in patients with a single brain mass. This is a particularly important consideration in patients with breast cancer and a dural-based tumor (Schoenbcrg ct al, 1975). Abscess, demyelination, progressive multifocal leukoencephaloparhy, cerebrovascular disease, and the effects of radiation or chemotherapy also simulate brain metastases. Although the clinical syndroms ami ilic ncuroimaging studies usually provide a diagnosis, brain biopsy is sometimes required,

Ncuroimaging

Ncuroimaging advances since the early 1970s have made the diagnosis of brain metastases relatively easy in almost all cases. This topic is covered fully elsewhere in this section, and this discussion is limited to recent comparisons of various imaging modalities. Noncontrast magnetic resonance imaging (MRI) is as sensitive as contrast-enhanced computed tomography (CT) scan for detection of brain metastases. Metastases larger than 1 cm in diameter almost always produce an abnormality on T2-weighted images, whereas those smaller than 0,5 cm rarely do. Use of gadolinium-containing contrast agents dramatically improves the sensitivity of MRI, making it markedly superior to double-dose CT scanning with delayed imaging. Triple-dose administration of contrast further improves the sensitivity of MRI. Although the two dosages are equivalent for detecting metastases larger than 1 cm in diameter, triple dose studies demonstrate three times as many metastases smaller than 0.5 cm in diameter (Yuh et al. 1995). Delayed imaging after standard dose contrast is intermediate in sensitivity between single- and triple-dose gadolinium.

The differentiation of patients with one brain metastasis from those with multiple metastases has important therapeutic implications. In the pre-MRI era, approximately half of all patients had a single brain metastasis. Currently, 70-75% of patients with brain metastases have multiple metastases when studied with MRI. Lung cancer and melanoma are somewhat more likely to produce multiple cerebral metastases, whereas renal cell, breast, and colon cancer tend to produce single metastases. A distinction is made between single and solitary brain metastases: A solitary brain metastasis occurs in a patient with a single brain lesion and no systemic metastases, whereas single brain metastasis implies nothing about the extent of cancer elsewhere in the body.

Management

Supportive Care

Although the use of corticosteroids and antiepilcptic drugs (AEDs) are addressed in other chapters, a few comments pertinent to their rational use in brain metastases are appropriate. Corticosteroids improve symptoms associated with brain metastases in two thirds of patients. Their use improves median survival in otherwise untreated patients from 1 to 2 months. One randomized, controlled trial examined different doses in patients with brain metastases. These patients al! had a Karnofsky Performance Score (KPS) less than or equal to 80 (Tabic 58G.1). All patients received standardized whole-brain radiotherapy after receiving dcxamethasone for 1 week. In the first part of the trial, patients were randomized to receive either 8 or 16 mg daily in divided doses. The two groups did equally well, with slightly less toxicity related to steroids in the lower-dose group. Other patients were then randomized to either 4 or 16 mg daily. The lower-dose group did slightly less well at 7 days (although the difference was not significant) and better at 28 days, with significantly less toxicity than the high-dose group. The authors concluded that unless patients were in danger of herniation, 2 mg twice daily was an appropriate starting dose (Vecht et al. 1994).

Approximately 10-20% of patients with brain metastases present with seizures and require treatment with standard anticonvulsants. The use of prophylactic anticonvulsants in patients who have not had seizures is controversial. Fewer than 20% of these patients experience seizures later in the course of their illness, and this risk does not appear to be reduced with prophylactic anticonvulsants. Consequently, the American Academy of Neurology has issued a practice parameter recommending against the

Tabic 58G.1: Karnofsky performance status

KPS 100	Normal; no complaints; no evidence of disease
KPS 90	Able to carry on normal activity; minor signs or symptoms of disease
KPS Nn	Norma! activity with effort; some sign or symptoms of disease
KPS 70	Cares for self; unable to carry on normal activity or do active work
KPS 60	Requires occasional assistance, but is able to care for most personal needs
KPS 50	Requires considerable assistance and frequent medical care
KPS 40	Disabled; requires special care and assistance
KPS 30	Severely disabled; hospitalization is indicated, although death not imminent
KPS 20	Very sick; hospitalization necessary; active support treatment is necessary
KPS 10	Moribund; fatal processes progressing rapidly
KPS I'	Dead

prophylactic use of anticonvulsants in patients with brain metastases who have not had a seizure (Glantz et al. 2000). Potential exceptions to this guideline include patients with metastases from melanoma (which may be more epileptogenic because of multiplicity- or hemorrhage), tumors in motor cortex, or concomitant parenchymal and leptomeningeal brain metastases.

Management

Radiation Therapy. The goals of radiation therapy (RT) are to alleviate neurological deficits attributable to tumor and to shrink the tumors and prolong survival. In terms of meeting the first goal, approximately three fourths of patients undergoing RT experience symptom palliation, and two thirds maintain this improvement (('airik KISS el a I, 1980). With respect to tumor shrinkage, this depends on the size and radiosensitiviry of the metastasis. With standard doses of whole-brain radiation therapy (WBRT), 37% of patients with SCLC, 35% with breast cancer, 25% with squamous cell cancer, and 14% with nonbreast adenocarcinomas achieve a complete response (CR) (Nieder et al. 1997). Tumors with a pretreatment volume of less than 0.5 ml. had a 100% CR rate, whereas tumors with a pretreatment volume larger than 10 ml. had little likelihood of disappearing in the same study. These results highlight the unfortunate fact that CR of brain metastasis to WBRT is the exception, not the rule.

The Radiation Therapy Oncology Group (RTOG) has conducted a series of clinical trials exploring and comparing the results of different dose-fractionation schemes. Schedules ranging from 5 fractions of IOO cGy to 20 fractions of 250 cGy have resulted in similar outcomes. With all of the schedules, the median survival with WBRT is approximately 4 months, and the 1-year survival is 15%. Approximately 40% of patients succumb to their intracranial disease; the remainder die from progression of extracranial tumor.

The large RTOG database has permitted the application of statistical techniques such as recursive partitioning analysis (RPA) to separate patients with brain metastases treated with WBRT into different prognostic classes based on clinical features at presentation. Patients with brain metastases can be divided into three classes. Class 1 consists of patients with a KPS greater than or equal to 70 (see Table 58G.1), age younger than *65* years, primary site of tumor resected or controlled with treatment, and no extracranial sites of metastatic tumor. Such patients have a median survival of 7.1 months. Class 3 is composed of all patients whose KPS is less than 70; the median survival in this group is only 2.3 months. Class 2 contains all patients who do not fall into classes 1 and 3; class 2 patients have a median survival of 4.2 months (Caspar et al. 1997).

Radiation sensitizers with selective tumor uptake offer the theoretical promise of increasing the efficacy of WBRT. A recent randomi/.ed clinical trial of motexafin gadolinium administered prior to each radiation treatment did not find any prolongation of survival or time to intracranial tumor progression. However, patients with brain metastases from NSCI.C had significantly prolonged time to tumor progression with this agent. This finding requires confirmation. RSR-13, an allosteric modifier of hemoglobin that allows more oxygen to he released to hypoxic tissue, has shown promising results in phase II studies, and is currently being evaluated in a phase III trial.

Radiation Toxicity. With standard fractionation schemes, WBRT is tolerated well. Patients should expect temporary alopecia and fatigue. Headache and nausea occasionally occur, but are generally alleviated with corticosteroids and antiemetics.

Long-term survivors of brain metastases are at risk of suffering late complications of WBRT. Of WBRT recipients for brain metastases, 10-30% develop cognitive impairment by I year (Benin and Delattre 2002). Symptoms commonly include poor short-term memory, abulia, gait unsteadiness, and urinary urgency. MRI frequently reveals extensive, symmetric periventricular white matter changes termed radiation leukoencephalopathy, ventrieulomegaly, and sometimes cortical atrophy. The clinical picture may resemble normal-pressure hydrocephalus, but a positive durable response to ventriculoperitonea! shunt is uncommon (DcAngeiis et al. 1989). Because the risk of this complication is greater with larger fraction sizes, many radiation oncologists treat patients with good prognosis with 20 fractions of 200 cGy or similar regimens.

Prophylactic Cranial Irradiation. Brain metastases are extremely common in SCLC, being present in 10% of patients at diagnosis, increasing to 20% during therapy, and 35% at time of autopsy (Jeyapalan and Henson 2002). At 2 years postdiagnosis, the cumulative risk of brain metastasis is 47% for patients with limited disease and 69% for those with extensive disease. Presumably the brain is a pharmacologic sanctuary for microscopic tumor against systemic chemotherapy, which does not penetrate the intact blood-brain barrier. This has led to numerous trials designed to test whether prophylactic cranial irradiation (PCI) would decrease the incidence of brain relapse and improve survival in patients who achieved systemic CR. Typically, 24 to 36 Cy W^{f}BRT has been administered in 2-2.5 Gy fractious. A metaanalysis of these studies indicated that PCI reduced the risk of subsequent brain metastasis in half the patients and modestly increased 3-year survival from 15.3 to 20.7% {p = .01) (Auperin et al. 1999). Controversy still remains over whether the benefits of PCI outweigh its toxicities, particularly leukoencephalopathy. Two large prospective randomized trials of PCI did not document increased neuropsychological deficits among PCI recipients. Others have argued that the smalt numbers of long-term survivors in these trials

precluded accurate assessment of the risk of leukoencephalopathy, and that because PCI benefited only about one fourth of its recipients, it should not be considered standard therapy.

Surgery. For several decades, neurosurgeons resected single brain metastases in selected patients and argued that surgery produced better results, particularly noting improvement in the percentage of long-term survivors, than with radiotherapy alone. In 1990 a randomized controlled trial verified the neurosurgeons' contention. In this study, eligible patients had a single surgically accessible metastasis identified by contrast CT or MRI scan. Patients with highly radiosensitive primary rumors were excluded. Patients were randomized to biopsy followed by WBRT (36 Gy in 12 fractions) versus resection and radiotherapy. Patients who underwent surgical resection of the metastases followed by RT developed fewer local recurrences (20% versus 52%), and significantly improved survival (40 weeks versus 15 weeks) compared with those patients who received only a biopsy and RT. Patients who underwent surgical resection also had improved performance status and a reduced risk of dying as a result of neurological causes. Multivariate analysis showed that surgery and longer time between diagnosis of the primary tumor and the development of brain metastases were associated with increased survival, whereas disseminated disease and increasing age were associated with decreased survival (Patchell et al. 1990). Thus in patients with surgically accessible single brain metastases and absent or controlled systemic cancer, surgical resection has become the standard of care.

The role of WBRT following resection of a single metastasis is uncertain. In one trial, patients with a single metastasis on gadolinium MRI scan who underwent complete resection were randomized to receive either 50.4 Gy in 28 fractions versus no radiation (Patchell ct al. 1998). The recurrence rate either locally or distantly in the brain was significantly reduced in the radiation group (18%) compared with the observation group (70%). However, overall sin \ p. .il did not Jrlri M;;iii[ic.i:itly ktwivr [lirlwo groups. Radiation substantially reduced the death rate resulting from neurological causes; however, patients in the observation group who did not die of neurological causes appeared to live longer than similar patients in the radiotherapy group. There was no difference in how long patients maintained functional independence. In the absence of survival benefit to postoperative WBRT, its use must be decided on an individual case basis. For some patients and physicians, the reduction in recurrent brain metastasis and neurological death will outweigh the potential side effects of radiotherapy.

Stereotactic Radiosurgery. Like conventional surgery, stereotactic radiosurgery (SRS) has emerged as a means of enhancing long-term local control of brain metastases. SRS is a technique of external irradiation that uses multiple convergent beams to deliver a high single dose of radiation to a radiographically well-circumscribed treatment volume. SRS is generally administered either with a gamma knife apparatus or a modified linear accelerator. With either technique, the use of a stereotactic head frame and the radiation delivery system allows for great precision with a rapid drop-off in radiation dose within millimeters of the target lesion, sparing normal brain the potentially deleterious consequences "1 high ilos;[1] radiation.

Numerous single institution experiences with radiosurgery for single or oligometasraric brain lesions have been published. In a review summarizing published series comprising more than 2000 patients treated over 8 years in the 1990s, Locffler found that SRS achieved permanent local control in more than 80% of patients w[r]ith complications in fewer than 10%. Outcome appeared independent of the number of metastases treated {Loeffleret al. 1999). Median survival following SRS is approximately 9-10 months, very similar to surgical series. Radiosurgical treatment is also effective for metastases that have recurred following fractionated radiotherapy.

One consistent and remarkable finding across SRS series is that metastases from highly radio-resistant tumors like melanoma and renal cell carcinoma, which respond very poorly to fractionated radiotherapy, respond virtually as well to SRS as do tumors far more sensitive to conventional radiation.

SRS offers the potential of treating lesions in locations generally considered surgically inaccessible. Metastases in eloquent cortex, basal ganglia, thalamus, and even the brainstem can be treated with relatively low risk. A technical limitation of SRS compared with conventional surgery is the inability to treat metastases greater than 3.5 cm in median diameter. Another advantage of surgery is its ability to alleviate mass effect quickly. Approximately 7% of metastases treated with SRS transiently increase in diameter on scan, reflecting a radiation reaction.

Because the results for SRS appear similar to those from surgery, one might ask whether SRS has been proven to improve the patient's outcome, as has surgery, when administered with fractionated radiation. A recently concluded RTOG clinical trial has affirmed this hypothesis by randomizing patients with one to three brain metastases to WBRT with or without radiosurgery. Patients with a single brain metastasis had a significant survival benefit from the addition of radiosurgery, as did patients younger than 50 and those in RPA class 1.

The role of WBRT following radiosurgery for brain metastases is also uncertain. Two retrospective cohort studies have examined this issue. Pirzkall ct al. (1998) compared outcomes in 158 patients treated with radiosurgery alone versus 78 receiving radiosurgery plus fractionated WBRT. All patients had three or fewer brain metastases. The overall median survival was 5.5 months, with no difference between treatment groups. However,

median survival in patients without extracranial tumor was increased in pal ictus gelling both forms oi radiation (15.4 versus 8.3 months, $p = .08$), There was a trend for superior local control in patients getting combined therapy. A similar smaller study also found no difference in median survival (11 months) or I year progression-free survival. Brain relapse was significantly more common in patients receiving radiosurgery alone; however, most patients who did relapse could still be salvaged. A phase III clinical trial addressing this issue in patients with one to three brain metastases is underway.

The effectiveness of radiosurgery versus surgery in patients with brain metastases has never been ascertained. Although surgeons occasionally remove two or three brain metastases, surgery is generally restricted to single lesions. Radiosurgery appear?, more i osl i ffcclivc llian MHL> IV, although surgery alleviates symptoms of mass effect much more rapidly and reliably than SRS. Phase III trials comparing these two modalities have been proposed, but no major trial has yet been undertaken.

Treatment Options for Recurrent Brain Metastases

Rcirradiation. Several ease series have examined the safety and efficacy of administering a second course of fractionated WBRT to patients with recurrent or progressive brain metastases. In general, this option is considered only in patients who had a good and relatively durable response to their prior course of WBRT. Sometimes the entire brain is reirradiated, but if metastases are not widespread, fractionated radiation may be delivered to a limited portion of the brain. A majority of patients achieve symptom palliation, which lasts a median of 3 months. Because survival under these circumsrances is generally limited (median survival 4 months), clinical radiation-induced leukoencephalopathy is relatively uncommon (Wongetal. 1996).

Chemotherapy, The concepi of administering chemotherapy for brain metastases is attractive. Not only could systemic chemotherapy potentially treat all the brain metastases, it would reach the systemic tumors that are often present. One difficulty is that most patients have already received treatment with those drugs that are mosr active against their primary tumor. As a result, these drugs are often not effective in eradicating the brain metastases, ! lie relative miperme.ibilit) ot the blood brain barrier to many chemotherapeutic agents is another complicating factor, although the presence of contrast enhancement in virtually all brain metastases indicates that the blood-brain barrier is partially disrupted in brain metastases,

Numerous studies have been conducted with various chemotherapeutic regimens in lung, breast, and other primary tumors. The role for chemotherapy is perhaps clearest in germ cell tumors, in which chemotherapy can often provide a durable CR. SCLC is another relatively chemosensitive tumor. Unfortunately, it is exceptional for patients with brain metastases from NSCI.C, melanoma, and breast cancer to have a radiographic response or prolonged disease stabilization with currently available chemotherapy. The development of new, more active agents offets the hope of improvement.

SPINAL CORD COMPRESSION

Epidemiology

Epidural spinal cord compression (ESCC) refers to compression of the spinal cord or cauda equina from a neoplastic lesion outside the spinal dura. This complication of systemic cancer is estimated to affect approximately 25,000 Americans each year (Sehiff 2003). Although every type of cancer is capable of producing ESCC, several tumors predominate. Thus in most series breast, lung, and prostate cancer each account for about 20%, whereas renal cell carcinoma, non-Hodgkin's lymphoma (NHL), and multiple myeloma typically account for 5-10% each (Sehiff 2002). Ewing's sarcoma and neuroblastoma are particularly common causes in children. Of all ESCCs, 20% occur in patients not previously known to have cancer; among this group, lung cancer, lymphoma, and multiple myeloma are the typical underlying tumors.

Pathophysiology and Pathology

A protective ring of bones encloses the spinal cord. The ring is composed of the vertebral body anteriorly, and the lamina, pedicles, and spinous processes posteriorly. The thecal sac lies within this bony ring. The outermost layer of the thecal sac is composed of dura mater that is continuous with cranial dura mater and fuses with periosteum of the sacrum at S2. The spinal epidural space lies between the periosteum of the vertebral bones and the dura, and normally contains fat, connective tissue, and a venous plexus. Tumor cells generally seed the vertebral bones (usually the vertebral body) rhrough hematogenous dissemination via arteries or the valveless, low-pressure venous plexus of Batson. The tumor gradually expands and forms an epidural mass, producing compression of the spinal cord. The tumor takes the path of least resistance, frequently encircling rhe spinal cord. Collapse of the vertebral body may occur, exacerbating the severity of spinal cord compression. Less commonly, primary or metastatic tumor in the paravertebral region grows through the neural foramen to produce ESCC. Animal models suggest that both demyelination, produced with slowly expanding masses and often reversible, and venous infarction, play a role in spinal cord dysfunction. Of ESCCs, 60% arise in the thoracic spine and 30% in the lumbar spine (Sehiff 2002).

Clinical Presentations

Back pain, present in 83-95% of patients at the time of diagnosis, is usually the first symptom of ESCC (Schiff 2002), On average, the pain precedes the development of neurological symptoms by approximately 2 months. The duration of pain is often related to the rate of tumor growth, with slower growing tumors presenting with longer duration of pain. Most patients have local pain, related to disruption and stretching of cortical hone and periosteum. Cough, movement, and recumbency commonly exacerbate the pain. Eventually, the pain takes on a radicular distribution, which in the thoracic spine may produce a bilateral gripping sensation. Pain is often quite severe by the time ESCC is diagnosed.

Motor involvement, the must dreaded of F.SCC manifestations, is present in 80% of patients (Hclweg-Larsen and Sorensen 1994). Once weakness is present, ptogression is often rapid, and diagnostic workup and thetapy must proceed expeditiously. This is particularly impottant because pretreatment neurological function is a major predictor of post-treatment outcome. Approximately 50% of patients with ESCC are ambulatory, 35% are paraparetic, and 15% are paraplegic at diagnosis. Weakness is typically bilateral and symmetric; the iliopsoas muscles may be disproportionately affected.

Sensory loss is detectable in about 75% of patients at diagnosis, typically reflecting the extent of weakness. Patients frequently experience ascending numbness and paresthesias. A correlation exists between the extent of sensory loss and the inability to ambulate (Schiff 2002). Radicular sensory loss may help to localize the level of r.SCC. However, the spinal sensory level detected on examination is often sevetal levels below the responsible lesion (Posncr 1995). Lesions above the cauda equina generally result in sparing of saddle sensation, whereas cauda equina lesions may produce saddle sensory loss. Occasionally, ESCC in the cervical cord may be associated with Ehermitte's sign, which is characterized by an electrical sensation in the spine and extremities with neck flexion,

Bowel and bladder dysfunction arc evident in a majority of patients with ESCC, taking the form of urinary retention, incontinence, and constipation. However, isolated bowel or bladder disturbance in the absence of back pain, weakness, or sensory loss is rarely related to ESCC, Isolated gait ataxia is another uncommon manifestation of ESCC,

Differentia! Diagnosis

The differential diagnosis of ESCC in cancer patients is broad and can be separated into neoplastic and non-neoplastic causes (Table 58G.2). Spine metastases not impinging on the thecal sac can produce severe pain mimicking ESCC. These may be clinically indistinguishable from ESCC. Patients with radiographically high-grade ESCC may not show features of radiculopathy and myelopathy if cord compression has developed slowly. Intramedullary spinal cord metastases are rare as compared with ESCC. The clinical features are similar to ESCC, although many patients pass through a stage in which spinal cord dysfunction is unilateral or at least very asymmetric, unusual with ESCC. Leptomeningeal metastases (LMs), which, like intramedullary spinal metastases, are discussed later, occasionally produces a cauda equina syndrome which may resemble ESCC. Radicular pain predominates over local pain in this condition, and bowel and bladder involvement may be particularly prominent compared with ESCC. Neoplastic masses in the brachial or lumbosacral plexus may also simulate ESCC, although unilateral findings are the rule. Malignant plcxopathy often coexists with ESCC, given the proximity to the spinal cord (Figure 58G.2),

Two rare neurological conditions related to, but not a direct result of, cancer are radiation myelopathy and paraneoplastic myelopathy. Radiation myelopathy may occur if the spinal cord was included in prior radiotherapy treatment ports (Benin and Delattre 2002). The most common form, *chronic progressive radiation myelopathy*, generally develops 1 to 2 years after radiotherapy. Ascending numbness and pyramidal tract dysfunction often occur in an asymmetric fashion, suggesting the Btown-Scquard syndrome. The risk of myelopathy is increased by high radiation doses, long length of irradiated spinal cord, and a latge radiation fraction size. Paraneoplastic disorders are a rare cause of myelopathy. The most common clinical syndrome Is a painless myelopathy accompanied by encephalitis or sensory neuropathy.

Table 5S(!,2: Differential diagnosis of epidural spinal cord compression

Causes that should be considered in cancer patients
Vertebral metastases without ESCC
Intramedullary spinal cord metastases
Leptomeningeal metastases
Malignant plcxopathy
Radiation myelopathy
Paraneoplastic myelopathy
Benign causes
Osteoarthritis
Rheumatoid arthritis
Tophaceous gout

KpiduiM lipomatosis
Sarcoidosis
Histiocytosis

ESCC = epidural spinal cord compression.

FIGURE 5 KG.2 This 65-year-old woman with lung cancer presented with a left apical lung tumor, and 3 months of distal left arm weakness and pain. She then developed distal right arm weakness consistent with C7, C8, and T1 pd/radiculopathy. Tl - and T2-weighted magnetic resonance imaging (MRI) scans demonstrate the apical mass extending into the neural foramina and vertehral bodies at C6 and C7, displacing [he cord anteriorly and to the right. Also seen is a pathological compression fractute at T3 producing moderate canal stenosis. (A) Coronal TI-weighted MRI showing left apical lung tumor extending into the neural foramina and vertebral bodies at Cfi and C7 *{arrow}*. (B) Sagittal Tl-weighted MRI showing tumor infiltrating vertebral bodies at C6 and C7 and displacing the spinal cord. Also seen is a pathological compression fracture at T3, producing moderate canal stenosis. (C) Sagittal T2-weighted MRI showing the same rumor infiltrating vertebral bodies at C6 and C7 and displacing the spinal cord. Also seen is a pathological compression fracture at T3, producing moderate canal stenosis.

A necrotizing myelopathy, without associated antibody or other serum markers, is also described with cancer.

Of the benign conditions that mimic ESCC, osteoarthritis is the most important. Features that may help differentiate the pain of FSCC from musculoskeletal disease include the frequent localization of pain from ESCC to the thoracic spine compared with the lumbosacral and cervical localization of pain from benign causes, and the tendency for recumbency to i\.Kerb a re the pain from I'SCC and relieve pain from benign causes. Other benign causes that should be considered in the differential diagnosis of ESCC include other types of arthritis such as rheumatoid arthritis and tophaceous gout, benign tumors such as meningiomas and neurofibromas, vascular malformations, epidural hematomas, extramedullary hematopoiesis, epidural lipomatosis, sarcoidosis, and histiocytosis.

Ncuroim aging

The availability of MRI has revolutionized the definitive diagnosis of ESCC (see Figures 58G.2B and 58G.2C). Prior to MRI, myelography with or without CT scanning was the gold standard. Prior to myelography, patients were often screened with plain radiographs or hone scans. Plain radiographs demonstrating vertebral collapse or pedicle erosion at a level corresponding to clinical findings were highly predictive of F'SCC. However, false negative studies were common. Radionuclide bone scanning was more sensitive, although this test could be normal in neoplasms without increased blood flow or new bone formation like multiple myeloma. Moreover, abnormal studies were frequently related to benign causes.

MRI and myelography are rhe only studies capable of demonstrating the thecal sac compression characteristic of ESCC. Myelography produces good images of the entire thecal sac as long as a complete block is not present; in that event, a second punctutc rostral to the block may be necessary to delineate the upper extent of epidural tumor. Disadvantages of myelography, in addition to its invasiveness, include its insensitivity to intramedullary pathological conditions and the potential risk of precipitating a cerebral or spinal herniation syndrome. Patients suspected of having cerebral metastases should undergo brain imaging prior to myelography. Additionally, neurosurgical consultation should be sought prior to the procedure in case patients with complete subarachnoid block deteriorate neurologically following the myelogram ("spinal coning"). Patients with pacemakers, certain aneurysm clips, and shrapnel who cannot undergo MR] remain dependent on myelography.

MRI produces excellent images of the spinal cord, thecal sac, and bony spine, demonstrating metastases in each of these areas when they are present. Typically radiologists perform scans in the sagittal plane, with selected axial images through regions of interest identified on the sagittal images. MRI allows the entire spine to be screened for epidural metastases, an important advantage because 30% of patients with ESCC have multiple epidural deposits. Noncontrast Tl- and T2-weighted MRIs are generally satisfactory to screen for abnormalities in the bone and epidural space. Gadolinium administration may be helpful

in delineating the epidural tumor and leptomeningeal metastases.

Management

Corticosteroids

A few years after the beneficial effect of corticostetoids on brain tumors was established, corticosteroids were observed to ameliorate the clinical features of ESCC. Since then corticosteroids have been routinely used in patients with ESCC. Subsequently, rodent models of ESCC confirmed a benefit with dexamethasone. One randomized controlled trial of dexamethasone in patients with carcinomatous ESCC undergoing radiation showed that the use of dexamethasone increased the likelihood of patients remaining ambulatory (Sorensen et al, 1994). The optimal dose of corticosteroids for ESCC remains unresolved. Based on extrapolation from a dose that was demonstrated to be effective in rodent models, some protocols have suggested an initial dose of 100 mg dexamethasone, followed by 24 mg four times daily. Retrospective cohort studies suggest that substantially lower doses (e.g., 10 mg initially and then 4 mg four times daily) achieve equivalent results with fewer serious corticosteroid complications such as gastrointestinal bleeding (Heimdal et al. 1992). If the higher dosage is used, one reasonable strategy is to taper the dose by 50% every 3 days so long as the patient is stable.

Radiotherapy

Radiotherapy is the treatment of choice for most patients with ESCC. By stopping tumor growth and sometimes shrinking the tumor, radiotherapy usually alleviates pain and stabilizes or improves neurological function. Radiation ports are created on the basis of the radiological studies, and traditionally extend one vertebral level above and below the site of epidural tumor. Ports arc widened when a paravertebral mass is known to be present. Radiation dose represents *A* compromise among tumor control, risk of radiation myelopathy, and treatment duration compatible with the patient's condition. No prospective controlled trial has examined different dose-fractionation schemes. Commonly, radiation oncologists deliver approximately 3000 cGy in 10 fractions over 2 weeks.

Prognosis with ESCC following radiotherapy depends most heavily on pretreatment neurological function. Another important factor is the radiosensitivity of the underlying tumor. Some cancers, like lymphoma, myeloma, and prostate cancer, are quite radiosensitive; others, including renal cell carcinoma and non-SCLC, are relatively radioresistant. Patients with radiosensitive rumors are much more likely to have tumor shrinkage and long-term local tumor control with radiotherapy than those with radioresistant ones. Finally, the degree of subarachnoid block is a prognostic factor; patients with high-grade block tend to fare worse than patients with minimal deformation of the thecal sac from epidural tumor.

In general, almost all patients who are ambulatory at the onset of radiorherapy remain ambulatory at its conclusion. Among patients who are Aira paretic and una Mi[1] u> W.LX, one third regain ambulation. Only 2-6% of patients regain the ability to walk when treatment is delayed until after the patient is paraplegic. Median survival following ESCC is approximately 6 months, and is better in patients who remain ambulatory. Eocally recurrent ESCC occurs in one half of 2-year survivors.

Recently, neurosurgeons and radiation oncologists have been working to modify radiation equipment to deliver SRS to the spine. Although few data have been reported in detail, and precision with high-dose radiation around the spinal cord will be crucial, such techniques offer the promise of treating rumors resistant to fractionated radiotherapy.

Surgery

Decompressive laminectomy had been standard practice for patients with ESCC. In the 1970s, it was widely recognized that the results from radiotherapy were at least as good as those from laminectomy with less morbidity. One of the major shortcomings of laminectomy was that epidural tumor usually arose anterior to the spinal cord in the vertebral body. In this situation, not only did laminectomy fail to provide exposure to debulk the main tumor mass, it removed one of the elements of the spinal column still providing stabilization.

More recently, surgeons have performed vertebral corpectomy to treat patients with ESCC. In this procedure, tumor in the vertebral body is curetted out from an anterior or lateral approach. The spine is then stabilized with methylmcthacrylate or hone graft and instrumentation. The complication rate of this procedure is relatively high and includes infection, stabilization failure, wound breakdown, and hemorrhage. However, it does allow for more complete tumor resection than laminectomy for anteriorly situated tumors. An ongoing clinical trial is comparing the outcome of vertebral corpectomy to radiotherapy. Vertebral corpectomy particularly should be considered in cases of spinal instability, rctropulsed bone within the spinal canal, local recurrence during or after radiotherapy, and radioresistant tumors when other sites of metastasis are limited.

Chemotherapy

Chemotherapy is a rational means of treating ESCC when the causative tumor is chemosensitive. Most common solid tumor causes of ESCC arc not chemosensitive. b'or Hodgkin's lymphoma, germ cell tumors, and neuroblastoma, chemotherapy may effectively treat both the ESCC

and other sites of disease. Hormonal manipulation has been documented to be of benefit in cases of ESCC from prostate and breast cancer.

INTRAMEDULLARY SPINAL CORD METASTASES

Metastases are capable of spreading to the substance of the spinal cord, either by hematogenous spread, or secondary to leptomeningcal invasion and subsequent centripetal growth. Intramedullary spinal cord metastases cause progressive myelopathy, which often initially takes the form of a *hemicord* syndrome *(Brown-Sequard syndrome)* with ipsilateral pyramidal weakness and posterior column sensory loss, and contralateral spinothalamic sensory loss. Lung cancer accounts for about half of all cases, with small cell histology being particularly common. Melanoma, lymphoma, and renal cell carcinoma are other common causes. MRI scanning generally reveals a contrast-enhancing mass with a larger surrounding region of T2 signal abnormality (edema). Most patients with this complication cither have concurrent or prior brain metastases. Treatment generally consists of corticosteroids and fractionated radiotherapy, which usually stabilize neurological function for several months (Schiff & O'Neill 1996).

LEPTOMENTNGEAL METASTASES

Involvement of the lep to meninges by tumor is an increasingly common problem in patients with cancer, and leads to significant morbidity and mortality (Mason 2002; Kesari and Barchelor 200.3). The factors that have contributed to the increased incidence are a greater awareness of the condition among oncologists, improved diagnostic tests, and longer survival among patients with systemic malignancies. Longer survival of patients with systemic cancers results in a higher incidence of central nervous system (CNS) metastases.

Epidemiology

Approximately 5% of cancer patients have LM (Posner 1995). The incidence varies with different tumor types. LM occurs in up to 8% of patients with solid tumors, 5-29% of patients with NHL, and 11-70% of leukemias (Wen and Fine 1937; Kesari and Batchelor 2003).

Among solid tumors, adenocarcinomas have a particular propensity to metastasize to the leptomeninges. In several large series, breast cancer accounted for 1 1-64% of patients with LM, followed by lung cancer (14-29%), melanoma (6-18%), and gastrointestinal cancers (4-14%). Primary brain rumors, especially medulloblastomas and high-grade gliomas, also have a tendency for cerebrospinal fluid (CSE) spread. Some solid tumors, such as head and neck cancer, thyroid cancer, prostate cancer, carcinoid, and bladder cancer rarely seed the leptomeninges (Wen and Line 1 997; Kesari and Batchelor 2003).

LM associated with acute lymphoblastic leukemia (ALL) in children was previously common, but CNS prophylaxis has reduced the incidence from 667u to 5%, The incidence of LM in adults with ALL remains high, despite similar prophylactic measures. Patients with acute myelogenous leukemia have a 20-50% risk of meningeal involvement, whereas LM is uncommon in patients with chronic myelogenous leukemia and hairy cell leukemia. Leptomeningcal involvement is present in up to 50% of patients with chronic lymphocytic leukemia at autopsy, although it is almost always asymptomatic during life (Grossman and Moynihan 1991).

Seeding of the leptomeninges occurs in approximately 6% of patients with NHL. The highest risk occurs in those with diffuse, lymphoblastic, or Burkitr's histology, or those who have involvement of the bone marrow, testes, or cxtranodal sites. Leptomeningcal disease is rare in patients with Hodgkin's disease, mycosis fungoides, and multiple myeloma (Grossman and Moynihan 1991).

Pathogenesis

Tumor cells usually reach the leptomeninges by direct extension from pre-existing tumor in the brain parenchyma or epidural space or by hematogenous spread (Posner 1*99S).* Tumor cells may also spread along spinal nerve roots from a paraspinal mass or along cranial nerves from a head and neck tumor. Once tumor cells reach the leptomeninges, they spread along the surface of the brain, spinal cord, and nerve roots (Figure 58G.3). Exfoliated tumor cells are carried by the flow of CSF to other parts of the ncuraxis, especially to the basal cisterns and Cauda equina, where they tend to settle as a result of gravity and slow CSF flow.

The presence of tumor cells in the leptomeninges produces neurological dysfunction in several ways. Direct invasion of spinal and cranial nerves can cause demyelination and subsequent axonal degeneration of the nerves. Tumor cells may also grow along the Virchow-Robin spaces and directly invade the brain or spinal cord, producing symptoms of confusion and seizures (Wasserstrom 1995). LM may also produce CNS dysfunction by causing hydrocephalus. Tumor cells can occlude the CSF outflow foramina of the fourth ventricle or impede the reabsorption of CSF through the arachnoid granulations, leading to hydrocephalus. Occasionally the intracranial pressure may be increased without enlargement of the ventricles, and, rarely, herniation may occur. Tumor cells may interfere with the blood supply, decreasing cerebral blood flow and even producing transient ischemic attacks and strokes. Tumor cells may also directly compete with neurons for oxygen and essential metabolites such as glucose. This is

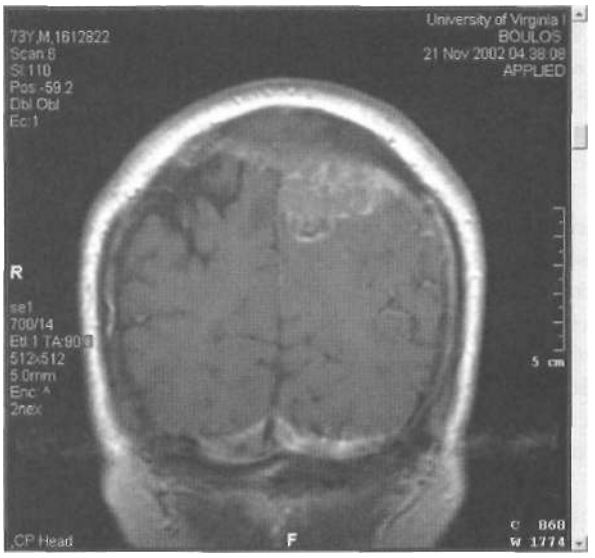

FIGURE 58G.3 Gross appearance of tumor infiltrate in the subarachnoid space as evidenced by clouding of the Ieptomeninges. (Courtesy of Dr. Umberto De Girolami, Division of Neuropathology, Brigham and Women's Hospital.)

the mechanism proposed for the weight gain seen in children with leukemic meningitis and infiltration oi the hypothalamus (Posner 1995).

Clinical Features

LM is usually a late complication of systemic cancer, occurring 6 months to 3 years after the diagnosis of the primary tumor (Wasserstrom 1995). In rare patients with breast carcinoma and melanoma, an interval of up to 10 years may exist between the diagnosis of the primary tumor and the Leptomeningeal relapse. LM usually occurs in the setting of active disease outside the nervous system, although as systemic therapy improves, increasing numbers of patients are developing LM as the sole site of relapsed disease. In 5% of patients, leptomeningeal involvement is the initial presentation of a neoplasm (Posner 1995).

The presentation of LM can be extremely variable and requires a high index ol suspicion. The diagnosis should be considered in any cancer patient, especially if there are symptoms and signs involving several different sites in the neuraxis.

Cerebral symptoms occur in up to 50% of patients (Kaplan et al. 1990; Wasserstrom 1995). The most common are headaches, which can be nonspecific or have features suggestive of increased intracranial pressure. Other symptoms include nausea, vomiting, cognitive changes, and occasionally seizures. Focal cerebral symptoms are relatively rare. Papilledema may occasionally be present in patients with hydrocephalus. Rarely, LM may produce a diencephalic syndrome, diabetes insipidus, central hypoventilation, cerebral infarction, and complex partial status epilepticus (Wen and Fine 1997).

Thirty percent of patients have cranial nerve symptoms and 50% have cranial nerve signs. Involvement of the third, fourth, and sixth nerves is most common, followed by facial weakness, decreased hearing, and involvement of the optic, trigeminal, and hypoglossal nerves.

Approximately 60% of patients have spinal symptoms, especially in the lumbosacral region, as a result of involvement of nerve roots. The most common symptoms are pain, weakness, and paresthesias. Sphincter dysfunction is less common. More than 70% of patients have signs of spinal cord dysfunction, including asymmetric weakness, sensory loss, and depressed reflexes.

Diagnostic Tests

The most useful tests for the diagnosis of LM are summarized in Table 58G.3.

Cerebrospinal Fluid Examination

Examination of the CSF is the most important test for the diagnosis of LM. The finding of malignant cells in the CSF is the definitive diagnosis. However, the CSF is almost always abnormal even if the cytological examination result is negative. These abnormalities may include lymphocytic pleocytosis, elevated opening pressure, increased CSF protein, and a decreased glucose concentration (Fosner 1995; Kesari and Batchelor 2003). In 3% of patients, the CSF is normal. This usually occurs in patients who have a block in the CSF pathway with the result that the area of CSF sampled (e.g., ventricular CSF) may not be connected

Table 58G.3: Diagnostic tests for leptomeningeal metastases

Test	*Measurement*	*Positive findings*
Lumbar puncture	Lymphocytic pleocytosis	>70%
	Elevated opening pressure	50%
	Elevated protein	75%
	Reduced glucose	30-40%
	Cytology after ILP	50%
	Cytology after 3LPs	90%
	CSF markers	Variable
	Immunohistochemistry	Variable
	PCR	Variable
Brain MRI	Meningeal enhancement	>50%
	Enlarged ventricles	<50%
Spine MRI/ myelogram	Subarachnoid masses	<25%
	Meningeal enhancement	>50%

CSF = cerebrospinal fluid; MRI = magnetic resonance imaging; PCR — polymerase chain reaction.

to the areas involved by leptomeningeal tumor (e.g., cauda equina).

The opening pressure is elevated in approximately 50% of patients with LM as a result of tumor cells obstructing CSF outflow from the ventricles or interfering with CSF reabsorption by the arachnoid granulations,

The CSF white blood cell count is elevated in more than 50% of patients with LM. This increase in cell count may range from a few cells to more than 1000. This is usually a lymphocytic pleocytosis, but occasionally polymorphonuclear cells may be found. Rarely, patients with Hodgkin's disease, NHL, and leukemia have eosinophils in the CSF.

The CSF protein is elevated in most patients as a result of a combination of disruption of the blood CSF barrier and exudation of serum protein into the CSF, and breakdown of tumor cells and lymphocytes. In most, the protein is moderately elevated, but levels in excess of 2 g/dl can be seen. Because normal levels of CSF protein are lower in the ventricle (10 mg/dl) than in the lumbar space (40-45 mg/dl), a CSF protein level of 40 mg/dl from an Ommaya's reservoir should be considered abnormal. In patients with leptomeningeal myeloma CSF immunoglobulin (Ig)M may be elevated.

Low CSF glucose (hypoglycorrhachia) is present in approximately 30% of patients with LM (Wassertrom et al. 1982). The precise cause of the low CSF glucose is unknown. Possible reasons include impaired carrier mediated transport of glucose across the blood-CSF barrier and increased utilization of glucose by tumor cells and reactive lymphocytes.

A positive CSF cytological examination result is diagnostic of LM. Ideally, fresh samples of CSF should be sent to the laboratory for cytological examination. When not possible, the CSF should be stored in a refrigerator until it can be analyzed. Positive cytological examination result is found in approximately 50-60% of patients with the initial lumbar puncture and in up to 90% of patients with repeated sampling (Posncr 1995). In general, the CSF cytological examination result is more likely to be positive when obtained from the lumbar CSF than ventricular CSF. The presence of malignant cells in CSF tends to correlate with more extensive leptomeningeal disease. In 8-10% of patients with LM, the CSF cytological result remains persistently negative. This may result from malignant cells remaining adherent to the leptomeninges without being shed into the CSF, or from a blockage in the CSF pathway so that the area from which CSF is being sampled is not in communication with the site of LM. In patients with subarachnoid blocks and cerebral or cranial nerve symptoms, a cisternal puncture may increase the diagnostic yield. Rarely, false positive cytological results may occur in parients who have brain metastases without leptomeningeal involvement, as a result of laboratory error, or when reactive lymphocytes are misinterpreted as malignanr.

When the CSF cytological examination result is negative, biochemical markers can sometimes be useful in assisting the diagnosis of LM and monitoring the response to therapy (Wen and Fine 1997; Kesan and Batchelor 2003). Some of the more commonly used markers are listed in Table 58C.4. Although some of these markers are fairly specific, their usefulness is often limited by their relative lack of sensitivity. Occasionally, parenchymal metastases adjacent to leptomeningeal or ependymal surfaces falsely elevare die levels of biochemical markers in the CSF.

In some patients immunocytochemistry can increase the sensitivity for detecting malignant cells. Monoclonal antibodies against surface markers on lymphocytes can be especially useful in distinguishing lymphoma cells, which are usually monoclonal B-cells, from reactive T lymphocytes. ITowever, because malignant lymphocytes can be mixed with reactive T cells, the presence of polyclonality does not exclude tumor. When the diagnosis of leptomeningeal lymphoma is difficult, polymerase chain reaction (PCR) techniques can be used to determine

Table 58G.4: Cerebrospinal fluid tumor markers in leptomeningeal metastases

Marker	*Tumor*
Relatively specific	
AFP	Tcratocarcinoma, yolk sac tumor, ECC, endodermal sinus tumor
CA-125	Ovarian cancer
CA-15-3	Breast cancer
CAI9-9	Adenocarcinoma, biliary disease
Creatine kinase BB	Small cell lung cancer
HCG /J-subunit (,8-HCG)	Choriocarcinoma, ECC, germ cell rumor
5-HIAA	Carcinoid
HPAP	Germinoma
IgM	Myeloma
Melanin	Melanoma
PSA	Prostate cancer
Tissue polypeptide antigen	Breast cancer
Nonspecific	
fii -microglobulin	Lymphoma, infection, other tumors
/(-glucuronidase	Nonspecific
CEA	Colon, ovarian, breast, bladder, lung
HMFG1 mAb	Nonspecific
l.DH isoenzymes	Carcinoma, non-specific
Tclomcrasc	Non-specific.
VEGF	Non-specific

AFP = alpha fetoprotein; CA = carbohydrate antigen; CEA = carcinoembryonic antigen; ECC = embryonal cell carcinoma; HCG = human chorionic gonadotropin; HIAA — hydroxyindoieacetic acid; HMFG — human milk fat globule; HPAP — human placental alkaline phosphatase; IgM = immunoglobulin M; LDH = lactate dehydrogenase; PSA = prostate specific antigen; VEGF = vascular endothelial growth factor,

whether the Ig gene rearrangement is identical in all the lymphocytes, suggesting a neoplastic process (Thomas ct al. 2000).

Neuroimaging

MR1 is the most sensitive neuroimaging test for detecting LM, Meningeal enhancement is present in half of patients with LM. Also observed arc small enhancing cortical nodules and communicating hydrocephalus from impaired CSF absorption. Rarely, focal LM may mimic a meningioma. Whenever possible, MR1 should be performed before lumbar puncture. Lumbar puncture occasionally results in intracranial hypotension and meningeal enhancement, which leads to an erroneous diagnosis of LM. Myelography shows thickening and nodularity of nerve roots in 25-33% of patients with LM, and may be helpful when MRI can not be done. Increasingly, the diagnosis of LM is established in patients with characteristic clinical and radiological findings, even if the CSF cytological examination result is negative (Freilich et al. 1995).

Other Tests

Cerebral angiography may show areas of narrowing resulting from spasm of pial vessels or infiltration of their walls by tumor, but is now rarely performed. Electroencephalography (EEG) is usually normal or shows nonspecific changes including focal or generalized slowing or sharp activity. Rarely, EEG shows triphasic waves or seizure activity. Electromyography (EMG) may show evidence of polyradiculopathy and prolonged F-wave latencies, but is rarely useful. When the diagnosis of LM is strongly suspected, but routine tests are all normal, a meningeal biopsy may be helpful.

Diagnosis

The diagnosis of LM is based on the combination of characteristic clinical, radiological, and CSF features, and ideally, the presence of a positive CSF cytological examination result. Other conditions causing subacute neurological deficits at multiple sites in the neuraxis may mimic LM (Table 58G.5). These include parenchymal and epidural tumor deposits and subacute and chronic meningitides such as syphilis, sarcoidosis, Lyme disease, and fungal and tuberculous meningitis. Routine imaging, CSF studies, and positive cytological examination result usually distinguishes other entities from LM. Specific serological tests arc also useful. These include Lyme antibody titers; serum angiotensin converting enzyme (sarcoidosis); fluorescent treponemal antibody (syphilis); cryptococcal antigen; fungal cultures; and PCR for herpes simplex, varicella zoster, and tuberculosis. A meningeal biopsy may be useful when the diagnosis remains in doubt.

Treatment

Despite more than three decades of effort, the treatment options for LM remain limited. Reasons for the difficulty include (1) the need to treat the entire neuraxis because of widespread dissemination of tumor cells throughout the subarachnoid space; (2) the close proximity of the tumor cells to neural structures; (3) the need to limit the administered doses of radiation and chemotherapy because of potential neurotoxicity; (4) the blood-CSF barrier, which limits access of many systemically administered drugs into the CSF; and (5) the intrinsic resistance of many solid tumors.

The goal of therapy is to improve or stabilize the patient's neurological status and prolong survival. The specific treatment depends on the tumor type, the site of the leptomeningeal tumor, and the clinical condition of the patient. Without treatment, the median survival of patients with LM is 4 to 6 weeks. Death usually results from progressive neurological dysfunction. With treatment, the median survival is increased to 3-6 monrhs. The response rate is 50-60% for carcinomas, and more than 80% for **NHL** (Wen and Fine 1997). Although treatment often provides effective local control, LM usually occurs in the setting of systemic relapse, and most patients who survive beyond the first month (two thirds of the total) eventually die of their systemic disease. As systemic therapy improves, LM will become the sole site of relapse. LM will then become an increasingly important problem. The patients who benefit most from treatment are those with minimal neurological deficits, good performance status, slowly

Tabic 58G.6: Treatment of ieptomeningeal metastases

Radiation therapy to sites of symptomatic and bulky disease
Intrathecal chemotherapy
Methotrexate (10 mg twice weekly) + leucovorin
Thiotepa (10 mg twice weekly)
Cytarabine (50 mg twice weekly)
Cytarabine (DepoCyt) (50 mg every 2 weeks)
Systemic chemotherapy (e.g., high-dose methotrexate)
Optimal treatment of systemic disease

progressive systemic disease with little or no systemic metastases, and a diagnosis of NHL or breast cancer (Grossman and Moynihan 1991).

Because tumor cells are disseminated throughout the subarachnoid space, the entire neuraxis must be treated if therapy is to be effective. If only symptomatic sites are treated, early relapse is likely secondary to seeding from residual tumor cells in untreated areas of the leptomeninges. Currently, standard therapy for LM involves radiation to sites of symptomatic and bulky disease, intraventricular administration of chemotherapy via an Ommaya or Rickham reservoir, and optimal treatment of systemic disease (Table 58G.6).

Radiation Therapy

RT is limited to symptomatic areas and sites of bulky disease, where the penetration of intrathecal drugs is limited. Although RT is more effective than chemotherapy in treating tumor cells in the Virchow Robin's spaces and nerve root sleeves, the use of craniospinal radiation to the entire neuraxis is rare because of bone marrow suppression. This is of particular concern in patients with LM because many have systemic metastases that require treatment with chemotherapy. The dose of radiation is approximately 3000 cGy, administered over 2 weeks.

Chemotherapy

The administration of chemotherapy for LM is directly into the CSF, using an intraventricular cannula with a subcutaneous reservoir under the scalp (Ommaya or Rickham reservoirs) to bypass the blood-CSF barrier. Intraventricular administration of chemotherapy produces better CSF distribution than intrathecal (IT) therapy administered to the lumbar subarachnoid space. In addition, it is less uncomfortable and avoids epidural and subdural leakage of the drug. In many patients with extensive LM, obstruction of CSF flow in the subarachnoid space decreases the effectiveness of intrathecal chemotherapy, and increases the likelihood of toxicity. In these patients, ^{L11}Indium-DTPA CSF flow studies may be helpful in defining the CSF blocks (Mason et al. 1998). These blocks require treatment with RT.

Only a limited number of chemotherapeutic agents are available for IT administration (Wen and Fine 1997; Mason 2002; Kesan and Batchelor 2003). Methotrexate (MTX) is the most widely used drug. It is an antimetabolite and interferes with DNA synthesis by inhibiting dihydrofolate reductase. It is active against leukemia, lymphoma, breast cancer, and other solid tumors lo a much lesser extent. The typical treatment is 10-12 mg twice weekly for 5-8 treatments, or until the CSF clears. This is followed by weekly and then monthly maintenance therapy. The most effective duration of treatment is unclear, but standard recommendations suggest treatment for at least 3 to 6 months, and perhaps indefinitely. Therapeutic concentrations (>10" ^{A} molar) are attained in the CSF for 48 hours by administration of 12 mg of MTX. The MTX is gradually reabsorbed into the blood stream by bulk flow, and transport via the choroid plexus results in a low systemic concentration {peak systemic concentration of >10~ molar), which may cause myelosuppression and mucositis. To reduce these systemic side effects, leucovorin (10 mg orally twice daily) is often given for *3—4-* days after administration of MTX. Complications of IT MTX include aseptic meningitis, teukoencephalopathy, mucositis, myelosuppression, encephalopathy, and opportunistic infections (Kesari and Batchelor 2003). High-dose intravenous MTX may also be effective in some patients (Glantz et al. 1998).

Cytosinc arabinosidc (ara-C) is a synthetic pyrimidine nucleoside with activity against leukemias and lymphomas but not most solid tumors. The half-life of ara-C is very-short in the serum, but is significantly longer in the CSF because of low levels of cytidine deaminase. The standard IT dose of ara-C is 50 mg twice a week. Intrathecal ara-C has relatively little systemic toxicity because any drug reaching the systemic circulation is rapidly deaminated. Neurological complications associated with intrathecal ara-C include transverse myelopathy, aseptic meningitis, encephalopathy, headaches, and seizures (Kesari and Batchelor 2003).

A slow-release, liposomal formulation of cytarabine (DepoCyt) was recently approved for IT use in patients with lymphomatous meningitis (Glantz, Jaeckle et al. 1999; Giant/., LaFollette et al. 1999). An important advantage of this drug is that cytotoxic concentrations of cytarabine (>0.1 ng/mL) are maintained in the CSF for 2 weeks. In a randomized study of 28 patients with lymphomatous meningitis treated with either cytarabine (every 2 weeks) or ara-C (twice a week) for one month, the response rate in the cytarabine-treated patients was significantly higher compared with the ara-C treated patients (71% versus 15%) (Glantz, LaFollette et al. 1999). Patients treated with cytarabine also had increased time to neurological progression and improvement in KPS compared with those treated with ara-C. A second study compared the efficacy of IT MTX and cytarabine in the treatment of LM from solid tumors. Cytarabine was slightly more effective with respect to cytologieai response (26% verus 20%, p = .76) and median survival (105 days versus 78 days, p — .15).

Cytarabine treatment was significantly better in delaying the time to neurological progression (58 days versus 30 days, $p = 0.007$) (Glantz, Jaeckle et a). 1999; Kesari and Batchelor 2003). Arachnoiditis can occur in up to 60% of patients receiving cytarabine. Oral dexamcthasone (4 mg twice daily for 5 days) reduces the frequency of arachnoiditis significantly.

High-dose systemic ara-C (3 g/m^2 every 12 hours) penetrates well into the CNS and is sometimes used in patients with leukemia or NHL who have both systemic and CNS disease.

Thiotepa (N, N', N"-triethylenethiophosphoramide) is an alkylating agent with activity against a variety of tumors, including leukemia and breast cancer. The dosage is 10 mg administered twice weekly. The usefulness of thiotepa is potentially limited by its rapid clearance from the CSF. However, in one randomized trial of IT chemotherapy in patients with LM, thiotepa was as effective as MTX and less toxic (Grossman et al. 1993).

Unlike combination chemotherapy for many systemic cancers, combinations of IT agents have not been shown to be more effective than single agents and tend to be more toxic.

Although IT chemotherapy is generally considered standard treatment for LM in conjunction with radiotherapy, its usefulness has been challenged (Sicgal et al. 1994). Further studies will be required to define the precise role of IT chemotherapy.

Hormonal Therapy

Hormonal therapy may occasionally be of benefit in patients with LM caused by hormone sensitive tumors such as breast cancer and prostate cancer (Wen and Fine 1997).

Prognosis

Without treatment, patients with LM usually survive only 1-2 months, with occasional long-term survivals. With treatment, the median survival increases to 3-6 months (Posner 1995). Patients with NHL and breast cancer tend to respond better to treatment than those with other cancers, and the percentage of long-term survivors is increased. The 1-year survival rate for breast cancer is approximately 11%, whereas that for NHL is 6-23%. In general, fixed neurological deficits, such as cranial nerve palsies or paraplegia, do not improve significantly with therapy, but encephalopathies may improve dramatically.

Newer Therapies

More effective treatment programs for LM are under investigation. The strategies being evaluated include intrarhecal administration of drugs such as busulphan, gemcitabine, and mafosfamide; radiolabeled monoclonal antibodies; immunotoxins, interlcukin-2; and viral mediated gene therapy.

SKULL AND DURAL METASTASES

As with other nervous system metastases, the incidence of skull and dural metastases appears to increase with prolonged patient survival and improved neuroimaging (Posner 1995; Jansen and Sillevis Smitt 2002). Skull and dural metastases may he asymptomatic and detected incidentally on neuroimaging studies or produce symptoms by compression of adjacent neural structures (see Figure 58G.3). Treatment of these metastases is usually effective.

Skull Metastases

Skull metastases occur in 15-25% of all cancer patients, usually in the setting of bony metastases elsewhere in the body. At least half are asympromatic. Skull metastases usually arise from hematogenous spread via either the arterial circulation or Batson's plexus. The most common primary tumors that metastasize to the skull base and calvarium are breast, lung, and prostate, followed by renal, thyroid, and melanoma (Jansen and Sillevis Smitt 2002), Renal cell and thyroid carcinoma may produce solitary calvarial metastasis. Rarely, extracranial tumors may extend centrally along cranial nerve branches and enter the skull through foramina. Tumors with a predilection for perineural growth include squamous cell carcinoma of the nasopharynx, esthcsioneuroblastoma, lymphoma, nerve sheath tumors, and skin cancers.

Calvarial metastases are often asymptomatic. Occasionally they produce localized pain or a palpable mass. When metastases enlarge, they may cause focal neurological deficits or seizures. Rarely, calvarial metastases invade or compress cerebral venous sinuses, producing increased intracranial pressure and venous infarction.

Skull base metastases often present with characteristic clinical features (Greenberg et al. 1981) (Table 58G.7). The differential diagnosis includes leptomeningeal and parenchymal metastases, as well as benign conditions such as granulomatous or infectious diseases. Biopsy may be indicated if the diagnosis is not conclusive following clinical and radiological evaluation and CSF examination (to exclude leptomeningeal disease).

Calvarial metastases appear as irregular lucencies on skull radiographs. In 90% of patients, bony metastases are present elsewhere in the body. CT and JVlRI usually show lesions involving all three tables of the skull bone, and provide information regarding the extent of intracranial extension and relation to venous sinuses (Jansen and Sillevis Smitt 2002), The differential diagnosis of multiple skull defects includes normal structures such as venous

Table 58G.7: Classification of clinical syndromes caused by skull base metastasis

Site of skull base metastasis	*Symptoms and signs*
Orbital	Local pain, proptosis, sensory loss V[, diplopia, decreased vision (late)
Pa r ase 1 la r/ca ve rn o us sinus	Unilateral frontal headache, oculomotor palsies (III, IV, VI), sensory loss Vi
Middle cranial fossa	Facial numbness or pain (V23), sometimes abducens or facial nerve palsy (VI, VII)
Jugular foramen	Unilateral postauricular pain, hoarseness, dysphagia (IX, X), sternocleidomastoid or trapezius weakness (XI)
Occipital condyle	Unilateral occipital pain, stiff neck, unilateral tongue weakness (XII)

Source: From Greenberg, H, S., Deck M. D. F., Vikrara, B., Chu, F. C. H., et al. 1981, "Metastasis to the base of the skull: Clinical findings in 43 patients," *Neurology*, vol. 31, pp. 530-537.

lakes, pacchionian granulations, and parietal foramina. Pathological conditions include Langerhans' cell histiocytosis, hyperparathyroidism, osteomyelitis, and radiation necrosis. For single calvarial lesions, the differential diagnosis includes meningiomas (including primary intraosseous meningioma), hemangiomas, epidermoid cysrs, leptomenirigeal cysts (in children), Langerhans' cell histiocytosis, Paget's disease, postsurgical defect, and osteomyelitis (Jansen and Sillevis Smitt 2002). In patients not known to have cancer, comparison with prior imaging studies may he helpful.

Radiological diagnosis of skull base lesions tends to be more difficult. Contrast-enhanced MRI is the most useful diagnostic test, but CT scans with thin cuts through the skull base may help detect bony lesions. Occasionally, hone scans are useful.

Treatment of skull metastases depends largely on the presence of symptoms and the radiological findings. Asymptomatic metastases often require no specific therapy. Symptomatic lesions respond well to RT. CChemotherapy may be of benefit for chemosensitive tumors, and hormonal therapy may benefit subsets of breast and prostate cancers. Occasionally, surgery is necessary.

The prognosis of skull metastases depends on systemic tumor control as well as local factors, including invasion of venous sinus or dura, leptomeninges, and brain parenchyma (Jansen and Sillevis Smitt 2002). In general, better outcomes are associated with starting treatment less than 1 month after diagnosis.

Dural Metastases

Dural metastases occur in up to 20% of patients in autopsy studies (Posner 1995), but symptomatic lesions are much less frequent. The most common tumors giving rise to dural metastases arc NSCLC, prostate cancer, and breast cancer. Less commonly, melanoma, gastric, colon, SCLC, and renal cell carcinoma, pleural mesothelioma, carcinoid tumors, and lymphoma may be responsible (Rodas and Greenberg 1997), Metastases usually reach the dura by invasion from rumors in the adjacent skull or brain parenchyma, or by hematogenous spread.

Dural metastases cause symptoms by compressing or invading the underlying brain, by obstructing adjacent venous sinuses, ot by producing subdural fluid collections and hematomas (Rodas and Greenberg 1997). The subdural collections are often indistinguishable from subdural hematomas and hygromas from benign causes. The relation of the subdural collections to an underlying neoplasm may only be determined by finding malignant cells at surgery.

MRI usually establishes the diagnosis. However, small dural metastases arc often difficult to distinguish from meningiomas. This is especially important in patients with breast cancer who may have an increased incidence of meningiomas (Schoenberg et al. 1975).

Patients usually respond to treatment with RT, which may be either whole-brain radiation or focal irradiation. The indication for whole-brain radiation is the existence of concurrent intra parenchymal or leptomeningeal disease. Chemotherapy may he an effective alternative for some chemosensitive tumors such as lymphoma, SCLC, breast carcinoma, and germ cell tumors. Surgical resecrion is indicated for patients with a large symptomatic lesion, or in cases in which the differential diagnosis from meningioma is in doubt.

The prognosis for patients with dural metastases is slightly better than for parenchymal metastases (median survival of 24 weeks versus 18 weeks). The most important variable for prognosis of dural metastases is the extent of systemic disease (Jansen and Sillevis Smitt 2002).

PLEXUS METASTASES

Brachial Plexopathy

Invasion of the brachial plexus is by local spread of tumor from lung or breast carcinoma or axillary lymph nodes (Kori et al. 1981; Kori 1995; Briemberg and Amato 2003) (see Figure 58G.2A). Rarely, tumor may reach the brachial plexus by hematogenous or lymphatic spread. The lower trunk of the brachial plexus is usually involved. Most patients experience constant, severe pain radiating from the shoulder down the medial aspect of the arm into the fourth and fifth digits. Numbness and paresthesias may be associated. Examination shows weakness, atrophy, and sensory loss in the distribution of the lower trunk of the brachial plexus (C8-T1 nerve roots). Horner's syndrome is present in 50% of patients and reflects involvement of the

stellate ganglion. The main differential diagnosis is epidural and leptomeningeal disease affecting cervical nerve roots, and radiation plexopathy. Radiation plexopathy usually occurs 1 year or more (median 40 months) after RT with doses of 6000 cGy or more. Features suggesting radiation injury rather than tumor are the relative absence of pain, involvement of the upper trunk or entire brachial plexus, severe lymphoedema, slow progression or stabilization, absence of Horner's syndrome or associated epidural disease, and myokymic discharges (spontaneous rapid semi-rhythmic bursts of potentials} on EMC (Kori 1995). CT or MRI of the brachial plexus usually establishes the diagnosis. Occasionally, MRI of the cervical spine may be necessary to exclude epidural disease. When standard imaging studies and positron-emission tomography cannot establish the diagnosis, surgical exploration and biopsy of the brachial plexus may be necessary. The treatment for neoplastic brachial plexopathy is RT. Approximately half of patients experience improvement in pain but neither strength nor sensory symptoms improve.

Lumbosacral Plexopathy

Lumbosacral plexopathy usually results from direct extension of tumor or from metastases to local lymph nodes or bone. The most common tumors associated with lumbosacral plexopathy are colorectal cancer, lymphoma, cervical carcinoma, and sarcomas (Jaeckle et ah 1985). The initial features are pain, numbness, paresthesias, weakness, and edema of the leg. Impotence and incontinence may occur. Examination findings may include weakness, sensory loss, reflex asymmetry, leg edema, and rarely, a pelvic mass on rectal examination. Bilateral lumbosacral plexopathics occur in 25% of patients; the usual cause is metastatic breast cancer. Occasionally, patients develop isolated obturator neuropathy. MRI or CT scan of the lumbosacral spine and pelvis establish the diagnosis. A significant minority of patients have spread of tumor to the epidural space. Radiation injury to the lumbosacral plexus is less common than radiation injury to the brachial plexus, but is in the differential diagnosis, Radiation injuries tend to be less painful than tumor infiltration and LMG may show myokymia. Treatment of neoplastic lumbosacral plexopathy involves RT and, occasionally, surgery,

PERIPHERAL NERVE METASTASES

Very rarely, mononeuropathies, mononeuropathy multiplex, and even a symmetric polyneuropathy may result from direct nerve infiltration by tumor (BHemberg and Amato 2003). Lymphomas and leukemias, particularly chronic lymphocytic leukemia, have been associated with peripheral neuropathy resulting from malignant infiltration of nerve (Amato and Dumitru 2002).

CONCLUSION

Because patients with systemic malignancy survive longer, the incidence of nervous system metastases increases. These metastases must be distinguished from nonmetastatic complications of cancer, including metabolic disturbances, infections, complications of therapy, cerebrovascular disorders, and paraneoplastic syndromes. The widespread availability of MRI has greatly facilitated the diagnosis of brain and epidural metastases as well as spinal cord compression. For other nervous system metastases such as LM, the diagnosis remains difficult and requires careful clinical evaluation.

Chapter 58
Cancer and the Nervous System

H. PARANEOPLASTIC DISORDERS OF THE NERVOUS SYSTEM

Myrna R. Rosenfeld and Josep Dalmau

Paraneoplastic neurological syndromes (PNSs) are a heterogeneous group of disorders caused by cancers not located in the central nervous system. The mechanism of PNS is other than metastases or any of the following complications of cancer: metabolic and nutritional deficits, infections, coagulopathy, and side effects of cancer treatment. PNSs may affect any part of the nervous system (Table 58H.1), and their frequency varies according to the type of syndrome and cancer.

In general, PNSs are difficult to diagnose and treat. The symptoms of PNS may occut before the presence of systemic cancer is known, making diagnosis all the more difficult. The onset of neurological features is often acme or subacute, followed by stabilization within a few weeks. This time course suggests that by the time most PNSs are diagnosed, the pathological damage is already irreversible. For all PNSs, treatment of the tumor is the most effective step in controlling, or at least stabilizing, the neurological disorder (Graus et al. 200 1 j.

PATHOGENESIS

Evidence is increasing that most PNSs are immune mediated (Dalmau et al. 1999). The current concept is that the expression of neuronal proteins by a tumor provokes an immune response against both the tumor and the nervous system. This hypothesis is supported by the frequent detection in the serum and cerebrospinal fluid (CSF) of antibodies reacting with antigens expressed by the tumor and nervous system (onconeuronal antigens) (Table 58H.2) (Dalmau et al. 1999). Most antibodies associated with PNSs of the central nervous system are considered highly specific for the presence of cancer. In contrast, antibodies associated with some PNSs of the neuromuscular junction and peripheral nerves (e.g., Lambert-Eaton myasthenic syndrome [LEMS], myasthenia gravis [MG], neuromyotonia) may occur with or without cancer.

The role of antineuronal antibodies in the pathogenesis of PNS remains uncertain for most syndromes. Antibodies with a ditect pathogenic effect are found in some disorders of the peripheral nerve or neuromuscular junction, and can also occur in the nonparancoplastic setting. These include antibodies to P/Q-type voltage-gated calcium channels (VGCCs) in patients with LEMS, antibodies to the acetylcholine teceptor in patients with MG, and antibodies to voltage-gated potassium channels (VGKCs) in patients with ncutomyotonia.

Data suggest that cytotoxic T-cell tesponses are important in the pathogenesis of PNS, especially of the ecnttal nervous system. These data include the presence of prominent infiltrates of CDS ' and $CD4^+$ T cells in the nervous system, and in vitro studies showing the cytotoxic effect of these lymphocytes on cells exptessing the onconeuronal antigens (Albert et al. 1998; Bcnyahia et al.

Tabic 58H.1: Paraneoplastic neurological syndromes

Syndromes affecting the central nervous system
Cerebellar degeneration
Ence pha 1 om yeli tis *
Opsoclonus-myoclonus
Stiff-man syndrome
Necrotizing myelopathy
Motor neuron syndromes[1,] (ALS; subacute motor ncuronopathy; upper motor neuron dysfunction)

Syndromes affecting the visual system
Retinopathy
Optic neuritis
Uveitis (usually in association with encephalomyelitis)

Syndromes affecting the peripheral nervous system
Sensory neuronopathy
Vasculitis of the nerve and muscle
Subacute or chronic sensorimotor peripheral neuropathy
Sensorimotor neuropathies associated with plasma cell dyscrasias and li-cdl lymphoma
Autonomic neuropathy[1,]
Brachial neuritis
Acute polyradiculoneuropathy (Guillain-Barre syndrome)
Peripheral nerve hyper excitability

Syndromes affecting the neuromuscular junction and muscle
Lambert-Eaton myasthenic syndrome
Myasthenia gravis
Derma tomyositis
Acute necrotizing myopathy
Carcinoid myopathy*
Cachectic myopathy[1]

"Includes focal cortical, limbic, and brainstem encephalitis, cerebellar dysfunction, and myelitis.
'Not discussed further in this chapter.
ALS — amyotrophic lateral sclerosis.

1999; Tanaka et al. 1999). Because the T-cell and humoral immune responses appear to be directed against the same antigens, it is likely that PNSs result from the cooperation of both arms of the immune response. The immune response has an antitumor effect in some PNSs (Gratis et al. 1997a).

GENERAL DIAGNOSTIC APPROACH

The specificity of paraneoplastic antineuronal antibodies for PNSs or some types of cancer makes them useful diagnostic tools (see Table 58H.2). In approximately 60% of patients with PNS, the neurological symptoms precede the tumor diagnosis. Therefore in the right clinical context the detection of a paraneoplastic antibody in the serum or CSF helps to diagnose the PNS and focus the search for the neoplasm.

Most paraneoplastic antineuronal antibodies can also be detected, usually at low titers, in the serum of a variable proportion of patients with cancer but without PMS. This should be considered when a paraneoplastic antineuronal antibody is identified in the serum or CSF of a patient suspected to have PNS. Other causes for the neurological dysfunction should be considered if the detected antibody is not usually associated with the neurological syndrome. Similarly, if the detected cancer is not the histological type typically found in association with the antibody (e.g., anti-Yo with lung cancer rather than breast or ovarian cancer), a second neoplasm should be suspected (Miyamoto et al. 2002). A search for another neoplasm is required if die tumor cells do not express the target antigen of the paraneoplastic antibody (Graus et al. 2001). Clinical experience

Table 58H.2: Paraneoplastic antineuronal antibodies, associated syndromes, and cancers

Antibody	*Syndroms*	*Associated cancers*
Anti-Hu	Focal encephalitis, PEM, PCD, PSN, autonomic dysfunction	SCLC, other
Anti-Yo	PCD	Gynecological, breast
Anti-Ri	PCD, opsoc 1 onus - my oclo n us	Breast, gynecological, SCLC
Anti-Tr	PCD	Hodgkin's lymphoma
Anti-CV2/CRMP5	PEM, PCD, peripheral neuropathy	SCLC, other
Anti-Ma proteins*	Limbic, brainstem encephalitis, PCD	Germ cell tumors of testis, other solid tumors
Antiamphiphysin	Stiff-man syndrome, PEM	Breast
Anti-VGCCf	LEMS	SCLC
Anti-AChRt	MG	Thymoma
Anti-VGKCt	PNH	Thymoma, others
Anti recover! m	Retinopathy	SCLC
Antibipolar cells of the retina	Retinopathy	Melanoma

[5]Patients with antibodies to Ma2 arc usually men with testicular cancer. Patients with additional antibodies to other Ma proteins are men or women with a variety of solid tumors.
These antibodies can occur with or without a cancer association,
tOther antibodies reported in a few or isolated cases include antibodies to tubby-like protein and the photorcceptor-spccific nuclear receptor.
AChR. = acetylcholine receptor; LEMS = Lambert-Eaton myasthenic syndrome; MG — myasthenia gravis; PCD = paraneoplastic cerebellar degeneration; PEM = paraneoplastic encephalomyelitis; PNH = peripheral nerve hyperexcit ability; PSN = paraneoplastic sensory neuronopathy; SCLC = small cell lung cancer; VGCC = voltage-gated calcium channels; VGKC = voltage-gated potassium channels,

suggests that finding high titers of paraneoplastic antibodies in the CSF is confirmatory evidence of PNS of the central nervous system.

The diagnosis of PNS is relatively straightforward for patients who develop symptoms of a well-defined syndrome that is typically associated with cancer. Patient age is important because symptoms that often associate with paraneoplastic mechanisms in adults (e.g., subacute cerebellar dysfunction) are less typical of paraneoplasia in children. Conversely, the development of opsoclonus in children is often paraneoplastic, but in adults, is usually due to other causes. In these settings, the detection of an antibody-known to be associated with PNS or cancer is practically-confirmatory of paraneoplasia. If a cancer is not discovered, rhe presence of an occult neoplasm is assumed unless proven otherwise. Body positron emission tomography scans may detect tumors that escape detection by other Standard imaging methods (Antoine et al. 2000; Recs et a). 2001). Although almost any neoplasm can cause PNS, the tumors most commonly involved are small cell lung cancer (SCLC), cancers of rhe breast, ovary, thymoma, neuroblastoma, and plasma cell tumors. The development of PNS frequently heralds tumor recurrence in patients with a history of cancer or those who have recently gone into tumor remission.

The diagnosis of PNS is more difficult in patients who develop less characteristic symptoms (e.g., brainstem dysfunction, myelopathy), especially if no antibodies are found in the serum or CSF. Most PNSs have an acute or subacute onset compared with noninflammatory neurodegenerative disorders that arc chronically progressive. If the patient is known to have cancer, the possibility of metastases and nonmetastatic neurological complications of cancer (side effects of tteatment, metabolic encephalopathy, infection, or cerebrovascular disorders resulting from coagulopathy) should be considered before the diagnosis of PNSs. Neuroimaging, in particular magnetic resonance imaging (MRI), can help to exclude some of these complications, although the MRI may be abnormal in some PNSs (best seen on T2 and FLAIR sequences) (Gultekin et al. 2000; Rosenfeld et al. 2001). The CSF profile in patients with PNS of the central nervous system often suggests an inflammatory process: pleocytosis, increased protein concentration, intrathecal synthesis of immunoglobulin (Ig)G, and oligoclonal bands. If paraneoplasia remains a consideration, every attempt should be made to find the associated neoplasm.

SPECIFIC PNSs AND THEIR TREATMENT

Paraneoplastic Cerebellar Degeneration

Clinical Findings

Paraneoplastic cerebellar degeneration (PCD) is characterized by the rapid development of severe pancerebeliar dysfunction. Clinical features include truncal and appendicular ataxia, dysarthria, and downbeat nystagmus. In adults, the subacute onset of PCD differentiates it from chronic degenerative diseases of the cerebellum. A subset of patients with SCLC develop PCD associated with LEMS, often before the tumor is diagnosed (Mason et al. 1997). LEMS may be overlooked unless it occurs prior to the onset of PCD.

Tumor Association

SCLC, cancer of the breast and ovary, and Hodgkin's disease are the most commonly associated tumors.

Immune Responses

Anti-Yo is the most frequent and well-characterized antibody associated with PCD. The antibody is usually associated with breast or gynecologic tumors (Peterson et al. 1992). Women with neither breast nor gynecological tumors are anti-Yo negative. Anti-Yo antibodies have been identified in a few male patients with PCD and cancer of the salivary gland, lung, and esophagus. Some patients with predominant truncal ataxia and ocular movement abnormalities may harbor an antibody called anti-Ri. In such cases, the tumor is usually a breast carcinoma or, less frequently, gynecological cancer, bladder cancer, or SCLC (Luque et al. 1991), These patients may also develop dementia, mixed peripheral neuropathy, axial rigidity, and myoclonus. PCD may occur as part of paraneoplastic encephalomyelitis (PFM) associated with anti-Hu antibodies. Patients with PCD associated with Hodgkin's disease may develop anti-Tr antibodies (Gratis et al. 1997b). The neurological disorder may develop before or after the diagnosis of the lymphoma, sometimes heralding tumor recurrence.

Treatment

Several single case reports describe patients with PCD who improved after trearment of the tumor, plasma exchange, intravenous immunoglobulin (IVIg), or immunosuppression with cyclophosphamide or steroids (Blaes et al. 1999; David et al. 1996). However, most patients with PCD do not improve with any of these treatments.

Paraneoplastic Encephalomyelitis (Including Limbic Encephalitis, Focal Cortical Encephalitis, Brainstem Encephalitis, Cerebellar Dysfunction, and Myelitis)

Symptoms

Patients with paraneoplastic encephalomyelitis (PFM) may develop clinical features of dysfunction at several different

levels of the neuraxis (Gratis et al. 2001). Many develop a sensory ncuronopathy (see paraneoplastic sensory neuronopathy [PSN]). Approximately 20% have symptoms of limbic encephalopathy. These include confusion, depression, agitation, anxiety, memory deficits, dementia, and partial complex seizures. Symptoms of cerebellar dysfunction, in particular gait ataxia, predominate in approximately 15% of patients. Most develop a pancerebellar syndrome and involvement of other areas of the nervous system. Brainstem encephalopathy characterized by oscillopsia, diplopia, dysarthria, dysphagia, gaze abnormalities, subacute hearing loss, and facial numbness develops in one third of patients. Lower motor neuron involvement secondary to myelitis occurs in approximately 20%; the presence of symptoms affecting other areas of the neuraxis helps to rule out pure motor neuron disorders. Approximately one fourth of patients with PEM develop autonomic nervous system dysfunction; symptoms include postural hypotension, gastroparesis and intestinal dysmotility, sweating abnormalities, neurogenic bladder, and impotence. Respiratory or autonomic failures are frequent causes of death.

Tumor Association

PEM, with or without PSN, can be associated with almost any tumor, but in the majority of patients the underlying tumor is lung carcinoma, particularly SCLC (Gratis et al. 2001).

Immune Responses

Patients with PEM/PSN and SCLC often have anti-Hu, and a much lower frequency of anti-CV2/CRMP5 antibodies, or both (Graus et al. 2001). In these patients, neurological symptoms usually precede the cancer diagnosis. Anti-CV2/CRMP5 antibodies are also associated with thymoma and other cancers. Patients younger than 45 years of age with symptoms of limbic, hypothalamic, and brainstem dysfunction with antibodies to Ma proteins usually have an underlying germ cell tumor of the testis. These antibodies are also encountered in older patients with similar neurological symptoms and other cancers (Gultekin etal. 2001).

Treatment

In genetal, PEM is poorly responsive to any type of treatment. Symptom stabilization or improvement may occur with prompt treatment of the tumor (Graus et al. *1999).* Limbic encephalitis is the most likely symptom to improve with tumor treatment and immunomodulation with steroids and IVIg (Gultekin et al. 2001). The therapeutic roles of plasma exchange or immunosuppression with cyclophosphamide and steroids are uncertain.

Paraneoplastic Opsoclonus-Myoclonus

Symptoms

Opsoclonus-myoclonus consists of spontaneous, arrhythmic, large-amplitude conjugate saccades occurring in all directions of gaze that are associated with myoclonus of the head, trunk, or extremities. In children, paraneoplastic opsoclonus-myoclonus usually has a subacute onset with frequent fluctuations and is accompanied by ataxia, hypotonia, and irritability (Russo et al. 1997). Although it may resolve spontaneously, most children are left with behavioral abnormalities and psychomotor retardation. In adults, symptoms range from opsoclonus with mild truncal ataxia to a more severe syndrome characterized by opsoclonus, myoclonus, ataxia, and encephalopathy that can lead to stupor and death. Spontaneous remissions rarely occur.

Tumor Association

In children, opsoclonus-myoclonus is usually a manifestation of neuroblastoma, although similar neurological symptoms may be associated with viral infections. The neurological symptoms precede the tumor diagnosis in 50% of patients. Children with neuroblastoma and opsoclonus have a better tumor prognosis than those without paraneoplastic symptoms. In adults several underlying tumors have been reported, but the most common is SCLC.

immune Responses

Some adult patients, in particular those with SCLC and 5—10% of children with neuroblastoma, have anti-Hu antibodies in their sera. Patients with breast and gynecological cancers may harbor anti-Ri antibodies {Luque et al, 1991). Antibodies to Ma proteins have been reported in a few patients with lung cancer (Rosenfeld et al. 2001). However, many adults and children with neuroblastoma do not have paraneoplastic antibodies.

Treatment

Neuroblastoma induced opsoclonus-myoclonus often responds to treatment of the tumor (chemotherapy), steroids, adrenocorticotrophic hormone, IVIg, or plasma exchange (Veneselli et al. 1998); however, developmental and neurological sequelae are common (Russo et al. 1997). Paraneoplastic opsoclonus-myoclonus in the adult may partially respond to immunosuppression and IVIg, Patients whose tumors are treated promptly have a better neurological outcome than those whose tumors are not treated (Bataller et al. 2001). In the latter group, the disorder often progresses to severe encephalopathy and death. Neurological improvement has been reported with

several treatments, which include depletion of serum IgG using protein-A columns, clonazepam, piracetam, valproic acid, and thiamine (Batchclor et ai, 1998).

Stiff-Man Syndrome

Symptoms

Stiff-man syndrome is characterized by fluctuating rigidity of the axial musculature with superimposed spasms. Muscle stiffness primarily affects the lower trunk and legs, but it can extend to the arms, shoulders, and neck. Muscle spasms are usually precipitated by emotional upset and auditory or somesthetic stimuli. Electrophysiological studies show continuous activity of motor units in the stiffened muscles " that improve after treatment with diazepam. The rigidity disappears during sleep and after local or general anesthesia. Muscle spasms and rigidity may-occur as a fragment of PEM.

Tumor Association

The paraneoplastic form of stiff-man syndrome is usually associated with breast and lung cancers and Hodgkin's disease (Folli et al. 1993).

immune Responses

The main autoantigen of the paraneoplastic form of the disorder is amphiphysin. However, in approximately 80% of patients with stiff-man syndrome, the disorder develops as a nonparaneoplastic phenomenon in association with diabetes and polyendocrinopathy and, often, antibodies to glutamic-acid decarboxylase (GAD) (Brown and Marsden 1999).

Treatment

Treatment of the tumor and the use of steroids may improve paraneoplastic stiff-man syndrome. IVIg is useful in patients with nonparaneoplastic stiff-man syndrome (Dalakas et al. 2001). Because GAD and amphiphysin are part of gamma aminoburyric acid/glycine inhibitory synapses and both are located at the presynaptic level, it is reasonable to suspect that IVIg may also improve symptoms in patients with autoimmunity to amphiphysin.

Paraneoplastic Necrotizing Myelopathy

Symptoms

Paraneoplastic necrotizing myelopathy is rare disorder that develops acutely or subacutely, first affecting the thoracic portion of the spinal cord and then progressively ascending or descending the spinal cord to involve the brainstem. Some patients present with back pain or pain radiating toward the legs, whereas others have no pain. Additional symptoms include sphincter dysfunction, segmental sensory deficits, and flaccid or spastic paraplegia that evolve to tetraplegia, and ultimately respiratory failure and death. The CSF shows elevated protein concentrations and, rarely, a mild pleocytosis. MRI studies may show enlargement of the spinal cord, T2-weighted abnormalities and, sometimes, contrast enhancement. Because paraneoplastic necrotizing myelopathy is extremely rare, other cancer-associated neurological complications should first be considered in the differential diagnosis. Leptomeningeal, epidural, or intramedullary metastases are distinguishable by the more consistent presence of pain, characteristic neuro-imaging findings, and positive CSh' cytological examination in cases of leptomeningeal metastases. A history of spinal or mantle irradiation should raise the suspicion of postradiation myelopathy. In patients with lymphoma and leukemia, a syndrome identical to paraneoplastic necrotizing myelopathy may be caused by viral infections, particularly the herpes group, as well as by toxic effects of intrathecal chemotherapy, and more rarely by septic infarcts.

Tumor Association

The syndrome has been reported in association with several carcinomas and lymphoma.

immune Responses

No antibodies or other biological markers are associated with paraneoplastic necrotizing myelopathy. In most instances, a definitive diagnosis cannot be established without postmortem study.

Treatment

Effective treatment is not available and supportive care should be offered.

Paraneoplastic Sensory Ncuronopathy

Symptoms

PSN is characterized by progressive sensory loss that may involve limbs, trunk, and face, and sometimes sensorineural hearing loss. Painful dysesthesias are common. At onset, symptoms are usually asymmetrical and can be confused with radiculopathy or polyneuropathy. All modalities of sensation are eventually affected, and, with progression, the sensory deficits result in ataxia, gait difficulty, and pscudoathetoid movements. PSN may develop alone or more commonly in association with PEM (Graus et al,

2001; Lucchinetti ct al. 1998). Neurological dysfunction precedes the cancer diagnosis in two thirds of patients. Typically, nerve conduction studies show small-amplitude or absent sensory nerve action potentials, although motor nerve and F-wave studies are usually normal. These findings arc consistent with the pathological involvement of the dorsal root ganglia, hut some patients also have electrophysiological evidence of axonal and demyelinating neuropathy (Camdessanehe et al. 2002). For patients with no known cancer, PSN should be suspected when sensory symptoms develop subacutely and asymmetrically, and involve the trunk and cranial nerves, particularly if the patient is a smoker. The CSF often shows an increased protein level with plcocytosis, oligoclonal bands, and intrathecal synthesis of IgG.

Tumor Association

Approximately 70% of patients with PSN have cancer of the lung, usually SCLC, but virtually any type of neoplasm may be found.

immune Responses

The anti-Hu antibody is almost always detected in the serum of patients with PSN and SCLC, but is rarely present in PSN associated with other tumors (Molinuevo et al. 1998). A few patients with PSN have been reported with antibodies to amphiphysin and CV2/CRMP5 (Antoine et al. 2001; Saw et al. 1999).

Treatment

A recent study of patients with SCLC and anti-Hu-associatcd PSN and PEM indicated that neurological symptoms in patients whose tumors completely responded to therapy were more likely to stabilize or improve as compared with those with untreated tumors or tumors that did not respond to therapy (Graus et al. 2001). In some patients, prompt treatment with steroids may partially improve sensory deficits (Oh ct al. 1997a).

Vasculitis of the Nerve and Muscle

Symptoms

Vasculitis of the nerve and muscle usually occurs in older men. A painful symmetric or asymmetric, subacute, sensorimotor polyneuropathy, or, less frequently, mono neuropathy multiplex develops (Oh 1997). Electrophysiological findings are compatible with axonal degeneration involving motor and sensory nerves. The erythrocyte sedimentation rate and the CSF protein concentration are elevated. Nerve and muscle histology shows intramural and perivascular inflammatory infiltrates composed of $CD8^+$ T cells.

Tumor Association

SCLC and lymphoma are the tumors most commonly associated.

Immune Responses

Serological markers of paraneoplasia arc not usually associated, although anti-Hu antibodies are found m some patients with SCLC.

Treatment

The vasculitis often responds to treatment with steroids, cyclophosphamide, or both (Oh 1997).

Subacute and Chronic Peripheral Neuropathies

Symptoms

A mild peripheral neuropathy is common in patients with cancer, especially in the advanced stages of the disease. The cause is multifactorial, and includes metabolic and nutrirional deficits and toxicity from chemorherapy. Paraneoplastic sensorimotor neuroparhy may develop before or after the diagnosis of cancer. The onset may be subacute or acute, and the course is usually progressive. A relapsing and remitting course suggests chronic inflammatory demyelinating polyneuropathy (CIDP) (Antoine et al, 1999).

Tumor Association

The tumors most commonly associated arc lung and breast cancers.

Immune Responses

Serum antineuronal antibodies are not usually present, although some patients with lung cancer and rhymoma may harbor CV2/CRMP5 antibodies (Antoine et al. 2001).

Treatment

Patients with electrophysiological signs of demyclination may improve with steroids or IVIg {Antoine ct al. 1999).

Peripheral Neuropathy Associated with Plasma Cell Dyscrasias and B-Cell Lymphoma

Several malignancies of plasma cells and lymphocytes are associated with neuropathy. Included are multiple myeloma, osteosclerotic myeloma, Waldenstrom's macroglobulinemia and B-cell lymphoma (Ropper and Gorson 1998).

A sensorimotor neuropathy may develop in patients with multiple myeloma that is similar to those seen in other advanced cancers. If the myeloma is complicated by amyloidosis, the neuropathic symptoms often include autonomic dysfunction and lancinating and burning dysesthesias (Ropper and Gorson 1998). In both cases, treatment of the myeloma does not affect the neurological symptoms.

Osteosclerotic myeloma is often associated with a symmetrical, distal sensorimotor neuropathy with predominant motor symptoms that resemble CIDP. Some patients with osteosclerotic myeloma and neuropathy develop additional symptoms indicative of the POEMS syndrome (polyneuropathy, organomegaly, endocrinopathy, *M* protein, and skin changes). A radiological survey demonstrates a solitary or reduced number of osteosclerotic lesions that tend to involve the axial skeleton (truncal and proximal long bones) and spare the skull. Treatment of the osteosclerotic lesions with excision, radiation therapy, or chemotherapy may improve the neurological and systemic symptoms,

Among patients with Waldenstrom's macroglobulinemia, less than 10% develop a symmetrical, dcmyelinating, sensorimotor neuropathy predominantly involving large sensory fibers, especially those for vibration sense. The IgM paraprotein sometimes reacts with myelin-associated glycoprotein (Dimopoulos et al. 2000). The neuropathy may respond to treatment directed at Waldenstrom's macroglobulinemia, plasma exchange, IVIg, rituximab, chlorambucil, cyclophosphamide, or fludarabine (Latov 2000; Levine and Pestronk 1999).

Castleman's disease, or angiofollicular lymph node hyperplasia, is actually a group of lymphoproliferative disorders with common clinical and histological features. These are often accompanied by a severe systemic inflammatory response that can be complicated by acquired systemic amyloidosis. Multicentric Castleman's disease is associated with several neuropathies that include a painful sensorimotor neuropathy, a chronic relapsing sensorimotor neuropathy, and a predominantly motor neuropathy (Vingerhoets et al. 1995). Additional symptoms that indicate POEMS syndrome are common. Specific serum antibodies arc absent and serum levels of interleukin-6 are often elevated. Neurological improvement is reported with cyclophosphamide and prednisolone or immunosuppression.

Brachial neuritis, and an acute paraneoplastic polyradiculoneuropathy identical to Guillain-Barre syndrome may be associated with Hodgkin's disease. Evidence does not exist for an association with malignancy. The course of the neurological syndrome is independent of the lymphoma, and symptoms can develop either during active disease or during remission. The differential diagnosis of brachial neuropathy should include the more common causes of brachial plexopathy in cancer patients. These include tumor infiltration, radiation injury, ischemic neuropathy, and traumatic injury of the plexus. Treatment for both disorders is the same as in the noncanccr patient: and includes plasma exchange or IVIg.

Peripheral Nerve Hyper excitability

Symptoms

The term *peripheral nerve hyper excitability (PNH)* has been adopted to include a disorder previously described with several names (neuromyotonia, undulating myokymia, Isaac's syndrome) and the cramps-fasciculation syndrome (Hart et al. 2002). These terms characterize the motor manifestations of spontaneous and continuous muscle fiber activity of peripheral nerve origin that can be triggered by voluntary muscle contraction. Other symptoms include motor weakness and hyperhidrosis. Electromyographic studies show fibrillation, fasciculation, and myokymic electromyography (EMG) discharges (doublet, triplet, or multiplet motor unit discharges) in most patients. Patients with the cramps-fasciculation syndrome do not have myokymic EMG discharges.

Tumor Association

PN[r]II can develop without associated cancer, but when paraneoplastic, thymoma and lung cancers are the usual tumors. Patients with thymoma may also have MG.

Immune Responses

Many patients have antibodies to VGKCs that contribute to the nerve hypcrexcitability by increasing the release of acetylcholine resulting in prolongation of the action potential (Shillito et al. 1995). Patients with PNH and thymoma, with or without MG, may also harbor antibodies to acetylcholine receptors (Hart et al. 2002).

Treatment

Symptomatic improvement is reported with diphenylhydantoin, carbamazepine, and plasma exchange.

Lambert-Eaton Myasthenic Syndrome

.*Symptoms*

Neurological symptoms usually develop before the tumor diagnosis and gradually progress over weeks or months. Less often, the onset of symptoms is acute. The common features are fatigue, muscle weakness, myalgia, and paresthesias (O'Neill et al. 1988), More than half of patients have cholinergic dysautonomias that include dry mouth, erectile dysfunction, and blurry vision (O'SLiilleabhain et al. 1998). Transitory cranial nerve

dysfunction may produce diplopia, ptosis, or dysphagia. Neurological examination shows proximal weakness, occurring in the legs more than the arms, and absent or depressed tendon reflexes, which may potentiate after a brief muscle contraction. Strength may improve after brief exercise, but continued exercise increases weakness. The diagnosis is based on electrophysiological studies. Nerve conduction studies show small amplitude compound muscle action potentials. At slow rates of repetitive nerve stimulation (2-5 Hz), a decremental response of greater than 10% is obtained. At fast rates of repetitive nerve stimulation (20 Hz or greater) or after maximal voluntary muscle contraction, facilitation occurs and an incremental response of at least 100% is seen.

LEMS can develop in association with other paraneoplastic syndromes such as 1'CO and PEM (Mason et al. 1997). Recurrence of LEMS after remission often heralds tumor recurrence.

Tumor Association

Approximately 60% of patients with LEMS have SCLC or rarely other tumors, such as lymphoma.

Immune Responses

Patients with LEMS have scrum antibodies against P/Q type VGCCs (Motomura et al. 1997). The antibodies interfere with the quantal release of acetylcholine at the presynaptic neuromuscular junction, resulting in failure of neuromuscular transmission. When I.EMS develops in association with PEM, patients often have anti-Hu antibodies.

Treatment

Most patients with cancer improve neurologically with combined treatment of their cancer and therapy for LEMS. The latter includes medication to increase the release of acetylcholine and immunomodulation (Sanders 1995). The use of 3,4-diaminopyridine results in moderate to marked neurological improvement in 80% of patients. If 3,4-diaminopyridine is not available, a combination of pyridostigmine and guanidine may be beneficial (Oh et al. I 997b). Plasma exchange and fVIg are useful for treating severe weakness; strength improves within days or weeks, but the benefits are transient (Bain et al. 1996), Long-term immunosuppression with prednisone or azathioprine should be considered if symptoms continue despite the use of 3,4-diflminopyridine.

Myasthenia Gravis

Symptoms

MG is a postsynaptic disorder of neuromuscular transmission. The main features are weakness and fatigability of skeletal muscles that improves with rest and worsens with activity. Ptosis and diplopia occur in most patients, and symptoms remain localized to the extraocular and eyelid muscles in 15% of patients. In the rest, weakness becomes generalized and can impair respiration to the extent that mechanical ventilation is necessary. Tendon reflexes and sensation are normal.

Tumor Association

A thymic epithelial tumor (thymoma or thymic carcinoma) is found in 10% of patients with MG, and one third of patients with thymoma develop MG, In a few instances, MG has been reported in association with other tumors, including thyroid gland tumors, SCLC, breasr cancer, and lymphoma.

Immune Responses

Antibodies to acetylcholine receptors are found in 80-90%i of patients with generalized MG, and in 70% of those with ocular MG. Other antibodies found in patients with MG are antistriated muscle antibodies and antititin antibodies. The detection of antititin antibodies was thought to predict tumor bur this is not the case (Somnier and Engel 2002).

Treatment

Trearmcnt is firsr directed at the underlying tumor. Additional strategics include symptomatic treatment (e.g., anticholinesterase drugs), immunomodulation (plasma exchange, IVIg), and immunosuppression (steroids, azathioprine, and others).

Derma tomy o sitis

Symptoms

Dermatomyositis and polymyositis are immune-mediated inflammatory diseases of muscle. An association exists between cancer and dermatomyositis in adults, but not with polymyositis (Leow and Goh 1997). The symptoms of paraneoplastic dermatomyositis arc the same as those in patients without cancer. Cutaneous changes include purplish discoloration of the eyelids (heliotrope rash) with edema and erythematous lesions over the knuckles. The presence of necrotic skin ulcerations and pruritus are suggested to indicate an underlying cancer (Gallais et al. 1996). The typical presentation is the subacute onset of proximal muscle weakness. Neck flexors, pharyngeal and respiratory muscles, arc commonly involved and may lead to aspiration and hypoventilation. Tendon reflexes and sensation are normal. Scrum creatine kinase concentrations are often elevated, although normal levels are occasionally found, even in patients with profound muscle weakness. EMG shows increased spontaneous activity (fibrillations,

positive sharp waves, and complex repetitive discharges), and short duration, low-amplitude polyphasic units on voluntary activation. Muscle histology shows inflammatory infiltrates ($CD4^+$ T cells predominate in dermatomyositis and $CD8^+$ T cells in polymyositis) and muscle necrosis; the presence of peri fascicular atrophy is characteristic of dermatomyositis.

Tumor Association

Several tumors are associated with dermatomyositis; most common are breast, lung, ovarian, and gastric malignancies. Less frequently associated arc cancer of the pancreas, thymoma, germ cell tumors, melanoma, nasopharyngeal cancer, and lymphoma.

Immune Responses

Abnormalities of both humoral- and cellular-mediated immunity are found in patients with dermatomyositis, although the target antigen is not known. An antibody directed against histidyl-tRNA synthetase (anti-Jo-1) is present in approximately 50% of patients with dermatomyositis associated with interstitial lung disease.

Treatment

In some patients, muscle and dermatologicat symptoms improve coincidently with treatment of the tumor. No studies are available on the efficacy of immunosuppressants in cancer-associated dermatomyositis, hut it seems reasonable to use strategies similar to those used in nonparaneoplastic dermatomyositis (steroids, azathioprine, IVIg) (Amato and Barohn 1997).

Acute Necrotizing Myopathy

Symptoms

This rare disorder is characterized by the acute onset of painful proximal muscle weakness with rapid generalization and involvement of respiratory and pharyngeal muscles. Serum creatine kinase concentrations are markedly elevated and electrophysiological studies demonstrate myopathic findings. Muscle histology shows severe necrotic changes with minimal or no inflammatory infiltrates. The causes of an acute necrotizing myopathy in patients with cancer include chemotherapy and cytokine-induced rhabdomyolysis (Andetiini et al. 1995).

Tumor Association

Acute necrotizing myopathy occurs in association with several solid tumors including carcinoma of the lung, bladder, breast, and gastrointestinal tract (Levin et al. 1998).

Immune Responses

A specific immune response has not been identified.

Treatment

Only in rare instances does treatment of the tumor result in neurological improvement (Levin et al. 1998).

Paraneoplastic Visual Syndromes

Symptoms

Paraneoplastic involvement of the visual system may affect the retina, and less frequently, the uvea and optic nerves (Jacobson 1998). Because paraneoplastic visual syndromes are rare, the more important considerations are metastatic infiltration of the optic nerves, toxic effects of chemotherapy or radiation therapy, and severe anemia. The symptoms of paraneoplastic retinopathy are photosensitivity, progressive loss of vision and color perception, central or ring scotomas, and night blindness. Attenuation of photopic and scotopic responses is recorded on the elcctroretmogram (ERG). Funduscopic examination shows nonspecific arteriolar narrowing. When one eye is affected, the other becomes symptomatic within days or weeks. Imaging studies and evaluation of the CSF are not revealing.

Melanoma-associated retinopathy (MAR) affects patients with metastatic cutaneous melanoma (Boeck et al, 1997). Patients typically present with the acute onset of night blindness and shimmering, flickering, or pulsating photopsias. Symptoms often progress to complete visual loss. The ERG typically demonstrates reduction in the b-wave amplitude.

Paraneoplastic optic neuritis is very uncommon, and, although it may develop in isolation, it is usually associated with PEM. The onset is subacute with painless, bilateral visual loss. Papilledema may be presenr.

Tumor Association

SCLC is the tumor most commonly associated with paraneoplastic retinopathy, other than melanoma with MAR.

Immune Responses

Serum antibodies that specifically react with retinal proteins are detected in some patients. The term *cancer-associated retinopathy* was originally used to describe patients with antibodies to recoverin, a retinal-specific calcium binding protein. Antibodies to other retinal antigens, such as tubby-like protein 1 and the photoreccptor-specific nuclear recepror, have since been reported. Patients with MAR typically have antibodies that react with the bipolar cells of

the retina, Anti-CV2/CRMP5 antibodies are reported in some patients with PEM and uveitis.

Treatment

Although the paraneoplastic retinopathies rarely improve with treatment, responses to steroids, plasma exchange, and IVIg are reported.

Chapter 59
Infections of the Nervous System

Ashok Verma

Infectious diseases remain a major cause of death and disability for millions of people around the world, despite decades of dramatic progress in their treatment and prevention. Each infectious agent can cause a spectrum of illnesses, which challenges the physician's diagnostic skills. Infections must be considered in the differential diagnosis of syndromes affecting many organ systems, including the central nervous system (CNS).

The CNS may appear protected from perturbations in the environment by a blood-brain barrier—a system of tight junctions around capillaries—that resists the entry of pathogens, inflammatory cells, and macromolccules into the subarachnoid space and the hrain. However, the barrier fails to resist the ingenuity of the microbial world. Many pathogens have devised highly specialized, yet poorly understood, mechanisms to breach this barrier. For example, certain highly encapsulated bacteria and fungi possess surface components that allow them to traverse the tight capillary junctions to enter into the brain. The degree of specialization required for this mechanism is demonstrated by the predilection for only certain serotypes of organisms within a species to cause meningitis. Type 3 strains of group B streptococci account for the vast majority of cases of neonatal meningitis caused by this organism, even though other serotypes cause much of the invasive disease outside the CNS. This disparity appears to be due solely to the arrangement of the component sugars of the capsular polysaccharide; other serotypes of group B streptococcus rarely cause neonatal meningitis, even though their capsules possess the same four component sugars in different structural arrangements. Another example of a unique strategy employed by organisms such as herpes simplex virus and rabies virus is to travel by retrograde axonal transport within the peripheral nerves to reach the CNS.

Many infectious pathogens exhibit highly specific tropism to a particular site or even a specific cell type in the CNS. In paralytic poliomyelitis, for example, the poliovirus is tropic only to the anterior horn cells of the spinal cord and the homologous motor neurons in the brainstem. Why only a minority of poliovirus infections affects the CNS is a mystery; paralytic poliomyelitis occurs in far less than 1% of all human poliovirus infections.

Under circumstances ideal for a given microorganism, nearly any known human pathogen can cause CNS infection. Old and established CNS infectious agents may appear in new places in this age of rapid travel and changing environment. West Nile virus, for example, has found new terrains in the United States. The potential for infectious agents to emerge in novel and unexpected ways requires that physicians and public health officials be knowledgeable, vigilant, and open minded in their approach to the consideration of unexplained brain diseases. Additionally, entirely new infectious agents have emerged in recent decades, and new CNS infectious diseases continue to be identified. The role of infectious agents in the etiology of brain diseases once believed to be noninfectious is being increasingly recognized. For example, it is now widely accepted that Epstein-Barr virus is the cause of primary CNS lymphoma in HIV-infected individuals.

The advent of antimicrobial agents led some to believe that infectious diseases would soon be eliminated and might become history. Hundreds of chemotherapcutic agents have been developed and are effective not only against bacteria, but also against viruses, fungi, and parasites. Nevertheless, we now realize that, as we developed new antimicrobial agents, microbes developed the ability to elude our best weapons and counteract them with new survival strategies. Antibiotic resistance occurs at an alarming rate among all classes of human pathogens. Diseases once thought to have been nearly eradicated from the developed world—CNS tuberculosis, for example—have rebounded in recent years. These pathogens have an incredible adaptability and diversity. Retroviruses such as human immunodeficiency virus (HIV) continue to humble us despite an understanding of their pathogenesis at the most basic molecular level.

Optimal therapy for CNS infections requires a broad knowledge of medicine, a close liaison with the microbiology laboratory and personnel, and careful clinical judgment. Many CNS infections, including bacterial meningitis, viral encephalitis, and cerebral malaria, are life-threatening conditions and must he treated emergently, often before the specific causative organism is definitively identified. Initial antimicrobial agents must be chosen empirically and must be active against the range of potential infectious agents consistent with the clinical scenario.

Bacterial diseases are considered in Chapter 59A, viral infections in Chapter 59B, fungal infections in Chapter 59C, and parasitic infections in Chapter 59D. HIV-related diseases of the CNS are discussed in Chapters 59E and 59F, and the spongiform encephalopathies (prionoses or protein conformation disorders) are covered in Chapter 59G. Sarcoidosis, a granulomatous disease of uncertain etiology, is not considered an infectious disease and is discussed in Chapter *55,*

Chapter 59
Infections of the Nervous System

A. BACTERIAL INFECTIONS

Ashok Verma and Marylou V. Solbrig

Bacterial infections reach the intracranial structures in one of the three ways: by hematogenous spread (bacteremia, emboli of bacteria, or infected thrombi), by extension from juxtacranial structures (ears, paranasal sinuses, osteomyclitic foci in the skull, congenital sinus tracts, or penetrating cranial injuries), or from an iatrogenic source (brain or spine surgery, ventriculoperitoneal shunt, and rarely following lumbar puncture). However, in many cases of bacterial central nervous system (CNS) infections, the pathway of infection cannot be determined, even at autopsy.

Increasingly, infection in urban hospitals is nosocomial (i.e., acquired in-hospital); in large hospitals of developed countries, nosocomial meningitis is now at least as frequent as the community-acquired variety. Medical care may increase the sick patient's risk of acquiring systemic and CNS infections in a number of ways (Scheld et al. 1997; Cohen and Powderly 2003): (1) through contact with pathogens during hospitalization, (2) through breached barriers (surgical incisions, intravenous devices, endotracheal tubes, or bladder catheters), (3) through introduction of foreign bodies such as a pacemaker that provides a nidus for bacterial colonization, (4) through alteration of the natural flora by antibiotics, and (5) through treatment with immunosuppressive drugs.

With hematogenous infection usually a single type of virulent organism gains entry to the cranial cavity. In adults the most common pathogenic organisms are *Streptococcus pneumoniae, Neisseria meningitidis, Haemophilus influenzae, Listeria monocytogenes,* and staphylococcus. More common in neonates are *Escherichia coli* and other gram-negative bacilli and group B streptococcus, and in the infant and child, *H. influenzae* infections arc more common. By contrast, when septic material embolizes into the brain from an infection elsewhere, more than one type of pathogen common to these sources may be transmitted. The mechanism of meningitis and brain abscess from infection of the parameningeal structures occurs in one of the two ways: (1) infected thrombi may form in diploic veins and spread along these vessels into the dura! sinuses (into which the diploic veins flow) and from there, in retrograde fashion, along the meningeal veins into the brain, and (2) an osteomyelitic focus may form, with erosion of the inner table of bone and invasion of dura, subdural space, pia-arachnoid, and even the brain. Infections that follow neurosurgical procedures or the placement of an intracranial appliance are usually staphylococcal; a small number arc due to mixed flora, including anaerobes, or enteric organisms. Bacterial pathogens invading intracranial structures through any of these pathways can cause pyogenic meningitis, brain abscess, septic thrombophlebitis, epidural abscess, or subdural empyema. The age and the immune status of the patient, the clinical setting (community-acquired, nosocomial, or postsurgical), and evidence of systemic and local cranial disease all must be taken in account in determining the most likely invading intracranial organism and, thereby, the most appropriate empiric emergency therapy, before the exact pathogen is identified.

BACTERIAL MENINGITIS

Definition

Bacterial meningitis may be defined as an inflammatory response to bacterial infection of the pia-archnoid and cerebrospinal fluid (CSF) of the subarachnoid space. Because the subarachnoid space is continuous over the brain, spinal cord, and optic nerves, infection in this space extends throughout the cerebrospinal axis unless there is obstruction of the subarachnoid space. Ventriculitis to some degree is nearly always present in patients with bacterial meningitis, but frank ventriculitis is uncommon in meningitis because of the bulk flow of *CSV* from the ventricles into the subarachnoid space.

Epidemiology

Acute bacterial meningitis occurs throughout the world. Although precise figures are unavailable, the incidence of bacterial meningitis is between 3 and 5 per 100,000 people per year in the United States (Quagliarello and Scheld 1997). More than 2000 deaths due to bacterial meningitis are reported annually in the United States. The disease is more common and the mortality higher in the developing countries. The relative frequency of isolation of various bacterial species as a cause of meningitis varies with age. Worldwide, three main pathogens, *H. influenzae, S. pneumoniae,* and *N. meningitidis,* account for 75-80% of cases after the neonatal period. *E. coli* and other enteric bacilli, /„ *monocytogenes,* and group B streptococci are major pathogens in neonatal meningitis.

Before the introduction of the conjugate vaccines, *H. influenzae* type b was the most common cause of bacterial meningitis in the United States, causing 45% of cases. *S. pneumoniae* accounted for 18% of cases, and N. *meningitidis* for 14%. Widespread vaccination against *H. influenzae* type b since 1987 has markedly reduced the frequency of *H. influenzae* meningitis in children. With the resulting 82% reduction in *H. influenzae* meningitis between 1985 and 1991 among children under age 5 in the United States, *S. pneumoniae* and N. *meningitidis* have become the principal causes of meningitis in children older than 1 month (Quagliarello and Scheld 1997). However, *H. influenzae* bacteremia and meningitis are increasing in frequency among adults who test positive for human immunodeficiency virus (HIV) (Munoz et al. 1997).

In Africa, the meningococcal A + C polysaccharide vaccine has modified the cyclic pattern of epidemic meningococcal meningitis (Soriano-Gabarro ct al. 2002). The sub-Saharan (Sahel) regions of Africa between 5 and 15 degrees north latitude, with annual rainfall of 30-110 cm, constitute the African meningitis belt. Regional prevalence of meningococcal meningitis in epidemic years is 400-1000 cases per 100,000 of population. Used for prophylaxis and outbreak control, the vaccine has broken the earlier 8- to 14-year patterns of recurrence of meningococcal meningitis, with the appearance of smaller epidemics, with shortened interepidemic intervals in some countries, in addition to outbreaks of meningitis in countries outside the belt (Varaine et al. 1997).

Simultaneously, there has been a worldwide increase in infection with strains of *S. pneumoniae* resistant to penicillin (Koedel et al. 2002), other ^-lactam antibiotics (second- and third-generation cephalosporins), and even chloramphenicol. Altered penicillin-binding proteins, and not jfj-lactamase production, mediate penicillin resistance. Early reports of drug resistance from Spain, Hungary, and South Africa were followed by similar reports from Japan and multiple centers in the United States, In 1994, isolates from 25% of patients with invasive pneumococcal infection in Atlanta, Georgia, hospitals were resistant to penicillin. Moreover, 9% of pneumococci from this study group also were resistant to cefotaxime and cephtriaxone, third-generation cephalosporins commonly used to treat meningitis, highlighting the growing problem of antibiotic resistance (Quagliarello and Scheld 1997).

Pathogenesis

S. pneumoniae, N. meningitidis, and *H. influenzae* are spread by droplets or exchange of saliva. Bacterial meningitis develops most commonly when pathogens colonizing the nasopharynx cause bacteremia and breech the blood-brain barrier. However, meningitis can also arise as a consequence of parameningeal infection, after traumatic or surgical disruption of the blood-brain barrier, or when a cerebral abscess ruptures into the ventricular or subarachnoid space.

The immediate effect of bacteria or other microorganism in the subarachnoid space is to cause an inflammatory reaction in the pia and arachnoid membranes as well as in the CSF. The inflammation results in hyperemia of the meningeal venules and capillaries and an increased permeability of these vessels, resulting in exudation of proteins and the migration of neutrophils into the pia and subarachnoid space (Scheid ct al, 2002). If untreated, subarachnoid exudate increases rapidly, particularly over the cerebral convexities and at the base of the brain. The exudate extends into the sheaths of cranial and spinal nerves and, for a short distance, into the perivascular spaces of the cortex. During the first few days, polymorphonuclear infiltrates are the predominant cells. Within a few days, lymphocytes and histiocytes increase gradually in relative and absolute number. Although fibroblasts begin to proliferate early, they are not conspicuous until later, when they take part in the organization of the exudates, resulting in loculation of pockets of exudate. During the process of resolution, the inflammatory cells disappear in almost the same order as they had appeared. The completeness of resolution depends to a large extent on the stage at which the infection is arrested.

Clinical Features

The classical clinical presentation of adults with bacterial meningitis comprises headache, fever, and neck stiffness, often with signs of cerebral dysfunction; these manifestations are found in more than 85% of patients. Nausea, vomiting, myalgia, and photophobia are also common. The neck stiffness may be subtle or marked, accompanied by Kcrnig's and/or Brudzinski's signs. These signs are elicited in over half of adults, but less in neonates and elderly; absence of clinical meningeal signs does not rule out the diagnosis of bacterial meningitis. Cerebral dysfunction is manifested by confusion, delirium, and a declining level of consciousness that ranges from lethargy to coma. Seizures occur in approximately 40% of cases. Cranial nerve palsies involving III, VI, and VII are found in 10-20% of cases and result from direct damage to the nerve by the surrounding infection or endarteritis of the vasa nervorum, Occasionally there are other focal neurological deficits such as hemiparesis and dysphasia due to endarteritis obliterans of the major arteries passing through the pools of infected material in the subarachnoid spaces. Recurrent seizure activity and focal neurological deficits are more common in the early stages of pneumococcal meningitis than in H. *influenzae* or meningococcal disease. Bilateral Vt cranial nerve palsy may indicate raised intracranial pressure (ICP), Papilledema is rare in acute bacterial meningitis and should suggest a different diagnosis, such as a brain abscess. Focal neurological deficits, seizure activity, and encephalopathy may arise from cortical and subcortical ischemia and/or infarction, from increased 1CP, or from development of subdural empyema.

Classical clinical features of bacterial meningitis are commonly absent in neonates, and the only clinical clue in them may be listlessness, high-pitched crying, refusal to feed, irritability, or other nonspecific manifestations. In the elderly patients, meningitis often has an insidious onset with lethargy or obtundation and with variable signs of meningeal irritation and no fever. In this subgroup of patients, an altered mental status should not be ascribed to other causes until bacterial meningitis has been excluded by examination of CSF. Many of the signs of bacterial meningitis, including altered mental status, may be present in patients following neurosurgery or head trauma, Meningitis is difficult to judge in such a situation, and the physician should have a low threshold for performing CSF examination if any unexpected clinical deterioration occurs.

Certain clinical features may suggest a specific etiologic diagnosis in patients with meningitis. Meningococcemia with or without meningitis presents with a prominent rash, principally in the extremities. Farly in the disease process, the rash is often erythematous and macular, but typically it evolves quickly into a petechial phase with further coalescence into a purpuric form. A similar rash may be seen in other forms of meningitis (echovirus type 9, *S. aureus, Acinetobacter* spp.), in Rocky Mountain spotted fever and other rickcttsioses, in S. *aureus* endocarditis, in rapid overwhelming sepsis, and in some noninfectious disorders such as vasculitis and thrombotic thrombocytopenic purpura. An additional suppurative focus of infection, typically pneumonia, otitis media, or sinusitis, is seen in about 30% of patients with pneumococcal or *H. influenzae* meningitis. Patients in whom meningitis develops in the wake of a CSF leak may have rhinorrhea or otorrhea, and the causative organism is often 5. *pneumoniae.*

The likelihood of infection with a specific pathogen relates, in large part, to age of the patient (Table 59A.1). Group B streptococci, *Listeria,* and gram-negative bacilli cause meningitis and invasive disease at the extremes of life, in neonates and the elderly. In the United States, *N. meningitidis* is now the predominant pathogen among children aged 2-18 years and *S. pneumoniae* among adults (Schuchat et al. 1997).

Table 59A.1: Empiric antibiotic therapy of bacterial meningitis

Age of patient	*Likely organism*	*Antimicrobial therapy**	*Adverse effects*
0-12 weeks	Group B Streptococcus *E. colt* *L. monocytogenes*	Third-generation cephalosporin + ampicillin (+ dexamcthasonc first 2 days in >4-week-old infant)	Vomiting, diarrhea, maculopapular rash, cosinophilia, biliary pseudolithiasis
3 months-50 years	*S. pneumoniae* *N. meningitidis* *H. influenzae*	Third-generation cephalosporin -I- vancomycin (± ampicillin)	Nausea, vomiting, diarrhea, maculopapular rash, eosinophilia, biliary pseudolithiasis, leukopenia, "red man"[1]' syndrome
>.50 years	*S. pneumoniae* *L. monocytogenes* Gram-negative bacilli	Third-generation cephalosporin + vancomycin -I- ampicillin	Nausea, vomiting, diarrhea, maculopapular rash, cosinophilia, biliary pseudolithiasis, transient increase in liver enzymes, leukopenia, "red man" syndrome
Base of skull fracture	Staphylococci Gram-negative bacilli 5. *pneumoniae*	Third-generation cephalosporin -I- vancomycin	Nausea, vomiting, diarrhea, eosinophilia, biliary pseudolithiasis, leukopenia, "red man" syndrome
Head trauma, neurosurgery, CSF shunt	Staphylococci Gram-negative bacilli *S. pneumoniae*	Vancomycin -I- ceftazidime	Nausea, vomiting, diarrhea, transient increase in liver enzymes, leukopenia, "red man" syndrome
Immunocompromised state	*L. monocytogenes* Gram-negative bacilli *S. pneumoniae* *H. influenzae*	Vancomycin -I- ampicillin -I- ceftazidime	Nausea, vomiring, diarrhea, maculopapular rash, eosinophilia, biliary pseudolithiasis, transient increase in liver enzymes, leukopenia, "red man" syndrome

'Tor all age groups from 3 months onward, an alternative treatment is meropenem -I- vancomycin. In case of severe penicillin allergy, consider vancomycin + chloramphenicol for meningococcus and trimethoprim/sulfamethoxazole for listeria. A higher failure rate has been reported wirh chloramphenicol or regimen without vancomycin in meningitis with drug-resistant pneumococcus.

"Red man" syndrome ranges from mild, flushing of upper body and erythema, reported in up to 70%, wiiich may rarely extend to prutitic rash, high fever, and exfoliative dermatitis. Caused by hypersensitivity reaction to vancomycin and related antibiotics.

Diagnosis

The patient with suspected bacterial meningitis requires blood cultures and urgent lumbar puncture (LP). Cranial computed tomography (CT) before LP is indicated when focal findings or clinical evidence of raised ICP are present (Hasbun et al. 2001; Kastenbauer et al. 2002). When the need for CT scanning significantly delays LP, blood cultures should be obtained and empiric antibiotic therapy administered appropriate to the clinical setting (Figure 59A.1}. LP is then performed as soon as possible following CT.

CSF examination reveals elevated pressure (200-500 mm H_20) and protein (100-500 mg/dL, normal 15-45 mg/dL), decreased glucose (<40% scrum glucose), and marked pleocytosis (100-10,000 white blood cells [WBC]/uL, normal <5) with 60% or greater polymorphonuclear leukocytes. The CSF Gram stain result is positive in at least 60% of cases, and CSF culture results are positive in approximately 75%. The likelihood of finding Gram stain or culture-positive CSF may decrease to 5-40% if antibiotics were administered before the LP. However, antibiotics given 1-2 hours before the spinal tap do not decrease diagnostic sensitivity of CSF culture done in conjunction with blood cultures and latex particle agglutination and counterimmunoelectrophoresis testing of CSF for bacterial antigens. Latex agglutination detects the antigens of *H. influenzae* type b, *S. pneumoniae, N. meningitidis, E. colt* Kl, and group B streptococci. Some test kits may not include tests for group B meningococci because its coat polysaccharide is weakly antigenic (Chadwick and Lever 2002). Because antibiotic therapy takes longer than 12 hours to sterilize CSF, culture results are often positive for the first several hours after antibiotics. Early in disease, 10-20% of patients have CSF cell counts of less than 1000 cells/pL. Otherwise, cell counts below 1000 cells/pL in a patient with a compatible clinical syndrome indicate partially treated meningitis, concurrent immunosuppression, or a nonbacterial cause. Rarely, cell counts of less than 100 cells/uL are seen in the apurulent bacterial meningitis syndrome of pneumococcal meningitis (Felgenhauer and Kober 1985), with overwhelming bacterial meningeal infection and absent CSF neutrophil response. Blood cultures reveal the causative organism in 50% of bacterial meningitis cases, consistent with the importance of bacteremia in pathogenesis. Neuroimaging studies may be normal or reveal complications of bacterial meningitis, such as cerebral edema, communicating or obstructive hydrocephalus, infarction, or venous sinus thrombosis.

The differential diagnosis includes viral, rickettsial, tubercular, fungal, or parasitic meningitis; subarachnoid

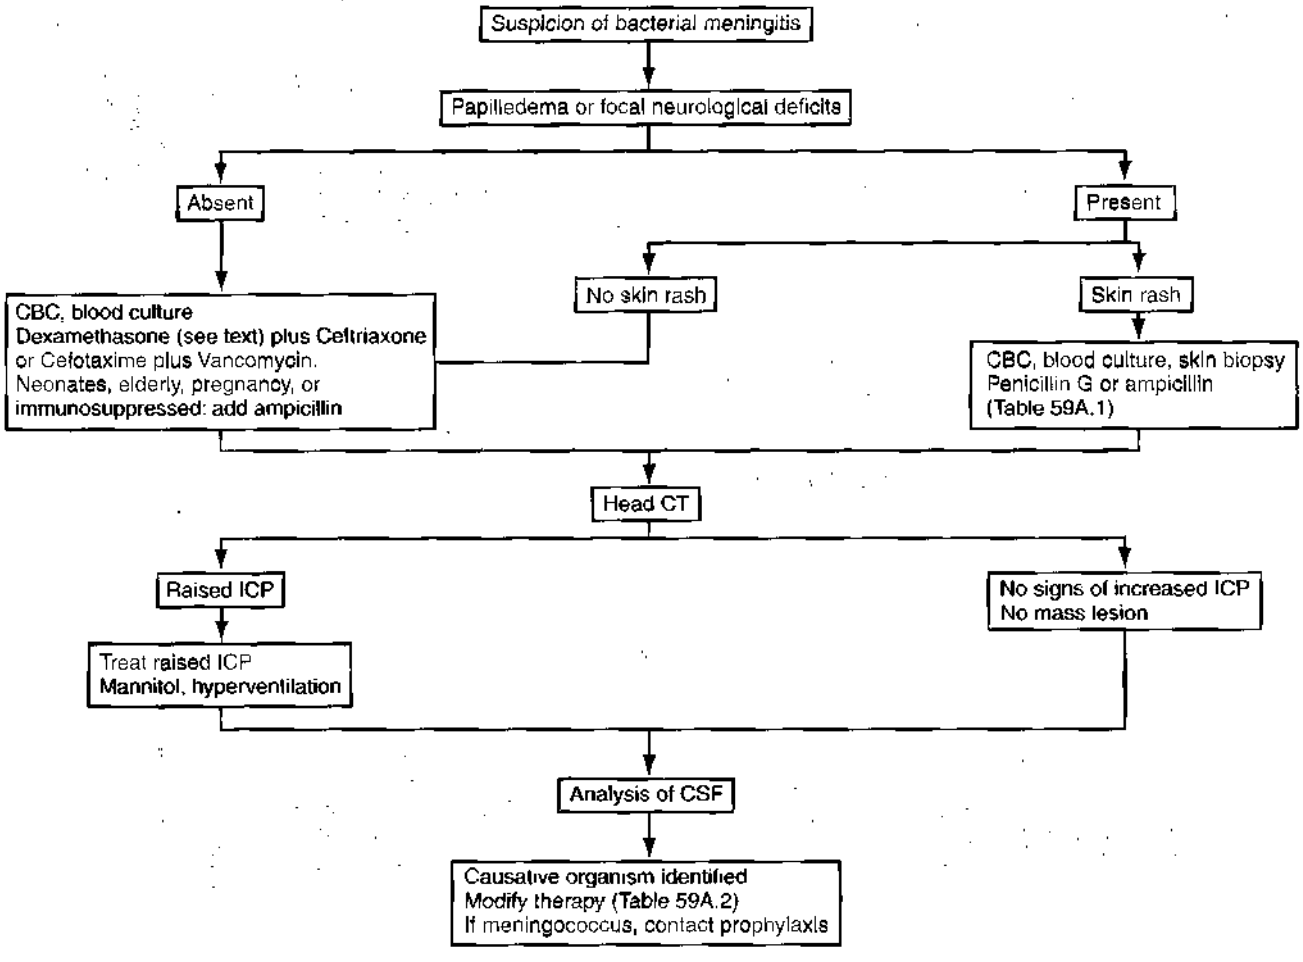

FIGURE 59A.1 Algorithm for the initial management of patients with acute bacterial meningitis. CBC = complete blood count; CSF : cerebrospinal filud; ICP = intracranial pressure.

hemorrhage; and carcinomatous meningitis. When meningeal signs are less prominent, cerebral or epidural abscess, subdural empyema, and viral encephalitis are additional diagnostic considerations.

Treatment

Antibiotic selection depends on the clinical setting in conjunction with allergies, local resistance patterns, and CSF results. When LP is delayed or the Gram stain result is nondiagnostic, empiric therapy is initiated (see Table 59A.1 and Figure 59A.1). Ampicillin or penicillin G and a third-generation cephalosporin ate typical first-line agents. Until recently, empiric coverage included ampicillin to cover most pneumococcus, meningococcus, and *Listeria* and a third-generation cephalosporin, such as cefotaxime, ceftriaxone, or ceftazidime, to cover gram-negative organisms and ampicillin-resistant *H. influenzae.* However, with the emergence of resistant pneumococcus, these recommendations are changing, and local resistance patterns influence empiric antibiotic coverage in adults with community-acquired meningitis. In patients with recent head trauma or neurosurgical procedures, vancomycin should he added to a third-generation cephalosporin to cover *S. aureus.* Ceftazidime, unlike other third-generation cephalosporins, covers pseudornonas and is reserved for situations in which meningitis with this organism is suspected or proven. Current antimicrobial recommendations for bacterial meningitis caused by specific bacterial pathogens are summarized in Table 59A.2.

When the CSF Gram stain result or culture reveals a particular bacterial pathogen, treatment is directed toward the specific pathogen. In meningitis caused by 5. *pneumoniae* of unknown antibiotic sensitivity, vancomycin combined with a third-gene rati on cephalosporin that achieves adequate CSF levels should be given, because of the emergence of penicillin-resistant pneumococcus. Therefore, bacterial meningitis with gram-positive cocci is treated with vancomycin plus a broad-spectrum cephalosporin. Gram-negative cocci are treated with penicillin G. Gram-positive bacilli are treated with ampicillin (or penicillin G) plus an aminoglycoside. Gram-negative bacilli are treated with a third-generation cephalosporin and an aminoglycoside.

Table 59A.2: Antibiotic treatment for bacterial meningitis*

Antibiotic	*Bactericidal/ bacteristatic*	*Therapeutic to toxic ratio*	*Cerebrospinal fluid penetration*	*Organism*	*Intraven (adult)*
Penicillins					
Penicillin G	Cell wall damaged; bactericidal	Wide, except in renal failure and the elderly	3+	N. *meningitidis,* some *S. pneumoniae,* group B Streptococcus	24 millio
Ampicillin	Bactericidal	Wide	3+	As for penicillin G + some H, *influenzae, L. monocytogenes,* 60-70% *E. coll*	12 g/day
Extended-spectrum penicillins	Bactericidal	Wide	3+	As for ampicillin + *P. aeruginosa, K. pneumoniae,* indole positive *Proteus, Serratia*	Carbem (q4h) 12-20 azloc and m 10-15
Ami staphylococcal penicillins	Bactericidal	Wide	2+	*S. aureus, S, epidermidis*	Methicil oxaci (q4h)
Vancomycin	Bactericidal	Narrow	3+	*S. aureus* including methicillin-resistant strains, S- *epidermidis,* penicillin-resistant pneumococci, enterococci, diphtheroids, and *F, meningosepticum*	3 g/day
Third-generation cephalosporins	Bactericidal	Wide	3+	Broad-spectrum; some gram-positive and especially gram-negative *E. coli, Klebsiella, Proteus, Serratia, N. meningitidis, H. influenzae* (including /J-lactamase-sccrcting strains)	Cefotaxi (q4h) Ceftri 4 g/d Cefta 8 g/da
Chloramphenicol	Bacteriostatic; hactericidal in therapeutic concentrations against *Haemophilus, S. pneumoniae,* and meningococcus	Narrow; peak serum levels should be maintained between 15 and 25 mg/liter	4 1	*H. influenzae, S. pneumoniae, N. meningitidis*	4 g/day admin *TV* pr vomit

Aminoglycosides	Bactericidal but not uniformly so because of acidic pH and low CSF levels	Narrow	f+; consider intrathecal or intraventricular administration	Gram-negative enteric organisms, *P. aeruginosa*	Netilmicin and gen 200 mg Kanam 1 g/day
Trimethoprim-sulfa met h-oxazolc	Bacteriostatic or bactericidal	Narrow	**4+**	Broad-spectrum *S. pneumoniae, H. influenzae,* meningococcus, gram-negatives, *Staphylococcus, L. monocytogenes, Nocardia*	Trimethop sulfam 6 g/day (trimet 15 mg/ ql2b}
Metronidazole	Bactericidal	Narrow	**4+**	Anaerobes	1.5 g/day
Rifampin	Bactericidal	Narrow	**4+**	Prophylaxis for meningococcus and *H. influenzae;* given with vancomycin for resistant *Staphylococcus* **and** *F, meningosepticutn*	600 mg/d
Fluoroquinolones	Bacterid da I	Narrow	Ciprofloxacin 1+; Ofloxacin 2+; Pofloxacin .3—	Gram-negative including *P. aeruginosa* and Staphylococcus; use selectively for multidrug-resistant gram negative bacteria and M. *tuberculosis;* prophylaxis for meningococcus	Ciproflox (q12h} Pefloxa 800 m
Unique ^-lactams	Bactericidal	Narrow	**2+, 3+**	Broad-spectrum most gram-positive and gram-negative nosocomial *Fonterobacter* and *Acinetobacte.r,* polymicrobial bacteremia	Imipenem

4+ = excellent; 3+ = very good; 2- = good; 1+ = poor; CSF = cerebrospinal fluid.

"Readers should check the product information sheet included in the package of each drug and follow those instructions.

^-Lactamase inhibitors (e.g., clavulanate or sulbactam) may be used with ampicillin, amoxicillin, or ticarcillin to inhibit ^-lactamases

^Ceftriaxone can be administered once a day if necessary. It is eliminated by kidneys and liver, and impaired function of either or

Ceftazidime is especially effective against *Pseudomonas* species. As single agents, ceftriaxone and cefotaxime arc the most frequently u

babies younger than 3 months because it displaces bilirubin.

[s] Avoid in newborns ("gray baby syndrome"). Serum levels should be monitored. Levels >40 mg/L are toxic. Levels >*25* mg/L can

Idiosyncratic irreversible marrow aplasia (1:30,000 patients) is the most feared complication.

'Also causes neuromuscular blockade—caution in myasthenia gravis, respiratory failure, and postoperatively when curare has been u

• CNS toxicity includes seizures (2-8% of patients).

Current antibiotic recommendations, when culture results reveal a specific pathogen, are listed in columns five and six of Table 59A.2,

Because bacteria! meningitis develops in an immunologically privileged site lacking a lymphatic system, bactericidal, rather than bacteriostatic, antibiotics that rapidly achieve adequate CSF levels should be selected. Therefore, antibiotic selection and reevaluation arc made in the context of several general pharmacological principles. Meningeal inflammation increases permeability of the blood-brain barrier to /^-lactam antibiotics from 0.5-2.0% to 5-10% of serum concentration. For more lipid-soluble antibiotics, such as chloramphenicol, rifampin (RIF), and trimethoprim/sulfamethoxazole (TMP/SMX), CSF levels reach 30-40% of serum concentrations even without meningeal inflammation. The low pFI of infected CSF impairs aminoglycoside activity, and increased CSF protein reduces the concentrations of active free drug for the ^-lactams, which are highly protein bound. Antibiotics used in meningitis, their relevant properties, and specific indications appear in summary form in Table 59A.2.

Optimal duration of therapy is not known for bacterial meningitis. Parenteral antibiotics are administered for 7-10 days for meningococcal and *H, influenzae* meningitis, 10-14 days for pneumococcus, and longer courses of 14-21 days for *L, monocytogenes* and Group R streptococci, and 21 days for gram-negative bacilli other than *H. influenzae* (Quagliarello and Scheld 1997). Treatment of bacterial meningitis sometimes extends to include family, medical personnel, and other contacts who may require che mo prophylaxis (vide infra). In many instances, proven or suspected bacterial meningitis requires notification of public health authorities to ensure accurate surveillance.

Adjunctive Therapy

Despite the availability of bactericidal antimicrobial therapy, the morbidity and mortality from bacterial meningitis remain unacceptably high. Recent studies have focused on the pathogenesis and pathophysiology of tissue injury in bacterial meningitis because the simple introduction of powerful antimicrobial agents may not improve the situation. Experimental evidence from animal models supports a role for inflammatory cytokines in the pathophysiology of bacterial meningitis (Scheld et al. 2002), The proinflammatory cytokines, interleukin 1 and 6, and TNF-a, produced by CSF leukocytes in response to a bacterial stimulus, whether whole organism, component, or toxin, mediate CNS inflammation, cerebral edema, cerebrovascular dysregulation, and brain injury in these models. Corticosteroids have a beneficial effect by inhibiting the synthesis of proinflammatory cytokines at the level of messenger RNA (mRNA) and by decreasing CSF outflow resistance and stabilizing the blood-brain barrier; therefore, their use in bacterial meningitis has been proposed. The available evidence on adjunctive dexamethasone therapy confirms a benefit for *H. influenzae* type b meningitis in reducing audiological sequelae and suggests a benefit in reducing audiological and neurological sequelae in pneumococcal meningitis in children. Adjunctive dexamethasone therapy, recommended in children over 3 months of age and many adults (Tunkel and Scheld 2002) with bacterial meningitis, should be started intravenously at the same time as, or shortly before, the first dose of antibiotic as 0.15 mg/kg body weight and administered every 6 hours for 2 to 4 days (Mclntyre et al. 1997; de Cans and Van de Beek 2002}. The rationale for giving dexamethasone before antibiotic therapy is that dexamethasone inhibits the production of TNF-a (mRNA level) if administered to macrophages and microglia before they are activated by bacterial cell wall components. Dexamethasone is unable to regulate TNF-a production once mRNA induction occurs.

Advantage of corticosteroid therapy for meningitis, especially pneumococcal, in adults is not as clear as in children with *H. influenzae.* In a single 1989 study, dexamethasone, 12 mg intravenously every 12 hours for 3 days, was beneficial in patients with pneumococcal meningitis. Flowever, with increasing pneumococcal resistance to antibiotics, the effect of corticosteroids on CSF antibiotic penetration would influence the recommendations for management of pneumococcal meningitis. For example, experimental evidence in animal models of meningitis shows that concurrent corticosteroid administration reduces vancomycin penetration into CSF. As a result, currently recommended treatment of pneumococcal meningitis in adults receiving adjuvant dexamethasone, pending antibiotic sensitivities, consists of ceftriaxone plus RIF. In treating penicillin-resistant pneumococcal meningitis, a second CSF study in 24-48 hours is recommended to document bacteriological improvement, because adjuvant dexamethasone may mask clinical signs of poor antibiotic response (Quagliarello and Scheld 1997).

Other adjunctive treatment may be useful in critically ill patients with bacterial meningitis. Patients with increased 1CP may benefit from the insertion of an ICP monitoring device and vigorous treatment of raised ICP. To avoid status epilepticus, seizures should be treated promptly with appropriate agents, such as lorazepam or diazepam and phenytoin. Treatment of shock and disseminated intravascular coagulation may be necessary. Plasma exchange has proved life saving in some patients with fulminant mcningococcemia, but this treatment must be considered experimental.

Complications

Focal cerebral signs such as hemiparesis usually imply arteritis, septic venous thrombophlebitis, ot cerebritis. Meningeal inflammatory processes in bacterial meningitis can cause cranial neuropathies. Cranial nerve VI palsy and a

deteriorating level of consciousness within the first 48 hours usually indicate an increase in ICP. Subdural effusions may develop in children, particularly with *H. influenzae* or other gram-negative meningitis. Indications for tapping and culturing a subdural effusion include persistent fever, rapidly enlarging head circumference in the absence of hydrocephalus, or focal neurological signs related to the effusion. Subdural effusions are aspirated under CT guidance. Sterile effusions often resolve spontaneously; subdural empyemas require more aggressive neurosurgical management (Bleck 2002). Depending on clinical circumstances, hydrocephalus may require intervention with serial LPs (if communicating) or external ventricular drainage. Obstructive hydrocephalus may be monitored expectantly with serial CTs.

SOME SPECIFIC PATHOGENS AND PUBLIC HEALTH ISSUES

Pneumococcus

Meningitis occurs in approximately 4% of patients with invasive *S. pneumoniae.* Associated conditions include otitis media, skull fractures, alcoholism, and sickle cell disease. Pneumovax, the pneumococcal vaccine composed of polysaccharides of 23 pneumococcal types, is recommended for patients with surgical or functional asplenia (such as sickle cell disease) and chronic illnesses. Of all blood culture isolates of pneumococci in the United States, 88% are contained in the 23-vaIent vaccine.

Rare pneumococcal meningitis cases have been classified as apurulent by the absence of CSF pleocytosis. Turbid CSF, masses of pneumococci, elevated protein, fewer than 100 cells/jiL, and low CSF glucose are characteristic. Within 24 hours after initiating antibiotic treatment, CSF cell counts can increase to more than 2000 cells/uL and the pneumococci disappear from the CSF.

Penicillin G and ampicillin are equally effective in treating meningitis caused by penicillin-sensitive strains of *S, pneumoniae.* For patients with *S. pneumoniae* resistant to both penicillin and ampicillin, treatment is by ceftriaxone combined with vancomycin. Consideration should be given to using intraventricular vancomycin in patients not responding to intravenous vancomycin. Intraventricular vancomycin is safe and is not associated with increased seizure activity.

Meningococcus

N. meningitidis infection may manifest as fever and bacteremia without sepsis, meningococcemia without meningitis, or meningitis with or without meningococcemia (Ferguson et al. 2002). Meningitis occurs in an estimated 48% of cases of invasive disease. Penicillin G is the antibiotic of choice for meningococcal meningitis; ampicillin may also be used. Rare NT. *meningitidis* isolates produce ^-lactamase or have altered penicillin-binding proteins. In the event of poor initial response to penicillin or ampicillin, isolates should be tested for sensitivities and therapy changed to ceftriaxone or cefotaxime. Treatment of systemic infection may not eliminate nasopharyngeal carriage. During widespread outbreaks or epidemics, when up to 1% of the population may be affected, a single injection of long-acting oily preparation of chloramphenicol (Tifomycine) at a dose of 3 g intramuscularly has been used successfully,

Current commercial vaccines include the quadrivalent vaccine with activity against serogroups A, C, Y, and W135. Protective antibodies persist for up to 5 years in adults, but only 1-2 years in children younger than 4 years. Vaccination is recommended for patients with complement deficiency or asplenia, as well as military recruits and travelers to hyperendemic or epidemic areas in Africa, Asia, and South America. Most vaccinations arc given during outbreaks. A vaccine against serogroup B has been developed in Cuba and used in some areas of South America.

Prophylaxis for meningococcal meningitis is recommended for the index case and all household members and medical personnel who may have had close contact with infected patients. A 2-day course of oral rifampin (RIF) is given in doses of 600 mg every 12 hours for adults, 10 mg/kg every 12 hours for children 1 month to 12 years old, and 5 mg/kg every 12 hours for infants younger than 1 month of age. Alternatives include ceftriaxone intramuscularly, recommended for pregnant and lactating women or children younger than 2 years (250 mg for adults, 125 mg for children), or minocycline or ciprofloxacin.

Haemophilus Influenzae

Meningitis complicates approximately 10% of *H. influenzae* infections, often in the setting of a paramemngeal ear or nose infection or basal skull fracture. The H. *influenzae* type b conjugate vaccine series is administered at 2, 4, and 12-18 months of age. Chemoprophylaxis with oral RIF is recommended for all household members under 4 years of age. The doses are the same as for meningococcal prophylaxis, but treatment is given for 4 days.

Listeria Monocytogenes

Listeria, a common meningeal pathogen in immunosuppressed hosts and neonates, also causes meningitis in the normal host. Meningitis develops in 36% of cases of invasive listeriosis. Ampicillin plus gentamicin is recommended for patients of all ages with *Listeria* meningitis, because neither ampicillin nor penicillin is bactericidal for *Listeria* in vitro, and third-generation cephalosporins are inactive against Listeria. TMP/SMX may be used in penicillin-allergic patients.

Listeria cerebritis or rhombencephalitis is a distinct nonmeningitic syndrome, which presents as headache,

fever, nausea, and vomiting, followed by cranial nerve palsies, decreased consciousness, seizures, and focal deficits. The CSF may contain few or no WBCs. CSF Gram stain and culture results are negative, but blood culture results are positive. *Listeria* cerebritis requires 6 weeks of treatment.

Nosocomial Agents

Increasing numbers of nosocom hilly acquired mlections, including meningitis, are encountered in hospitalized sick patients. Gram-negative bacteria of the *Enterobacteriaceae* family *(E. colt, K. pneumoniae), Pseudomonas* species, and gram-positive cocci (staphylococci, pneumococci) frequently cause hospital-acquired meningitis. Members of the genus *Acinetobacter,* especially multircsistant strains of *A. baumannii,* increasingly cause nosocomial pneumonia, bacteremia, and meningitis in the intensive care units (ICU). Associated systemic features include petechial rash in 30% of patients and Waterhouse-Friderichsen syndrome in some cases. *Acinetobacter* and meningococcus thus share clinical, as well as microbiological, features, leading to diagnostic confusion. *Acinetobacter* are rod-shaped gram-negative organisms during rapid growth and coccoid in the stationary stage. Most *A. baumannii* are now resistant to ampicillin, carbenicillin, cefotaxime, chloramphenicol, gentamicin, and other aminoglycosides. Imipenem, carbenicillin plus an aminoglycoside, and amoxiciilin-clavulanic acid are treatment alternatives.

Brain Abscess

Brain abscess is a focal suppurative process of brain parenchyma, accounting for an estimated 1 in 10,000 general hospital admissions. Brain abscesses develop most frequently by spread from a contiguous infected cranial site, such as ear, sinus, or teeth. Other predisposing causes include open head trauma, previous neurosurgical procedures, and craniofacial osteomyelitis. Hematogenous spread from a remote source also can cause brain abscesses, particularly in the setting of congenital heart disease with right-to-left shunt or pulmonary disorders such as lung abscess, bronchiectasis, or arteriovenous fistula. Metastatic, or blood-borne abscesses, are usually found at gray and white matter junctions, in the distribution of the middle cerebral artery, and are often multiple. However, 20% of abscesses are occult, without an additional source of infection (Anderson 1993). Classifying brain abscesses by likely entry point of infection allows physicians to predict likely pathogens and choose appropriate empiric therapy (Lu et al. 2002).

Frontal abscesses arise most often from paranasal sinus infection, temporal or cerebellar abscesses from an otogenic source, and multiple abscesses from a remote site. Experimental evidence suggests that bacteria require a damaged brain, such as the microscopic or macroscopic area of necrosis resulting from septic thrombophlebitis, emboli, or hypoxemia, to establish infection. The predilection of metastatic abscesses for gray-white matter junctions, for example, may be a consequence of the fluctuations in blood supply to those areas. Once infection is established, the abscess passes through the stages of cerebritis, central necrosis, capsule development, and maturity over a period of approximately 2 weeks or so.

Clinical Features

Patients with brain abscess present with signs and symptoms of an expanding mass lesion, with progressive headache, altered mentation, focal deficit, or seizures. About one half of patients develop nausea and vomiting. Approximately the same proportion has fever, and hence the diagnosis should not be excluded based on normal temperatute alone. Acute worsening of headache and nuchal pain, together with an increase in temperature, can signify rupture of the abscess into the subarachnoid space, with consequent pyogenic meningitis, a serious event.

Diagnosis

Neuroimaging studies reveal one or more ring-enhancing masses with surrounding edema (Figure 59A.2). The ring of enhancement may be thicker near the cortex and thinner near the ventricle; large abscesses tend to have thin, enhancing rings of relatively uniform thickness. Associated sinus or ear infection also may be identified by cranial imaging, though dedicated sinus or temporal bone CT may be necessary, in order to better visualize the primary site of infection. An early lesion in the cerebritis stage appears as a nonenhancing focal low-density area on CT scan or hypointensity on magnetic resonance imaging (MRf). Air within a brain mass, in the absence of recent neurosurgical procedures, suggests an abscess. An indium-labeled leukocyte scintillation scan demonstrating an active inflammatory focus may complement CT or MRI studies.

Peripheral leukocytosis may be mild or absent and should not be relied on for considering the diagnosis. Because of the risk of herniation or precipitating rupture, LP is contra indicated in suspected or proven brain abscesses. CSF reveals only nonspecific findings of elevated protein and lymphocytic pleocytosis with normal glucose and rarely yields positive culture results unless the abscess has ruptured into the subarachnoid space.

Pathogens

Occurring as mixed infections 30-60% of the time, brain abscess pathogens vary with the clinical setting. In immunocompetent patients the most commonly encountered aerobic organisms arc the a-hcmolytic and nonhemolytic

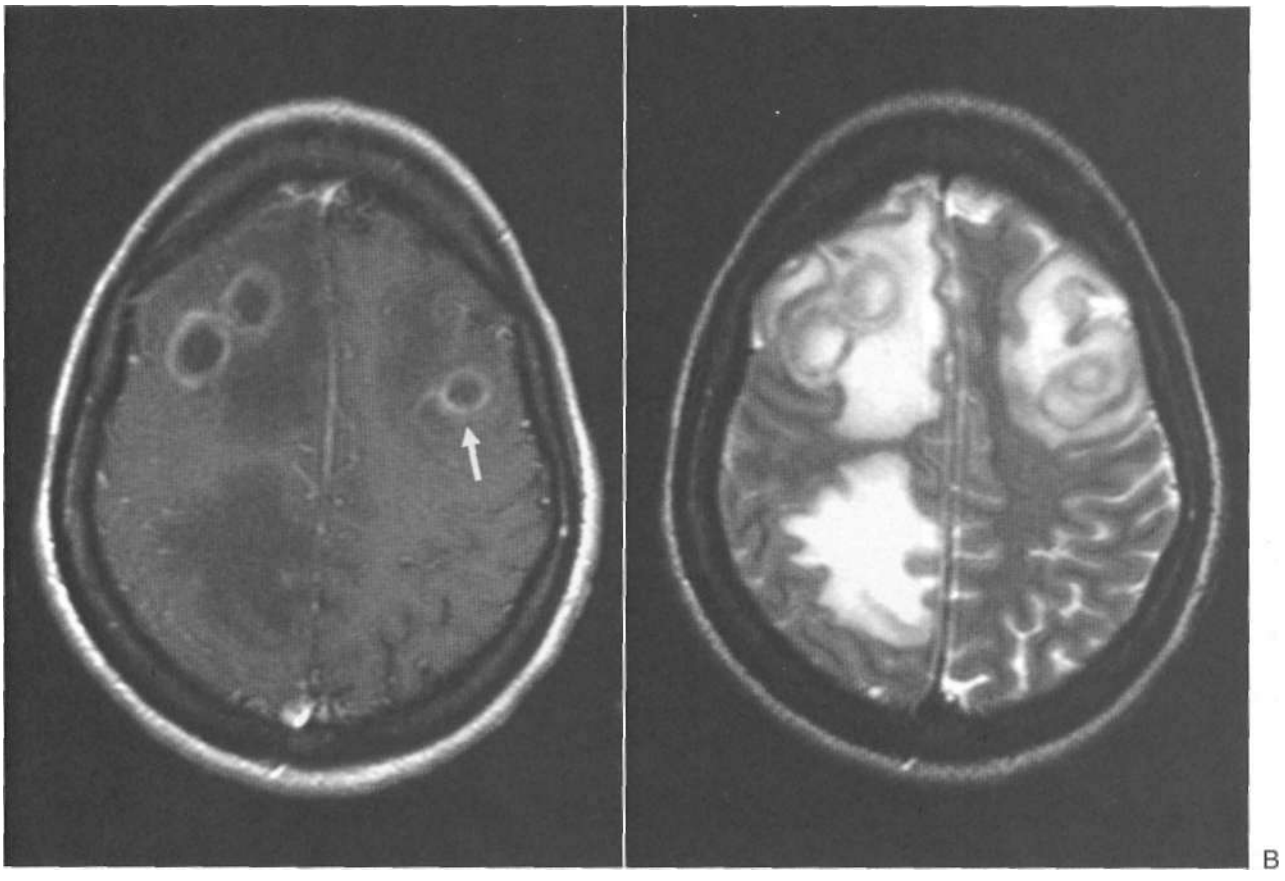

FIGURE 59A.2 Brain abscess. Postgadolinium axial T1W-MRI showing multiple ring-enhancing lesions (some multiloculated, *arrow,* A) with surrounding edema best seen in T2W sequence (B) and with associated intralesional diffusion restriction (DW-MRI, C). Prominent lactate *(arrow)* and inverted peak at 0.9 ppm *(arrowhead)* in single voxel from the lesion {H^1 spectroscopy, D and E) are typical of bacterial abscess. (Courtesy Dr. S. Ouanounou.) *Continued*

streptococci (such as *S. milleri), S. aureus,* and *Enterabacteriaceae.* Other important pathogens include anaerobes such as *Bacteroides., Fusobacterium, Peptostreptococcus,* and *Propionibacterium;* gram-negative bacteria such as *Eikenella, Actinobacitlus,* and *Haemophilus;* and enteric gram-negative bacteria such as *E. colt, Klebsiella,* and *Pseudomonas.* Several important associations include 5. *milleri* or pneumococcus with a sinus source; *Bacteroides, Enterobacter, Proteus,* streptococci, or *Pseudomonas* with an ear source; anaerobic streptococci with pulmonary infections; *Actinomyces* with dental procedures; and *S. aureus* in patients with head trauma, recent neurosurgical procedures, or cranial osteomyelitis. Various other bacteria may occasionally be found in brain abscesses, including *Clostridium* spp. after trauma and wound contamination by soil, C. *diversus* in neonates, *Salmonella* spp., .S. *moniliformis* (the agent of rat-bite fever), and *Brucella* spp. Except for pneumococcus and *H. influenzae,* typical bacterial meningitis pathogens irif requently cause brain abscess (Case Records 1993).

Geography and immune status are other important determinants of brain abscess microbiology and its differential diagnosis. Tuberculomas frequently cause space-occupying lesions in countries with high tuberculosis (TB) prevalence. Amcbae, toxoplasmosis, cysticcrcosis, or other helminths, including schistosomal species, Paragonimus, trichinosis, sparganosis, and echinococcosis, cause parasitic cerebral abscesses. *P. boydii* fungal abscess may follow a near-drowning episode by 2-4 weeks.

In immunocompromised patients with T-ccll or mononuclear phagocyte defects, causes of brain abscesses include L. *monocytogenes, N. asteroides, G, terrae* (an environmental actinomycete), *Mycobacterium* spp., and parasites such as *Toxoplasma, Acanthamoeba, Cryptococcus,* and T. *cruzi.* In HIV-infected patients, polymicrobial pyogenic abscesses with *S. bovis, Fusobacterium, Peptostreptococcus,* and group Gl streptococcus have been reported, along with abscesses with unusual combinations of organisms, such as *Candida* and staphylococci (Maniglia et al. 1997). Neutrophil abnormalities lead to an increased incidence of *Enterobacteriaceae* and *Pseudomonas* abscesses and fungal abscesses caused by *Aspergillus, Mucor,* or *Candida;* and *Strongyloides.*

Differential Diagnosis

In the febrile patient with headache, altered mentation, and laterali/.ing findings, the differential diagnosis includes

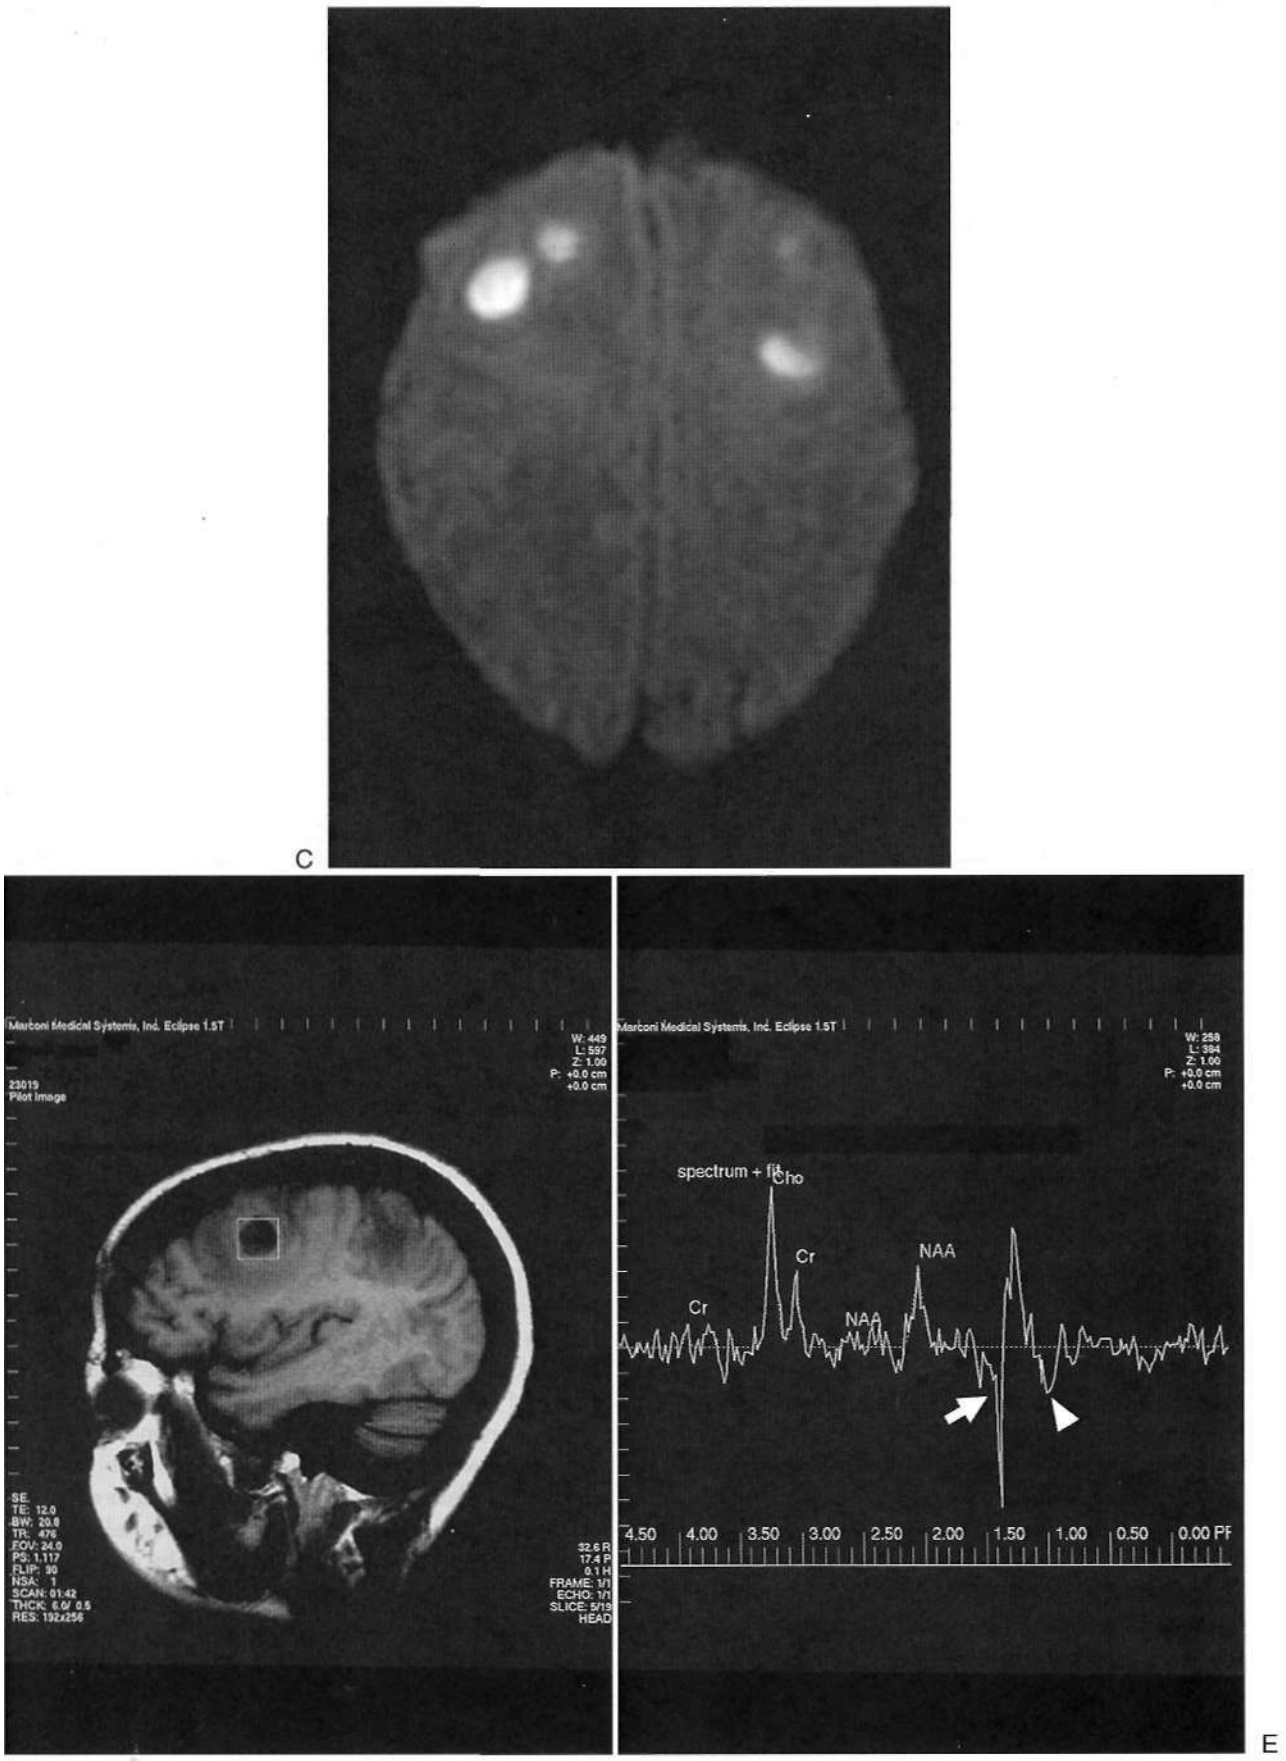

FIGURE 59A.2, cont'd. (Courtesy Dr. S. Ouanounou.)

other infectious etiologies, such as subdural empyema, epidural abscess, viral encephalitis, bacterial or acute aseptic meningitis, septic thrombophlebitis, and endocarditis with septic embolism or mycotic aneurysm rupture. When fever is low grade or absent, primary or metastatic brain tumor is also a consideration. Occasionally, demyelinating lesions presenting as focal deficits or seizures appear as ring-enhancing masses on neuroimaging studies. Resolving cerebral hemorrhages also appear as ring-enhancing lesions on neuroimaging studies, particularly brain CT. Brainstem infection with *L. monocytogenes* or *P. acnes* may produce brainstem encephalitis (rhombencephalitis) that clinically mimics brainstem abscess.

Treatment

Successful treatment of brain abscess requires antibiotics in all patients and surgery in many cases. Antibiotics must not only penetrate brain tissue, but also reach the abscess cavity and retain activity at its characteristically low pH. For years, standard brain abscess therapy combined high-dose penicillin (24 million U per day intravenously) with chloramphenicol (1 g every 6 hours). Because metronidazole (1 g loading dose, followed by 500 mg every 6 hours) provides excellent anaerobic coverage and penetrates well into brain abscesses, it has replaced chloramphenicol, which carries the additional risk of aplastic anemia. Hence, empiric antibiotic therapy for brain abscess usually includes metronidazole and either penicillin or a third-generation cephalosporin (cefotaxime, ceftriaxone, or ceftazidime), which covers the streptococci and aero-to let ant anaerobes resistant to metronidazole. Following head trauma or neurosurgical procedures, when *S. aureus* is a concern, an antistaphylococcal penicillin (nafcillin, methic.illin) or vancomycin is added.

Current recommendations for empiric therapy, based on location of abscess and inferred source of infection, are metronidazole with either penicillin or a third-generation cephalosporin for frontal abscesses; penicillin, metronidazole, and ceftazidime for temporal or cerebellar abscesses; nafcillin, metronidazole, and cefotaxime for multiple (metastatic) abscesses; nafcillin and cefotaxime for penetrating wounds; and vancomycin and ceftazidime for postoperative abscesses {Mathisen and Johnson 1997). Intravenous treatment must continue for 6-8 weeks and may be followed by oral therapy for 2-3 months. Surgical excision may shorten the time course of intravenous therapy by 1 or 2 weeks.

Optimal therapy usually requires neurosurgical intervention. Although controversy continues as to whether aspiration under stereotactic CT guidance or total excision yields better results, excision is recommended for gas-containing, multiloculated, or fungal abscesses. Patients for whom medical management alone may be the better choice include those with multiple, deep, or dominant hemisphere abscesses; simultaneous meningitis or ependymitis; abscesses measuring less than 3 cm; or abscesses that shrink after antimicrobial therapy. Surgery is not performed in the cerebritis stage until a capsule forms. Ear, nose, sinus, and dental infections should be evaluated and treated by the appropriate surgical specialists.

Adjunctive medical therapy for medical or surgical cases includes corticosteroids for mass effect, hyperosmolar agents for worsening cerebral edema and raised ICP, and prophylactic or symptomatic anticonvulsants. Decreased mortality from brain abscesses over the last two decades, from more than 50% to less than 10%, reflects improvements in neuroimaging and neurosurgical techniques. One half of survivors recover completely. Rapid disease progression before hospitalization and altered consciousness at the time of admission portend poor outcome. Intraventricular rupture of a brain abscess is associated with mortality exceeding 80%.

After treatment, patients are followed with neuroimaging studies at monthly intervals for approximately 6 months or until contrast enhancement disappears. Persistent contrast enhancement predicts recurrence in up to 20% of patients. Seizures occur in 25-50% of patients during their early period of hospitalization, and anticonvulsants initiated during hospitalization are continued for 6-12 months. When administered prophy tactically, anticonvulsants are continued for a minimum of 3 months after surgery.

Subdural Empyema

Subdural empyema is a collection of pus between the dura and arachnoid. It develops most commonly as a consequence of ear or sinus infection. Other causes include cranial osteomyelitis, penetrating head trauma or neurosurgery, infection of subdural effusions in childhood meningitis, and hematogenous spread from a remote source. Purulent material tracks over the brain surface of the hemispheres (Figure 59A.3), along the falx, or adjacent to the primary focus. Posterior fossa involvement is unusual; spinal subdural empyemas are rare and always meta static.

Clinical features

Patients typically present acutely with prominent headache, fever, stiff neck, seizures, focal neurological deficit, and rapid clinical deterioration. The diagnosis should be considered in all patients with meningeal signs and deficits indicating extensive, unilateral hemispheric dysfunction or in patients with sinusitis who develop meningeal signs. A parafalcine collection would be indicated by leg weakness, paraparesis, or sphincter disturbance. Children younger than 5 years may develop subdural empyemas after *H. influenzae* or gram-negative bacterial meningitis and present with irritability, poor feeding, and increasing head circumference. Radicular pain and signs of cord

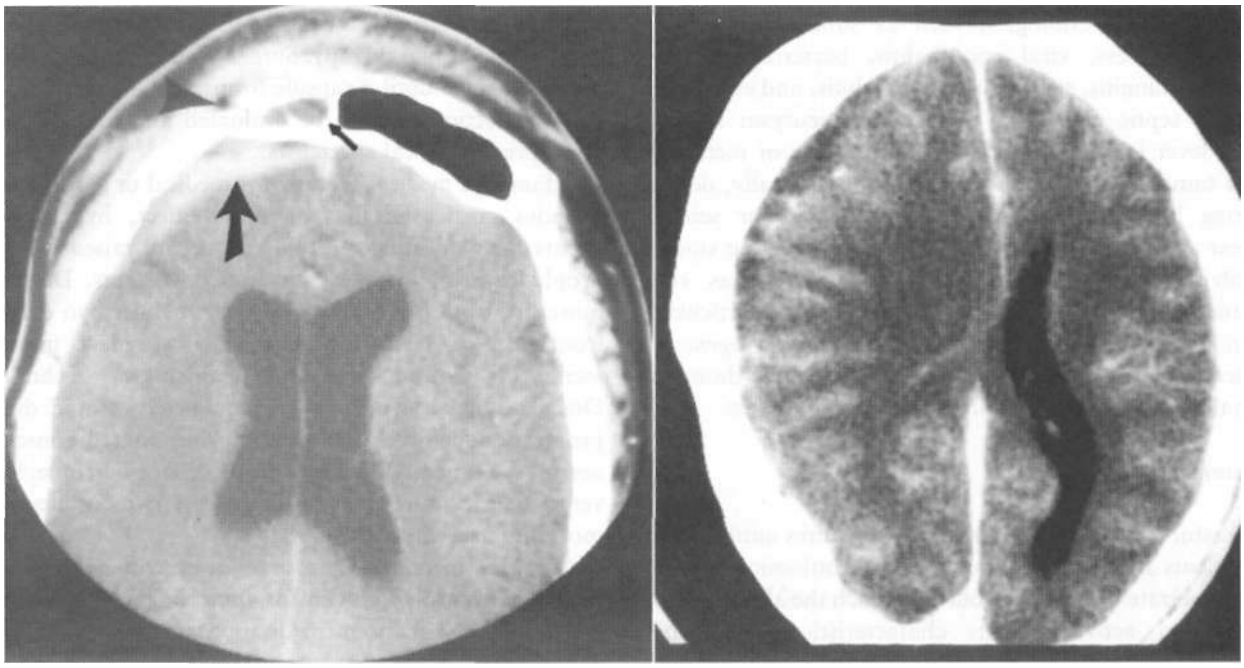

FIGURE 59A..1 Subdural empyema. (A) Contrast-enhanced computed tomographic scan showing right frontal sinus infection *(short arrow)* that has spread to the right subdural space *[long arrow)* and forehead *[arrowhead),* (B) In a second patient, the contrast-enhanced computed tomographic scan shows an extra-axial fluid collection and midline shift disproportionately greater than the size of the subdural collection,

compression in the absence of vertebral tenderness suggest spinal subdural empyema.

Diagnosis

Because there are similarities between subdural empyema and bacterial brain abscess with regard to pathogenesis and clinical presentation, the disorders share many aspects of diagnosis and management. Bacterial pathogens for both disorders are similar, although subdural empyemas are less often mixed. Neuroimaging studies help establish the diagnosis, but may underestimate the size of the empyema. In infants, the diagnosis may be made by subdural taps. The empyema fluid is usually too turbid to tran si Humiliate. Spinal cases are examined by MR! or myelography.

Treatment

Because subdural empyema progresses rapidly, combined medical and surgical management should proceed emergcntly (Bleck 2002), Untreated, subdural empyemas are uniformly fatal. Whether craniotomy or burr hole aspiration is the better surgical treatment remains controversial. Burr holes work well for early cases, but pus may reaccumulate. Craniotomy is recommended in posterior fossa cases or if cranial osteomyelitis coexists. Otitis or sinusitis may require simultaneous surgical therapy. Empyema fluid should be cultured, and antibiotic treatment is continued for at least 3 weeks. In as many as one fourth of cases, no organism can be cultured from pus (Anderson 1993).

Overall mortality is 14-18%. Rapid disease progression before hospitalization and depressed level of consciousness at admission arc associated with poor prognosis. Mortality is 75% in comatose patients. An estimated 42% of survivors develop seizures within 16 months.

Cranial Epidural Abscess

Cranial epidural abscess, an infection in the space between dura and skull (Figure 59A.4), begins as cranial osteomyelitis complicating ear, sinus, or orbital infection and nasopharyngeal malignancy. Diagnosis, urgent management, and prognosis are similar to subdural empyema. Because *S. aureus* is a frequent cause, particularly after trauma or surgery, antibiotics should cover *staphylococcus* as well as the aerobes, anaerobes, and gram-negative organisms encountered in brain abscesses and subdural empyemas. Brain abscess, subdural empyema, and epidural abscess may occur simultaneously in the same patient.

Septic Venous Sinus Thrombosis

Septic thrombosis of cerebral veins or venous sinuses may complicate meningitis or epidural or subdural abscesses or develop during the intracranial spread of infection from extracranial veins. Once established, infection and clot

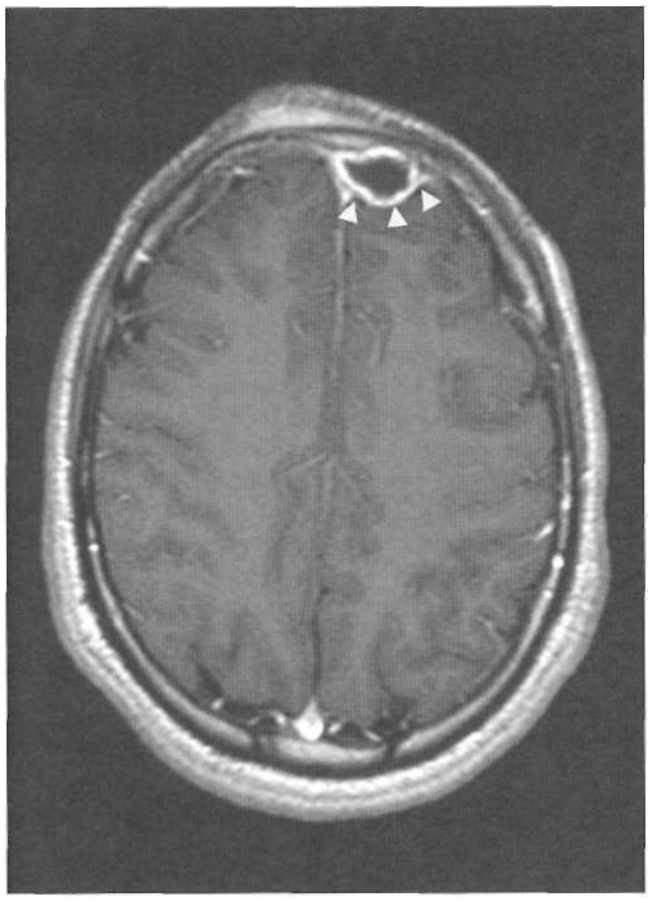

FIGURE 59A.4 Epidural abscess associated with frontal sinus disease. Postgadolinium axial T1W-MR1 showing thiek-wallcd enhancing epidural collection close to the inner table of the frontal bone *{arrowheads)* with adjacent soft tissue swelling. (Courtesy Dr. S. Ouanounou.)

spread through the venous system, aided by the absence of valves in intracranial veins. Fortunately, antibiotics have rendered this grim complication of facial, sinus, ear, dental infection, or bacterial meningitis itself less common. The most common bacterial pathogens depend on the source of initial infection; with sinusitis they arc *staphylococcus,* aerobic and microaerophilic streptococci, gram-negative E. *coli,* and/or anaerobes, whereas .*S. aureus* predominates when facial infection is the source. Otitis media or mastoiditis may be complicated by the development of the lateral sinus thrombosis.

Clinical Features

Thrombosis may develop in the cavernous, superior sagittal, or lateral sinuses, depending on the site of primary infection. Specific presenting features vary with the site involved and include headache, altered mentation, seizures, cranial neuropathies, fluctuating focal deficits, nonartcrial distribution strokes, and increased ICP. Cavernous sinus thrombosis is indicated by ipsilatcral proptosis and facial edema, retinal vein engorgement, retinal hemorrhages or papilledema, and clinical involvement of the third, fourth, sixth, and ophthalmic division of the fifth cranial nerves. Lateral (transverse) sinus thrombosis is accompanied by papilledema, extension to the jugular bulb with involvement of cranial nerves IX, X, and XI and extension to petrosal sinuses with involvement of cranial nerves V and VI. Sagittal sinus thrombosis is associated with papilledema, focal or generalized seizures, leg weakness, aphasia, or cortical sensory deficits.

Diagnosis

CT scan or **MRI** may demonstrate the primary infection or clot within the sinus. Clot within the sinus may appear as hyperdensity in the sinus on noncontrast CT, but may be missed by **MRI,** because acute thrombus may appear hypointense on T2-weighted images. **MR** venography or cerebral angiography with venous phase studies may be necessary to confirm the diagnosis.

Treatment

Treatment is directed towatd the primary infection. As with subdural and epidural empyema, empirical therapy is directed at gram-positive organisms, including staphylococci, aerobic gram-negative bacilli, and anaerobes. Anticoagulants are generally contraindicated because venous cerebral infarcts aire often hemorrhagic. However, they may help prevent clot propagation, particularly in early cases. Polycythemia, if present, is treated with volume expansion.

Spinal Epidural Abscess

Spinal epidural abscess follows infection elsewhere in the body in most cases. Infection develops in the epidural space by direct extension of vertebral osteomyelitis or soft tissue infections (retroperitoneal, mediastinal, perinephric, psoas, or paraspinal abscess) following penetrating trauma or decubitus ulcers or by hematogenous spread from skin or parenteral drug use. Rarely, back or abdominal surgery, LP, or epidural anesthesia has been contributory.

Clinical Features

Localized back pain and radicular pain are common early symptoms, frequently overshadowed by rapid evolution of paraparesis or quadriparesis. The thoracic spine is involved in 50-80% of cases, lumbar in 17-38%, and cervical in 10-25%.

Diagnosis

The combination of fever, back pain with local spine tenderness, and radiculopathy or myelopathy mandates

FfGURE 59A.5 Spinal epidural abscess. Postgadolinium sagittal T1W-MRI of lumbar spine demonstrating enhancing epidural collection *[arrowheads]* with irregularity of the adjacent verrebral endplates suggesting discitis, osteomyelitis, and associated epidural abscess. (Courtesy Dr. S. Ouanounou.)

emergent evaluation. Peripheral WBC count and erythrocyte sedimentation tate are usually, but not always, elevated. The diagnosis depends on MRI or myelography, if MR! is not available. MRI is the test of choice because it is noninvasive and provides images of the cord and epidural space in sagittal and transverse planes, as well as direct visualization of inflammatory tissue (Figure 59A.5). LP risks spinal herniation or spreading infection to the subarachnoid space should the needle pass through the abscess. Even so, because outcome depends so heavily on early diagnosis, myelography should be performed in suspected cases when MRI cannot be obtained emergently. Blood culture results ate often positive and cotrelate well with abscess pathogens. Differential diagnosis includes transverse myelitis, spinal osteomyelitis, or less commonly, spinal subdural empyema, epidural hematoma or metastases, primary spinal tumots, spinal artery syndromes, and discitis. More chronic cases may resemble the hypertrophic spinal pachymeningitis (progressive dural fibrosis with motor root compression) associated with TB or syphilis.

Treatment

Once MRI or myelography has established the diagnosis, utgent surgical decompression and antibiotic thetapy are needed. Antibiotics to cover *S. aureus* and gram-negative bacilli are administered, pending definitive identification by cultures of blood or intraoperative specimens. *S. aureus* is the most common pathogen, detected in 50-90% of cases, followed by streptococci and gram-negative enteric bacilli in 10-20% of cases. Other pathogens include *M. tuberculosis, Salmonella, Listeria, Brucella, Actinomyces* spp,, *Nocardia,* fungi {cryptococcosis, aspergillosis, mucormycosis, coccidioidomycosis, blastomycosis), and parasites (cysticercosis, echinococcosis, schistosomiasis). Corticosteroids are frequently administered preoperative^- and postoperatively during the first week of treatment. Antibiotic treatment continues for 3-4 weeks in uncomplicated spinal epidural abscess and for 6-8 weeks if osteomyelitis is apparent. Prognosis for recovery is good if surgery is performed in the early stages. Neurological recovery is often dismal if surgery is performed more than 24 hours after the onset of paralysis.

Shunt Infections

S. epidermidis causes most infections of external ventricular catheters, ICP monitors, shunt devices, and Ommaya reservoirs, followed by *.S. aureus.* Infection, often within 2 weeks of installation, is signaled by fever, shunt malfunction, and wound infection (Figure 59A.6). Signs of meningitis may be absent, but CSF pleocytosis is present, Although CSF cell counts may be gteater in ventricular compared with lumbar CSF, both should be examined and cultured. Because most infections are hospital acquired, the organism should be assumed to be methiciilin resistant, and initial treatment is with vancomycin, combined with a third-generation cephalosporin and often an aminoglycoside, to cover gram-negative bacilli. Intraventricular vancomycin and aminoglycoside may be necessary, along with removal of the shunt (Kim and Pons 1994),

MYCOBACTERIAL DISEASES

Tuberculosis

Although TB most commonly involves the lungs, it can produce disease in nearly every organ system. Approximately 1% of TB infections arc complicated by neurological disease such as tuberculous meningitis, tuberculoma, or tuberculous involvement of the spine with myelopathy (Pott's disease). The TB bacilli are obligate aerobic organisms infecting humans and other animals. Two main species ate recognized, *M. tuberculosis* and *M. bovis.* Other less common species include M. *africanum*

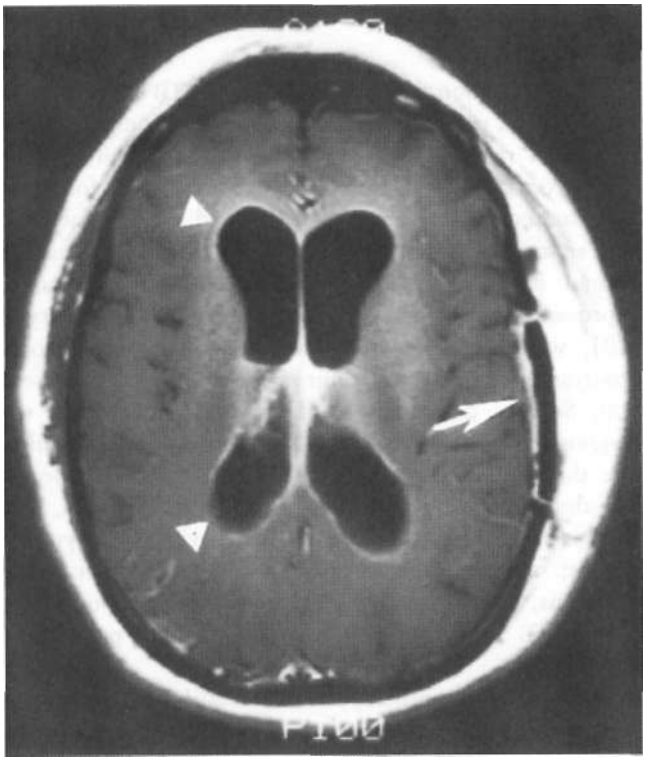

FIGURE 59A.6 Ependymitis secondary to shunt infection. Gadolinium-enhanced axial Tl-weighted magnetic resonance image showing abnormal contrast enhancement of ependymal lining of dilatated lateral ventricles *(arrowheads);* swollen, infected contrast-enhancing craniotomy site; and dural enhancement *(long arrow)* after removal of shunt.

in West and Central Africa and M. *ulcerans.* The atypical or nontuberculous mycobacteria, M. *avium-intracellulare,* arc widely distributed saprophytes and cause multisystem infections, including meningitis, in immunocompromised patients.

Epidemiology and Current Trends

TB is the most important infectious disease in the world, with an estimated one third of the population infected with the TB bacillus. As is the case for other infections introduced to new, susceptible populations, TB occurs in epidemic waves. Unfortunately, this wave is taking 300 years to pass and has not yet crested in many countries of Asia and Africa. Each year an estimated 8 million individuals around the world develop active TB. Approximately 70,000 of these patients worldwide and 4000 patients in the United States acquire TB meningitis. The majority of these individuals develop a subacute meningitis that if left untreated soon produces severe brain damage. HIV infection in recent decades has been associated with an increasing numbers of new cases and with a higher risk of extrapulmonary TB.

Pathogenesis

Neurological TB may develop during primary infection (Tung et al. 2002) or reactivate as a consequence of immunosuppression. TB meningitis develops most commonly after a two-stage process. Tubercle bacilli spread hematogenously from the lung or other organs fotm tubercles (Rich focus) in the brain parenchyma, and at a later stage, rupture into the subarachnoid or ventricular space. In other instances, meningitis may arise in the course of miliary TB or from parameningeal infection. Inflammatory exudate spreads along the subarachnoid space and pial vessels to the brain. Pott's disease, or spinal TB, develops when hematogenous spread of tubercle bacilli to the spine causes vertebral osteomyelitis, adjacent joint space infection, and subsequent paravertebral abscess.

Tuberculosis Meningitis

Clinical Features. TB meningitis typically follows a subacute course with low-grade fever, headache, and intermittent nausea and vomiting, followed by more severe headache, neck stiffness, altered mentation, and cranial (usually III, but also II, VII, and VIII) nerve palsies. Untreated disease progresses with more pronounced meningeal signs, seizures, and focal neurological deficits, including hemiparesis, increasing drowsiness, and signs of increased ICP. Other presentations of tuberculous meningitis include acute meningitis, behavioral or intellectual disturbances without meningeal signs, encephalopathy, seizures, isolated cranial neuropathies, stroke, increased ICP, and recurrent serous or aseptic meningitis. Overall, meningeal signs are present in approximately 70% of cases, cranial nerve palsy in 25%, and focal neurological findings in 16-18%. Purified protein derivative (PPD) testing is positive in 50% and active chest infection in some of the patients.

Diagnosis. Identifying tubercle bacilli on CSF acid-fast bacilli (AFB) smear or culture establishes the diagnosis. Serial LPs and centrifugation of specimens increases the yield of the AFB smear, a test that is diagnostic in only 10-30% of cases. CSF culture results arc positive for *M. tuberculosis* in 45-70% of patients but may take 6-8 weeks to become positive. Because a negative CSF AFB smear result does not rule out TB meningitis and the culture may not yield organisms for weeks, a presumptive diagnosis is often made based on other clinical criteria so that empiric anti-TB therapy can be started as early as possible.

CSF examination demonstrates normal or elevated opening pressure, elevated protein {80^400 mg/dL), low glucose (<40 mg/dL), and pleocytosis (averaging 200-400 WBC/uL with lymphocytic predominance). However, patients with miliary TB or CNS tuberculomas may have a normal CSF initially. CSF WBC counts of less than 5/u.L

have been reported in up to 11% of HIV-scropositive patients, and 5% of HIV-seronegative patients shown to have TB meningitis. In other instances, an early polymorphonuclear or eosinophilic CSF cellular response may be seen. The lack of sensitivity and specificity of standard CSF analysis and AFB smears has prompted the search for additional diagnostic tests. As a result, polymerase chain reaction (PCR) technique has been applied and is now routinely available for the diagnosis of TB meningitis, with reported sensitivities of 70-75%. Enzyme-linked immunosorbent assay (FLISA) and radioimmunoassay tests for and mycobacterial antibodies in the CSF have also been developed (LoBue and Catanzaro 1997).

Additional investigations should include general examination for lymphadenopathy and hepatosplenomegaly, retinal examination for choroidal tubercles, chest radiography for lung infection, tuberculin test, and brain neuroimaging study. Cranial CT or MRI showing basal meningeal and sylvian exudates and enhancement with hydrocephalus suggests the diagnosis.

Differential diagnosis includes untreated or partially-treated bacterial meningitis, other granulomatous meningitides (spirochetes, *Brucella,* most fungi, and parasites such as *Amoeba, Toxoplasma,* and trypanosomes), other conditions that elicit a subacute or chronic granulomatous response (CNS sarcoid, lupus, Behcet's, Vogt-Koyanagi-Harada disease, granulomatous angiitis), and lymphomatous or carcinomatous meningitis. TB should also be considered when suspected bacterial meningitis fails to resolve with antibacterial therapy.

Tuberculomas

Tuberculomas, the parenchymal form of TB, occur as single or multiple brain or spinal cord lesions and present with signs and symptoms of space-occupying lesions. On CT or MRI scan, the lesions may be of low or high intensity, with ring enhancement. Miliary disease is characterized by multiple small (1-2 mm) lesions. Open or stereotactic biopsy may be necessary if definitive diagnosis of TB cannot he made at an extraneural site. In regions in which TB is prevalent, the decision to initiate anti-TB therapy may be made without histological confirmation.

Spinal Tuberculosis

The most common site of involvement by TB of the spine is in midthorax region. Back pain is the chief complaint, and paraspinal muscle spasms or kyphotic deformity of the spine (from collapse of vertebra, a gibbus) may be found on examination. Plain films show decreased bone density and joint space destruction in long-standing disease, but may be normal in early disease. Radionuclide bone scanning improves detection of spinal TB, but the best modality is MRI, which simultaneously visualizes the spinal cord. Progressive paraparesis requires urgent surgical intervention. Surgery also may be indicated for biopsy if the diagnosis is in doubt or to obtain cultures for sensitivities. The differential diagnosis of vertebral bacterial diseases includes infections with staphylococci, streptococci, and typhoid and other gram-negative bacilli; paratyphoid disease; and brucellosis. Compared with other bony infections, there is less sclerosis in tuberculous spondylitis. Skeletal TB appears to be rare in HIV-infected patients.

Treatment. Chemotherapy for TB requires a combination of several bactericidal drugs to sterilize lesions and avoid inducing resistance. Commonly used anti-TB medications and their side effects arc summarized in Table 59A.3. Optimal drug combinations vary with region of the body, clinical setting, and local resistance patterns (Small and Fujiwata 2001). One recommended regimen for initial treatment of CNS TB is with isoniazid (INH), RIF, pyra/.inamide, and ethambutol or streptomycin (SM). RIF, SM, and INFI (when there is meningeal inflammation) penetrate to the CSF well. If there is satisfactory clinical improvement after 2 months, three- or four-drug regimens can be consolidated to two agents, usually INH and RIF, for an additional 10 months. In areas with high prevalence of drug-resistant disease and HIV infection, treatment begins with five to seven drugs until drug-susceptibility results are known. Additional agents include ethionamide, which penetrates CSF well, cycloserine, para-aminosalicylic acid, thiacetazone, clofazimine, ofloxacin, and rifabutin, which is active against *M. avium* infections and penetrates CSF well. Oral pyridoxine (25-50 mg/day) is given concurrently with INH to prevent neuropathy. Monthly

Table 59A3; Commonly used antimicrobial agents for tubercular meningitis

Drug	*Dose (tng/kg/day) and route*	*Major toxicity*
Isoniazid (INH)	.5-10 (max 300 mg) PO, add pyridoxine to prevent neuropathy (Child 25 mg/day PO, Adult 50 mg/day PO)	Hepatitis (1-2%), neuropathy (5%), seizures
Rifampin (RIF)	Child 15 PO, Adult 10 PO"	1 lepatiris : 1-2% i, hypt-i-si'iiMtivitv
Pyrazinamide	25 (max 2.5 g/day) PO	Arthralgia (5%!, hepatitis (1-5%), hyperuricemia, gout, rash
Streptomycin	Child 30 IM Adult 15 (max 1 g/day) IM	Hearing loss, vestibular imbalance (1-5%)
Ethambutol	15-25 (max 2.5 g/day) PO	Optic neuritis (3%), neuropathy (1-2%), rash

Source: Adapted from Davis, J. K. 2002, "Tuberculous meningitis," in *Current Therapy in Neurologic Disease,* 6th ed., eds R. T. Johnson, J. W. Griffin, and"J. C. McArther, Mosby, Philadelphia.

vision and color identification studies are recommended for patients taking ethambutol to monitor for toxic optic neuropathy. Monthly hearing evaluations are necessary when SM is used, and the drug should be stopped at signs of vestibular toxicity. Liver enzyme levels are monitored also, because INH, RIF, and pyrazinamide are hepatotoxic. Treatment can be continued with elevated liver enzyme levels if the patient remains anicteric or without other signs of liver toxicity. RIF induces cytochrome P450 and thus can alter levels of concurrently administered phenytoin, RIF also accelerates methadone metabolism and may precipitate withdrawal symptoms in patients receiving maintenance therapy.

During treatment CSF is reexamined to monitor treatment efficacy and drug levels. Neuroimaging studies are performed 2-3 months after the start of treatment and again at 3- to 6-month intervals to verify improvement in lesions. Two years of treatment may be necessary for tuberculomas. Chemotherapy alone is effective treatment for most spinal TB without cord involvement.

Complications. TB meningitis, particularly when advanced, can be an acute, life-threatening illness. Untreated, it is nearly always fatal, usually within 3-6 weeks of presentation. Even with treatment, a 21% mortality rate for immunocompetent patients and 33% for HIV-infected patients has been reported. Complications of untreated, late, or incompletely treated CNS TB include progressive hydrocephalus (Figure 59A.7), which may require shunting; blindness caused by damage to the optic nerves and chiasm in the suprasellar cistern; the syndrome of inappropriate secretion of antidiuretic hormone; tuberculoma-associated edema; vasculitis; stroke; arachnoiditis; spinal cord atrophy; and syringomyelia. Arachnoid adhesions may lead to abnormal CSF circulation or ventricular trapping (Figure 59A.8); CSF flow studies before shunt placement may be beneficial.

Although definitive clinical trial data are lacking, corticosteroid therapy has been generally accepted for specific indications: (1) increased ICP; (2) complicated meningitis with hydrocephalus, vasculitis, or arachnoiditis; (3) very high CSF protein with impending spinal block; (4) tuberculoma with surrounding edema; (5) destructive ocular lesions; (6) replacement therapy for adrenal insufficiency; and (7) severely debilitated patients with drug-sensitive strains. Dooley et al. (1997) analyzed data from seven studies conducted from 1955-1991 and concluded that adjuvant corticosteroids improve neurological outcome in patients with tuberculous meningitis of moderate severity (drowsiness, cranial nerve palsies, or hemiparesis, but not coma). Specifically, a regimen of dexamethasone at 8-12 mg per day (or prednisone equivalent) tapered over 6-8 weeks, hastened resolution of CSF abnormalities, reduced the appearance of new neurological complications, and improved long-term neurological and general function of patients with intermediate meningeal

FIGURE 59A.7 Tubercular meningitis. Axial FLAIR-MR] showing marked hy peri n tensity of the basal eisterns and prominent temporal horns in a patient with mild communicating hydrocephalus. (Courtesy Dr. 6. Bowen.)

disease. Other treatment modalities including intrathecal streptomycin for meningitis and intrathecal hyaluronidase for spinal arachnoiditis have also been used.

Prevention. Vaccination is by intracutaneous injection of bacille Oalmettc-Guerin (BCG) vaccine. Enormous variation in protection, from 6-77%, has been reported, but BCG is thought to help in preventing meningitis in children in developed countries. As a live vaccine derived from *M. bovis,* BCG is contraindicated in immunocompromised patients and should not be administered with other live vaccines.

Leprosy (Hansen's Disease)

Leprosy, caused by the acid-fast bacterium M. *leprae,* is an infection of superficial tissues, primarily peripheral nerves and skin. Leprosy has been the most common cause of crippling hand disease in the world and is a frequent cause of blindness. There were an estimated 10-12 million cases worldwide in the early 1980s. By 1994, following the widespread use of multidrug therapy, numbers were reduced to 2.4 million. Leprosy cases are distributed nonhomogencously across South and Southeast Asia,

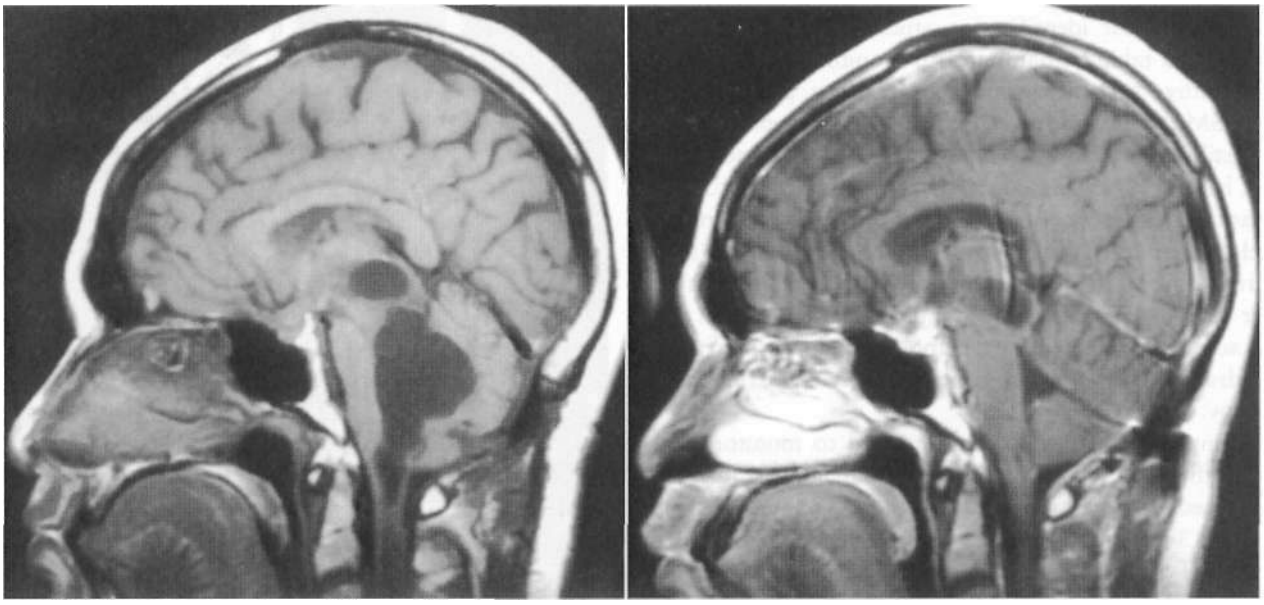

FIGURE 59A.8 Tuberculosis meningitis with arachnoid adhesions and trapped fourth ventricle. Preoperative (A) and postoperative (B) Tl-weighted sagittal magnetic resonance images showing dilatation of the fourth ventricle, posterior third ventricle, and a syrinx, resolving (B) after placement of right lateral and fourth ventricular shunts.

Africa, and Central and South America, with India, Indonesia, Myanmar, Nigeria, and Brazil collectively contributing nearly all registered cases. BCG vaccination, background prevalence of *M. tuberculosis,* and the atypical environmental mycobacteria influence leprosy epidemiology. In East Africa, for example, a reciprocal relationship between numbers of cases of TB and leprosy exists. Insufficient data exist to support the comorbidity of HIV and leprosy.

Leprosy is spread by the respiratory route or skin-to-skin contact, although transmission by insects has not been completely excluded. Most exposed individuals are naturally immune. Susceptible individuals develop one of three forms: lepromatous, borderline, or tuberculoid. All patients with leprosy manifest some degree of nerve involvement that varies with the immune response to the infection. Lepromatous leprosy is more common in Africa and Mexico, and tuberculoid leprosy is more frequent in India.

Clinical Features

The unique clinical features of leprosy result from the peripheral nerve tropism of *M. leprae* and its preference for temperatures 7" to 10°C lower than core body temperature. The long incubation period varies from *6* months to 40 years and is a consequence of its very slow growth, doubling only once every 11-13 days. Early signs include hypopigmented anesthetic skin patches, areas of cutaneous sensory loss without skin patches, and multifocal or diffuse skin infiltration. Sensory impairment proceeds in a predictable sequence, with loss of temperature sensation first, followed by pain, and then touch, with sparing of proprioception and vibration. Sweating is diminished also.

Patients with impaired cell-mediated immunity develop lepromatous leprosy. Bacilli distribute widely through skin and nerves, producing a symmetrical dermal and neural syndrome. Mulriple small macules, infiltrations, papules, and nodules appear, affecting cooler areas of the body first. Peripheral nerves thicken in the superficial, and thus cooler, portions of their course, but the strict correlation between skin lesions and anesthetic areas, characteristic of early and tuberculoid forms, does not apply in lepromatous cases. As disease progresses, sensory disturbances worsen, with sparing of sensation in the palms, soles, midchest, and midback until late in the course and after motor involvement begins. Visual impairment and blindness may result from exposure keratitis caused by lagophthalmos or corneal anesthesia, iritis, or cataracts, caused by intraocular bacteria. Destructive lesions of the respiratory tract above the larynx, testes, and structures of hands and feet develop, and diffuse systemic disease may cause lymphedema, hepatosplenomegaly, nephritis, and renal amyloidosis. Lucio reactions, sloughing ulcerations on the lower extremities or throughout the body, a consequence of arteriolar vasculitis and infarction, has been described in untreated Central or South American lepromatous patients.

Patients with good resistance develop tuberculoid leprosy, with multifocal, often asymmetrical, lesions of nerve and sometimes skin. Compared with lepromatous leprosy, infection is less disseminated, and anesthesia is confined to a few well-defined widely scattered hypopigmented or erythematous areas with palpable outer edges, hair loss, and anhidrosis. Thickening of the nerve supplying

sensation to the affected area may be found nearby. Nerve damage results from bacterial multiplication within Schwann cells or granulomatous damage to the perineurium. When more proximai nerve trunks are involved; a clinical syndrome resembling mononeuritis multiplex results. In tuberculoid leprosy, the ulnar nerve is involved most frequently, and nerves are more vulnerable than usual to trauma and pressure palsies. Radial motor involvement occurs late, owing to its deep course in the arm and forearm, whereas its distal superficial sensory portion may become thickened and palpable earlier. Painful granulomas or abscesses in the course of affected nerves may occur and require urgent medical and surgical attention. Loss of protective sensation in the hands and feet leads to traumatic, nonhealing injuries of the fingers and toes (acrodystrophic neuropathy). Sympathetic nerve injury also contributes to trophic and osteoporotic changes in the small bones of the hands and feet.

Borderline (dimorphous) leprosy, an intermediate form with features of both tuberculoid (localized) and lepromatous (widespread) disease, includes the polyneuritic form of leprosy.

Diagnosis

The diagnosis of leprosy should be considered in patients with transient, recurrent, or persistent numbness or paresthesias or when a chronic, asymptomatic, atypical skin rash does not respond to standard treatments. Palpable nerves commonly identified include greater auricular nerve in the neck, ulnar at the elbow, median at the wrist, terminal branch of the radial near the wrist, peroneal at the head of the fibula or in front of the ankle, posterior tibial below the inner malleolus, and sural on the lateral foot. Peripheral nerve electrophysiological studies demonstrate focal or multifocal neuropathy in tuberculoid cases or a more diffuse sensory neuropathy in lepromatous cases. Radial nerve sensory conduction study is one of the more sensitive indicators of disease. Absence of response to sweat tests or to intradermal pilocarpine or histamine confirms dermal sympathetic nerve involvement.

Demonstrating M. *leprae* in skin, nasal mucous membrane, or nerve biopsy establishes the diagnosis. In the slit-scrape method, smears of scrapings from skin lesions are stained for AFB. Skin biopsy facilitates correct classification and may be repeated to assess treatment response. Nerve biopsy is performed in purely neural cases or when a skin biopsy has not been diagnostic. The lepromin test can be used to classify the type of leprosy and to assess resistance to disease. Lepromin reagent, a suspension of killed *M. leprae* and cellular material from host tissue, is injected intra dermally in a dose of 0.1 mL. The early Fernandez reaction, read at 48 hours, is an allergic reaction similar to the tuberculin reaction. The degree of erythema and induration is assessed. The Fernandez reaction is positive in all forms of leprosy. The Mitsuda reaction, read at 4-5 weeks, is an indicator of resistance. It is positive in tuberculoid patients, weakly positive or negative in borderline patients, and negative in lepromatous patients. Because healthy individuals with no exposure to leprosy may have positive Mitsuda reactions, the test is not used for diagnosis.

The differential diagnosis includes other causes of hypertrophic neuropathy (Charcot-Marie-Tooth disease Type I, Refsum's disease, Dejerine-Sottas disease, primary amyloidosis, sarcoidosis, neurofibromatosis, chronic inflammatory demyelinating polyneuropathy), conditions causing distal anesthesia with ulcers and loss of digits (syringomyelia, tabes, diabetic pseudotabes, yaws, congenital in sensitivity to pain), and other causes of peripheral and multifocal neuropathies.

Treatment

Therapy should consist of two or more drugs and should begin as soon as the diagnosis is made and classification as multibacillary or paucibacillary is determined, Multibacillary leprosy is treated with RIF, 600 mg once a month; dapsone (a folate antagonist), 100 mg daily; and clofazimine, 50 mg daily plus 300 mg once a month for a minimum of 2 years, or until skin-smear results are negative, which typically takes approximately 5 years. Dapsone neuropathy, a symmetrical distal sensory neuropathy, may arise during long-term treatment, and clofazimine has been associated with retinopathy. Paucibacillary leprosy is treated with RIF, 600 mg once a month, and dapsone, 100 mg daily for 6 months. Additional drugs include the thioamides, fluoroquinolones, minocycline, and clarithromycin. Hemolytic reaction to dapsone is a concern in patients with glucose-6-phosphate dehydrogenase deficiency,

Reactions and Complications

Reversal, or type I reaction, develops after the initial therapy for borderline leprosy releases *M. leprae* antigen, Augmented cell-mediated immunity upgrades the disease toward the tuberculoid end of the clinical spectrum, and patients develop fever, inflammation within existing skin lesions, and neuritis. Urgent therapy prevents permanent nerve damage and consists of prednisone, 40-60 mg daily, tapered over 2-3 months. Antileprosy treatment is continued. Declining cell-mediated immunity in a patient with borderline leprosy leads to lepromatous disease, known as the downgrading response.

Erythema nodosum leprosum, or type 2 reaction, may be precipitated by treatment of lepromatous disease, intercurrent infection, or stress. Ninety percent of lepromatous leprosy patients experience erythema nodosum leprosum reactions after starting therapy. Antigen release from dying mycobacteria in the face of high circulating antibodies to *M. leprae* antigens provokes an Arthus-type reaction. Clinical manifestations include painful papules, neuritis,

fever, uveitis, and lymphadenitis. Mild reactions may be treated with chloroquine or salicylates, and more severe reactions with a short course of corticosteroids. Recurrent erythema nodosum Icprosum reactions arc treated with thalidomide, which inhibits TNF-a secretion, starting with 200^-00 mg as a single oral bedtime dose and followed by 50-100 mg daily after 1-2 weeks. Thalidomide must not be used in women of child bearing age because of the risk of producing phocomelia in the fetus. Long-term thalidomide therapy may produce a toxic neuropathy. Eye reactions, such as acute iridocyclitis, should be treated with topical atropine and corticosteroids.

Hands and feet require careful, regular inspection for swelling, ulceration, and functional or sensory loss during treatment. Protective footwear and wound care are provided as needed. Nerve abscesses may occur in tuberculoid or neural leprosy patients and require surgical decompression and drainage. Because relapses have been reported more than 8 years after triple-drug therapy, patients require long-term follow-up.

Prevention

Chemoprophylaxis of household contacts is not routine, although exceptions have been made for children in contact with a lepromatous patient, who then receive monthly R1F for 6 months. BCG or vaccines derived from killed or chemically modified *M. leprae* and research strains have been used. BCG's protective effect varied from 80% in Uganda to 20-30% in Myanmar and India.

Spirochetes

Spirochetes belonging to the genera *Treponema, Borrelia,* and *Leptospira* are important human pathogens. Except for the endemic treponemal diseases (yaws, pinta, bejel), all produce multiphasic or relapsing diseases with multifocal neurological involvement. Diagnosis and management of these infections, which are increasing in frequency throughout the world, are hampered by suboptimal diagnostic methods, incomplete treatment, and potential relapses, despite therapy.

Syphilis

Syphilis, a chronic multisystem disease caused by the spirochete *T. pallidum,* is spread venereally or vertically (i.e., mother to child). Venereally acquired disease is characterized by episodes of active disease separated by periods of latency, with neurological involvement in secondary and later stages. An estimated 4-9% of patients with untreated syphilis develop symptomatic neurosyphilis, with meningovascular syphilis in 2-3%, general paresis in 2-5%, and tabes dorsalis in 1-5%.

Clinical Features

Primary syphilis is characterized by one or more primary skin lesions, called chancres, which develop at the site of inoculation from 3-90 days {average, 20) after exposure. Spirochetes can be demonstrated in the lesions by darkfield microscopy. Neurological disease is not a feature of primary syphilis, although asymptomatic spread to the CNS has been documented in 30% of cases of early syphilis.

Secondary syphilis occurs 2-12 weeks after contact. Disseminated infection manifests clinically by constitutional symptoms such as fever, malaise, generalized lymphadenopathy, rash, and neurologically as syphilitic meningitis or cranial neuropathies, including hearing loss and ocular changes. Approximately 30% of secondary syphilis patients develop CSF changes indicating meningeal infection, but only 1-2% of patients are symptomatic. CSF shows lymphocytic pleocytosis, elevated protein, and low-to-normal glucose. Spirochetes can be detected by darkfield microscopic examination of secondary skin lesions and, occasionally, in CSF and the anterior chamber of the eye. After the second stage resolves, the patient enters a latent, asymptomatic period, with disease apparent only by serology. CSF at this stage is usually normal; abnormalities indicate asymptomatic neurosyphilis (Table 59A.4).

Up to one third of untreated patients develop late syphilis (tertiary syphilis), a slowly progressive inflammatory disease that includes gummatous (granulomatous), cardiovascular,

Table 59A.4: Algorithm for diagnosis and treatment for neurosyphilis

Lumbar puncture and CSF analysis if patient has any of the following
Clinical neurological involvement with syphilis
Concomitant HIV infection with syphilis of unknown duration
Active cxtraneural tertiary syphilis (aortitis, iritis, gumma etc.)
Treatment failure
Diagnostic CSF criteria for CNS syphilis
CSF pleocytosis (>5 cells/mm)
Reactive CSF VDRL test (CSF without blood contamination)
Positive CSF FTA-ABS test (highly sensitive but less specific)
No single test will diagnose all cases of neurosyphilis
Treatment recommendations
Penicillin G 18-24 million U/d (3-4 million U q 4hr IV for 10 to 14 days), or
Procaine Penicillin 2.4 million U/d 1M plus probenecid 500 g PO qjd for 10-14 days, or
Ceftriaxone *2 vjA* IM or IV for L0-.I4 d;n-s, plus hen/,athin;: penicillin 2.4 million U IM, one dose at 2 weeks
Follow-up monitoring
If CSF pleocytosis, repeat CSF every month until cell count is normal
If CSF cell count has not decreased after 6 months, or if CSF is not normal after 2 years, consider retrcatment

Source: Adapted from Rompalo, A. N. 2002, "Neurosyphilis," in *Current Therapy in Neurologic Disease,* 6th ed., eds R. T. Johnson, J. W. Griffin, & J. C. McArther, Mosby, Philadelphia.

and neurological forms. Early neurological manifestations of tertiary neurosyphilis include pure meningeal or meningovascular disease, with a 5- to 10-year latency from primary infection, and parenchymal forms, which occur 10-30 years after initial infection. General paresis refers ro parenchymal cerebral involvement and tabes dorsalis to syphilitic myeloneuropathy. Syphilitic gummas, granulomas that presenr as space-occupying lesions in brain or cord, may occur at any stage of disseminated disease.

Neurosyphilis spans all stages of disseminated disease. Meningeal, meningovascular, and parenchymal syndromes are perhaps best viewed as a continuum of disease, rather than as discrete disorders. Syphilitic meningitis, meningovascular syphilis, general paresis, and tabes are different clinical expressions of rhe same fundamental pathological events, specifically meningeal invasion, obliterative endarteritis, and parenchymal invasion. Especially in the antibiotic era, symptomatic neurosyphilis may present, not as one classic syndrome, but as mixed, subtle, or incomplete disease (Cintron and Pachner 1994). All of the neurological complications of syphilis have been reported in HIV disease, which may accelerate the onset and progression of neurosyphilis.

Syphilitic meningitis typically occurs earlier than other forms of neurosyphilis and is often asymptomatic. Rare complications of acute syphilitic meningitis include hydrocephalus, myelitis, or lumbosacral radiculitis. Meningovascular syphilis usually occurs 4-7 years after primary infection (range, 6 months to 12 years). In addition to stroke, involvement of large and small cerebral vessels also causes headache, vertigo, insomnia, and psychiatric or personality disorders.

General paresis, the encephalitic form of neurosyphilis, typically presents as progressive dementia beginning 15-20 years after original infection (tange, 3-30 years). The clinical picture also may include delusional or apathetic states, dysatthria, myoclonus, intention tremor, seizures, hyper-reflcxia, and Argyll Robertson pupils {small, irregular pupils that constrict with accommodation but not light). Disease manifestations may be remembered using the mnemonic *paresis:* personality, effect, reflexes, eye, sensorium, intellect, and speech.

Tabes dorsalis, the spinal form of syphilis, develops approximately 15-20 years after the original infection (range, 5-50 years). Tabes is characterized by lightning pains, autonomic dysfunction (urinary incontinence), and sensory ataxia. Affected patients have normal strength and lack reflexes in the legs; a positive Romberg's sign accompanies impaired proprioception. Pupils are abnormal in more than 90% of cases, with Argyll Robertson pupils observed in approximately one half. Other associated features include optic atrophy, ophthalmoplegia, ptosis, gastric or other visceral crises (pharyngeal, laryngeal, genitourinary, intestinal, rectal), impotence, fecal incontinence, and pain and temperature loss leading to trophic changes such as Gharcot's (neuropathic) joints and perforating foot ulcers.

Syphilitic inflammatory diseases of rhe eye include uveitis, chorioretinitis, and vasculitis. Each may accompany acute syphilitic meningitis or present as an isolated complication of secondary syphilis. Optic attophy evolves over months to years and may coexist with other forms of neurosyphilis, particularly tabes. Optic nerve degeneration usually begins peripherally and extends to the center of the nerve, producing progressive constriction of the visual fields with ptesetved acuity. Syphilitic otitis, an unusual manifestation, presents as unexplained hearing loss or vestibular abnormalities, with positive treponemal serology.

At birth, congenitally infected infants may show signs of serous nasal discharge (snuffles), rash, condylomas, hepatosplenomegaly, or osteochondritis. If left untreated, the classic stigmata of Hutchinson's teeth, saddle nose, interstitial keratitis, saber shins, mental retardation, hearing loss, and hydrocephalus develop.

Diagnosis

Syphilis can be diagnosed by demonstration of spirochetes in lesions of primary, secondary, or early congenital syphilis. More commonly, however, treponemal and nontreponemal serologic tests are used to make the diagnosis. Treponemal tests include fluorescent treponemal antibody absorption, microhemagglutination assay, fluorescent treponemal antibody-absorption double staining, hemagglutination treponemal test for syphilis, and T, *pallidum* immobilization. Treponemal test results become positive 3–4 weeks after inoculation and usually remain positive for life. Nontreponemal or reagin tests detect antibodies to membrane lipids of T, *pallidum,* using antigens such as cardiolipin, lecithin, or cholesterol, and include the Venereal Disease Research Laboratory (VDRL) test and rapid plasma reagin test. More sensitive but less specific than treponemal serologies, nontreponemal test results become positive 5-6 weeks after exposure and usually become negative in the year following adequate treatment.

Patients with classic neurosyphilis syndromes require serum serologies and CSF examination. Because syphilitic eye disease often is associated with neurosyphilis, patients with syphilis and oculat manifestations should also undergo LP. The Centers for Disease Control and Prevention (CDC) recommends CSF examination for all patients with syphilis who have neurological or ophthalmic symptoms and signs or active tertiary disease (aortitis, gumma, iritis) or have failed therapy (see Table 59A.4). In addition, the CDC advises that HIV-infected patients with late latent syphilis or latent syphilis of unknown duration undergo LP prior to treatment (Centers for Disease Control 1998; Pao et al. 2002).

The diagnosis of neurosyphilis depends on clinical evidence, CSF findings, and serology. CSF mononuclear pleocytosis (>5 cells per pi) and elevated protein support the

diagnosis of neurosyphilis. CSF-VDRL is very specific; it is more sensitive in meningovascular syphilis and general paresis than in asymptomatic neurosyphilis and tabes. False-positive CSF-VDRL may occur if blood contaminates CSF, as occurs with traumatic LP. Intrathecal *T. pallidum* antibody production, oligoclonal antibodies, IgM antibodies, or PCR-amplificd products may increase sensitivity of CSF examination (Cinque et al. 1997), Serum VDRL may be negative in up to 25% of patients with late neurosyphilis, but specific treponemal tests remain reactive. The CSF of patients with tabes may show less-pronounced inflammatory changes than other forms of neurosyphilis.

False-positive treponemal tests occur in Lyme borreliosis, nonvencreal treponematoses, genital herpes simplex, pregnancy, lupus, alcoholic cirrhosis, scleroderma, and mixed connective tissue disease. Transient false-positive reactions to nontreponemal tests can result from mycoplasma or enterovirus infection, mononucleosis, pregnancy, parenteral drug use, advanced TB, scarlet fever, subacute bacterial endocarditis, viral pneumonia, brucellosis, rat-bite fever, relapsing fever, leptospirosis, measles, mumps, lymphogranuloma venereum, malaria, trypanosomiasis, and varicella. Chronic false-positive reactions may be caused by malaria, leprosy, lupus, other connective tissue disorders, parenteral drug use, Hashimoto's thyroiditis, rheumatoid arthritis, reticuloendothelial malignancy, and advanced age.

The differential diagnosis of neurosyphilis includes other inflammatory meningovascular or CNS granulomatous diseases, such as TB or cryptococcal meningitis, brucellosis, Lyme disease, CNS sarcoid, and cerebral vasculitides.

Treatment

Diagnosis and treatment of neurosyphilis is summarized in Table 59A.4. Optimal treatment of neurosyphilis is aqueous penicillin G at doses of 18-24 million units per day intravenously {3-4 million units every 4 hours) for 10-14 days. The alternative, procaine benzyl penicillin, 2.4 million units intramuscularly daily, with probenecid, 500 mg orally four times daily, both for 10-14 days, has been associated with treatment failures. In penicillin-allergic patients, alternatives include oral doxycycline, 200 mg twice daily for 4 weeks, or skin testing to confirm allergy and consideration of desensitization. A patient with a positive serum treponemal antibody test result and neurological disease compatible with neurosyphilis should be treated with penicillin in doses adequate for neurosyphilis, even in the absence of CSF confirmation. Because of sequestration of spirochetes in the inner ear and poor antibiotic penetration to that area, syphilitic otitis may require a longer duration of thetapy, from *6* weeks to 3 months.

Patients with documented neurosyphilis should be followed after therapy. Clinical symptoms or signs of syphilis should prompt consideration of retreatment, as should fourfold increase of serum titers or failure of CSF titers greater than 1 to 32 to decrease at least fourfold by 12-24 months. If pleocytosis was present, LP should be performed every 6 months until cell count normalizes. Patients in whom CSF cell count does not decrease after 6 months, or in whom CSF does not return to normal after 2 years, may require retreatment.

Complications of and Response to Treatment

Jatisch-Herxheimer reactions most frequently complicate treatment in patients with early syphilis. Clinical features of this systemic response to release of heat-stable pyrogens from spirochetes include rigors, fever, hypotension, and leukopenia. The response to treatment varies according to the chronicity of the neurological damage. In meningovascular syphilis, signs that remain 6 months after treatment usually persist indefinitely. Treatment of general paresis may improve the cognitive or psychiatric disease in relatively early cases or arrest disease progression in approximately one half of advanced cases. Residual symptoms of tabes continue after the CSF has normalized and require symptomatic treatment of joint deformities with orthotics, visceral crises with atropine, and pain with anticonvulsants or amitriptyline. Pretreatment optic atrophy and extensive perioptic meningeal infiltrate may presage progressive vision loss during treatment. Adequate-treatment of a mother with syphilis before the sixteenth week of gestation prevents congenital syphilis.

Lyme Disease (Borreliosis)

Lyme disease, a systemic disease with dermatological, rheumatological, neurological, and cardiac manifestations, is caused by *Borrelia burgdorferi* and transmitted by the hard-shelled deer ticks: *Ixodes dammini* in the eastern United States, *Ixodes pacificus* in the western United States, and *Ixodes ricinus* in Europe.

Clinical Features

The existence of both early and late neurological manifestations, diagnostic uncertainty, and potential for relapse despite therapy have fueled continuing debate over the spectrum of Lyme-related neurological disease. Best agreement exists for the early neurological syndromes, which include lymphocytic meningitis, cranial neuropathy (commonly unilateral or bilateral Bell's palsy), and painful radiculoneuritis, which can occur alone or in combination. Optic neuritis, mononeuritis multiplex, and Guillain-Barre syndrome are other infrequent manifestations of early neurological involvement. Neurological complications of more advanced Lyme disease include encephalomyelitis, with predominant white matter involvement and peripheral neuropathy. Lymphocytic meningitis is usually acute, but may cause chronic or relapsing meningitis and communicating hydrocephalus. Radiculoneuritis, beginning as

a painful limb disorder, may continue with exacerbations and remissions for up to 6 months. Encephalopathy with memory or cognitive abnormalities, confusional states, accelerated dementia, and normal CSF study results may occur. Other psychiatric or fatigue syndromes appear less likely to be causally related to Lyme disease (Steere 2001).

The most common form of neuroborreliosis in Europe, radiculoneuritis {lymphocytic mcningoradiculitis, Bannwarth's syndrome), is rare in the United States. The meningitic forms of borreliosis may resemble CNS lymphoma, because the CSF may contain atypical lymphocytes. The differential diagnosis of *Borrelia* encephalomyelitis includes a first episode of multiple sclerosis. Bites from uninfected ticks may produce similar neuropathies (Garcia-Monco and Benach 1995).

Several systemic disorders support the diagnosis of Lyme borreliosis. Dermatotogical manifestations include erythema chronicum migrans, a painless expanding macular lesion present shortly after initial infection in approximately two thirds of patients, and acrodermatitis chronicum atrophicans, a bluish-red discoloration of the legs that occurs after the first year of infection. Other extraneural features include Borrelia lymphocytoma, occurring 6-12 months after infection, recurrent monoarthritis or polyarthritis, and second- or third-degree cardiac conduction block.

Diagnosis

The best clinical marker for the disease is the erythema chronicum migrans rash that occurs in 60-80% of patients. The diagnosis of active neuroborreliosis is made by the presence of consistent history, signs, and symptoms, together with CSF pleocytosis, serum anti-B. *burgdorferi* antibodies, and evidence of intrathecal antibody production. Serologic testing by ELISA is performed as an initial screen, followed by Western blot confirmation. Culture of organisms and PCR testing of CSF are also available.

Treatment

Borreliosis is treated with parenteral antibiotics if there is evidence that infection has crossed the blood-brain barrier. Ceftriaxone (2 g once daily intravenously) or penicillin (3-4 million units intravenously every *3-A* hours) for 2-4 weeks are first-line drugs. Tetracycline and chloramphenicol are alternatives in penicillin- or cephalosporin-allergic patients. Jarisch-Merxheimcr reactions may occur within 2 hours of initiating therapy. Mepta/inol, a drug with mixed opiate agonist and antagonist properties, may mitigate the attack. Routine use of corticosteroids is not indicated. Recommendations for the use of corticosteroids in neuroborreliosis generally have been limited to patients tteatcd aggressively with intravenous antibiotics with evidence of severe inflammation that fails to improve with time.

CSF examination should be performed toward the end of the 2- to 4-week treatment course to assess the need for continuing treatment and again 6 months after the conclusion of therapy. Intrathecal antibody production may persist for years following successful treatment and in isolation does not indicate active disease. Patients in whom CSF pleocytosis fails to resolve within *6* months, however, should be retreated.

Peripheral or cranial nerve involvement without CSF abnormalities may he treated with oral agents, either doxycycline, 100 mg twice daily for 14-21 days, or amoxicillin, 500 mg every 8 hours for 10-21 days.

Relapsing Fever

The term *relapsing fever* applies to two distinct borrelial diseases, louse-borne relapsing fever and tick-borne relapsing fever. Both are characterized by episodic fever and spirochetcmia, systemic symptoms, and variable presence of neurological complications. The human body louse transmits .0, *recurrentis* and soft ticks of the genus *Ornithodoros* transmit other *Borrelia* spp., including *B. duttoni.*

Clinical features

Overcrowding and poor hygiene predispose to louse-borne relapsing fever. Clinical featutes may he mild, but sevete febrile illness with mortality reaching 40% in epidemic situations also is seen. Hepatosplenomegaly, jaundice, respiratory symptoms (cough and dyspnea), and myocarditis ate more common than in the tick-borne syndrome, and neurological manifestations, including meningitis, meningoencephalitis, cerebral hemorrhage, or neuropathy, develop in approximately 30% of patients.

Neurological syndromes associated with tick-borne relapsing fever appear at the end of the first bout of fever or with relapses. Cranial neuritis is the most common neurological manifestation of tick-borne disease, with facial weakness affecting up to 22% of patients. Lymphocytic meningitis, subarachnoid hemorrhage, encephalitis, transient or permanent focal deficits, iritis, iridocyclitis, optic atrophy, and sciatic neuralgias also have been described.

Diagnosis

Demonstrating borreliae in the peripheral blood of febrile patients using darkfield microscopy and Wright's or Gicmsa's stained blood smears establish the diagnosis. Proteus OX-K agglutinin titers are elevated in relapsing fever. Nervous system disease is accompanied by CSF lymphocytic pleocytosis and elevated protein. Spirochetes may be detected in CSF by smear or animal inoculation in approximately 12% of patients with CNS signs. In the westetn United States, the diffetential diagnosis of tick-borne relapsing fever includes Colorado tick fever and Rocky Mountain spotted fever.

Treatment

Louse-borne relapsing fever is treated with a single oral dose (500 mg) of tetracycline; erythromycin in the same dose is also effective. Tick-borne relapsing fever is treated with oral tetracycline or erythromycin, 500 mg every 6 hours for 5-10 days.

Leptospirosis

Many wild and domestic animals carry *Leptospira interrogans.* Leptospirosis is a worldwide zoonotic infection transmitted direct!;- to humans by contact with urine of infected rodents or domestic animals or indirectly via water or soil contaminated by infected urine. The severity of disease varies widely; jaundice, hemorrhage, and renal failure develop in severe cases. Approximately 15% of patients develop signs and symptoms of meningitis, and many more have lymphocytic CSF.

Clinical Features

The illness often follows a biphasie course. The first bacteremic phase is characterized by fever, headache, myalgias, nausea, vomiting, and abdominal pain. Dissemination of the organism in the acute phase leads to meningeal invasion, during which leptospirae may be cultured from blood and CSF but not urine. A second immune phase develops in the second week, once the patient has mounted an antibody response to the organism. This stage is characterized by more severe systemic illness, with meningitis, uveitis, rash, and in severe cases, hepatorenal and hemorrhagic syndromes. Eighty percent to 90% of patients have CSF abnormalities consistent with aseptic meningitis. CSF examination reveals lymphocytic pleoeytosis, elevated protein, and normal glucose levels, but the leptospirae have been cleared from the CSF by tins stage. CSF pressure is usually normal, yet LP may improve the headache. More-severe forms of illness are accompanied by conjunctival suffusion, myositis with rhabdomyolysis, meningoencephalitis, or myelitis. In Weil's disease, the most severe form, hepatorenal dysfunction and myocarditis accompany depressed consciousness and, occasionally, intracerebral hemorrhage. Cerebral arteritis is an unusual late complication, and a form of moyamoya disease has been thought to occur as a result of obstruction of the internal carotid arteries near the circle of Willis. Mononeuritis multiplex and Guillain-Barre syndrome have been reported. Invasion of the eyes by leptospirae during the acute phase may produce uveitis weeks or months after recovery.

Diagnosis

Jaundice, renal failure, and elevated serum creatine kinase (CK) following a febrile illness suggest the diagnosis. Organisms can be isolated from blood or CSF during the first 10 days of illness and from urine during the first month of illness. Serological test results, based on macroscopic or microscopic agglutination procedures, arc positive after the first week.

Treatment

Severe leptospirosis is treated with penicillin G, 1.5 million units intravenously every 6 hours for at least 7 days. 1 ess-severe cases are treated with doxycycline, 100 mg twice daily for 5-7 days.

RICKETTSIAE AND RELATED ORGANISMS

Rickettsiae are obligate parasites that appear microscopically as coccobacilli. The major ones are maintained in nature by a cycle involving an animal reservoir, an insect vector (lice, fleas, mites, and ticks), and humans. Q fever is an exception and is probably contracted by inhalation. In the early twentieth century, the rickettsial diseases, epidemic typhus in particular, were common and of grave health concerns. In Eastern Europe, between 1915 and 1922, there were an estimated 30 million cases of typhus, with 3 million deaths. Now, as a result of insect control and antibiotic therapy, the rickettsial diseases are uncommon. In the United States these diseases are quite rare, bur they are important because up to one third of patients have neurological manifestations, mainly headache and meningoencephalitis. Rocky Mountain spotted fever is the commonest form in the United States, with about 200 cases each year. All rickettsial diseases share the clinical triad of high fever, skin rash, and headache, with meningoencephalitis developing during the second week of illness in some cases. Rickettsiae infect small blood vessels throughout the body causing endothelial wall inflammation and proliferation, thrombosis, and perivascular inflammation. The vasculitis is most prominent in skin, heart, skeletal muscle, kidney, and CNS.

Lpidemic (Louse-Borne) Typhus

K. prowazekii is transmitted by the human body louse from person to person, causing epidemic louse-borne typhus. A nonhuman reservoir, the southern flying squirrel in the eastern and south-central United States, has been recognized as an alternative source of infection, but the vector insect is not known.

Clinical Features

The illness begins within 12 days of a louse bite with abrupt fever, headache, limb pain, nausea, vomiting, facial swelling, and rash (Sexron and Kaye 2002), The rash

appears first in the axillae and upper trunk, spreading to become confluent and hemorrhagic, but sparing the face, palms, and soles. Vacant, placid expressions or agitation are described during the high, unremitting fever, whereas meningitis or meningoencephalitis with focal neurological deficits, delirium, or coma accompany severe disease and complicate up to 50% of cases. Tinnitus, hyperacusis, deafness, dysphagia, and midbrain stroke syndromes are recognized consequences of brainstem microinfarction. Transverse myelitis, hcraiparesis, painful peripheral neuropathy, akinetic mutism, and psychiatric disturbances have been reported in survivors. Systemic complications include vascular occlusions and gangrene, myocarditis, shock, and secondary infections.

Diagnosis

The combination of a cold weather environment, crowded conditions, and infrequent bathing and changing of clothes provides an ideal setting for louse-borne typhus. Clinical suspicion and serological demonstration of heterophilc antibodies to *Proteus mirabilis* OX-19 and OX-2 strains, the Weil-Felix reaction, assist in diagnosis. CSF may show modest elevations in protein and lymphocyte count, with normal glucose. Specialized laboratories can make a diagnosis by organism isolation, agglutination or EI .ISA serologic tests, or PCR amplification.

Treatment

Early and specific treatment is indicated to avoid a potentially fatal outcome. Effective therapies include oral or intravenous chloramphenicol, 500 mg every 6 hours intravenously for 7 days; oral or intravenous tetracycline, 500 mg every 6 hours intravenously for 7 days; or doxycycline in a single oral dose of 200 mg for adults. Relapses arc retreated with the same regimen. Formaldehyde-inactivated *R. prowazekii* vaccine is recommended for persons with potential occupational exposure.

Rocky Mountain Spotted Fever

Rocky Mountain spotted fever, a tick-borne infection caused by *R. rickettsii,* is the most virulent of the spotted fevers, with fatality of 20% when treatment is delayed. Rocky Mountain spotted fever is present in the northwestern and eastern United States, Canada, Mexico, Colombia, and Brazil. Seasonality is predicted by activity of local ixodid tick species, including *Dermacentor andersoni* (wood tick) and *Dermacentor variabilis* in the western United States, *Amblyomma americanum* (lone-star tick) in the southern United States, *Rhipicephalus sanguineus* in Mexico, and *Amblyomma cajennense* in Brax.il and Colombia. Other forms of tick typhus, some in geographically overlapping areas, include *Rickettsia japonica* in japan, *Rickettsia australis* in Australia, Mediterranean spotted fever *(Rickettsia conorii)* in Asia, Africa, and the Mediterranean, and Siberian tick typhus *(R. siberica).*

Clinical Features

The illness begins with fever, headache, myalgia, and gastrointestinal symptoms 2-14 days after the tick bite. The rash appears first around the wrist and ankles from days 3-5 of the illness and spreads to the soles of the feet and forearms. Petechial and ecehymotic rashes, indicating microcirculatory injury, may foreshadow gangrene of the digits or rhabdomyolysis. Other complications include renal failure and pulmonary edema. CNS manifestations accompany severe cases. Meningitis or meningoencephalitis with microinfarcts causes focal neurological deficits, transient deafness, depressed consciousness, or coma. CSF examination reveals elevated protein and lymphocytic or polymorphonuclear plcocytosis in approximately 30% of patients, with low glucose in fewer than 10%. Electroencephalography shows diffuse abnormalities, which may persist into convalescence. Flame-shaped hemorrhages, venous engorgement, or arterial occlusion on ophthalmoscopic examination, indicate retinal vasculitis.

Diagnosis

R. rickettsii can be demonstrated by direct immunofluorescence or immunoperoxidase staining of skin biopsy in patients with rash. Other laboratory tests may indicate anemia, thrombocytopenia, coagulopathy, hyponatremia, and muscle tissue breakdown. Serology retrospectively confirms the diagnosis.

Rocky Mountain spotted fever and the other rickettsial diseases should be distinguished from other causes of meningoencephalitis with rash, insect exposure, or recurrent fever by tests specific for the alternative diagnoses: from meningococccmia by blood and CSF culture, viral hemorrhagic fevers or hemorrhagic measles by serology, relapsing fever and tularemia by blood culture, typhoid fever by blood or bone marrow culture, leptospirosis by clinical or laboratory evidence of myositis and hepatitis, Lyme disease by serology, malaria by blood films, secondary syphilis by serology, toxic shock syndrome by blood wound or vaginal culture, and thrombocytopenic purpuras and immune-mediated vasculitis by serological markers of collagen-vascular disease,

Treatment

Treatment is with oral or intravenous tetracycline (25-50 mg per kg per day) or chloramphenicol (50-75 mg per kg per day) in four divided doses or oral doxycycline, 100 mg twice a day for 7 days and continued for 2 days once the patient has become afebrile.

Other Rickettsial Diseases

Murine typhus is caused by *R. typhi.* The organism is harbored by rats worldwide and transmitted to humans by flea bites. Early disease is characterized by fever, headache, myalgia, nausea, and truncal rash in 18% of patients. Neurological symptoms, including confusion, drowsiness, seizures, and ataxia, and focal deficits may occur. Diagnosis is based on clinical suspicion, and the Weil-Felix reaction is the same as for louse-borne typhus. Treatment is with chloramphenicol, tetracycline, or doxyeycline.

Scrub typhus is a febrile disease in East and Southeast Asia with headache, painful adenopathy, eschars, and trunk and thigh rash. *R. tsutsugamushi,* the causative agent, is transmitted by the bite of larval-stage trombiculid mites (chiggers). Meningoencephalitis or myocarditis accompanies severe cases. Specific serological or PCR tests arc used for diagnosis when available. Treatment is with a single oral dose of doxyeycline, 200 mg for adults and 100 mg for children.

Q fever, an acute or chronic febrile illness that occurs worldwide, is caused by *Coxiella burnetii.* Cattle, sheep, and goats are the animal reservoirs. C. *burnetii,* though in the rickettsial family, differs from the other rickettsial infections by the aerosol route of transmission, absence of rash, and lack of cross-reacting antibodies to *Proteus* OX species. Characteristic clinical syndromes include atypical pneumonias or hepatitis. Also seen are endocarditis, vertebral osteomyelitis, and neurological syndromes, including aseptic meningitis and encephalitis. Diagnosis depends on ELISA or indirect fluorescent antibody serologic tests. Rarely, C. *burnetii* has been isolated from the CSF. Early, uncomplicated Q fever is treated with chloramphenicol, tetracycline, or doxyeycline. Endocarditis requires therapy with RIF and TMP/SMX or tetracycline. A formalinized vaccine is available for individuals with potential occupational exposure.

Ehrlichiosis

Ehrlichioses are tick-borne zoonotic infections caused by an intra leukocytic bacterium closely related to *Rickettsiae.* First recognized as a canine pathogen, two species of *Ehrlichia* have been associated with human disease, including a summertime meningitis, in the United States, and a third species with a mononucleosis-like illness in Japan.

In the United States, incidence peaks from spring through autumn. Patients presenr with fever, headache, myalgia, rash, and history of tick bite. Occasionally, meningitis is the sole clinical manifestation. Renal failure, disseminated intravascular coagulation, cardiomegaly, opportunistic infection, seizures, encephalopathy, or coma are among the serious complications in some cases (Fishbein et al. 1994).

Most patients have varying degrees of leukopenia, thrombocytopenia or anemia, and mild to moderate hepatic enzyme abnormalities. Diagnosis depends on epidemiological and clinical features, plus a high index of suspicion. Acute and convalescent sera confirm the diagnosis. PCR-based tests are available for early confirmation of acute infection. Treatment is with oral or intravenous doxyeycline, 100 mg twice daily, for 7 days.

Bartonella

Oroya fever and verruga peruana are two forms of the same disease, bartonellosis, caused by *Bartonella hacilliformis.* These two clinical forms were linked to bartoncllosis by the fatal self-inoculation experiment of the Peruvian medical student, Daniel Carrion, who, with the help of a colleague, injected himself with material from verruga peruana cutaneous lesions and contracted Oroya fever. Bartonellosis also is referred to as Carrion's disease. Oroya fever is associated with encephalitis and cerebral venous thromboses, and verruga peruana with intracranial nodules. These diseases occur in river valleys along the western slopes of the Andes in Peru, Ecuador, and Colombia at altitudes of 2000-8000 feet. Sandfly bite transmits the disorder.

B. hacilliformis can be seen in red blood cells in the acute febrile stage and in smears from verruga. The differential diagnosis for Oroya fever includes malaria, typhus, and typhoid. The verruga stage resembles yaws or secondary-syphilis. Chloramphenicol (4 g daily in divided doses) for at least 7 days is the drug of first choice. Penicillin, tetracycline, streptomycin, and eotrimoxazole are alternatives.

ZOONOSIS PATHOGENS AND RELATED ORGANISMS

Brucellosis

Brucellosis, a zoonosis caused by several *Brucella* species *(B. melitensis, B. abortus,* and *B. suis),* is a multisystem illness characterized by fever, frequent bone and joint disease (arthritis, sacroiliitis, spondylitis, osteomyelitis), and respiratory, gastrointestinal, cardiac, or neurological disease. Normally a disease of domestic and wild animals, Brucellosis is transmitted to humans by ingestion of infected unpasteurized milk, by aerosol spread, or by contact with infected animals or animal products. The disease exists worldwide, but is especially prevalent in Mediterranean regions, the Middle East, the Indian subcontinent, and Latin America. In the United States, the disease is rare, with less than 100 cases being reported annually since 1990.

Early complaints may include fatigue, sensations of malodorous sweat or abnormal taste, and symptoms of deptession. Untreated, an undulant fever pattern emerges in 2- to 4-week cycles. Meningitis can be the presenting manifestation, or it may occur late in disease. Acute or chronic meningitis, encephalitis, meningovascular disease, multifocal white matter disease, intracerebral or epidural abscess, subdural empyema, intracranial hypertension,

ruptured mycotic aneurysms, hydrocephalus, papilledema, cranial neuropathies, psychosis, parkinsonism, radiculopathies (usually lumbosacral) or myelopathy, peripheral neuropathies, and myositis have been reported. Endocarditis occurs in approximately 2% of cases.

Brucellosis figures in the differential diagnosis of nearly any neurological disease in endemic areas. Definitive-diagnosis depends on isolation of brucellae from blood, bone marrow, or other tissues. Because the organism is difficult to culture, diagnosis usually depends on (1) positive *Brucella* agglutination or FLISA test results with high titers of antibody in blood and CSF; (2) abnormal CSF with a lymphocytic pleocytosis, elevated protein, and low to normal glucose; and (3) response to therapy.

Uncomplicated brucellosis is treated with oral doxycyclinc, 200 rng daily, with streptomycin, 1 g intramuscularly daily, for 12 weeks, or another amino glycoside for the first 4 weeks, then followed by RIF (10-15 mg/kg per day) for an additional 4-8 weeks. Neurobrucellosis, endocarditis, and skeletal and other severe organ involvement are treated with three-drug therapy with doxycycline, an aminoglycoside, and RIF for at least 12 weeks. Children under 8 years of age are treated with trimethoprim/sulfamethoxazole (TMP-SMX) in combination with an aminoglycoside and RIF. Adjunctive corticosteroid therapy has been used for concurrent vasculitic or demyelinatiug disease.

Anthrax

Anthrax, caused by the gram-positive sporulating bacillus, *Bacillus anthracis,* is usually a disease of herbivores, acquired from contact with soil-containing spores. Less commonl\. anthrax causes hemorrhagic meningitis in humans after exposure to infected animals or their products. The three main forms of disease are cutaneous, respiratory, and gastrointestinal (Swartz 2001). Meningitis is seen in less than 5% of cases. For a diagnosis of anthrax meningitis, there should be a primary site of infection, such as a malignant pustule or pulmonary syndrome, plus CSF and blood containing *B. anthracis.* Treatment is with penicillin G, 4 million units cvety 4-6 hours for 7-10 days.

Plague

Plague, caused by *Yersinia pestis,* is a zoonotic infection of wild rodents, transmitted by the bites of infected fleas to humans, an accidental host. Meningitis is an unusual manifestation of plague, usually complicating bubonic plague, particularly if buboes are located in the axilla. Human infection takes the clinical forms of febrile lymphadenitis (bubonic plague), septicemic, pneumonic, or meningeal plague. Most meningitis cases follow inadequately treated bubonic plague by 9-15 days, but primary plague meningitis also occurs. Y. *pestis* can be found on CSF Gram stain and culture. Treatment of the primary infection is with streptomycin, 30 mg/kg per day intramuscularly in two divided doses for 10 days. Meningitis is treated with intravenous chloramphenicol, 25 mg/kg initially, followed by 60 mg/kg per day in four divided doses for 10 days, either alone or in combination with streptomycin.

Tularemia

Tularemia (rabbit fever, deer fly fever, Ohara's disease, yatobyo) is an infectious disease of rodents caused by *Francisella tularensis.* Tularemia is transmitted to humans by insect bite, handling infected animals, ingesting infected meat or water, or inhaling contaminated aerosols or dust. *F. tularensis* causes an acute febrile illness; classic forms include ulceroglandular, oculoglandular, pneumonic, pharyngeal, abdominal, or typhoidal (septicemic) disease. Dissemination may lead to meningitis or encephalitis with mononuclear pleocytosis, elevated protein, and low glucose. Encephalitis and Guillain-Barre syndrome accompanying the pneumonic and pleuritic form have been reported also. Clinical suspicion and serological studies aid in the diagnosis; culture and isolation of *F. tularensis* are difficult. Streptomycin, 1 g intramuscularly daily for 10-14 days, treats the infection. Gentamicin is an alternative.

Pasteurellosis

Pasteurellae, primarily animal pathogens carried in the nasopharynx or gastrointestinal tract of many domestic and wild mammals and birds worldwide, are rare causes of meningitis or brain abscess in humans during disseminated infections. Human *Pasleurella* infections, usually *P. multocida,* are either focal soft tissue infection after an animal bite, respiratory infection, or bacteremia. Diagnosis is by demonstration or culture of the organism from wound, sputum, or CSF, and treatment is with penicillin.

Glanders

Glanders, primarily an equine infection by *Pseudomonas mallei,* occasionally produces human disease consisting of suppurative infections, lymphadenopathy, and pulmonary disease. Meningitis or brain abscesses occur in up to one fourth of patients. A history of contact with horses, mules, or donkeys is typical, and transmission occurs through contamination of broken skin or mucosal surfaces by draining ulcers of an infected animal. Diagnosis is by microscopic examination of exudates. A 3-week course of sulfadiazine, 100 mg/kg daily in divided doses, is recommended.

Melioidosis

Melioidosis, caused by the ubiquitous soil saprophyte *Fseudomonas pseudomallei,* is a glanderslike infectious disease of animals and humans, with meningitis or brain abscess sometimes complicating disseminated forms (Woods et al. 1932). A role for a neurological toxin in the development of aseptic meningitis or brainstem encephalitis, bulbar and respiratory weakness, and peripheral motor neuropathy of Guillain-Barrc type, in the absence of direct CNS infection, has been suggested but not proven.

The diagnosis should be considered in patients with a radiological pattern of TB from which AFB-staining bacteria cannot be found. Melioidosis is diagnosed by identifying organisms with bacteriological staining and culture techniques. Patients are seropositive by indirect fluorescent antibody or ELISA tests. Septicemic forms are treated with TMP/SMX plus ceftazidime, 120 mg/kg per day, with intravenous therapy for 2 weeks and oral treatment for 6 months.

Cat-Scratch Disease

Cat-scratch disease, a slowly progressive regional adenitis caused by *Bartonella henselae* or, less often, *Afipia felts* is associated with aseptic meningitis in immunocompetent individuals and encephalitis, myelitis, or radiculoneuritis in HIV-infected patients. Several clinical patterns have been recognized. Immunocompetent individuals may have one or several bacteremic episodes with fever, arthralgias, headache, and aseptic meningitis, but the illness is self-limited in the majority of cases. HIV-infected patients with disseminated *B. henselae* infection may have bacillary angiomatosis (neovascular proliferative skin lesions), which resemble the cutaneous stigmata of verruga peruana or Kaposi's sarcoma, oculoglandular syndrome with preauricular adenitis, palpebral or conjunctival granulomas, anemia, hepatosplcnomcgaly, or encephalomyelitis. Direct plating of homogenized tissue of accessible lesions has yielded bacteria, but cultivation of *Bartonella* spp. is technically difficult and slow. ELISA tests and PCR amplification from infected tissues are available. Intravenous gentamicin is recommended for encephalitis and oral doxycycline, erythromycin, or ciprofloxacin for bacillary angiomatosis.

Rat-Bite Fever

Rat-bite fever is a systemic febrile illness caused by *Streptobacillus moniliformis,* which is transmitted by the bite of a rat or other small rodents. Patients develop rash or purpuric skin lesions, asymmetrical polyarthralgias, or septic arthritis, with the additional complications of meningitis, brain abscesses, endocarditis, or myocarditis. Diagnosis is by visualization or culture of organisms from blood, joint fluid, or purulent material. Treatment is with penicillin, streptomycin, or a cephalosporin in penicillin-allergic patients.

STAPHYLOCOCCAL SYNDROMES

Toxic Shock Syndrome

Toxic shock syndrome (TSS), epidcmiologically linked to several toxigenic *Staphylococcus aureus* strains, is a multisystem disorder characterized by desquamating skin rash, especially on the palms and soles, high fever, hypovolemic shock, vomiting or diarrhea, renal failure, hypcrcmic mucosal surfaces, thrombocytopenia, liver enzyme abnormalities, myalgias, and encephalopathy. Several related exotoxins, chiefly TSS toxin 1 (TSST-1), produced by isolates of 5. *aureus* from patients, cause the disease. TSS has been reported in children, in menstruating women using hyperabsorbent tampons, and following gynecological and other surgical procedures. CNS complications may be more frequent in nonmenstrual TSS.

Confusion, disorientation, agitation, or somnolence independent of anoxic or metabolic changes arc described. Other features include headache, generalized electroencephalographic abnormalities, poor concentration, memory impairment, and other cognitive dysfunction. CSF is usually normal. Serum CK levels, elevated in over one half of patients, reflect the severity of toxic myositis and convalescent-stage weakness. Although blood, vaginal fluid, or wounds may be cultured for *S. aureus* and isolates tested for production of TSST-1, TSS remains a clinically defined syndrome. Other febrile exanthems with hypotension, such as Rocky Mountain spotted fever, leptospirosis, meningococcemia, gram-negative sepsis, viral exanthems, and drug reaction, should be excluded. Management requires aggressive fluid replacement and treatment with a *fi*-lactamase-resisrant antistaphylococcal antibiotic or clindamycin, 300 mg intravenously every 8 hours for 10-14 days.

Tropica! Pyomyositis

Tropical pyomyositis is a subacute syndrome caused by staphylococcal infection, characterized by the spontaneous appearance of bacterial abscesses within the fascial boundaries of large-bulk skeletal muscles. Tropical pyomyositis accounts for 3^1% of surgical admissions to hospitals in sub-Saharan Africa. Although early staphylococcal pyomyositis may respond to an antistaphylococcal penicillin or vancomycin alone, drainage of abscess cavities is usually necessary. In temperate regions, a different, hyperacute pyomyositis, caused by group-A beta-hemolytic streptococcal infection, is recognized. When it occurs, it is usually the earliest sign of critical, potentially fatal, disseminated infection, designated streptococcal TSS.

Therapy includes penicillin or ampieillin, a third-generation cephalosporin, surgical drainage, and supportive treatment with volume expansion.

FILAMENTOUS BACTERIAL INFECTIONS (ACTINOMYCETOSIS)

Nocardiosis

Nocardiosis is a locally invasive or disseminated infection caused by the aerobic actinomycetes *Nocardia asteroides, N. otitidiscaviarum,* and *N. brasiliensts.* The organisms are soil saprophytes, spread to humans by inhalation, through broken skin, from the gut, or after dental procedures. Primary infection, typically manifests as pneumonia with cavitary pulmonary lesions, but sinusitis, keratitis, cutaneous abscesses and fistulae, septic arthritis, or vertebral osteoarthritis are seen also. Disseminated disease commonly involves the CNS. The CNS syndromes, including cerebral abscesses, meningitis, and rarely, hemorrhagic meningitis develop in approximately one third of all pulmonary cases and primary CNS infection in another 5-7%. Cerebral abscesses ofrcn appear as complex multiloculated structures with satellite extensions on neuroimaging studies. Brain abscesses tend to burrow into a ventricle or our to the subarachnoid space, so meningitis is often associated with abscesses.

Nocardia spp. appear as weakly gram-positive, branching filaments in sputum, drainage from fistulas, or histological specimens. Dense bacterial concentrations resemble Chinese calligraphy. *Nocardia,* when stained with modified acid-fast procedures, are partially acid fast. Because nocardiosis is an infection with a variable, often chronic, course, treatment with sulfonamides (TMP/SMX) may need to extend for months. The recommended intravenous dose is TMP (15 mg/kg per day) and SMX {75 mg/kg per day), rhc equivalent of two double-strength tablets every 8 hours. Second-line drugs include minocycline, imipenem, or an aminoglycoside in combination with a thitd-generation cephalosporin.

Actinomycosis

Actinomycosis, characterized by abscesses that cross fascial planes to form sinuses, is a rare cause of brain abscesses. Actinomycosis is caused by a variety of gram-positive anaerobic or microaerophilic rods of the genera *Actinomyces* (most commonly *Actinomyces israelii* and A, *arachnid,* normal mouth and female genital tract flora). Most infections are either cervicofacial, thoracic, abdominal, or pelvic. Cervicofacial actinomycosis or "lumpy jaw" is the most common form and may develop following dental procedures or oral mucosa trauma, as a complication of dental caries or periodontal disease, ot without antecedent trauma or predisposing infection. Abscesses and draining sinuses form and exudates contain sulfur granules, so named because they are yellow. Actinomyces reach the brain by direct extension of oral-cervicofacial disease or hematogenous sptead. Brain abscess is the most common CNS presentation. Abscesses may be single or multiple and may appear multiioculated with ring enhancement (Figure 59A.9) or more homogeneous enhancement on neuroimaging studies. Chronic meningitis may develop as a consequence of spread from a parameningeal extracranial site or paraventricular or parameningeal brain abscess. Spinal epidural abscess, dural sinus rhrombosis, and spinal cord subdural empyema also have been reported.

Macroscopic and microscopic examination of pus and granules, followed by culture, establishes the diagnosis. Actinomycosis resembles nocardiosis, but the latter does not form granules in visceral organs. Actinomycosis occurs in immunocompetent patients, whereas nocardiosis is a disease of immunosuppressed patients. Treatment is with penicillin, initially 18-24 million units in divided doses intravenously per day for 2-6 weeks, followed by oral penicillin or amoxicillin for 6-12 months. Surgical drainage and excision may be indicated. Clindamycin penetrates

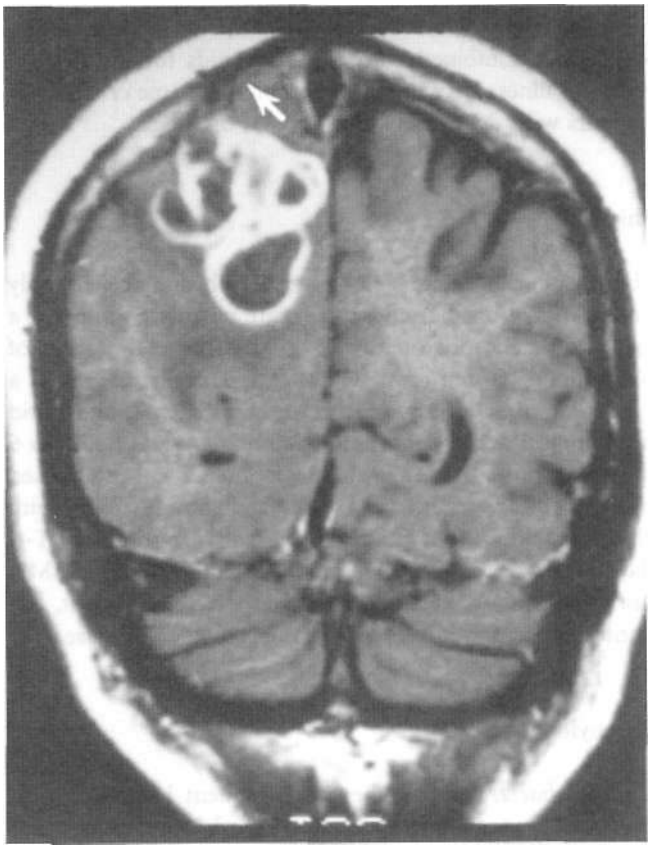

FIGURE 59A.9 Actinomycosis. Gadolinium-enhanced coronal Tl-weighted magnetic resonance image showing multiioculated, ring-enhancing lesion in a patient with intracerebral spread of actinomycosis abscesses from a skull infection. Skull involvement is indicated by resorption of normal fatty marrow signal *{arrow).*

bone well and may be the drug of choice if there is bony involvement.

ENTERIC BACTERIA

Salmonellosis

A common cause of neonatal meningitis, *Salmonella* species are associated also with brain abscess, subdural empyema, and recurrent bacteremia in HIV-infected parients, *Salmonella typhi* and *S. paratyphi* are recognized agenrs ot enteric fever, vascular (endothelial) infection leading to aortoduodenal fistulas and chronic carrier states. Disseminated intravascular coagulation complicates severe infections. Atypical manifestations include pneumonitis, pericarditis, sacroiliitis, arthritis, and osteomyelitis, the last being particularly common in patients with sickle cell hemoglobinopathies. Until recently, chloramphenicol was used to treat typhoid fever. However, because of outbreaks associated with resistant strains in Latin America, the Middle East, and South and Southeast Asia, ciprofloxacin for adults (500 mg orally twice a day for 10-14 days) or ceftriaxone for children (100 mg/kg per day intravenously or intramuscularly for 10-14 days) or adults (1-2 g daily) are considered better choices for patients in these areas. Antibiotics combined with corticosteroids for the first 48 hours of illness may improve outcome in some critically ill patients with delirium, stupor, coma, or shock.

Shigellosis

Shigella species, members of the Enterobacteriaceae family and agents of bacillary dysentery, are postulated to cause a fatal, toxic encephalopathy in children by elaboration of Shiga toxin (Goren et al. 1992). The encephalopathy is a syndrome of sudden headache, cerebral edema, and rapid neurological decompensation, beginning several hours to 6 days after onset of diarrheal illness. Shigellosis is diagnosed by stool culture. Enteric and systemic disease is treated with ciprofloxacin (500 mg orally twice daily for adults for 1-5 days) or TMP/SMX (160 mg of TMP and 800 mg of SMX orally twice daily in adults) and supportive treatment, but antibiotics may not influence the neurological disease.

Campy 1 obactcrios is

Campylobacter, among the most frequent bacterial infections of humans worldwide, causes both acute enteric and systemic illnesses. Sources of infection include raw milk, water, and poultry. *Campylobacter jejuni* has been identified as the most common antecedent pathogen for the Guillain-Barre syndrome, accounting for an estimated 20^10% of all cases. The onset of Guillain-Barre syndrome is usually 2-3 weeks after the diarrheal illness and follows an estimated I per 1000-2000 *Campylobacter* infections. The presence of anti-GMj antibodies in Guillain-Barre patients infected with C. *jejuni* Penner serogroup 19 and anti-GQlb ganglioside antibodies in Miller-Fisher variant patients infected with *C. jejuni* Lior serogroup 7 has led to the hypothesis that lipopolysaccharides of these *Campylobacter* isolates induce neuropathic disease by molecular mimicry (Yuki 1997; Yuki et al. 1997). *Campylobacter* infection is diagnosed by isolation and identification of the organism from stool or blood. Most strains are treated adequately with erythromycin, 250 mg orally four times daily for 5-7 days.

Whipple's Disease

Whipple's disease, caused by *Tropherym.a wbippelii,* is a multisystem disorder characterized by gastrointestinal disease (abdominal pain, diarrhea, weight loss), arthritis, lymphadenopathy, addisonian symptoms (hypotension, asthenia, cutaneous hyperpigmentation), and protean neurological manifestations including dementia, oculofaciomasticatory myorhythmia, supranuclear ophthalmoplegia, meningitis, neuropathy, and myopathy (Anderson 2000). Classically, the disease occurs as coexisting neurological and gastrointestinal disease, and the diagnosis is made by identifying periodic acid-Schiff-positive bacilli in macrophages in tissue obtained from duodenal or jejunal biopsy. Brain biopsy, demonstrating periodic acid-Schiff-positive material, has been used to establish the diagnosis in the absence of intestinal disease. For its numerous other presentations, sarcoidosis, collagen vascular disease, malabsorption syndromes, Addison's disease, frontotemporal dementia, Creutzfeldt-Jakob disease, progressive supranuclear palsy, or Wernicke's encephalopathy are differential diagnostic considerations. Treatment is with oral double-strength TMP-SMX twice daily for 1 year. Severely ill patients are treated with thrice daily TMP/SMX for the first 2 weeks, together with folinic acid. Oral chloramphenicol, parenteral ceftriaxone, or penicillin arc other treatment options for those who respond poorly.

RESPIRATORY PATHOGENS

Chlamydial Diseases

Each of the three chlamydial species, *Chlamydia psittaci, C. trachomatis,* and C. *pneumoniae* arc human pathogens, with C. *psittaci* most consistently associated with neurological complications.

Psittacosis (or ornithosis), caused by C. *psittaci,* is transmitted from bird to humans by the aerosol route. Fever, cough, myalgia, headache, and hepatomegaly are presenting clinical features, occasionally accompanied by

cranial nerve palsy, myelitis, meningoencephalitis, seizures, or cerebellar ataxia. CSF contains few or no lymphocytes and normal protein, although elevated protein has been reported with myelitis. Psittacosis is diagnosed by serology and treated with oral tetracycline or erythromycin, 500 mg four times per day for 10-14 days. In the absence of a firm diagnosis, erythromycin may be preferable, because it also covers other *Legionella* and *Mycoplasma,* which also cause atypical pneumonias with neurological symptoms.

C. trachomatis causes ocular and venereal disease. Treatment is with erythromycin or tetracycline.

Mycoplasma Syndromes

The human mycoplasmas are *Mycoplasma pneumoniae, M. hominis,* M. *urealyticum,* and M, *genitalium.. M. pneumoniae,* responsible for most clinical disease, causes respiratory infections. Systemic illness with cough and fever are the most consistent clinical presentations, 1 Extrapulmonary involvement includes rash, cardiac abnormalities, arthralgias, vascular diseases (Raynaud's phenomenon, internal carotid artery occlusion, stroke;-, and neurological syndromes (aseptic meningitis, meningoencephalitis, leukoencephalitis, transverse myelitis, brainstem syndromes, Guillain-Barre syndrome, and peripheral neuropathy). Diagnosis depends on recognizing the clinical syndrome and may be confirmed by demonstration of cold agglutinins or complement-fixing antibodies. Erythromycin, 500 mg every 6 hours in adults, 1 g per day in older children, and ."50-50 mg/kg per day in young children for 21 days is the recommended treatment. Tetracycline is an alternative in adults and children older than 8 years.

Legionellosis

Legionella pneumophila causes Legionnaires' disease, which can complicate myositis, encephalitis, and meningitis. *L. pneumophila* is transmitted to humans from its natural aquatic habitat by aerosol or airborne droplets, particularly where humidifiers or air conditioners are used. Legionnaires' disease is characterized by mild to severe pulmonary disease, gastrointestinal disease, hyponatremia, myalgias or myositis, and encephalomyelitis. Encephalopathy, manifesting as altered mental status, is the most common neurological abnormality; ataxia, cranial nerve palsy, mild inflammatory CSF changes, and electroencephalographical abnormalities, have been reported. The diagnosis is suspected in patients with pneumonia and purulent sputum with few or no organisms seen on Gram's stain or in patients who fail to respond to ^-lactam or aminoglycoside antibiotics. Diagnosis is made by culture, serology, or DNA probe. Treatment is with erythromycin, 1 g intravenously every 6 hours until clinical improvement, followed by 2 g orally in divided doses for 3 weeks. Alternative agents include clarithromycin, doxycycline, ciprofloxacin, and RIF.

Pertussis

Bordetella pertussis causes pertussis (whooping cough), an upper respiratory catarrhal infection followed by paroxysmal coughing in a series of short expiratory bursts and an inspiratory gasp. Pertussis is a severe disease in children younger than 1 year, associated with seizures and encephalopathy. Subconjunctival, scleral, or CNS hemorrhages can follow the increased intrathoracic and intra-abdominal pressures during violent coughing at any age. Definitive diagnosis is by isolation of *B. pertussis,* but because the organism is difficult to culture, a clinical case definition (cough of 2 weeks' duration in the setting of a community outbreak) is used. Treatment is with erythromycin at doses of 40-50 mg/kg per day for 14 days, and erythromycin for prophylaxis of household contacts may be necessary. A vaccine composed of one or more components of the organism combined with diphtheria and tetanus toxoids (DPT) is used for immunization.

CARDIAC INFECTIONS

Endocarditis

When cerebral emboli from all sources are counted, approximately 3% result from infective endocarditis. Common pathogens include enterococci, *Streptococcus viridans, S. aureus, S. epidermidis,* or *Pseudomonas aeruginosa.* Cerebral embolization occurs in at least one third of all infective endocarditis cases, commonly in middle cerebral artery territory. Bland or hemorrhagic cerebral infarcts, arteritis, single or multiple abscesses, mycotic aneurysms (often at bifurcation points of distal branches of the middle cerebral artery), intra parenchymal or subarachnoid hemorrhage, cerebritis, meningitis, and asymptomatic CSF pleocytosis can develop during active endocarditis.

Blood culture, a critical diagnostic test for endocarditis, may give negative results in 2.5-31.0% of cases. Reasons for culture-negative endocarditis include fungal endocarditis, slow growth of fastidious organisms such as *Haemophilus,* variant streptococci or *Brucella,* failure to culture intracellular pathogens such as chlamydiae or rickettsiae, right-sided endocarditis, and recent antibiotic use. CSF examination, if clinically indicated, most consistently shows increased numbers of polymorphonuclear leukocytes, red cells, elevated protein, and normal glucose levels. Treatment is with parenteral antibiotics for at least 4 weeks. Indications for valve replacement include more than one significant embolic episode or failure of antibiotic therapy; mycotic aneurysms may require neurosurgical intervention.

Rheumatic Fever

Rheumatic fever, a sequelae of group A streptococcal infection, is diagnosed by one or more clinical criteria (carditis, migratory polyarthritis, subcutaneous nodules, erythema marginatum, chorea), plus culture evidence of recent group A streptococcal infections or elevated anti-streptolysin O titers. The childhood chorea, Sydenham's chorea, occurs in less than 10% of patients. Onset may be immediate or several months after the index infection. Even patients with chorea only are treated, according to the American Heart Association guidelines, which advise prophylactic monthly intramuscular injections of 1.2 million units of benzathine penicillin G or daily oral penicillin V to prevent recurrent attacks.

DISORDERS DUE TO BACTERIAL TOXINS

Neurotoxigenic Clostridia: Botulism and Tetanus

Clostridia, strictly anaerobic gram-positive bacilli, form highly resilient spores that are ubiquitous in the environment. Unlike pathogens that cause neurological disease by inducing inflammation or forming mass lesions, and the consequent tissue injury, several clostridial species elaborate exotoxins that gain access to the nervous system by avid and specific binding to motor nerve terminals. The resulting clinical syndromes are motor disorders that often are accompanied by autonomic dysfunction. Botulism and tetanus require notification of public health authorities, both to obtain therapeutic antisera and to initiate appropriate epidemiological investigation. Knowledge of their characteristic clinical features facilitates early diagnosis of these rare, but rrearable, disorders.

Botulism

An unusual cause of acute generalized weakness, botulism develops when the extremely potent neurotoxin secreted by *Clostridium botulinum* blocks peripheral cholinergic transmission. *Clostridia botulinum* spores are widespread in soil and aquatic sediment. Seven botulinum toxin serotypes define the various C. *botulinum* strains (Case Records 1997). Types A, B, E, and rarely, F cause human disease. Types C and D cause botulism in animals, and type G does not appear to cause human or veterinary illness. Food-borne botulism, described in 1895 by van Ermengen, develops when preformed toxin is ingested from contaminated food. Wound botulism, first recognized in 1942, occurs when C. *botulinum* in an infected wound releases botulinum toxin directly into the tissue. Toxin production by C. *botulinum* colonizing the gut causes infantile botulism. Less commonly, gut colonization causes botulism in adults with pre-exisring gasrrointestinal disorders, such as intestinal surgery or inflammatory bowel disease (Midura 1996).

Pathogenesis and Pathophysiology

Borulinum toxin blocks acetylcholine release at peripheral synapses, leading to the paralytic and autonomic clinical manifestations of botulism (Montecucco and Schiavo 1994). With a median lethal dose as low as 1 ng/kg in mice, it is the most potent toxin known. Unlike C. *botulinum* spores, the toxin is heat-labile. Botulinum toxin is initially synthesized as a single 150-kD prorein chain and contains a single disulfide bond. Proteolysis forms heavy (100 kD) and light (50 kD) chains. The ("'-terminal region of the heavy chain binds tightly and specifically to presynaptic membranes, whereas the N-terminal domain governs internalization of the toxin into the motor neuron. Once internalized, botulinum toxin cannot be neutralized by therapeutically administered antibodies. After translocation across vesicular membranes into the cytosol, cleavage of the disulfide bond liberates the light chain, which contains the catalytic activity of botulinum toxin. The light chain is a zinc endopeptidase that targets various proteins mediating exocytosis. Hence, botulinum toxin causes irreversible blockade at peripheral cholinergic synapses. Recovery requires sprouring of new nerve Terminals, accounting for rhe protracted clinical course of botulism.

Public Health Issues

Although the disease is ubiquitous, five western states (California, Washington, Colorado, New Mexico, and Oregon) account for more than half of all reported outbreaks in the United States. First reported in 1976, infant botulism is now the most common form of botulism in the United States. Among adults, food-borne botulism is much more common than wound botulism. Outbreaks of poisoning are more often due to home-preserved than to commercially canned products, and vegetables are incriminated more commonly rhan any other food product. Since the late 1980s, injection drug use, specifically "skin popping" heroin, has been linked to wound botulism. Skin popping refers to subcutaneous injection, typically by chronic addicts whose poor venous access precludes inrravenous administration. Since 1990, a sharp increase in wound botulism in California has been associated with skin popping "black tar" heroin (Centers for Disease Control 1995).

Clinical Features

Whether toxin is ingested or elaborated in situ from gut colonization or an infected wound, common early symptoms of botulism include diplopia, ptosis, dysarthria, and dysphagia. Extraocular and bulbar muscle weakness

progresses rapidly to the limbs, typically symmetrically, and also to respiratory muscles. Alertness and cognition are normal, unless hypoxemia or hypercarbia supervene because of respiratory failure. Reflexes are depressed or absent, and sensation is normal. These symptoms and signs all indicate neuromuscular blockade. In botulism, impaired cholinergic transmission also involves autonomic synapses, as indicated by dilated poorly reactive pupils, dry mouth, paralytic ileus, and occasionally bradycardia.

In food-borne botulism, nausea, vomiting, and diarrhea often accompany early neurological symptoms, typically 12-36 hours after toxin ingestion. Gastrointestinal symptoms may be less prominent in early wound botulism. Clinical features of infantile botulism vary widely (Midura 1996). Constipation, poor suck, weak cry, and listicssness are common, and the baby often appears floppy. The incubation period may be as brief as a few days or as long as a month. A small percentage of cases of sudden infant death syndrome result from infant botulism. Honey has been implicated as the source of C. *botulinum* spores in infantile botulism. Dust is another important environmental source of spores; however, in most cases of infantile botulism, a source cannot be identified.

Diagnosis

The differential diagnosis includes other causes of acurc generalized weakness. Preserved alertness and lack of sensory or upper motor neuron signs help exclude acute brainstem disorders such as stroke, demyelinating syndromes, and encephalitis. The descending paralysis of botulism closely resembles the Miller-Fisher variant of Cuillain-Barre syndrome and overlaps with the clinical features of diphtheritic polyneuropathy. However, in botulism, sensation is normal, as is CSF. Electromyography and nerve conduction study results reveal changes indicating presynaptic neuromuscular blockade, in contrast to the often-elevated CSF protein and electrophysiological features that suggest the demyelinating neuropathies of Guillain-Barrc syndrome or diphtheria. Pupillary involvement and ileus help distinguish botulism from myasthenia gravis presenting in crisis. In addition, peripheral electrophysiological studies, particularly repetitive nerve stimulation, in myasthenia reveal a postsynaptic defect in neuromuscular transmission (decrement on slow repetitive stimulation; see Chapter 36B), rather than the presynaptic electrophysiological abnormalities that characterize botulism (increment on rapid repetitive stimulation). Normal CSF and prominent ocular signs differentiate botulism from poliomyelitis, in which pleocytosis is the rule and extraocular weakness and ptosis are rare. Tick paralysis also causes acute generalized weakness caused by impaired presynaptic neuromuscular transmission, but weakness typically ascends and spares extraocular muscles. Paralytic shellfish toxicity and organophosphate poisoning are other considerations; the latter causes a syndrome in which cholinergic, rather than anticholinergic, features predominate. The differential diagnosis of infantile botulism includes sepsis, pneumonia, failure ro thrive, myasthenia, polio, Guillafn-ftarre syndrome, brainstem encephalitis, meningitis, hypothyroidism, and metabolic disorders.

Symptoms and signs suggesting cholinergic blockade at both autonomic and neuromuscular synapses suggest the diagnosis of botulism. History of similar symptoms in family or acquaintances or of eating home-canned foods should be specifically sought, as should evidence of recent trauma or chronic infection. Alrhough many patients with wound botulism have a clinically obvious site of infection, it should be emphasized that the extremely high potency of botulinum toxin means that small, seemingly trivial abscesses can cause botulism.

In a patient with a compatible clinical syndrome, the diagnosis of botulism is confirmed by roxin assay or by culturing C. *botulinum.* Toxin detection requires mouse bioassay, which can be arranged through state health departments or the CDC. Appropriate samples for toxin assay include suspected food sources, blood, and stool in most instances, as well as gastric contents and enema fluid in infant botulism. Rapid determination of the source of toxin helps identify individuals at risk in fooddiorne cases. Because C. *botulinum* is a srrict anaerobe, culture specimens require special collection, transport, and culture procedures. Appropriate culture materials include suspected contaminated foods, wound specimens, and stool.

Treatment

Once taken up by neurons, botulinum toxin is invulnerable to antibody inactivation and irreversibly blocks exocytosis. Hence efforts to neutralize circulating antitoxin and eradicate its source often begin before roxin or culture results, which take days, are known (Burningham et al. 1994), In adults, trivalent (types A, B, E) equine antitoxin is given if initial testing reveals no hypersensitivity reaction. Nasogastric suctioning and enemas may help remove toxin in food-borne cases. In wound botulism, infected wounds, even if minor, should be debrided. Because the procedure could liberate more toxin, it may be prudent to debride wounds after antitoxin administration. Whether antibiotics active against C. *botulinum* should be given is controversial, because of the concern that bacterial lysis could release more toxin. If other intercurrent infections require antibiotic therapy, aminoglycosides are probably best avoided whenever possible, because they also impair presynaptic neuromuscular Transmission.

Meticulous supportive care plays a critical role. Close monitoring in an ICU is important, even in patients who do not require intubation at presentation, because respiratory decompensation can develop precipitously. Serial bedside pulmonary function tests are more sensitive than blood gas parameters in determining the need for mechanical ventilation, because vital capacity decreases before hypoxemia

and hypercarbia develop. Complications of prolonged immobility, such as stress ulcer, malnutrition, pneumonia, urosepsis, deep venous thromboembolism, and depression should be anticipated and managed appropriately. In infants, supportive care, including mechanical ventilation in many patients, is the mainstay of therapy. Treatment of infant botulism usually does not include antitoxin administration or antibiotics (Midura 1996).

Modern critical care has decreased mortality from 60% to 20% (Case Records 1997) in botulism. Because botulinum toxin irreversibly destroys the cellular apparatus responsible for acetylcholine release at neuromuscular junctions, motor recovery depends on motor axon sprouting, which takes weeks to months. Long-term ventilatory support and tracheostomy may be necessaty. Full recovery can take years.

Tetanus

Clostridium tetani secretes tetanospasmin, also known as tetanus toxin, and tetanolysin. The function of tetanolysin remains uncertain; tetanospasmin blocks release of inhibitory neurotransmitters by spinal interneurons, causing the dramatic muscle contractions that characterize tetanus. *C. tetani* spores can survive for years in soil and house dust. When introduced into the anaerobic environment of a suitable wound, conversion to the toxin-producing vegetative form may cause tetanus. Neonatal tetanus complicates umbilical sepsis, which is usually related to improper umbilical stump care. Septic procedures during pregnancy or abortion can cause maternal tetanus. Other circumstances favoring the growth of C. *tetani* include deep puncture wounds, chronic skin or dental infections, decubitus ulcers, and other contaminated, necrotic wounds. Although trauma precedes most cases, a responsible wound is not identified in 20% of patients. Tetanus, a preventable disease, is an important international public health problem, particularly in the developing world.

Pathogenesis and Pathophysiology

Tetanospasmin inhibits release of *y*- amino butyric acid and glycine, which are inhibitoty neurotransmitters in the brainstem and spinal cord (Ernst et al. 1997). A single type of tetanus neurotoxin exists, in contrast to the multiple scrorypes of botulinum toxin. Interestingly, though botulinum and tetanus toxins cause dramatically different clinical syndromes, they share many biochemical featutes (Montecucco and Schiavo 1994). Both are 1.50-kD zinc endopeptidases consisting of light and heavy chains connected by a disulfide bond. The binding specificity and translocation reside in the heavy chain, in the C- and N-termini, respectively. The light chain is the zinc endopeptidase, which blocks exocytosis. Unlike botulinum toxin, which remains in the motor axon terminal, tetanus toxin travels to the anterior horn cell by retrograde axonal transport, moves into the intersynaptic space, and enters inhibitory neurons. Impaired exocytosis in these spinal inhibitory neurons causes uncontrolled muscle contraction, a prominent clinical feature of tetanus. Similar disinhibition in the intermediolateral column of the spinal cord is thought to produce autonomic dysfunction.

Public Health issues

Underreporting is the rule for all forms of tetanus in both industrial and developing countries (Galazka and Gassc 1995). Neonatal tetanus remains a significant public health problem in the developing world. In industrialized nations, tetanus is rare, owing to toxoid immunization programs, which usually target children. As a result, tetanus has become particularly rare in children and young adults and is primarily a disease of the elderly in industrialized countries. Interestingly, immunization efforts also decrease mortality from neonatal tetanus. Since the 1980s, tetanus outbreaks have developed among heroin addicts in Hong Kong, reminiscent of similar outbreaks in New York City during the 1960s (Sun et al. 1994),

Clinical Features

The typical incubation period is 2 weeks but can range from hours to a month or more. Cardinal features include muscle rigidity and spasms, which may be accompanied by autonomic hyperactivity. Local tetanus, in which symptoms remain limited to a limb, is a rare form. Far more common is generalized tetanus, also called lockjaw, as trismus heralds the disorder in over 75% of cases. Tetanus resulting from infected head and neck wounds may present with facial or ocular muscle spasms, so-called cephalic tetanus. Sustained contraction of facial muscles causes a sneering grimace known as risus sardonicus. Other early symptoms include dysphagia and axial muscle involvement, such as neck stiffness, abdominal rigidity, and back pain. Early involvement of face, neck, and trunk muscles has been ascribed to the shorter axons of motor neurons supplying cranial and axial muscles, as compared with the limbs. Laryngospasm compromises ventilation and makes intubation extremely difficult. Sustained contraction of back muscles causes opisthotonos, an arching posture of the back. As tetanus progresses, reflex muscle spasms develop, triggered by sensory stimuli, movement, or emotion. Examination can be difficult, as it may prompt spasms.

Diagnosis

Differential diagnosis includes hypocalcemia, strychnine poisoning, dystonic reactions to neuroleptics or antiemetics, meningitis, encephalitis (including rabies), status epilepticus, and the acute abdomen. Oral infection or mandibular

fracture or dislocation may cause isolated trismus, without the generalized features of tetanus. Immunization status should be established, if possible, and a history of chronic infection should be sought. The characteristic muscle contractions elevate serum CK, but there are no pathognomonic laboratory abnormalities in tetanus. CSF is normal. Wound cultures must be interpreted cautiously. Positive culture results may indicate wound colonization, rather than true infection with subsequent toxin production. Moreover, in most established cases, wound cultures do not yield C. *tetani.*

Treatment

Therapeutic goals include protecting the airway, neutralizing circulating tetanospasmin and preventing its further production, managing spasms and dysautonomia, and general supportive care (Ernst et al. 1997; Reddy 2002). The risk for precipitous respiratory decompensation, even in mild cases, warrants ICU management for all patients with tetanus.

Initial management of most patients with generalized tetanus includes endotracheal intubation, because laryngospasm may appear abruptly even in mild cases. Human tetanus immune globulin, given as a single dose of at least 500 IU intramuscularly, neutralizes circulating toxin. Infected wounds should be debrided after human tetanus-immune globulin administration, because the procedure may release further toxin. Metronidazole or penicillin should be given to eradicate C *tetani.* Because minute amounts of tetanospasmin can produce clinical disease, affected patients frequently do not mount a protective immune response. Hence tetanus toxoid should be administered, either primary immunization series or booster injection as appropriate, to all patients with tetanus,

A paucity of randomized clinical trial data means that treatment recommendations for tetanus depend heavily on clinical experience. This is particularly true for managing sympathetic hyperactivity. A quiet, dark environment minimizes sensory stimulation that may precipitate spasms or hypertensive crises. Benzodiazepines, such as parenteral diazepam, lorazepam, or midazolam, reduce rigidity and spasms. Such agents also provide effective sedation, an important consideration because severe tetanus typically requires weeks or months of ICU care. Most patients also require treatment with neuromuscular blockers, such as pancuronium or vecuronium, to control spasms. Intravenous dantrolene and intrathecal baclofen also have been used successfully to manage muscle rigidity and spasms in tetanus. Hypertension and tachycardia often respond to beta blockers such as propranolol or labetalol, although treatment may be complicated by cardiac arrest or hypotension. As with all critically ill patients, optimal supportive care includes attention to nutritional status and measures to prevent stress ulcers, deep venous thrombosis, and decubitus ulcers.

Tetanus is a reportable illness whose complex management poses considerable challenges for neurointensivists. It is worth noting that tetanus could be largely prevented with simple modifications in peripartum and neonatal care and more widespread use of tetanus toxoid, which is both inexpensive and safe.

Complications

Without treatment, generalized tetanus is uniformly fatal, The overall case-fatality rate in the United States from 1991 through 1994 was 25%, with substantially higher rates among older patients (Izurieta et al. 1997). Complications include acute respiratory failure from laryngospasm, long-bone fractures from severe tetanospasm, and cardiac arrest from dysautonomia. Patients with protracted courses may require tracheostomy or develop seizures or other evidence of withdrawal related to long-term use of benzodiazepines, Most survivors recover fully. Because the disease is caused by the binding of tetanus toxin to receptors, immunodeficiency neither lengthens nor shortens the pure tetanus-related disease.

Diphtheria

Diphtheria is an acute infectious disease of the tonsils, pharynx, larynx, nose, other mucous membranes, or skin caused by *Corynebacterium diphtherial..* The potentially-fatal effects of diphtheria depend on the production of an exotoxin, by a lysogenie tox^+ phage. Although toxic to all tissues, the exotoxin's most dramatic activity is against heart and peripheral nerves. Approximately 20% of patients develop myocarditis and neuritis.

Faucial diphtheria is the most common form, presenting with fever, sore throat, membranous pharyngitis, cervical lymph adenopathy, and edema. In North America and Europe, skin infections with C. *dtphtheriae* are now more common than nasopharyngeal disease. Cutaneous diphtheria appears as a pustule or nonhealing ulcer with a gray, dirty membrane. Toxic complications of cutaneous infections are rare, with neuritis more likely than myocarditis.

The toxin inhibits protein synthesis, causing segmental demyelination of motor and sensory myelinated axons, producing a toxic cranial and peripheral neuropathy. Early lower cranial nerve signs and symptoms, within 2 weeks of the appearance of faucial disease, suggest IX and X nerve dysfunction with paralysis of the soft palate, nasal speech, and nasal regurgitation of fluids. Blurred vision, caused by ciliary paralysis of accommodation, or diplopia, caused by oculomotor nerve paralysis, appear in the third or fourth week of the disease. Peripheral polyneuritis, more likely in severe cases, typically begins between the sixth and seventh weeks of illness, when the patient may appear otherwise stable. The neuropathy vaties widely in severity. Phrenic and further vagal nerve involvement may produce a rapidly

descending paralysis of pharynx, larynx, and diaphragm, A subacute motor neuropathy, involving proximal groups first, sometimes evolves slowly, halting after 1-2 weeks, or rapidly generalizes to quadriplegia and respiratory paralysis. Vibratory, proprioceptive, and other cutaneous sensory loss may be limited to the hands and feet or extend over mueh of the body. Sphincter dysfunction sometimes develops; cardiac vagal denervation can result in arrhythmias or baroreceptor abnormalities. Conduction abnormalities may follow the onset of neurological symptoms by several weeks and peak after clinical recovery has begun. CSF may be normal or reveal elevated protein, which is not a poor prognostic sign, when there is radicular involvement. Primary cutaneous diphtheria is characterized by early, localized anesthesia surrounding the skin ulcer, followed by weakness of surrounding muscles, before progression to generalized disease.

Definitive diagnosis requires isolation and identification of the organism from infected sites, but treatment with diphtheria antitoxin (equine hyperimmune serum) should be started as soon as a presumptive diagnosis is made. Diphtheria antitoxin can only neutralize circulating toxin before it enters cells. Antitoxin dose depends on the site of primary infection: 20,000-40,000 units for faucial diphtheria of less than 48 hours, 40,000-80,000 units for faucial diphtheria of longer than 48 hours, and 80,000-100,000 units for extensive disease or neck swelling. Patients with sensitivity to horse serum receive a 1 to 10 dilution test dose first and can be desensitized with increasing doses of antiserum, with epinephrine readily available. Antibiotics terminate toxin production and prevent further proliferation of the organism. Hither parenteral or oral penicillin G, 100,000 U/kg twice daily, or erythromycin, 5 mg/kg four times daily for 14 days, are recommended. Additional treatment is largely supportive, with respiratory and eardiac monitoring. Neurological recovery is the rule, although arrhythmias or heart failure may be fatal.

Diphtheria is included in the triple vaccine DPT (diphtheria, pertussis, and tetanus), which is administered as three primary doses at 2-month intervals beginning at 6-8 weeks of age. A fourth dose is given 6-12 months after the third, and DT is given at school entry.

Chapter 59
Infections of the Nervous System

B. VIRAL INFECTIONS

Roberta L. DeBiasi, Marylou V. Solbrig, and Kenneth L. Tyler

Hundreds of viruses exhibit tropism for the central and/or peripheral nervous system. The clinical spectrum of viral diseases is broad. Signs of primary viral infection may range from asymptomatic infection to systemic febrile illness with or without central (CNS) or peripheral (PNS) nervous system involvement. In the case of many viruses, involvement of the CNS or PNS is the predominant feature of illness, whereas in others, involvement of the nervous system is a rare complication of more generalized illness. The manifestations of viral nervous system involvement are myriad, including meningitis (acute or chronic), encephalitis (acute or chronic forms such as subacute sclerosing panencephalitis [SSPE]), myelitis, ganglionitis, and polyradiculitis. By virtue of their existence as foreign antigenic stimuli, viruses may also incite para- or postinfectious CNS inflammatory or autoimmune syndromes, such as acute disseminated encephalomyelitis (ADEM). The basic clinical featutes of each of these major clinical syndromes are overviewed in Chapter 47 (Neuroendocrinology). In this chapter, the most common etiologies of each of the major clinical syndromes will be discussed, with a review of diagnosis and treatment.

The most common viruses causing nervous system disease in North America are listed in Table 59B.1 in the relative order of frequency with which they occur and with an indication of their relative propensity to cause meningitis, encephalitis, postinfectious encephalomyelitis, or myelitis. Causes of viral nervous system disease that should be considered in patients who have recently traveled abroad arc shown in Table 5.9B.2. In Europe and the United States, the most common causal agents of aseptic encephalitis and meningitis arc enteroviruses (coxsackie and echoviruses), arboviruses, and Herpes simplex virus (HSV). Worldwide, there are over 50,000 encephalitis deaths from rabies each year, and in Asia at least 35,000 cases and 10,000 deaths from Japanese encephalitis (JE). In the United States, nearly 4000 cases of West Nile Virus encephalitis, with 250 deaths, occurred in 2002. Although the basic clinical features of most types of viral meningitis and encephalitis are generally similar, specific skin, mucous membrane, or other physical examination findings may help to narrow the possible viral etiologies of nervous system disease (Tables 59B.3 and 59B.4), It is important to recognize that several nonviral diseases can mimic the clinical features of viral CNS infection (Table 59B.5) (DeBiasi and Tyler 2002). The treatment, prophylaxis, and immunotherapy of specific viral infections are summarized in Tables 59B.7 and 59B.8.

SPECIFIC VIRAL ENTITIES

Herpesviruses

Herpesviruses are ubiquitous and can infect many mammalian, bird, reptile, and amphibian species. These viruses cause acute infection, but also share the biological capacity of latency, the ability to remain quiescent for periods of time in the host and to be reactivated. Members of **the** herpesvirus family causing neurological diseases in humans include HSV-type 1 and type 2, varicella zoster virus (VZV), cytomegalovirus (CMV), Epstcin-Barr virus (EBV),

Herpes Simplex Viruses Type 1 and 2 (HSV-1, HSV-2)

Herpes Simplex Encephalitis (HSE), HSV-1 encephalitis is the most common cause of sporadic, fatal encephalitis in the United States, accounting for approximately 10% of all eases of encephalitis. Early recognition is important hecause of the efficacy of the antiviral drug acyclovir in reducing morbidity and mortality. Mortality in untreated cases is 70% and is reduced to approximately 20% with rapid institution of antiviral therapy in a timely fashion. However, morbidity due to HSV-1 encephalitis, treated or untreated, remains high, with up to 70% of survivors demonstrating permanent neurological sequelae. HSV-1 strains are etiological agents in over 90% of cases of HSE in adults. Type 2 strains are more commonly isolated in monophasic or recurrent meningitis and congenitally acquired neonatal HSV meningoencephalitis. Both types 1 and 2 have been associated with myelitis. HSV-1 and -2 related CNS disease in immunosuppressed hosts is discussed in Chapter 59E.

HSV-1 is transmitted by respiratory or salivary secretions. Up to 33% of HSV-1 encephalitis cases may occur in conjunction with primary infection. In these cases, it has been postulated that virus may spread from the olfactory fibers in the nose to orbitofrontal cortex and temporal lobes. In the majority of cases, however, encephalitis is probably a consequence of reactivation and centripetal spread of virus latent in the trigeminal ganglia from a prior infection.

Fever and headache are consistent features of HSE. Onset of symptoms may be abrupt with focal or generalized seizures, or more protracted, with behavioral changes, an amnestic syndrome, aphasia, or other focal signs.

Rhabdovirus	Rabies	Many developing countries

The diagnosis of HSE should be considered in any febrile patient with an altered level of consciousness, with or without other focal neutological deficits. The presence of hallucinations, particularly olfactory hallucinations, should suggest the possibility of HSE. There is no pathognomonic set of clinical findings of HSE. Focal signs, hemiparesis, hemisensory loss, ataxia, or focal seizures are seen in approximately one half of patients at presentation. Multiple conditions may mimic the clinical presentation of HSV encephalitis, including other viral and postviral

Table S9B.3: Skin/mucous membrane findings suggesting specific viral CNS diseases

Exantkem or mucous membrane change	*Viral agent*	*Specific changes*
Vesicular eruption	Enterovirus	"Hand, foot and mouth disease"—macules/papules/vcsicles on palms, soles, buttocks
	Herpes simplex	Grouped small (3 mm) vesicles on an erythematous base
	Varicella zoster virus	Zoster: Vesicles in dermatomai distribution
		Primary VZV; multiple vesicles, papules, pustules in various stages of eruption
Maculopapular eruption	Epstein-Barr virus	Diffuse maculopapular eruption following ampicillin treatment
	Measles	Diffuse maculopapular erythematous eruption beginning on face/chest and extending downward
	HHV-6	Roseola: Diffuse maculopapular eruption following 4 days of high fever
	Colorado tick fever	Maculopapular rash in 50%
	LCMV	Occasionally occurs with lymphadenopathy
Erythema multiforme	(Mycoplasma)	Many rypes of rash
Confluent macular rash	Parvovirus	Confluent erythema over cheeks ("slapped cheek") followed by lacy, reticular rash over extremities (late)
Purpura	Parvovirus	Rare "stocking glove syndrome—purpuric lesions on distal extremities"
Pharyngitis	Enterovirus	"Herpangina"—vesicles on soft palate
	Adenovirus	Pharyngoconjunctivitis
Conjunctivitis	St. Louis encephalitis	Conjunctivitis
	Adenovirus	Conjunctivitis with pharyngitis (see above)

Table 59B.4: Other specific findings associated with viruses causing CNS disease

binding	*Viruses*
Alopecia	LCMV
Arthritis	LCMV, Pitrvovirus
Biphasic Illness	LCMV, Colorado tick fever
Lymph adenopathy	LCMV, Mumps
Mastitis	Mumps
Mononucleosis	CMV, EBV
Myelitis	St. Louis encephalitis vims, VZV, Herpes B virus, LCMV
Myocarditis/pericarditis	Enterovirus, (Mumps, LCMV)
Orchitis/oophoritis	Mumps (LCMV, EBV)
Paresthesias	Colorado tick fever, LCMV, Rabies
Parotitis	Mumps (LCMV)
Pneumonia	Influenza, Parainfluenza
Retinitis	CMV
Tremors	Arbovirus
Urinary problems	St. Louis encephalitis virus, VZV, Herpes B virus, LCMV

encephalitides (particularly those with focal involvement), cryptococcal abscesses, toxoplasmosis, septic emboli from bacterial endocarditis, amebic meningoencephalitis, sagittal sinus or other cerebral vein thromboses, and mitochondrial encephalopathy, lactic acidosis, and strokelike episodes (MELAS).

Examination of cerebrospinal fluid (CSF) is imperative, and the single most important diagnostic test in suspected cases of HSE. CSF is usually under increased pressure, with a lymphocytic pleocytosis of 10-1000 white blood count (WBC) per til.. Cases of documented HSE without CSF pleocytosis are tare, but can occur, particularly in neonatal disease or in immunocompromised patients. Red blood cells (often crenated) or xanthochromia may be present in the CSF, but this finding is neither sensitive nor specific for HSE. CSF protein is usually moderately elevated, and glucose is usuallv normal.

Virus may be cultured from the CSF in less than 5% of cases; however, HSV DNA can be detected in the CSF with polymerase chain reaction (PCR) techniques. CSF PCR testing has an estimated sensitivity of greater than 95% and a specificity approaching 100% for the diagnosis of IISV infections of the nervous system, including HSE (Whitley and Lakeman 1995; DeBiasi and Tyler 1999} and has replaced brain biopsy as the diagnostic test of choice for HSE (Table 59R.6). CSF HSV PCR is also useful in diagnosis of cases of HSV-2 brainstem encephalitis and myelitis. CSF PCR remains a sensitive technique for the detection of HSE even in patients who have received up to a week of antecedent antiviral therapy. Newer quantitative, real-time PCR methods, which allow rapid turnaround of CSF sample results within hours, should allow for improved accuracy and rapidity of diagnosis in patients with possible HSE (DeBiasi et ah 2002). Despite the sensitivity of PCR, several recent reports have emerged indicating that CSF PCR may yield false-negative results in patients in whom CSF is analyzed within the first 24 hours of illness (Weil et ah 2002). For this reason, HSV-specific antiviral therapy should not be discontinued m patients with suspected focal encephalitis on the basis of a single negative CSF PCR test if it is obtained within 72 hours of symptom onset, unless a suitable alternative diagnosis has been established.

CT and magnetic resonance imaging (MR1) have both been utilized to assist in the diagnosis of HSE, MRI is a more sensitive modality and is the preferred study. Up to 40% of patients with HSE with normal CT scans will have demonstrable abnormalities on MRI. MRI typically demon si rates focal abnormalities as areas of high signal intensity on T2-weigh ted images in fron to temporal regions (Figure 59B.1). Electroencephalogram (FFG) may be abnormal early in the course of disease, demonstrating diffuse slowing, focal abnormalities in the temporal regions, or periodic latcralizing epileptiform discharges (PLEDS). Brain biopsy is now only rarely performed for diagnosis of HSF. Biopsy is reserved for atypical cases in which the diagnosis remains in question or those who respond poorly to treatment. Biopsy specimens show hemorrhagic necrosis, HSV antigen in infected cells, and accumulations of viral particles forming acidophilic intranuclear inclusion bodies in neurons (Cowdry type A inclusions) (Plate 59B.I).

Because of its safety, empitic therapy with acyclovir should be instituted immediately in cases of focal encephalitis (see Table 59B.7). Acyclovir should be administered intravenously at a dose of 10 mg/kg every 8 hours in adults and 20 mg/kg every 8 hours in neonates and children. Treatment should be continued, unless a CSF HSV PCR (obtained 72 hours or later after onset of symptoms) is negative, and/or an alternative diagnosis is made, for a minimum of 14 days. Many experts favor a 21-day course of therapy in adults and neonates with HSV meningoencephalitis. Renal insufficiency is an infrequent, usually reversible, side effect of acyclovir therapy. Acyclovir dosing should be adjusted appropriately in patients with renal insufficiency. Treatment with acyclovir reduces mortality of HSF from 70% to 20%. Over one third of patients with HSE treated with acyclovir recover with mild or no neurological impairment. Relapses following treatment with acyclovir have been reported (more often in neonates and children than adults) and may be due to either immune-mediated mechanisms or continued active viral infection. These possibilities can be distinguished by CSF HSV PCR. Patients with immune-mediated relapse are PCR negative, whereas those with residual infection remain PCR positive. Patients with relapse who remain PCR positive should receive an additional course of acyclovir therapy and should be tested for the possibility ol acyclovir-resistant virus. Foscarnet is an alternative therapy for patients with suspected or proven acyclovir-resistant strains or with allergy to acyclovir. Vidarabine is no longer utilized as a treatment for HSF".

Table 5915.5: Diseases that can masquerade as viral nervous system disease

Etiology			*Suggestive features*
Infectious	Bacterial	Parameningcal focus (sinusitis, intracranial abscess)	Very mild pleocyrosis, focal neurological exam
		Partially treated bacterial meningitis	Prior antibiotic treatment, right shifted CSE
		Lyme disease	Tick exposure, arthritis, apnmpri.iie geography, erythema migrans
		Tuberculosis	Very high protein, hypoglycorrhachia
		Leptospirosis	Conjunctival suffusion, jaundice
		Syphilis	Chronic
		Brucella	Farm animal exposure
		Whipple's disease	GI complaints
		Bartonella (cat scratch disease)	Cat exposure, adenopathy
		Listeria	Brainstem encephalitis
		Typhoid fever	Exposure history, bradycardia
	Fungal	Cryptococcus	Usually immunocompromised pr.
		Coccidioides	Southwestern U.S. exposure, pulmonary symptoms
		Histoplasma	Pulmonary nodules
		Blastomycosis	Midwest, pulmonary symptoms
		Candida	Immunocompromised pt.
		Nocardia	Immunocompromised pt.
	Parasitic	Toxoplasma	Retinitis, cat exposure
		Cysticercosis	Calcified lesions
		Amoebic	Fresh water: Naegleria
		Malaria *(P. falciparum)*	Exposure history
	Rickettsial	Rocky Mountain spotted fever	Leukopenia, thrombocytopenia, hyponatremia, petechial rash
		Ehrlichia	See above
		Coxsiella brunetti (Q fever)	F.xposure to sheep, pulmonary disease
	Mycoplasma		Precedent pulmonary symptoms
Parainfectious	Acute disseminated encephalomyelitis (AD EM)		Characteristic MRI findings
Noninfectious	Connective tissue disorders	Systemic lupus erythematosis (SLE)	Malar rash, multisystem organ involvement
		Sarcoidosis	Hilar adenopathy, erythema nodosum
	Uveomeningitic syndromes	Behcet's	Genital/oral ulcers, uveitis
	Intracranial tumors and cysts		Recurrent episodes, dermal sinus tract
	Drugs	NSAIDs, antibiotics, immunomodulators, anticonvulsants	Exposure history
	Intracranial hemorrhage		
	Encephalopathy	Toxic or metabolic	

Neonatal Herpes Simplex Virus Meningoencephalitis

In contradistinction to adults, in which HSF is usually caused by HSV-1, HSV-2 is the most common causal agent of meningoencephalitis in neonates (although HSV-1 disease may also occur). Neonates who acquire HSV from the birth canal develop infection of the CNS in 50% of cases (Kimberlin et al. 2001), CNS disease occurs as either a componenr of an overwhelming sepsislike disseminated disease with multi-organ involvement (in the first week of life), or as isolated CNS disease, which usually presents later (weeks 2-10 of life), with or without accompanying vesicular skin, mucous membrane, or conjunctival lesions (skin, eye, mouth disease). The presence of vesicular skin or mucosal lesions in an infant of this age, even in the absence of fever or systemic symptoms, warranrs immediate evaluation of CSF for cell counts, chemistry, and HSV PCR because up to 30% of infants with presumed isolated skin, eye, and mouth disease may subsequently be identified as having CNS involvement. Neonates with possible HSV disease should be treated empirically with intravenous acyclovir 20 mg/kg every 8 hours while awaiting results of CSF HSV PCR. Treatment should be continued for 14 days in infants with isolated skin, eye, and mouth disease and 21 days in infants with sepsis or evidence of CNS involvement, Relapses of skin, eye, and mouth disease (with the potential for CNS involvement and subsequent neurological deficits) arc common in the first year of life following

CNS or non-CNS presentations of neonatal HSV disease. For this reason, the continuation of oral acyclovir prophylaxis for 3-6 months following intravenous therapy is currently being studied in a randomized multicenter trial (Kimberlin 2001). In the future, quantitative HSV PCR techniques may allow more accurate analysis of response to therapy, required duration of therapy, and determination of prognosis.

Meningitis Due to Herpes Simplex Virus

At the time of their first episode of genital herpes (generally due to HSV-2), approximately 36% of women and 11% of men have symptoms of meningitis, including fever, headache, and nuchal rigidity. Of these patients, 20% will develop recurrent episodes of meningitis (see Mollaret's meningitis following). When aseptic meningitis occurs in this setting, genital lesions are present an average of 1 week before the CNS symptoms. CSF viral cultures are invariably negative during recurrent episodes of meningitis, although the virus may be isolated during the first (primary) episode. Other neurological complications, such as paresthesias, urinary retention, and transverse myelitis, have been described with HSV-2 infections.

Recurrent meningitis, or discrete episodes of meningitis, has been linked to other viruses (including human immunodeficiency virus [HIV] and EBV), other infectious agents (such as partially treated or atypical bacterial or fungal pathogens, such as *Borrelia burgdorferi),* drug exposure (nonsteroidal anti-inflammatory agents, IVIG, monoclonal antibodies), dermoid cysts within CSF pathways that are leaking, and idiopathic inflammatory conditions (sarcoid, uveomeningitis syndromes). Recurrent aseptic meningitis should be distinguished from recurrent bacterial meningitis, in which underlying abnormalities should be sought, such as CSF leak, skull base fracture, dermal sinus, parameningeal infection, or impaired B-cell immunity (DeBiasi and Tyler 2000).

CSF PCR has identified HSV-2 in a large subset of patients with the syndrome of benign recurrent lymphocytic meningitis, also known as Mollaret's meningitis. This syndrome may be associated with the presence in the CSF of Mollaret's cells, large cells of monocyte-macrophage lineage. In one of the largest series to date, 85% of patients had detectable HSV DNA, of which 91% were HSV-2 (Tedder et al. 1994). These patients were predominantly females and experienced 3-9 attacks of meningitis over a period of 2-23 years. Of these, only 23% had a history of

Table 59B.7: Treatment and prophylaxis of viral infections

Antviral class	*Antiviral agent*	*Dnse*	*Indications*
Nucleoside analogs	Acyclovir	10 mg/kg/dose (IV) q8h x 14-21 days	HSV encephalitis in adults
		20 mg/kg/dose (IV) q8h x 21 days	Neonatal HSV encephalitis
		500 mg/m^2/dose (IV) q8h x 21 days (equivalent to 10-12 mg/kg/dose in adults and up to 20 mg/kg/dose in infants)	VZV encephalitis in normal or immunocompromised pt
		15 mg/kg/dose (IV) q8h x 10-14 days	Herpes B virus
		800 mg (PO) JX/day x 7 days	Dcrmatomal zoster or primary V in immunocompromised pt

*Live vaccines include yellow fever, measles, mumps, rubella, smallpox, polio, and varicella zoster virus. Killed vaccines include polio, rabies, influenza, arboviruses (Japanese encephalitis, tick-borne encephalitis, Kyasanur Forest, Rift Valley, eastern equine encephalitis, wcii.cni equine eccepl minis, a:id Vcnc/ueliin equine encephalitis). Soluble protein includes hepatitis *V*>.

genital herpes, none with lesions concurrent with their most recent episodes of meningitis.

Varicella Zoster Virus (VZV)

Primary Infection. VZV can involve virtually every part of the CNS and PNS. Primary VZV may produce encephalitis in immunocompromised patients and, rarely, a progressive, fatal encephalitis in healthy children. A self-limited cerebellar ataxia is often seen in otherwise healthy children during or immediately following primary VZV infection (chickenpox). Meningitis, brainstem encephalitis, and myelitis due to VZV can also occur in immunocompetent hosts, VZV can also cause both granulomatous arteritis leading to stroke and/or multifocal infarcts and small vessel vasculopathy (leukoencephalitis) (Kieinschmidt-DeMasters and Gilden 2001). Postinfectious encephalomyelitis follows an estimated 1 in 2500 cases of primary VZV infection. Reye's syndrome (2.5 per 10,000 cases) has been associated with primary VZV infection, particularly in children who concomitantly received aspirin.

Antiviral treatment of acute VZV encephalitis and myelitis is intravenous acyclovir, at the high dose of a 20 nig/kg (or 500 mg/m^2 per dose) every 8 hours. Treatment of immunocompromised children with primary VZV infection (in the absence of CNS disease) with intravenous acyclovir should begin within the first 24-72 hours after onset of the rash and be continued for a minimum of 7 days, or until lesions have crusted over. Foscarnet may be used for acyclovir-resistant zoster infections. Corticosteroids are often used for sighr-threatening complications (optic neuritis, orbital apex syndrome) and postviral cerebral (large vessel) vasculitic complications, but when utilized, should be accompanied by antiviral therapy. Corticosteroids may also be used to limit inflammatory response in myelitis. Brief courses of corticosteroid are also used to treat the small and large vessel vasculopathy that accompanies persistent VZV encephalitis in immunocompromised patients, although no clinical trials demonstrating its efficacy are available. VZV immunoglobulin is used for prophylaxis of seronegative immunocompromised patients and pregnant women who have been exposed to VZV. VZV immunoglobulin, one vial (125 units) per 10 kg of body weight intramuscularly, should be given within 96 hours and preferably within 48 hours of exposure (Arvin 1996).

Herpes Zoster. Following primary infection, VZV becomes latent in cells of the dorsal root ganglia. Reactivation of endogenous latent virus produces herpes zoster, or shingles. The virus can reactivate after injury or trauma to the spine or nerve roots or in response to waning cell-mediated immunity to VZV caused by age or immunosuppression related to HIV infection, cancer, cytotoxic drugs, or systemic illness. Herpes zoster is

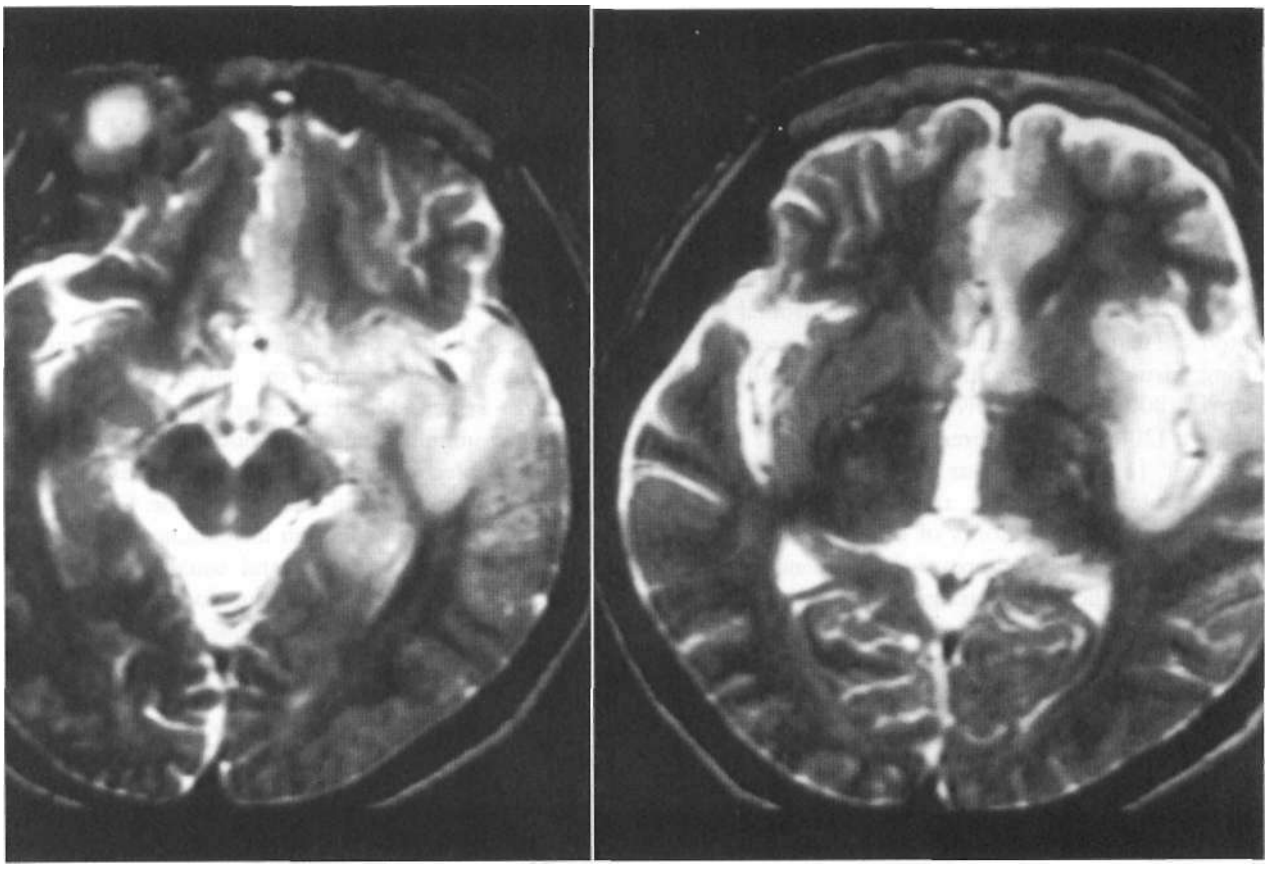

FIGURE 59B.1 Herpes simplex encephalitis. T2W-MRI showing increased signal in left media] temporal lobe, inferior frontal lobe, and insular cortex. (Courtesy J. Healy.)

frequently the first clinical presentation of underlying HIV infection, in which case it may he protracted and multidermatomal. In Africa, herpes zoster has a positive predictive value for HIV infection of *95%.*

Herpes zoster typically begins with pain and paresthesias in one or two adjacent spinal or cranial dermatomes. Pain is followed in 3-4 days by a painful pruritic vesicular eruption in the area supplied by the affected root. The eruption can last 10 days to 2 weeks. Occasionally, a few lesions appear outside the primary dermatome. Herpes /.oster most often involves the thoracic dermatomes, usually T5-T12. Fourteen to 20% of patients have disease in the distribution of a cranial nerve and 16% in lumbosacral dermatomes, usually LI or L2. Involvement of the first division of the trigeminal ganglion produces ophthalmic zoster and may be associated with conjunctivitis, keratitis, anterior uveitis, or iridocyclitis. Occasionally corneal transplantation may be required to correct visual impairment from corneal scarring. Vision loss following herpes zoster ophthalmicus is rare, however, and more commonly is caused by retrobulbar neuritis. Involvement of the geniculate ganglion produces otic zoster, or the Ramsay Hunt syndrome: painful facial paresis accompanied by tympanic membrane and external auditory canal vesicular rash. Older age and cranial nerve involvement are risk factors for zoster encephalitis, so all cases of ophthalmic zoster in older adults should be treated with antivirals. Herpes zoster involving cervical and thoracic levels may be associated with myelitis, and in the lumbosacral region may be accompanied by bladder dysfunction or ileus. The clinical variant, zoster *sine her pete,* refers to syndromes of prolonged radicular pain without zoster rash **but with** detectable VZV DNA in the CSF.

Herpes zoster should be considered in the differential diagnosis of new onset acute radicular pain. A CSF lymphocytic pleocytosis, with cell counts to several hundred cells per microliter, may precede the rash. Approximately 40% of healthy individuals with herpes zoster have elevated CSF cell counts and protein concentration, and VZV can frequently be isolated from the CSF of these patients. VZV DNA can be detected in the CSF by PCR techniques, and VZV may be cultured from vesicles or detected by microscopic examination of vesicular scrapings by direct fluorescent antibody testing.

Complications of zoster include postherpetic neuralgia, segmental motor atrophy in the affected dermatome, meningitis, myelitis, large vessel vasculitis (usually involving the carotid or its branches on the side of zoster ophthalmicus), and multi-focal leukoencephalitis or encephalitis with generalized cerebral vasculopathy. VZV

encephalitis with vasculopathy has been reported in AIDS and cancer patients and in individuals treated with cyclophosphamide or corticosteroids. The syndrome may occur without signs of cutaneous infection or may progress after cutaneous lesions have healed. Mixed ischemic and hemorrhagic infarcts in subcortical gray and white matter, plus ischemic, demyelinative, or both kinds of lesions in deep white matter, are noted radiologically and pathologically.

Risk factors for postherpetic neuralgia in patients with shingles include age over 50 years and prodromal sensory symptoms. Treatments are directed toward lessening pain, reducing virus shedding, and shortening healing time. Acyclovir (800 mg orally five times daily for 7 days), famciclovir (200 mg orally three times daily for 7 days), or valacyclovir (1 g orally four times daily for 7 days) accelerate cutaneous healing and decreases acute zoster pain if begun within 72 hours of onset of rash. Whether these agents significantly decrease the incidence, duration, or severity of postherpetic neuralgia is uncertain. In patients without contraindications, a short course of corticosreroids, such as 40 mg prednisolone per day, tapered over 3 weeks, may be added to antiviral therapy. Compared with acyclovir therapy alone, addition of corticosteroids has been shown to improve comfort levels (pain reduction during the acute phase) following herpes zoster, although its efficacy in reducing subsequent risk of postherpetic neuralgia remains uncertain. Intrathecal methylprednisolone and oral gabapentin have been studied as treatments for postherpetic neuralgia and have been efficacious in some studies. A live attenuated varicella vaccine boosts VZV immune responses in adults, raising hope that, in the future, it may be possible to prevent dermatomal zoster eruption (Jumaan 2001; Johnson 2002).

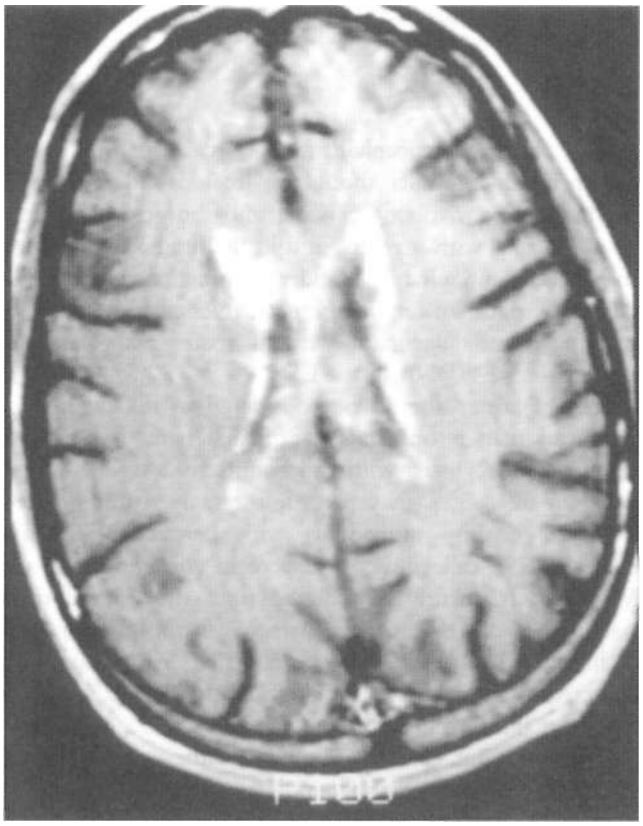

FIGURE 59B.2 Human cytomegalovirus ventriculitis. Axial gadolinium-enhanced 'I'lW-MRI showing contrast enhancement of ependyma of lateral ventricles. (Courtesy J. Hcaly.)

Cytomegalovirus (CMV)

CMV causes both acute and latent or persistent infections in humans. It is transmitted through saliva, milk, genital secretions, semen, blood transfusions, and organ transplants. In immunocompetent hosts, CMV may cause inapparent infection, a mononucleosis syndrome, aseptic meningitis, or the Guillain-Barrc syndrome. CMV encephalitis is exceedingly uncommon in immunocompetent hosts beyond the neonatal period and usually presents as an encephalopathy, with or without focal features, in the context of a subacute febrile illness. However, immunocompromised adults and developing fetuses are at high risk of developing CNS disease due to CMV. CMV may also infect the peripheral nerves, nerve roots, and spinal cord in patients with advanced HIV, presenting as an ascending myeloradiculitis.

Congenital CMV. CMV infection is the most common congenital infection affecting humans and can cause severe injury to the infected fetus. Up to 10% of infants born to mothers with primary CMV infection (the bulk of whom acquire CMV in the first trimester of pregnancy) are symptomatic at birth. 10% of symptomatic infants die, and 80% of survivors suffer severe neurological morbidity (9000 infants each year in the United States) (Ahlfors et al. 1999). Infection by passage through the birth canal or following breastfeeding in the perinatal period accounts for additional infantile cases. Persistent, high levels of viral replication in the eye and brain of the developing fetus produce encephalitis, ependymitis, and retinitis, a pattern similar to that seen in patients with opportunistic CMV infection in the setting of HIV infection. Pathologically, encephalitis occurs in a periventricular pattern and may cause polymicrogyria and hydrocephalus. (Figure 59B.2). CT scans characteristically show periventricular calcifications. Symptomatic infants usually have hepa to splenomegaly and thrombocytopenia in addition to CNS findings. Mild or subclinical congenital infections may also manifest later in childhood as sensorineuronal deafness or developmental delay. Congenital human CMV infection is the most common, nonhcritablc cause of hearing loss in the United States,

Although congenitally infected infants will excrete CMV in their urine throughout the first year of life, diagnosis of congenital CMV infection depends on the detection of virus by culture in urine, saliva, or CSF during the first 3 weeks of life. The clinical utility of CSF PCR for CMV

in the setting of congenital infection is being investigated, particularly with respect to correlating neurological outcome with CSF viral load. CMV inclusion-bearing cells are found in affected organs (Plate 59B.II) and in stained preparations of urinary sediment and saliva. Diagnosis of acute CMV infection in immunocompetent adults usually relies on serologic methods, specifically the detection of CMV IgM antibody because infected patients may intermittently excrete virus in their urine for years following infection, and CMV lgG persists for life following primary infection.

In a study evaluating the efficacy of intravenous ganciclovir therapy (4-6 mg/kg every 12 hours for 6 weeks) in neonates with symptomatic congenital CMV infection, quantitative excretion of CMV in the urine decreased initially, but returned to pretreatment levels after cessation of therapy. Hearing improvement or stabilization occurred in 16% of treated infants at *6* months or later posttreatment. However, a large proportion of treated infants developed cytopenias on prolonged ganciclovir therapy (Whitley et al. 1997).

CMV in Immunocompromised Adults. CMV encephalitis in the transplant patient (Tsclis and Lavi 2000) presents as a nonspecific febrile encephalopathy, with or without focal features. AIDS associated CMV encephalitis presents either as microglial nodular encephalitis wirh acute onset of confusion and delirium or as a more slowly progressive ventriculocncephalitis, characterized by confusion and cranial nerve palsies. There is a broad pathological spectrum of CMV infection of the brain in AIDS patients, ranging from scattered microglial nodules, to widespread necrotizing ependymitis and perivascular infiltrates, to necrotizing leukoencephalopathy. The broad spectrum of disease is likely related to variable degrees of immunosuppression resulting in wide ranges of viral load, as well as synergistic interactions between CMV and HIV.

Diagnosis of CMV encephalitis can be difficult, particularly by serological resting, because CMV antibody titers can fluctuate spontaneously. Serological and virus detection methods are currently being extended to focus on quantitation of viral burden (particularly in peripheral blood leukocytes) for patients with persistent infection, as well as to help predict which immunosuppressed patients might develop end-organ disease. CMV PCR has a reported sensitivity of 82% and specificity of *99%* in AIDS patients with CNS disease due to CMV (Cinque et al. 1997). Findings on brain imaging are poorly characterized in nonimmunocompromised and transplant patients. In AIDS patients, a wide spectrum of imaging results has been reported, ranging from normal to generalized atrophy, periventricular abnormalities, and focal, discrete lesions, often involving white matter. MRI is more sensitive than CT and most characteristically demonstrates periventricular increased signal on T2-weighted images and ependymal enhancement on TI-weighted images.

Ganciclovir, foscarnct, and cidofovir are all antiviral agents with efficacy against CMV, However, the clinical response of AIDS-associated CMV encephalitis to antiviral drugs appears to be poor. The response to peripheral nerve and nerve root infection with CMV appears to be better. Systemic and retinal CMV infections arc known to respond very well to ganciclovir and foscarnct, either alone or in combination. In immunocompromised patients with CMV retinitis, encephalitis, or myeloradiculitis, antiviral therapy should be instituted with intravenous ganciclovir, 5 mg/kg every 12 hours for 2 weeks of induction, followed by maintenance dosing of 5 mg/kg per day, 5 days per week. The addition of foscarnct should be considered. There is less clinical experience with cidofovir, which is currently licensed only for treatment of retinitis. Recently, valganciclovir, an orally administered prodrug that is rapidly hydrolyzed to ganciclovir, has been shown to be efficacious for the treatment of CMV retinitis (Martin et al. 2002). An extended discussion of CMV treatment in HIV-infected patients is presented in Chapter 59E. Because of the frequency of subclinical infection in the adult population, bone marrow transplant recipients should receive human CMV hyperimmune globulin as prophylaxis (see Table 59B.8).

Epstein-Barr Virus (EBV)

Primary EBV infection may be asympromatic, present as a nonspecific febrile illness, or classically, as the infectious mononucleosis syndrome with cervical lymphadenopathy, exudative pharyngitis, and splenomegaly. Nervous system disease occurs in less than 1% of EBV infectious mononucleosis cases and can manifest as meningitis, encephalitis, cerebellitis, transverse myelitis, optic neuritis, cranial neuropathy, Guillain-Barre syndrome, or as small fiber sensory or autonomic neuropathy syndromes. As a B-cell transforming virus, EBV is also associated with the development of CNS lymphomas. Detection of latent EBV nucleic acid has been demonstrated in the jaw, orbit, and CNS of patients with endemic and sporadic Burkitt's lymphoma, as well as in the CNS of patients with AIDS-associated CNS lymphoma.

The diagnosis of EBV is suggested by the presence of serum heterophile antibodies (monospot), although this is a nonspecific test that may be positive in other disease states such as hepatitis and lymphoma or in the presence of certain drugs. Specific diagnosis of CNS EBV disease requires the detection of serum and CSF EBV-specific antibodies. In serum, the presence of EBV Viral Capsid Antigen (VCA) IgM antibody is indicative of recently acquired, active infection. The presence of EBV VCA IgG antibody in the absence of VCA IgM and Epstein-Barr Nuclear Antigen (EBNA) antibodies is indicative of recent infection within the previous 2 months. The presence of EBNA antibodies indicates distant infection, and these antibodies remain positive for the lifetime of the infected individual.

CSF PCR for EBV is positive during the acute phase of illness in children with infectious mononucleosis and neurological complications such as transverse myelitis, meningoencephalitis, and aseptic meningitis. CSF PCR is negative in EBV-seropositive individuals in the absence of CNS infection. However, positive EBV PCR may be seen in patients with evidence of other viral or nonviral CNS infection, raising the possibility that these infections may trigger viral reactivation. EBV has been one of the most frequent agents associated with dual-positive CSF PCR testing and may not always correlate clinically with the presence of CNS infection known to be caused by this virus (Studahl et al. 2000). CSF PCR testing for EBV has been found to be nearly 100% sensitive as a tumor marker for EBV-related CNS lymphoma and has changed the way in which clinicians diagnose CMS lymphoma in immunocompromised individuals. EBV DNA may even be detectable in CSF before CNS lymphoma is clinically apparenr.

Immunomodulation with intravenous immunoglobulin may Improve EBV-associated small fiber sensory or autonomic neuropathies if treatment begins during acute disease. None of the currently available antiviral agents, including acyclovir, ganciclovir, and foscarnct, have significant activity against EBV. However, there are case reports describing successful treatment with ganciclovir of EBV meningoencephalitis following bone marrow transplantation. Vaccine and immune therapies are in development for treatment of these conditions, including the use of virus-specific cytotoxic T lymphocytes as prophylaxis for EBV lymphoproliferative disease in bone marrow transplant patients {Heslop and Rooney 1997).

Human Herpesvirus-Type 6 *(HHV-6)*

HHV-6 is a prevalent, E lymphotropic virus, causing a spectrum of diseases ranging from inapparent infection to disseminated, fatal disease. Exanthem subitum (or roseola) of infants or lymphadenopathy syndromes are the most common presentations of primary infection. HHV-6 genome has been demonstrated in CSF from children younger than 1 year of age who have febrile seizures and has also been seen in children with recurrent febrile convulsions with CNS involvement. However, primary infection may also rarely result in meningoencephalitis in immunocompetent children. Retrospective studies from Whitley's group indicated that approximately 6% of a series of children and adults with focal encephalitis had HHV-6 genome demonstrable in the CSF by PCR analysis. HHV-6 has increasingly been recognized as an opportunistic infection resulting in encephalitis in immunocompromised patients (Figure 59B.3), and can mimic HSV encephalitis. A possible role for HHV-6 in the etiology of multiple sclerosis (MS) has been suggested but remains unproven. (Caserta et al. 2001).

In a large study of immunocompromised (HIV-infected) patients, conducted to assess the diagnostic reliability of CSF PCR by comparison with biopsy or autopsy diagnoses, the most frequent false-positive herpesvirus detected was HHV-6. In another large study of mostly immunocompetent patients, detection of HHV-6 by CSF PCR did not always correlare clinically with the presence of a CNS infection known to be cause by that virus (Studahl et al. 2000). Additional large studies are necessary to determine

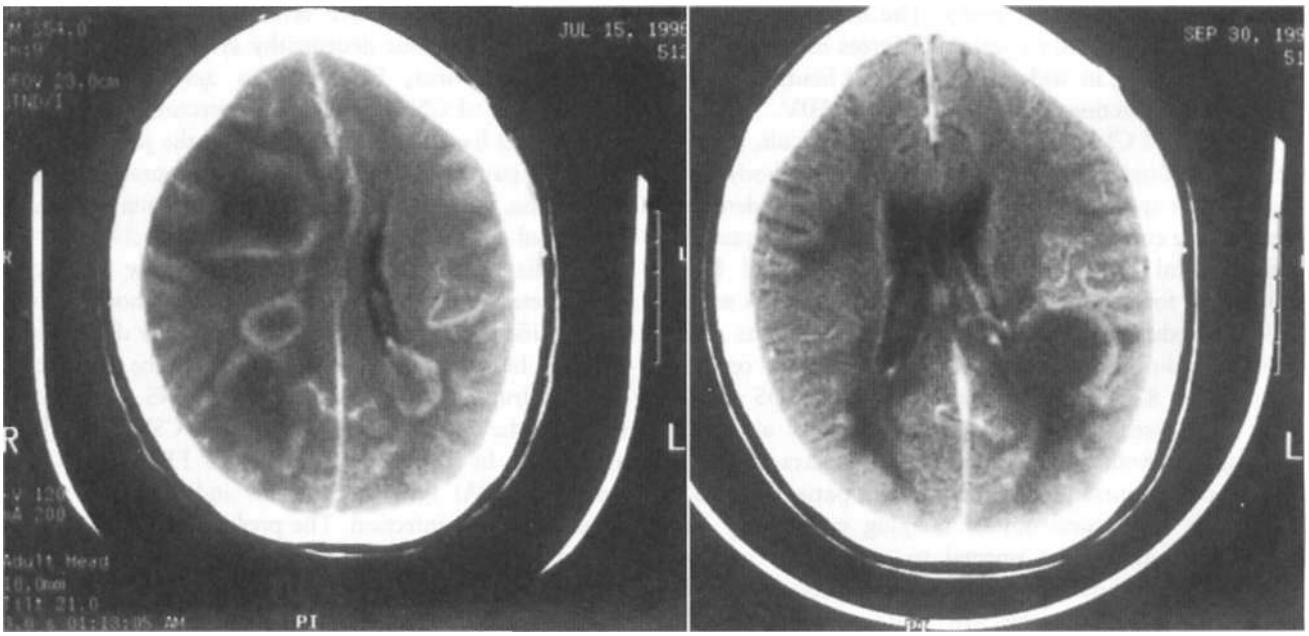

FIGURE 59B3 Concurrent human herpesvirus 6 and human immunodeficiency virus disease. Contrast CT scans showing multiple, ring-enhancing frontal, parietal, and occipital lesions. The second image shows parietal recurrence 3 months later. Pathology demonstrated perivascular lymphocytic infiltrates, demyehnation, and axonal sparing. (Courtesy S. Busono.)

PLATE 59B.I Hippocampal granule cell neurons in herpes simplex 1 encephalitis. Many of the nuclei contain acidophilic Cowdry type A intranuclear inclusions, which are surrounded by haloes and which marginate the nuclear chromatin. (Hematoxylin-eosin stain, x .350) (Courtesy R. Kim.)

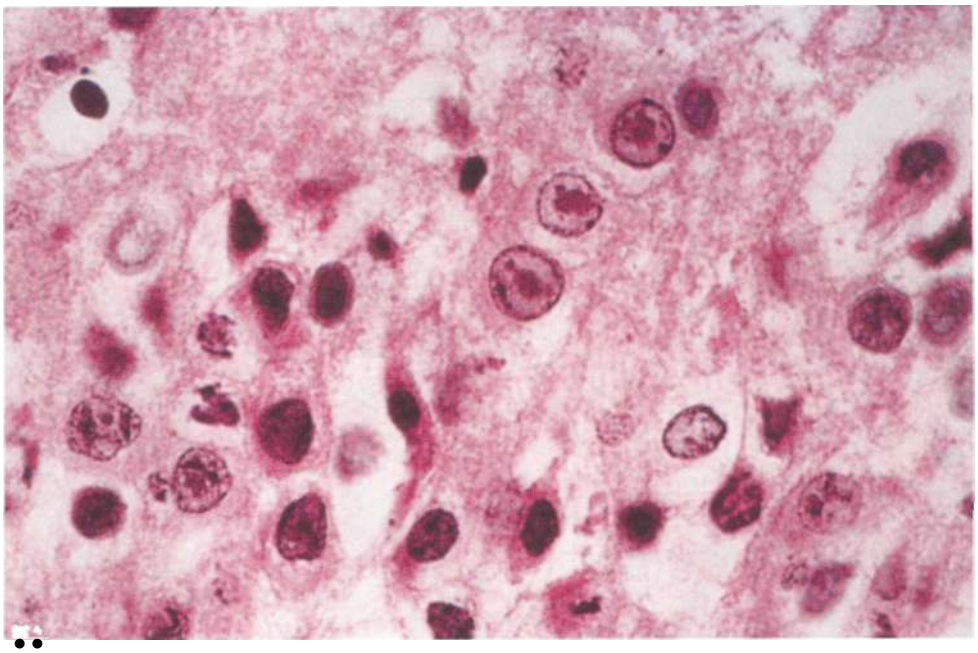

PLATE 59B.II Ballooned cell with eccentric nucleus in human cytomegalovirus encephalitis. An acidophilic Cowdry type A intranuclear inclusion body, with its surrounding halo, marginates the nuclear chromatin. The cytoplasm also contains granular inclusion material. (Hematoxylin-eosin stain, x 350) (Courtesy R.Kim.)

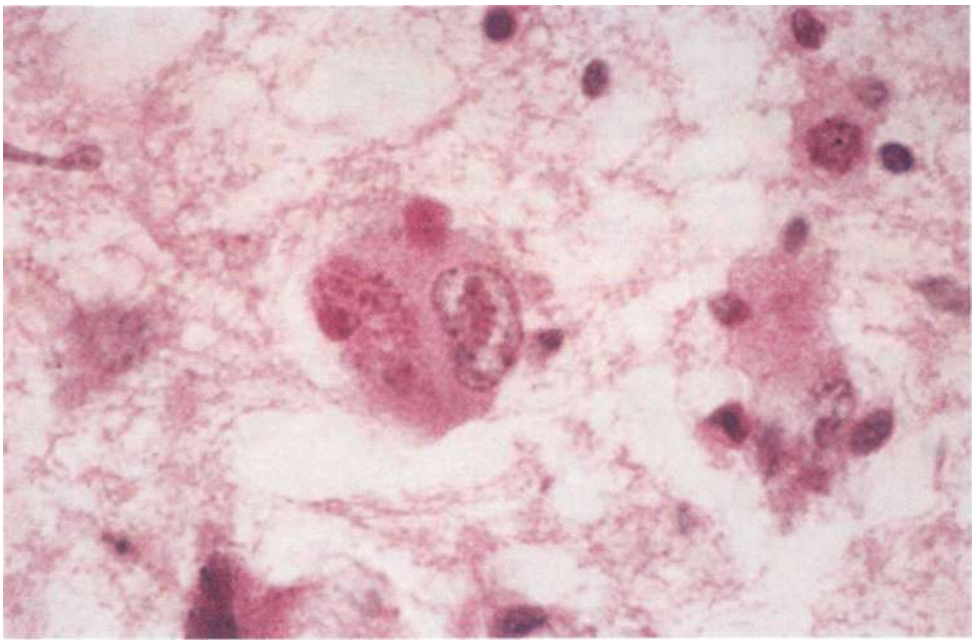

PLATE 59B.HI Hippocampal neurons in human rabies encephalitis. The cytoplasm of these neurons bears one or more rounded or oval Negri inclusion bodies. (Hematoxylin-eosin stain, x 350) (Courtesy R. Kim.)

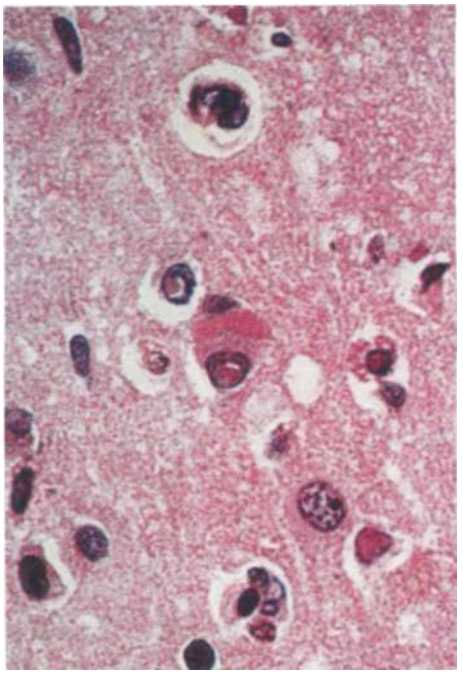

PLATE 59B.IV Cerebral cortex in subacute sclerosing panencephalitis. A pyramidal neuron contains both a Cowdry type A intranuclear inclusion and a cigar-shaped cytoplasmic inclusion, Cowdry A inclusions are present also in the nuclei of several nearby glia cells. (Hematoxylin-eosin stain, x 350) (Courtesy R. Kim.)

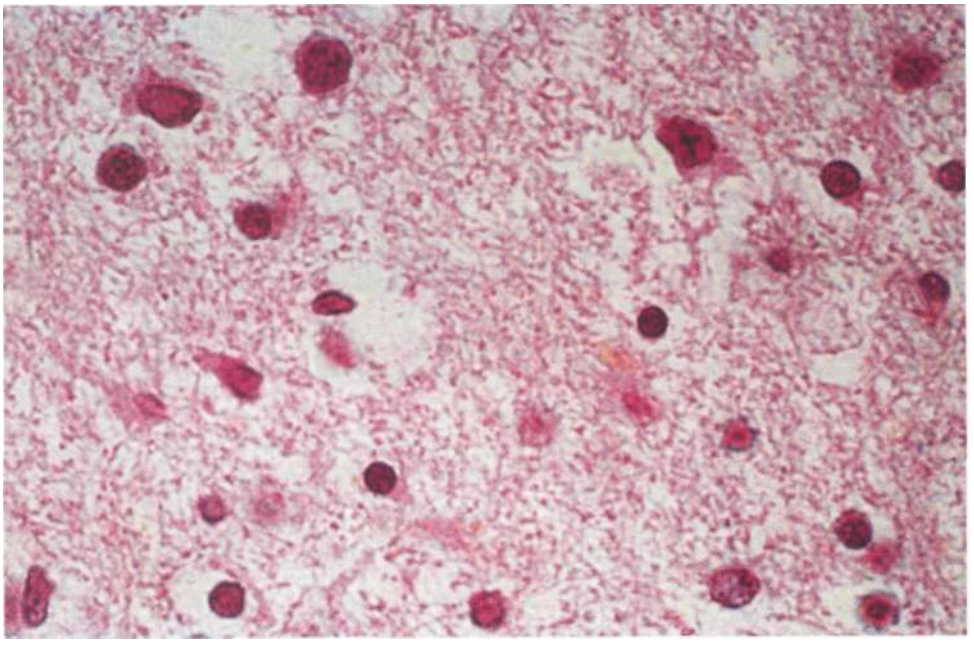

PLATE 59B.V Cerebral white matter in progressive multifocal leukoencephalopathy. Oligodendroglial cell nuclei are greatly enlarged and their nuclear chromatin replaced by glassy acidophilic material. (Hematoxylin-eosin stain, x 350) (Courtesy R. Kim.)

the reliability of positive CSF PCR results for HHV-6 in immunocompromised and immunocompetent hosts. The B variant of HHV-6, the variant most commonly isolated from immunocompromised patients, has a susceptibility to ganciclovir that is similar to the susceptibility of CMV in vitro.

Human Herpesviruses-7 and -8 (HHV-7 and HHV-S)

The role of HHV-7 in neurological disease is unclear, although detection of HHV-7 DNA in CSF and serum of children with roseola and encephalopathy has been reported. HHV-7 genome has also been detected by PCR in neoplastic brain tissue from patients with primary and metastatic brain tumors (Chan et al. 1999), but whether this represents reactivation from latency in an immunocompromised state, or contributes to the pathogenesis of tumor development is unknown. Encephalitis in immunocompromised individuals associated with HHV-8 has been described, but awaits additional confirmation (Said ct al. 1997). HHV-8 DNA has been detected in primary CNS lymphomas in some studies but not others.

Herpes B Virus (Cercopithecrine Herpes Virus 1)

Herpes B virus of Old World monkeys is highly pathogenic to humans, and infection is fatal in 70% of cases. Ocular, oral, and genital secretions of monkeys, as well as CNS tissues and CSE of monkeys, are potentially infectious. Disease is transmitted by direct contact with the virus, usually by animal bite or by virus-containing fomites. However, the first fatal case of B virus infection due to mucosal splash exposure was reported in 1998, leading to updated recommendations for prevention and treatment by the Centers for Disease Control (CDC) in 1999 (Cohen etal. 2002).

Fever, myalgia, herpctiform rash, meningismus, and early stage nystagmus or diplopia are followed by an ascending encephalomyelitis causing flaccid paralysis, urinary retention, and signs of CNS involvement, including seizures, progressive lethargy, and coma. Diagnosis is by wound or contact site culture and demonstration of increasing antibodies in paired acute and convalescent sera. Median nerve somatosensory evoked potential may identify early brainstem and cervical cord involvement and aid in differentiating R virus from HSV encephalitis.

Suggested preventative measures for primate workers include use of protective eyeware including side shields and a mask to protect from mucous membrane exposure. Should exposure occur, the most critical period for prevention of infection is within the first few minutes after exposure. Immediate cleansing of the affected skin surface should be undertaken by soaking or scrubbing the contact area with povidone-iodine, ehlorhexidine, or detergent soap for 15 minutes. Eyes or mucous membranes should be immediately irrigated with sterile saline solution or water for 15 minutes. Postexposure prophylaxis within 5 days of exposure can be considered using acyclovir, valacyclovir, or famciclovir. Based on animal studies, many experts prefer valacyclovir 1 g three times a day for 2 weeks. Symptomatic patients without CNS symptoms should be treated with either intravenous acyclovir, 15 mg/kg every 8 hours or intravenous ganciclovir 5 mg/kg every 12 hours, although some experts recommend ganciclovir for all symptomatic B virus infections due to the unpredictability of rapid and life-threatening brainstem involvement. When CNS symptoms are present, treatment should be initiated using intravenous ganciclovir 5 mg/kg every 12 hours. Treatment should be continued until symptoms resolve and the results of two sets of cultures are negative for B virus after being held for 10-14 days. Following IV therapy, most experts suggest that therapy should be switched to oral valacyclovir, famciclovir, or acyclovir in the dosages used for postexposure prophylaxis. Although no good data exist to aid in determination of when therapy should he discontinued, many experts recommend continuing trearmem for months to years, with regular cultures of the conjunctiva and oropharynx to assess for viral shedding.

Poliovirus and Other Nonpolio Enteroviruses

The enterovirus (EV) family comprises over 70 different serotypes, within the *Picornaviridae* family. They can be subgrouped into the polioviruscs, coxsackieviruses A and B, echoviruses, and the newer sequentially numbered enteroviruses. The most common forms of infecrion by any of the enteroviruses are subclinical or mild febrile illness. Collectively, the enteroviruses are the leading causes of viral meningitis for which a pathogen can be identified. However, severe neurological syndromes, including encephalitis and acute anterior poliomyelitis, are associated with several of these agents.

Poliovirus

Poliovirus, one of the most virulent members of the enterovirus group, is the agent of acute anterior poliomyelitis (infantile paralysis). The virus is worldwide in distribution (although wild-type poliovirus circulates only in six countries in Southeast Asia and Africa as of 2002), is more prevalent in temperate regions, and causes disease most commonly in late summer and early fall. Poliovirus is transmitted by fecal-oral contact and, during epidemics, also by pharyngeal spread. Three antigenically distinct types of poliovirus have been defined. All can cause paralytic disease through destruction of motor neurons in the spinal cord and brainstem.

Clinically apparent infection with poliovirus results in aseptic meningitis (8% of cases) or paralytic illness {1% of all cases). A 7- to 14-day incubation period is followed by

headache, fever, signs of meningeal irritation, drowsiness, and seizures in infants. Asymmetric flaccid weakness of limbs, diaphragm, or cranial nerve-innervated muscles develops within days and progresses, on average, for 3-5 days. Cercbellitis, transverse myelitis, and facial paresis also have been reported.

Diagnosis is suspected based on the clinical picture and presence of CSF pleocytosis and confirmed by serology, virus isolation, or PCR amplification of poliovirus RNA from CSF. In the CSF, polymorphonuclear cells predominate early, with a shift to lymphocytes after several days. CSF protein concentration is slightly elevated; levels of 100-300 mg/dL may accompany cases of severe paralysis. The differential diagnosis of nonparalytic polio includes viral meningitis caused by other pathogens. The differential diagnosis of an acute, pure motor neuronopathy with CSF pleocytosis is broad and includes West Nile virus, Japanese encephalitis virus infection, and carcinomatous meningitis. Bulbospinal disease with inflammatory spinal fluid is seen in the Russian spring and summer encephalitis variant of arbovirus infection and in rabies. The Guiilain-Barre syndrome is distinguished by antecedent rather than concurrent febrile illness, CSF albuminocytological dissociation, absent reflexes, more common facial nerve involvement, and nerve electrophysiological abnormalities consistent with proximal demyelination.

Approximately one quarter of polio patients develop progressive lower motor neuron weakness 30-40 years after acute polio ("the postpolio syndrome"). Atrophy, fasciculations, and electromyographic evidence of active denervation are found in previously involved muscle groups.

Treatment of poliomyelitis is supportive, with particular attention to ventilatory assistance. Mortality from paralytic poliomyelitis is less than 10%, but bulbar forms have a poorer prognosis, and mortality may approach 50%. Clinical and virologic improvement has been reported with pleconaril in several cases of wild-type and vaccine-associated paralytic polio (Rotbart et al. 2001).

The WHO has set 2005 as a goal for eradication of poliovirus from the globe. Great progress has been made toward this goal using aggressive vaccination campaigns. In 1988 there were 350,000 cases of wild-type polio occurring in 125 countries; as of 2002 there were approximarely 1400 cases of wild-type polio, with circulation restricted to only six countries in Southeast Asia and Africa. There have been no cases of circulating wild-type polio in the United States since 1979 and in the Western Hemisphere since 1991. Fot this reason, as of the year 2000, the Advisory Committee on Immunization Practices has recommended the use of inactivated (Salk, intramuscular) polio vaccine in the United States for the entire primary immunization series in the first year of life, as well as the booster dose prior to school entry. In areas of the world in which poliovirus is still endemic, primary immunization should be carried out with trivalcnt live attenuated (Sabin, oral) vaccine. The advantages of oral polio vaccine are ease of administration and induction of intestinal immunity. The disadvantage is the risk of reversion to neurovirulence and production of paralytic disease in vaccinees and contacts. Therefore, inactivated polio vaccine should always be used for vaccination of persons with immunodeficiency diseases, in which the risk of vaccine-associated paralytic polio from live attenuated vaccine strain is high. Vaccine-related cases of paralytic polio have included infants with unrecognized immunodeficiency who have received their first oral polio vaccine dose and immunocompromised patients who have been in contact with recipients of live attenuated oral polio vaccine.

Nonpolio Enteroviruses

The nonpolio enteroviruses may cause a wide spectrum of CNS and PNS disease, including aseptic meningitis, encephalitis, acute anterior poliomyelitis, acute cerebellar ataxia, peripheral and optic neuropathy, cranial polyneuritis, and epidemic myalgia. In neonates, encephalitis is generally part of an overwhelming sepsis-like illness, with up to 10% mortality. Congenital CNS defects are associated with infection acquired in utero. Infection of hypogammaglobulinemic patients commonly leads to progressive meningoencephalitis. Certain strains have also been associated with an acute motor neuron disease in association with epidemic hemotrhagic conjunctivitis.

Meningitis

Nonpolio enteroviruses are the most common cause of viral meningitis (Pallansch and Roos 2001). Over 75,000 cases of EV meningitis occut in the United States each year, and these also occur in a worldwide distribution. The strains most commonly isolated in aseptic meningitis are Coxsackie A9, B3-5, and echovirus 4, 6, 7, 8, 11, 18, and 30. Spread of infection is by fecal-oral and, rarely, respiratory routes. Outbreaks tend to cluster in the late summer and early fall and may be associated with pharyngitis and gastrointestinal symptoms, such as anorexia, vomiring, or diarrhea. Other findings suggestive of enteroviral infection include the cxanthem of herpangina or the rash of hand-foot-and-mouth diseases. Although EV is the most common cause of viral meningitis in the adult as well the pediatric population, children are epidemiologically over-represented as victims of enteroviral infection. Fortunately, EV meningitis occurring beyond the neonatal period in immunocompetent hosts is only rarely associated with severe disease or subsequent neurological deficits (Sawyer 2002).

Meningitis caused by coxsackievirus produces CSF cell counts typically up to 250 WBC per uL with 10-50% polymorphonuclear cells. Echovirus infections are associated with CSF pleocytosis from several hundred to greater than 1000 WBC per uL, 90% of which may be polymorphonuclcocytes in the first 24 hours of infection. Until

recently, recovery of enteroviruses was the primary means of establishing the diagnosis of CNS cntcroviral disease. Recovery of nonpolio EV from throat or rectal swabs is also suggestive, but not diagnostic, m .1 patient with viral meningitis because shedding from a previous, unrelated, F,V infection may be detectable for 1-3 weeks following infection in respiratory specimens and up to 6 weeks in stool specimens. The clinical utility of obtaining viral CSF culture is further limited by the amount of time required for EVs to grow (days to weeks), the relatively low sensitivity (65-75%), as well as the poor cultivability of some EV serotypes. The development of a reliable PCR for the detection of EV has been extremely useful in circumventing these problems (Ramcrs et al. 2000). PCR primers and probes are directed against the 5' nontranslatcd region of the viral genome, which is highly conserved among almost all cntcroviral strains. The newest generation of cntcroviral reverse transcriptase-polymerase chain reaction (RT-PCR) on CSF has >95% sensitivity and 100% specificity for known strains of EV. Conventional RT-PCR methods produce results within 24 hours, but more recently developed colorimetric assays, and real-time quantitative techniques can yield results in 4 hours. The availability of rapid turnaround EV RT-PCR should allow for more rapid diagnosis of this common illness and limit unnecessary hospitalizations, imaging procedures, and empiric antibacterial therapy.

Although treatment has been supportive to date, resolution of the atomic structure of EVs by x-ray crystallographic studies has led to the design of new antiviral therapy. These studies demonstrate a deep cleft or canyon in the center of each protomeric unit of the EV viral capsid, which engages specific cellular receptors on targer cells. The drug pleconanl was specifically designed to fit into this cleft and can block the cell/receptor interaction required for viral entry into the host. This drug may allow treatment of meningitis and encephalitis caused by EV and may be particularly useful in the case of more severe or overwhelming disease as in neonates and agammaglobulincmic patients. Clinical trials in childhood and adult meningitis demonstrated minimal improvement in symptoms, but the drug is available for compassionate release in more severe cases of EV disease, including vaccine-associated paralytic polio (Rotbart et al. 2001).

Meningoencephalitis

Although more commonly the etiologic agent in aseptic meningitis, EVs may also cause encephalitis, particularly in immunodeficient patients with hypogammaglobulinemia, and in neonates. Focal and generalized presentations of encephalitis have been reported. EV strain 70 has been implicated most frequently in instances of encephalitis. In neonates, meningoencephalitis is generally a component of an overwhelming sepsis-like illness, with up to 10% mortality. Infection of hypogammaglobulinemic patients leads to a chronic and progressive meningoencephalitis; these patients should be treated with IV inimnrniejolnilui therapy. Pleconaril, an antiviral therapy with activity against EVs (described earlier), has become available and can be used in neonates and immunodeficient patients on a compassionate use basis.

Epidemic Conjunctivitis and Acute Motor Neuron Disease

Enterovirus type 70 is the etiological agent of a syndrome of conjunctivitis and an acute motor neuron disease. Epidemic acute hemorrhagic conjunctivitis first appeared in Ghana, West Africa, in 1969 and spread across Africa, Asia, and Europe in 1970 and 1971 to involve tens of millions of people. The eye disease was characterized by severe eye pain, photophobia, blurred vision, and varying degrees of subconjunctival hemorrhage. In a minority of patients, usually young men, a neurological (polio-like) phase developed 2 weeks after the conjunctivitis as acute asymmetric hypotonic or flaccid weakness of the lower extremities. Isolated facial nerve palsy, upper limb weakness, radicular, myelopathic, dysautonomic syndromes, or multiple cranial neuropathies were also reported. Acute hemorrhagic conjunctivitis surfaced again in 1981 in many of the same countries, in French Polynesia, and in other Pacific Islands; was imported to the United States; and spread among household contacts. A similar disease caused by enterovirus type 71 has occurred in Bulgaria and moved around the world. The other agent of epidemic hemorrhagic conjunctivitis, coxsackie A24, has not been associated with an acute motor neuron disease. These are highly contagious viruses for which there is no specific antiviral treatment, underscoring the importance of surveillance, public health measures, and sanitation in limiting disease,

Enteroviruses and Amyotrophic Lateral Sclerosis

Viruses have been proposed to play a potential role in the pathogenesis of amyotrophic lateral sclerosis (AI.S) because of the predilection of viruses such as polioviruses for motor neurons and some climcopathological similarities between ALS and poliomyelitis. A report describing detection of echovirus 7 sequences by RT-PCR in formaldehyde-fixed spinal cord samples suggested a possible association between persistent enterovirus infection and ALS (Berger et al. 2000). However, subsequent studies have not confirmed this finding (Walker et al. 2001).

Arboviruses

The term *arbovirus* (ffrthropod-frorne *virus)* is a general term for viruses transmitted to humans by mosquito and

tick (arthropod) vectors. Arboviruses exist in nature in complex cycles involving birds and mammals, which serve as reservoirs of disease. When transmitted to humans, arboviruses can cause fever, headache, meningitis, and encephalitis. Arboviruses comprise a group of over 500 RNA viruses, of which > 100 are known ro infect humans. The three taxonomic families into which arboviruses are divided are togaviruses (subdivided into flaviviruses and alphaviruscs), reoviruses, and bunyaviruses. Considered l()j;e[her, .;rbovimsrs represent lhe li'.uliii;; , ausc of encephalitis worldwide (Lowry 1997). The salient features of arboviral infections occurring in North America are summarized in Table 59B.9.

St. Louis Encephalitis Virus (Flavivirus)

St. Louis encephalitis (SLE) virus is a cause of late summer encephalitis outbreaks in North America. In epidemic years, SLE accounts for a significant number of viral encephalitis cases reported in the United States. SLE virus cycles between *Cutex* mosquitoes and birds each summer. In the United States, there are an average of 135 endemic cases per year, although during epidemics there can be thousands of cases.

The illness is characterized by febrile headache only, aseptic meningitis, or encephalitis. Signs and symptoms of CNS infection progress over several days to a week. The incidence of encephalitis is higher in the elderly; in this population, case-fatality rates reach 30%. Season, place of residence, exposure, and presence of similar cases in the community are important considerations in the diagnosis. CSF cell counts are generally less than 200 WBC per uL, with lymphocytic predominance. CSF protein concentration is mildly elevated. Although the virus may be isolated from scrum or CSF, specific diagnosis usually relies on serological testing. IgM antibodies may be present in the CSF as early as day 3 of illness and are diagnostic. The slower evolution of neurological symptoms, the presence of generalised weakness and tremor, and the absence of focal findings and seizures favor a diagnosis of SLE over HSV encephalitis.

No specific antiviral treatment exists. Treatment, as for all the arboviral encephalitides, is supportive, with control of cerebral edema, hyperthermia, and seizures.

West Nile Virus {Flavivirus)

West Nile virus (WNV) was already one of the world's most widely distributed arboviruses, present in many parts of Africa, West Asia, the Middle East, Eastern Europe, and Australia, when it emerged in North America in 1999. l-'ili[1]. mm- people IVITI hospitalised with encephalitis or meningitis in late summer in the New York City metropolitan area, with seven resultant fatalities (Nash et al. 2001). Transmission occurs primarily by insect bite; however, person-to-person transmission through organ transplantation, blood and blood product transfusion, and intrauterine infection have been reported as of 2002. Mosquitoes of the genus *Culex* arc the principal maintenance vectors; wild birds served as the principal amplifying hosts for the New York epidemic. Concurrent epizootics with high mortality occurred in wild and exotic birds and horses. The rapid spread of the epidemic across the United States between 1999 and 2002 is causing concern that this virus has not only emerged, but also established itself as a major cause of viral meningitis and encephalitis in I he I iiiteJ States, with human cases reported in all but five states by the end of 2002. During the 2002 season, 4008 cases were reported, of which approximately 2500 cases presented as West Nile virus encephalitis (WNVF), resulting in 263 deaths. The 2002 WNV epidemic in the United States was the largest arboviral meningoencephalitis epidemic documented in the western hemisphere and the largest reported WNVE epidemic ever. West Nile should be included in the differential diagnosis of encephalitic illness in the summer and fall, particularly in patients with associated lower motot neuron weakness,

Most human infections are completely asymptomatic. Following an incubation period of 3-14 days, illness presents as a nonspecific febrile illness in approximately 20% of infected persons. One in 150 infected persons will develop encephalitis and/or meningitis, and the elderly (>50 years) are at most significant risk for severe neurological disease and death. The high frequency of associated motor weakness in patients with WNVE is a characteristic feature of nervous system involvement and has been reported in nearly 60% of cases. As illustrated by the New York epidemic, in which a large proportion of patients had some degree of associated weakness, patients may be flaccid, a reflex ic, or have milder weakness with diminished reflexes and cranial neuropathies (Tyler 2001). Nerve conduction studies show axonal or demyelinating neuropathy. More recently, it has been recognized that the bulk of cases preventing with weakness have a clinical and pathological picture more consistent with a poliomyelitis-like involvement of anterior horn cells, rather than Guillain-Barre type illness. The case fatality among hospitalized patients is approximately 12-14%.

Diagnosis is best achieved by detection of IgM antibodies in CSF and/or IgM and IgG antibodies in serum. CSF PCR is less sensitive than serological studies, although when positive, it is diagnostic, WNV may be isolated from serum, blood, and CSF early in the febrile stage and from brain tissue. Currently, commercial testing for WNV-spccific antibody is limited. Because of potential cross-reactions with antibodies to other flaviviruses (yellow fever, dengue, Japanese encephalitis antigen-complex members), experience in test interpretation is important, and positive tests should be confirmed by experienced laboratories such as the CDC and/or local public health departments (Marfan and Gulber 2001). Neuroimaging is often unremarkable, although meningeal and periventricular enhancement has been reported using MRI. CT scan is usually normal,

Table 59B.9: Details of North American arboviruses

Agent	*Geographic distribution*	*Reservoir*	*Vector*	*Season*	*Group affected*
Eastern equine	Atlantic and Gulf coasts, Great Lakes region	Birds	Mosquito	June-Aug	Children
\\ estern equi"t'	Western U.S. and Canada	Birds and small m a in in a Is	Mosquito	June-Sept	Infants, adults >50 ye
Venezuelan equine	Texas and Florida	Horses, small animals	Mosquito	Rainy season May-Sept	Adults
St. Louis	Throughout U.S.. but greatest prevalence in Texas, Florida, and Ohio-Mississippi River Valley	Birds	Mosquito	June-Aug	Adults >50 years
California (La Crosse)	Midwest and Northeast U.S., Southern Canada	Chipmunk, squirrel, small mammals	Mosquito	June-Sept	Children
West Nile virus	Throughout U.S.	Birds	Mosquito	June-October	All ages, adults >50 with severe disease
Powassan	North Central U.S., Eastern Canada	Squirrel, porcupine, groundhog	Tick	Spring /SuiniTU'r	
Colorado tick fever	U.S. and Canadian Rocky Mountains	Chipmunk, squirrel, rodent	Tick	March-Sept	Children and adulrs

Treatment of WNV encephalitis is supportive, but clinical response to intravenous immunoglobulin (1VIG) was reported after administration of an immunoglobulin preparation contained high titers (1:1600) of anti-WNV antibodies (Shimoni ct al. 2001), Unfortunately, the batches of IVIG currently available in the United States do not contain significant titers of WNV antibody and would therefore presumably be of limited benefit. Clinical trials are needed to determine optimal therapy for this disease.

laj'.uir-;f Encephalitis Virus Ehwirtrus) JEV)

JEV is widely distributed in Asia, through Japan, China, T:rv, .in, Korea, [he far Eastern former Soviet Union, Southeast Asia, and India. Worldwide, JEV infection is the most important cause of arboviral encephalitis and produces the greatest number of deaths worldwide each year. The virus cycles between *Culex, Aedes,* or *Anopheles* species of mosquitoes; pigs; and birds. Recently detected in Northern Australia, JE virus may soon become endemic on that continent as well (Mackenzie et al. 2001).

Following an incubation period of 6-16 days, patients may present with a febrile headache syndrome, aseptic meningitis, or encephalitis. The encephalitic form is characterized by a 2- to 4-day viremic prodrome of headache, fever, nausea, vomiting, dizziness, drowsiness, and abdominal symptoms in children, progressing to meningoencephalitis with signs of cortical, subcortical, extrapyramidal, bulbar, cerebellar, and spinal cord involvement. Excitability or delirium, seizures, hyperthermia, expressionless facies, axial rigidity, limb tremors and other involuntary movements, erratic eye movements, cranial nerve palsies, ataxia, limb paresis, including lower motor neuron type weakness in the arms, and segmental sensory disturbance are reported. Prolonged fever, seizures, coma, respiratory complications, and high CNS virus load arc all associated with a poorer prognosis. The case-fatality rate is 30-40%. Sequelae include parkinsonism, seizure disorders, paresis, mental retardation, and psychiatric diseirdci s,

In JEV encephalitis, there is a CSF pleocytosls with 10-500 (rarely up to 1000) WBC per LII„ with an early polymorphonuclear predominance later replaced by lymphocytes. CSF protein is elevated (50-100 mg/dE). Specific diagnosis is made by demonstrating a fourfold increase in IgG antibodies between acute and convalescent sera, or IgM antibodies in serum and CSF. Virus isolation from the blood is infrequent, but may be isolated from the CSF in one third of patients. MRI studies may show areas of abnormal signal in thalamus and basal ganglia.

No specific therapy is available for JEV encephalitis. A formalin-inactivated vaccine with excellent efficacy in prevention of disease is available for travelers to and residents of endemic areas. The risk of disease among travelers has been estimated to be between 1 in 5000 and 1 in 20,000 per week of travel. Primary immunization is with two doses, separated by 7-14 days and a single booster dose at 1 year. Revaccination is recommended at 3-year intervals.

California Serogroitp of Viruses (Family Bunyaviridae)

The California serogroup contains several viruses with mosquito vectors, small mammal or deer hosts, and limited geographic range. Among this group, La Crosse virus is an endemic cause of summer encephalitis in the mid western United States. Most cases are in children, who have seizures and polymorphonuclear or mononuclear pleocytosis on CSF examination. Children who recover may have sequelae including seizures (10%), cognitive dysfunction (2%), or weakness (<2%). Jamestown Canyon virus (Michigan, New York) and Snowshoe Hare virus (Alaska, Canada, and the northern United States) are other bunyavituses that can cause viral meningitis.

Equine Encephalitis Viruses (Family Aiphaviridae)

Eastern equine encephalitis (EEE) is the most severe of the arboviral encephalitidcs, with a mortality of 50-70%. There arc approximately five cases per year in the United States. Younger children are more susceptible to EEE than adults, as judged by higher case-infection ratios and more severe sequelae. EEE is a summertime epizootic encephalitis in the eastern United States. A prodrome of fever, headache, nausea, and vomiting progresses rapidly to delirium and coma. Meningeal signs and excessive salivation are common. Children show opisthotonus, generalized rigidity, or focal findings. The CSF may be under increased pressure, with a pleocytosis of 500-3000 WBC per pL, with polymorphonuclear leukocyte predominance and elevated protein concentration. The virus cycles in *Culex* mosquitoes and birds in the eastern United States. FEE-related horse or pheasant deaths in an area often precede human cases (sentinel infection). Diagnosis is made by virus isolation from sera or CSF or the documentation of seroconversion.

Western equine encephalitis (WF.F) is seen in mid-]Line through late September in the western United States. WEE is less virulent, with 5-10% mortality. Seizures, altered sensorium, rigidity, tremor, and other involuntary movements are noted during disease. CSF contains few to 500 WBC per pL, with monocytes being the predominant cell type. Moior or intellectual sequelae are common in infants. There are an average of five cases per year in the United States, although no documented cases have occurred in the United States the last several years. Highlands J virus, a WEE complex virus, cycles between bird- and riosquuoes :n freshwater swamp habitats ol the Atlantic coast and is a rare cause of encephalitis in the eastern United States.

Venezuelan equine encephalitis (VEE) virus causes a febrile illness with myalgias progressing to encephalitis and

coma in a small proportion of cases. Epilepsy, paralysis, tremor, hallucinations, and emotional lability may persist as permanent sequelae in children, and occasional cases of residual epilepsy or tremor have been reported in adults. Outbreaks have accompanied equine epidemics in Venezuela and other northern latitude areas of South America. Other favored ecological zones are tropical or subtropical forests of both Americas. Because the clinical presentation of Venezuelan equine encephalitis infection is rarely overtly encephalitic, the diagnosis may be missed unless recent travel in an area of disease activity in tropical America is taken into account. Both saliva and blood are infectious early in the disease.

A vaccine combining EEE, WEE, and VEE antigens has been used to protect laboratory workers or others in high-risk occupations, bin is nol general y offered In individuals not at high risk.

Colorado Tick Fever Virus (Orhi'virus)

Colorado tick fever virus causes a self-limited viral meningitis in persons exposed to wood ticks in the Rocky Mountains in spring and summer. The illness is classically biphasic, with an initial period of symptoms lasting 3 days, followed by a 3-day period of interim improvement, then relapse of symptoms for an additional 3-5 days. Diagnosis is made by serological detection of antibodies and, less commonly, virus isolation from blood.

Powassan Virus (Flavivirus)

Powassan encephalitis has been reported in Russia, Canada, and the United States. The virus cycles between ticks and small mammals. Powassan virus has been called the most herpes-like of the arboviruses because of the temporal lobe involvement noted in several cases. Neurological sequelae occur in an estimated 35% of survivors, ("Outbreak of Powassan encephalitis" 2001).

Modoc Virus (Flavivirus)

Modoc virus has caused viral meningitis in an individual exposed to deer mice in Modoc County, California. Virus has been isolated from the same rodent species in Oregon, Montana, and Alberta, Canada.

Murray Valley Encephalitis Virus (Australian X Disease; Flavivirus)

Murray Valley encephalitis virus has caused epidemics in Australia, primarily the Murray Valley region of New South Wales and Victoria, and sporadic cases in New Guinea. Outbreaks occur in summer months after years of heavy rainfall. The virus cycles between *Culex* and *Aedes* mosquito species and large water birds. Surveillance of virus activity in mosquitoes and birds, and targeted insect control efforts are practiced in areas of recurrent epidemics.

A 2- to 5-day viral prodrome is followed by rapid progression to ,u: eneephahtic illness, Most patients are in a coma when first examined. Treatment is supportive. Neurological sequelae are seen in 40% of milder cases and all patients who recover from coma. These include cognitive impairment, paraplegia, or ataxic gait.

Tick-Borne Encephalitis Virus (Flavivirus)

TBE occurs over a wide area of Europe and the former Soviet Union, corresponding to the distribution of ixodid tick vectors. Central European encephalitis virus and Russian spring-summer encephalitis virus, subtypes of the same virus, cycle between ticks and several wild rodent species and domestic livestock. Transmission also occurs by consumption of unpasteurized goat's milk.

The Central European form is a biphasic illness with systemic febrile illness followed by second-stage aseptic meningitis, encephalitis, myelitis, or radiculitis; there is a case-fatality rate of 1-2%, Russian spring-summer encephalitis is an indolent or more protracted febrile illness progressing to a meningoencephalitis, with a case-fatality rate of 20%. Neurological sequelae occur in 30-60% of survivors of Russian spring-summer encephalitis, particularly a bibrachial paresis. Serum antibodies arc usually present by the time neurological disease appears. Vaccines and TBE-immunoglobulin for preexposure or postexposure prophylaxis are available, Immunoglobulin should be given within 4 days of the tick bite. The TBE vaccine is also protective against Omsk hemorrhagic fever, a tick-borne hemorrhagic illness with geographical overlap to Russian spring-summer encephalitis.

Louping lit Virus (Flavivirus)

Louping ill was first recognized as a neurological disease in sheep in Scotland in the late 1800s. The virus is distributed among several domestic livestock species in the United Kingdom and spreads to humans by tick bites or to abattoir workers or veterinarians by direct exposure ro sick sheep. The human illness is biphasic, with an initial influenza-like illness followed by remission, and then a meningoencephalitis. Diagnosis is by CSF virus isolation or high antibody titers in the CSF. The western subtype TBE vaccine may confer cross-protection. Negtshi virus (flavivirus), antigenically related to louping ill, is a recognized cause of encephalitis in Japan and China.

Kyasanur Forest Disease Virus (Flavivirus)

Kyasanur Forest disease is a tick-borne biphasic illness in which an initial hemorrhagic fever is followed by remission and then meningoencephalitis. A formalin-inactivated

vaccine is in use in the Mysore state of India, its endemic area.

Rocio Vims (Flavivirus)

Rocio virus caused an encephalitis epidemic in the Sao Paulo state of Brazil in 1975-1976. The case-fatality rate was *4%.* Sequelae, including cerebellar, motor, and neuropsychiatry signs, were reported in 20% of survivors. The virus is presumed to cycle between *Aedes* mosquito species and wild birds.

Rift Valley Fever Virus (Bunyavirus)

Rift Valley fever is usually an influenza-like illness, but hemorrhage, hepatitis, meningoencephalitis, and retinitis are reported. Common complaints are of fever, headache, retto-orbital pain, and loss of vision. Macular and petimacular retinitis, with retinal hemorrhage and edema are seen. The virus cycles between a wide variety of mosquito species and large domestic animals. The disease is found in Egypt, Sudan, East Africa, southern Africa, and Mauritania, West Africa, at times of high mosquito density related to wet seasons or new dam constructions. Formalin-inactivated vaccines have been developed to protect laboratory and veterinary personnel working in disease areas.

Rabies

Rabies is a significant cause of encephalitis worldwide, with nearly 100% mortality. The disease is enzootic in all continents with the exception of Australia and Antarctica, as well as certain island states or nations: Great Britain, Ireland, Iceland, Japan, New Zealand, Hawaii, the Bahamas, and Bermuda. Reservoirs of infection are bats, wild carnivores (skunks, foxes, raccoons, coyotes, wolves), and nonimmunized dogs. In the United States, the bulk of human cases are related to bat exposure. Human rabies cases are frequently linked to bat exposures, often in rhe absence of a recognized or documented bite or scratch. Rare nonbite (aerosol) exposures have also been documented. liiles in [lie head and face carry the highest risk of mortality.

The incubation period is usually from 1-2 months, but may vary from 1 week to several years. A prodrome of headache, fever, paresthesias, and pain at the site of inoculation is followed by an acute neurological phase, then coma. Cases in which hyperactivity dominates have been called *furious* rabies. Characteristic neuropathologies! intraneuronal inclusions (Negri bodies) (Plate 59B.III) and inflammatory changes are maximal in the brainstem and limbic system. Up to 80% of patients exhibit hydrophobia or aerophobia: spasms of pharyngeal and nuchal muscles lasting from 1-5 minutes, triggered by swallow attempts or tactile, auditory, visual, and olfactory stimuli. The spasms arc thought to be an exaggerated respiratory rract protective reflex. As the disease progresses, attacks increase in frequency and are accompanied by agitation, hallucinations, autonomic hyperactivity, and seizures. Body temperature may reach 105" to 107° F. Paralytic, myelitic, or "dumb" rabies, accounting for 20% of patients, is characterized by paresthesias, weakness, and flaccid paralysis in rhe bitten extremity progressing to quadriplegia. Paralytic rabies is most often associated with bat rabies virus strains,

The diagnosis of rabies should be entertained in any patient with a history of exposure and clinical picture of agitated or paralytic encephalitic illness. When no history-can be obtained, rabies should be included in the differentia] diagnosis of any encephalitis progressing rapidly to coma, particularly if the patient has been to an endemic area. Othet differential diagnostic considerations include intoxications, postvaccination encephalitis, tetanus, which has a shorter (<2 week) incubation period and normal spinal fluid, or rabies phobia (a hysterical response to an animal bite).

Intracerebral inoculation of mice with patient saliva, examination of skin from the face or neck within the hairline (nuchal biopsy), and corneal smears for the presence of rabies antigen by immunofluorescence arc the most rapid methods of antemortem diagnosis. The presence of neutralizing antibodies in the scrum and CSF of an unimmunized patient is diagnostic, but are not highly sensitive methods. Active disease produces high diets (>1:5000), which may be helpful for diagnosing acute rabies in previously immunized individuals. High titers also distinguish acute rabies from postvaccination encephalomyelitis associated with vaccines detived from animal neural tissue. PCR protocols for detection of viral sequences in brain specimens have been established (Wacharapluesadee and Hemachudha 2001).

Transdermal bites or scratches and mucous membrane contact with saliva from known reservoir animal species constitute exposure. In addition, any history of bat exposure, with or without recognized bite, should be con si tiered .. significant exposure, (SF and other body fluids from rabies patients are highly infectious, and appropriate precautions should be taken. Postexposure treatment and prophylaxis of rabies includes wound care and the immediate administration of multiple doses of rabies vaccine and of antirabies immunoglobulin to nonimmune individuals. Wounds should be cleansed with soap and water, followed by povidone-iodine. Human diploid cell rabies vaccine (HDCV), rabies vaccine adsorbed (RVA), or purified chick-embryo vaccine (PCEC) should be administered intramuscularly on days 0, 3, 7, 14, and 28 into the deltoid or anterolareral thigh muscles ("Human rabies prevention" 1999). Previously immunized individuals are given vaccine on days 0 and 3. Human diploid ceil vaccines, in use in many areas of the world, are improvements over the biological products derived from animal (usually sheep) neural tissue, which have caused Guillain-Barre syndrome or acute disseminated

encephalomyelitis approximately once per 2000 vaccinations and other less-severe neurological complications as often as once in 120 vaccinations. Human rabies immunoglobulin, 20 IU/kg, should be administered once as soon .is possible after exposure (up to 7 days after the firsl dose of vaccine) at the beginning of prophylaxis to patients who have not been previously vaccinated. As much of the entire dose as possible should be administered in the area of the wound, and the remainder should be administered intramuscularly at a site distant from the vaccine administration. Because human rabies immunoglobulin may partially suppress active production of antibody, the recommended dose should not be exceeded.

Local pubhc health officials should be consulted before postexposure prophylaxis is started to avoid unnecessary vaccination and to assist in proper handling of the animal, from which infection is suspected, if confinement or testing is appropriate. A dog or cat immunized within the previous 3 years is considered an unlikely source of infection, hut should he confined and observed for 10 days. If ill, the animal should be euthanized, and the brain is examined at a regional health laboratory by iminunohistochemistry for rabies virus antigen. Wild animals belonging to known infected species, based on area health department data, should be considered as rabid until laboratory test results are negative. Treatment can he stopped if the animal remains healthy for the 10-day observation period or if the euthanized animal is confirmed antigen-negative.

Preexposure prophylaxis is available to veterinarians, animal handlers, laboratory workers, or travelers to endemic areas. One-milliliter injections of human diploid cell rabies vaccine administered intramuscularly or 0.1 mL intradermally is given on days 0, 7, and 21 or 28.

Novel Zoonotic Diseases of Oceana

Since 1995, the emergence of a number of zoonotic diseases in Southeast Asia and the western Pacific has lead to the detection of several new viruses of bats and livestock causing encephalitis in man (Mackenzie et al. 2001}.

Hendra virus

In 1994-1995 in Australia, Hendra, a new paramyxovirus originally called *Australian equine Morhillivirus,* was noted to cause fatal respiratory disease in racehorses and their trainer and fatal encephalitis in two horses and a farmer. Hendra virus has now been described as causing acute pneumonia, aseptic meningitis, and delayed encephalitis. Spread from horse to man is thought to occur through direct contact with secretions and body fluids of infected animals. Fruit bars (flying foxes) have been implicated as a reservoir host by the presence of anti-Hendra virus antibodies,

Nipah Virus

Nipah virus, another new paramyxovirus most closely related to Hendra virus, was discovered in 1999 during the investigation of an outbreak of encephalitis in Malaysia, A major outbreak of disease in pigs and man from September 1998-April 1999 resulted in 265 infected persons, 105 deaths, and the eventual destruction of 1.1 million pigs. Clinical signs and symptoms include fever, headache, myalgia, drowsiness, stupor, and coma. Most patients had a history of direct contact with pigs. A bat reservoir was again suspected, based on serologic testing.

Australia Bat Lyssavirus

Australia bat lyssavirus was isolated from fruit bats in 1996 during the investigation of the deaths of two bat handlers with clinical syndromes consistent with rabies encephalitis. Australia bat lyssavirus, closely related to rabies virus, possibly fills an ecologic niche that might otherwise be occupied by rabies, which is no longer found in Australia, due to effective vaccination and animal quarantine measures.

Measles

Despite the availability of an effective vaccine, measles, a highly contagious respiratory-borne disease, is still an important cause of childhood mortality and blindness in developing countries, as well as in sporadic outbreaks in industrialized nations. Measles causes four major CNS syndromes: acute encephalitis, postviral encephalomyelitis, measles inclusion body encephalitis, and SSPE.

Acute Encephalitis and Postviral Encephalomyelitis

Fever, maculopapular rash, cough, coryza, and Koplik's spots are characteristic of acute measles. CSF pleocytosis and EEG slowing may be documented in otherwise uncomplicated cases, but true encephalitis is infrequent. Keratitis and corneal ulceration accompany measles in children with preexisting malnutrition, particularly vitamin A deficiency. High-dose vitamin A supplementation, a single intramuscular dose of 400,000 1U for all ages, is recommended in regions with vitamin A deficiency or measles fatality rates greater than 1%. Postinfectious encephalomyelitis follows an estimated 1 in 1000 cases, usually within 2 weeks of the rash.

Measles Inclusion Body Encephalitis

Measles inclusion body encephalitis is a rapidly progressive dementing illness, with behavior changes, myoclonus, refractory focal or generalized seizures, delirium, oleoma developing 1-6 months after measles exposure in

individuals with deficiencies in cell-mediated immunity, Patients are afebrile, and CSF analysis is normal. Treatment consists of supportive care, the reduction in immunosuppression if possible, and passive immunoglobulin therapy.

Subacute Sclerosing Panencephalitis (SSPE)

SSPE is a rare late complication of measles, caused by persistent, nonproductive measles virus infection of neurons and glia. The pathogenesis of SSPE is related to defective measles virus maturation in neural cells. Aberrant M (matrix) protein as well as other envelope proteins interfere with assembly and budding of infectious virus. The virus remains in intracellular form and spreads by cell-to-ccll contact.

SSPE has an annual incidence from under 0.1 cases to 5 or 6 cases per million in nonimmunized populations. In areas of high early-life measle attack rates, SSPE accounts •'or ,1 nnipnnioTl <il' clrk: :KioJ iiei:i'o(.1q!,enei'ati'.\> conditions. Children infected in the first 2 years of life arc at greater risk, and case-series consistently show SSPE to be more frequent in boys. The median interval between acute measles infection and SSPE is 8 years, with a range from 2-12 years. The early stage is marked by behavioral or personality changes and declining school performance. Myoclonus, seizures, spasticity, choreoathetoid or ballistic movements, ataxia, and chorioretinitis follow in the second stage, Optii atrophy, quadripaivsis, autonomic bisuhiliiy, akinetic mutism, and coma are -ecu in the linal s'.agc. The majority of cases follow a progressive downhill course to death within a few years, some temporarily plateau or improve, and possibly 5% remit spontaneously (Garg 2002).

At the time neurological symptoms occur, neurons and glia contain nuclear and cytoplasmic viral inclusion bodies (Plate 59B.IV), and high titer antimeasles antibody is found in both serum and CSF. The CSF/serum antibody ratio is consistent with high levels of intrathecal synthesis of measles antibody. CSF pleocytosis is absent, glucose is normal, and total protein is normal or elevated. Acute symptoms, together with increased intracranial pressure, are poor prognostic signs. The earliest MRI findings are high-signal intensity on T2-weighted images of gray and subcortical white matter in posterior portions of the hemispheres. During the second stage of disease, the EEG shows a pattern of generalized slow-wave complexes with a regular periodicity (Figure 59B.4). The complexes may last up to 3 seconds and occur at regular intervals, between 4 and 14 seconds, against a background of depressed activity.

Some patients have improved or stabilized after one or several 6-week treatments with intraventricular interferon-a through an Ommaya reservoir, starting at 10 U/in^2 body surface area per day, with daily increments, up to 106 U/m per day on the fifth day, 5 days per week, combined with oral isopdnosine (Inosiplex), 100 mg/kg per day. There have also been reports of response to intravenous ribavirin in combination with intrathecal interferon-a (Tomoda et al. 200 i). The laboratory endpoint of treatment is the eradication of detectable measles antigen from the CSF. Systemic (subcutaneous) interferon-a, in daily doses of up to 5 million units, has been used with intrathecal interferon-a, to simultaneously tteat the peripheral reservoirs of measles virus, lymphoid, and glandular tissue. Prolonged or repeated treatments carry the risks of meningitis, interferon-a induced encephalopathy, and interferon-a upper and lower motor neuron toxicity.

Immunization with attenuated live measles vaccine is recommended for infants between 12 and 15 months of age; measles vaccine is one component of the trivalent measles-mumps-rubella (MMR) vaccine. In areas where measles circulates widely, immunization is performed early, at 6 or 9 months. Fata! infection has followed measles vaccine in severely immunocompromised children, but

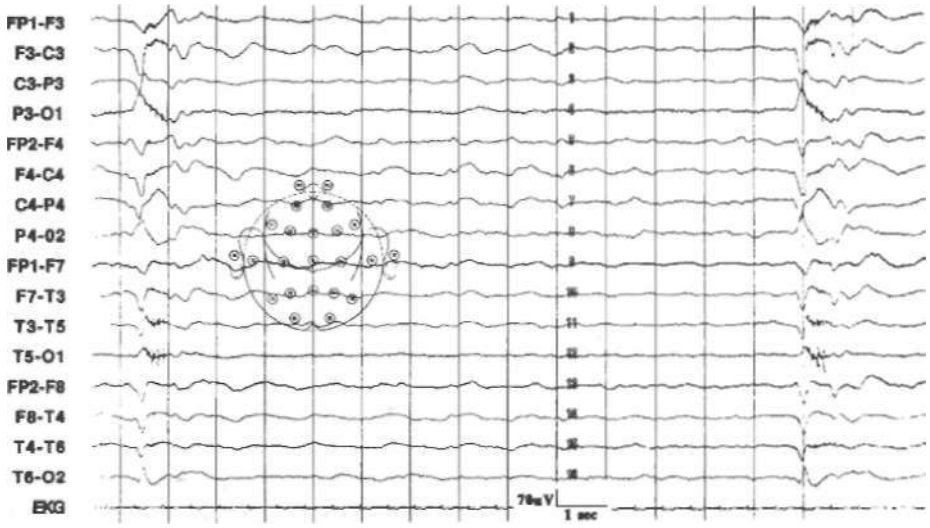

FIGURE 59B.4 Electroencephalogram of a 23-year-old man with subacute sclerosing panencephalitis showing generalized slow-wave complexes occurring approximately every 12 seconds. (Courtesy K. Nudleman.)

there is no epidemiological evidence that vaccination causes SSPE.

Rubella

Rubella virus infection in childhood or adult life is usually a mild illness. Maculopapular rash, fever, and lymphadenopathy characterize clinically apparent infection. Postinfectious encephalomyelitis is estimated to complicate 1 of 6000 cases, with onset 1-6 days after the appearance of the rash.

Gestational rubella, especially infection acquired during the first trimester, has serious consequences for the fetus. Eighty percent of children with a congenital rubella syndrome have some form of nervous system involvement. Signs in infancy include bulging fontancllc, lethargy, irritability, and abnormalities in muscle tone. CSF protein concentration is elevated, and the virus may be isolated from the CSF. Sequelae in survivors include mental retardation, sensorineural hearing loss, motor and posture abnormalities, cataracts, pigmentary retinopathy, and congenital heart disease. Congenital rubella syndrome has become rare in the United States since the institution of effective vaccination strategies in the 1960s (Reef et al. 2002).

An uncommon, late-onset rubella encephalitis, progressive rubella panencephalitis, may follow congenital rubella or natural childhood rubella. There is a prolonged asymptomatic period, followed by the onset of neurological deterioration during the second decade of life. Symptoms include behavioral changes, intellectual decline, ataxia, spasticity, and seizures. Although progressive rubella panencephalitis may exhibit some of the clinical features of SSPE, patients with progressive rubella panencephalitis tend to be older, have more protracted clinical courses, and lack generalized myoclonus or periodic burst-suppression IT(. patterns. Although .1 few spontaneous remissions have been reported, the typical course is one of progressive neurological decline, leading to death within 8 years. Sera and CSF from affected children contain antirubella IgG antibodies. Diffuse brain attophy may be found on MRI. Since institution of widespread administration of live attenuated rubella virus vaccine to preschool children (as a component of the MMR vaccine), the incidence of rubella and rubella-associated acute disseminated encephalomyelitis has drastically declined. Postexposure vaccination is not recommended,

Mumps

Mumps virus causes a mild childhood illness characterized by parotitis, but has the capacity for widespread invasion of visceral organs, the vestibular labyrinths, and the CNS. In unimmunized populations, mumps is a common cause of aseptic meningitis and encephalitis. Before introduction of widespread vaccination in the United States, mumps virus was the leading cause of viral meningoencephalitis in the United States, with over 200,000 cases reported in 1964. Since the introduction of effective vaccination strategies, there has been a steady decrease in the incidence of mumps virus infection, with an all-time low of 231 U.S. eases reported in 2001. The incidence of mumps meningitis and encephalitis varies with different epidemics from less than 1% to 70%. Mumps meningitis may precede parotitis and can occur without salivary gland enlargement in 40-50% of patients. In the remainder of cases, mumps meningitis or encephalitis develops approximately 5 days after the onset of parotitis. Postinfectious encephalomyelitis follows an estimated 1 in 6000 cases and develops 7-15 days after parotitis.

Seizures occur in 20-30% of patients with CNS symptoms, but follow-up EEGs are usually normal. Obtunded patients may have relatively mild EEC changes and recover with few sequelae. Complications include deafness from labyrinth membrane and sensory transducer damage, myelitis, or hydrocephalus following viral replication in choroidal and ependymal cells.

In mumps meningoencephalitis, there is a CSF pleocytosis of 25-500 WBC per |iL with lymphocytic predominance, although higher counts may occur occasionally, as high as 3000 WBC per ul„ CSF protein concentration is normal or moderately elevated and may include mumps-specific oligoclonal IgG; glucose concentration is depressed in 29% of cases. Mumps virus can be cultured from the CSF.

Mumps prevention is best achieved by vaccination with live attenuated virus at 12-15 months of age and an additional booster dose at 4-6 years of age; mumps vaccine is one component of the trivalent measles-mumps-rubella (MMR) vaccine. Infrequent reports of mumps meningitis had been reported from following vaccination with strains of mumps vaccine (Urabe strain) that are no longer in use in the United States. Recent studies evaluating the use of the current MMR vaccine (containing jeryl-Eynn strain) have not documented any association between vaccination and encephalitis, aseptic meningitis, or autism (Makcla et al. 2002).

Arenaviruses

Arenaviruses are rodent-borne viruses, with human infection originating primarily when humans come in contact with infected rodent excreta. The arenaviruses of neurological consequence are lymphocytic choriomeningitis virus (I.CMV), Lassa fever, and Argentine hemorrhagic fever viruses.

LGMV usually causes aseptic meningitis, but encephalitis has been diagnosed in 5-34% of serologically confirmed LCMV cases. CSF cell counts in excess of the 10-500 WBC

pi-r ul. range usually seen in viral meningitis may be present with LCMV. Ascending or transverse myelitis, bulbar syndromes, parkinsonism, and sensorineural bearing loss also have been reported. Hydrocephalus may arise as a sequelae of ependymitis or ventriculitis. LCMV infection of the fetus has produced hydrocephalus, diffuse parenchymal disease, mental retardation, and chorioretinitis.

Lassa fever, the West African viral hemorrhagic fever with high mortality, produces a multisystem disease with fevet, pharyngitis, hemorrhage, hepatic involvement, and shock plus neurological syndromes in 40% oi hospital ized patients. Imported cases have occurred in Europe, Israel, Canada, the United States, Japan, and Australia. Encephalitis with seizures, depressed consciousness, amnestic syndromes, dystonia or tremor, convalescent ataxic syndromes, and neuropsychiatry sequelae have been described. One third of all patients with Lassa fever develop hearing impairments, two thirds ot whom are left with significanl sensorineural hearing loss.

Ai:;cmme hemorrhagic fever may be accompanied b) acute ataxia. Arenaviral diagnosis is by viral culture and serology. lgM antibody to LCMV is present in serum, CSF, or both during acute meningitic disease. Ribavirin, a guanosine analogue, has proven efficacy in arenaviral hemorrhagic fever animal models. For the treatment of Lassa fever in humans, intravenous ribavirin is administered as a 2 g loading dose, followed by 1 g every *6* hours for 4 days, then 0.5 g thrice daily for 6 additional days. Anemia is the major side effect. Oral ribavirin is available through the CDC (Atlanta, Ceorgia) for the prophylaxis of contacts.

Other Hemorrhagic Fever Viruses

Arhoviral Agents of Hemorrhagic Fevers

Dengue (Flavivirus). In terms of size of epidemics and severity of disease, dengue fever and dengue hemorrhagic fever arc the most important arthropod-borne viral diseases of humans. Up to 100 million cases of dengue fever and 250,000 cases of dengue hemorrhagic fever occur each year in tropical Asia, Africa, Austtalia, and the Americas. Dengue virus cycles between humans and mosquitoes. *Aedes aegypti,* the most important vector, is a mosquito that has evolved to live in proximity to humans and breeds well in manufactured throwaway containers holding stagnant water. The expansion of *Aedes aegypti* throughout the Americas and the inadvertent import of another competent vector, *Aedes alboticus,* to the United States and Brazil from Asia, have established dengue on all continents with tropical and subtropical areas.

Dengue fever begins, after a 2- to 7-day incubation period, as a sudden febrile illness with headache, myalgias, arthtalgia, prostration, abdominal discomfort, and rash. Over the next 2-3 days the rash clears whereas the patient defervesces. A second, maculopapular rash appears, first on the trunk, and bleeding may follow. Dengue hemorrhagic fever is the severe form of disease, occurring in persons, usually children, previously sensitized by infection with a heterologous dengue serotype.

Neurological complications including encephalopathy, encephalitis, mononeuritis multiplex involving cranial and peripheral nerves, and Guillain-Barrc and Reye's syndromes have been associated with both self-limited (classic) dengue fever and dengue hemorrhagic fever (Solomon et al, 2000). Diagnosis depends on virus isolation from blood in the early stages or serological tests. The CSF may contain few (<30) or no WBC. The differential diagnosis of fever with rash, petechiac, or purpura includes malaria, typhoid fever, the viral exanthems (measles, rubella, enteroviruses), viral hemorrhagic fevers, syphilis, scarlet fever, meningococcemia, rickettsial diseases, gram-negative sepsis, drug reactions, and noninfectious causes of disseminated intravascular coagulation. Specific antiviral treatment has not been evaluated for dengue, and care is supportive. Salicylates are contra indicated because of the risk of hemorrhagic exacerbation and Reye's syndrome.

Yellow Fever (Flavivirus). Yellow fever occurs in tropical South America and sub-Saharan Africa. The risk of yellow fever returning to the Americas to produce large urban epidemics has increased due to the large numbers of susceptible people and successful expansion of the host range of the mosquito vector, *Aedes aegypti.* Vaccination with yellow fever 17kD, a live attenuated viral vaccine developed by the World Health Organization, has been associated with rare encephalitis cases in infants (within 30 days of immunization). Rare but severe cases of multisystemic illnesses and death following yellow-fever vaccination have recently been reported from Australia and the Americas. These events have caused revaluation of the vaccine's use. However, these reports should not deter visitors to endemic areas from being vaccinated (Monath and Cetron 2002). Because of the risk of encephalitis, the vaccine is con train dica ted for infants less than 4 months of age. A French vaccine, produced from infected mouse brains, was associated with a 1 % incidence of postvaccinal encephalitis and is no longer manufactured.

Filoviruses. Ebola and Marburg viruses are the two known members of the *Filoviridae.* Outbreaks of Ebolavirus occur in Africa, in regions of which the virus is endemic, and occurred most recently in Gabon (1996), Uganda (1998), Zaire (2000), and Uganda/Congo (2001) (Isaacson 2001). Both viruses are characterized by highly-efficient replication in liver, spleen, lymph nodes, GI tract, and lung, leading to fulminating hemorrhagic fever with severe shock and high mortality. Early headache and additional signs of a meningeal or encephalitic process are rapidly eclipsed by complications of hemorrhage, hypotension, hepatic failure, and disseminated intravascular

coagulopathy. Muscle necrosis caused by disseminated intravascular coagulopathy and intramuscular hemorrhage follows early myositis or muscle pain. A low-grade (<25 WBC) CSF pleocytosis has been reported in patients with Marburg virus early in their illnesses. The reservoir of Ebola virus is unknown. Treatment is supportive. No therapeutic role of convalescent sera or interferon has been established by controlled clinical trial. Blood and all body fluids are highly infectious.

Papovaviruscs and Progressive Multifocal Leukocnccphalopathy

Progressive multifocal lcukoencephalopathy (PML), a subacute, demyelinating disease of the CNS, is a result of infection of oligodendrocytes by an opportunistic papovavirus (Plate .59B.V). All well-documented cases have been caused byJC virus, though the JC virus, when contracted in early childhood, is not associated with illness. JC virus persists in the host and is reactivated in cases of diseases or medical treatments known to impair cell-mediated immunity: lymphoproliferative disorders, tuberculosis, sarcoidosis, prolonged immunosuppression, and inherited and acquired immunodeficiency diseases. Rare until the 1980s, **PML** is now encountered more frequently because of its association with AIDS. In a small number of cases, no underlying disease can be identified.

Onset is subacute, with signs and symptoms of multifocal, asymmetric white matter involvement. In non-AIDS-associated PML, early lesions tend to be in subcortical white matter of the occipital lobes, causing visual field deficits or cortical blindness. Motor weakness, behavior changes, cognitive impairment, cerebellar ataxia, dysarthria, and sensory abnormalities also are seen, whereas headache, seizures, and i:\itapyramidal syndromes are rarer. The disease progresses to dementia as the number of lesions increases.

CSF cell counts and protein levels are usually normal. Nenroimaging results help suggest the diagnosis. MR! studies show focal or multifocal lesions of subcortical white matter, sometimes involving the cerebellum, brainstem, and spinal cord, without mass effect or contrast enhancement. Fluid attenuation inversion recovery sequences, which remove CSF signals, are particularly good for demonstrating paraventricular disease (Figure 59B.5). White matter lesions are larger and more confluent than those of multifocal leukoencephalitis of VZV. Lack of CSF pleocytosis and an indolent course distinguish PML from paraviral and postviral encephalomyelitis. Brain biopsy establishes the diagnosis by showing characteristic changes, including oligonucleocytcs with enlarged nuclei that contain inclusion bodies, as well as viral particles and antigen or viral DNA. JC virus has never been cultured from CSF. *JC* virus DNA may be detected in CSF' using PCR amplification (Eggers et al. 1999). Finding JC virus DNA in CSF by PCR in the appropriate clinical setting is diagnostic of PML and obviates the need for bram biopsy. However, CSF PCR is less sensitive than biopsy, which may still be required to establish the diagnosis in PCR-negative cases.

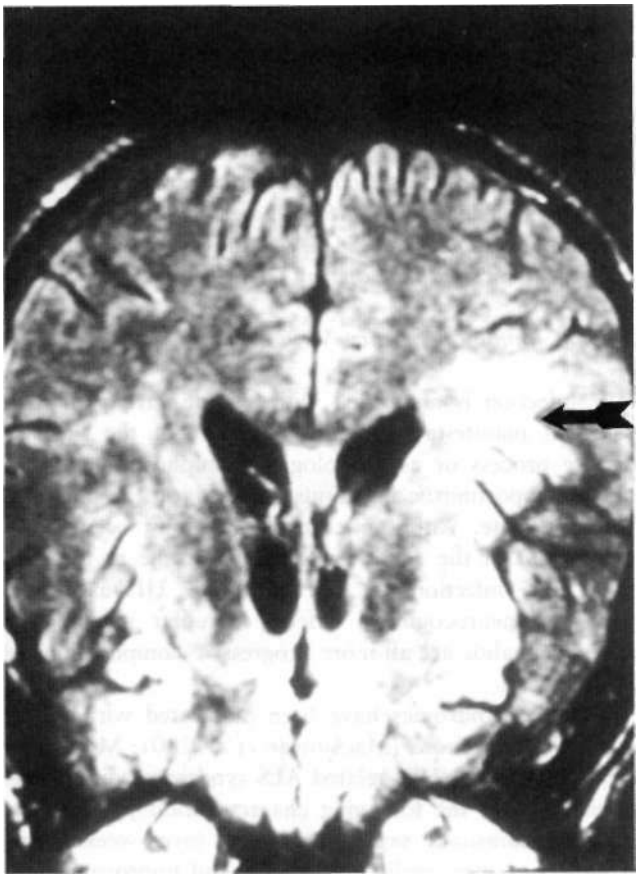

FIGURE 59B.S Progressive multifocal leukoencephalopathy. Coronal MRI fluid attenuation inversion recovery sequence, with arrow showing hypermtense temporal white matter. (Courtesy J. Hcaly.)

No specific therapy is available. Isolated reports of benefit from cytarabine were not confirmed in a randomized prospective clinical trial (Hall et al. 1998). Interferon-a has been reported to be of benefit in case reports but has not been tested in clinical trials. Cidofovir has also been suggested to be of benefit in patients with HIV-associated PML, although results in a recent prospective clinical trial were disappointing (Marra et al. 2002). Improvement of rhe immune deficiency with high intensity antiretroviral therapy has been reported to lead to regression of the PML. lesions.

Retroviruses: HIV and HT1.V-I and II

The *Retraviridae* is a large family of viruses, grouped initially by pathogenic features, but later revised on the

basis of nucleotide sequence and genome structure. Human T-cell lymphorropic virus (HTLV) types I and II belong to the HTLV-bovine leukemia group; HIV belongs to the lentivirus group. HTLV, the etiological agent of adult T-ce!l leukemia, was serologically linked to a progressive spastic paraparesis, known as *tropical spastic paraparesis fTSP),* in West Indies patients in 1985. Later, in Japan, a similar syndrome with elevated HTLV-I antibodies was named *HTLV-I associated myelopathy (HAM),*

Human Immunodeficiency Virus (HIV)

HIV infection is associated with a wide variety of neurological manifestations, either as part of the primary disease process or as neurological complications of secondary opportunistic infections occurring in the immunodeficient state. An aseptic meningitis may occur as a component of the acute retroviral syndrome at the time that HIV infection is first acquired. HlV-associated dementia, neurocognitive defects, vacuolar myelopathy, and encephalitis are all more progressive complications of HIV disease.

ALS-like syndromes have been associated with HIV-1 and H1V-2 infections (MacGowan et al. 2001; Moulignier et al. 2001). The HIV-related ALS syndromes differ from classic ALS in the following characteristics: younger age of onset, unusually rapid progression (over weeks), presentation as monomelic syndromes, and improvement or stabilization with highly active antitetroviral therapy. In most cases, ALS symptoms preceded the clinical diagnosis of acquired immunodeficiency syndrome (AIDS). Neurological manifestations of HIV infection ate discussed in detail in Chapters 59E and 59F,

Nonbuman Immunodeficiency Virus Retroviruses:

Human T-Cell Lymphocytotropic Viruses (HTLV-I and-Il)

HTLV-I is endemic in southern Japan, Taiwan, Okinawa, the Caribbean basin (including northeast South America), central and West Africa, southern India, and the Seychelles, In the United States and Western Europe, the incidence of HTLV infection is higher among intravenous drug users and homosexuals. Estimates show that 10-20 million people around the world are infected with HTLV-I. Most seropositive individuals are asymptomatic; less than 1% of infected patients develop spastic paraparesis. Spread of HTLV-I, as other retroviruses, is by sexual, parenteral, or vertical transmission. In the United States, all blood supplies have been screened for HTLV-I since **1988** (Osame et al. 1990).

With an incubation period of approximately 20 years, HAM is usually recognized in the fifth decade of life is .i progressive spastu paraparesis or myeloneiiroparhy. Occasionally, acute cases, resembling transverse myelitis, also occur. Neurological findings includi[1] lower iMivnmy weakness and spasticity that is usually symmetric, impotence, urinary and fecal incontinence, and generalized hyper-reflexia except in cases of concomitant sensory neuropathy. Inflammatory myosins, cerebellar ataxia, nystagmus, vertigo, deafness, optic neuritis, adult T-cell leukemia, uveitis (as vitreous opacities, iritis, retinal vasculitis), sicca syndrome, inflammatory arthropathy, and lymphocytic alveolitis may be present (Jacobson 2002), Conditions clinically similar to the subacute spastic paraparesis of HTLV-I include HIV-associated vacuolar myelopathy, idiopathic inflammatory conditions, hereditary spastic paraplegia, and toxic-metabolic disorders such as vitamin B_{12} deficiency, lathyrism (India), cycad poisoning (Pacific Islands), or konzo (Central Africa). HTLV-II is associated with atypical hairy cell Icukemias, mycosis fungoides, other lymphocytic or leukemoid malignancies, and a similar myelopathy.

Serological testing using an enzyme-linked immunosorbent assay, followed by Western blot confirmation, is used for diagnosis. False-positive serologic test results for syphilis and Lyme disease and antiphospholipid antibodies have been reported with HAM. The CSF contains mild elevations in lymphocytes and protein; elevated gamma-globulin fraction, oligoclonal bands, and CSF antibody levels, reflecting intrathecal synthesis. HTLV-I is usually not found in cells of the CSF, but has been detected in small populations of lymphocytes in the CSF by PCR, Spine MR] studies may show normal spinal cord, hyperintense signal abnormalities on T2-weighted images, or atrophy in late disease. The patterns of signal enhancement **tend to** be diffuse in HAM, in contrast to discreet or multifocal abnormalities seen in MS. Periventricular gray or white matter lesions may be seen also.

Treatments have been directed against the inflammatory components of disease. Primary therapy has been with initial intravenous injections of 1 g of methylprednisolone per day, followed by oral prednisone, 80 mg on alternate days for 2 months, then tapering by 10 mg each month for the next *6* months. Patients who fail prednisone therapy may receive intravenous immunoglobulin at 400 mg/kg per day for 5 days; repeated monthly for three or more cycles, intramuscular interferon-a, or plasmapheresis. The anabolic corticosteroid danazol, 400 mg thrice daily, has been reported to slow or reverse bladder symptoms. Because the progression of disease is most rapid during the first year, early treatment during this time has the best chance of improving outcome.

Influenza

Influenza virus has been associated with myositis, Reye's syndrome, acute cnccphalopathy/eneepbalitis, and post-influenzal encephalitis 2-3 weeks after recovery. The acute cncephalopa thy/encephalitis that has been reported

to occur within 1-3 days of onset of respiratory symptoms (associated with both influenza A and B) has a high rate of mortality/morbidity (Morishima et al. 2002). The postencephalitis syndrome, accompanied by an inflammatory spinal fluid, is transient, with full recovery in most cases. Oral amantadine or rimantadine are approved for use in treatment and prophylaxis of influenza A. Oseltamivir and zanamivir, two recently approved neuraminidase inhibitors, are effective against both influenza A and B and may have an additional advantage over amantadine and rimantadine, in that they rarely lead to selection of resistant isolates.

Thought to be a late sequelae of the 1917-1918 influenza pandemics, encephalitis lcthargica and postencephalitic parkinsonism have been historically linked to influenza. However, more recent studies using molecular biology techniques have failed to provide convincing evidence for this link. The postencephalitic parkinsonian syndrome was distinguished from idiopathic Parkinson's disease by its younger age of onset and the presence of hyperkinetic movements, oculogyric crises, respiratory tics, and behavior disorders.

Adenovirus

Adenoviruses cause acute respiratory disease in children and military recruits, conjunctivitis, hemorrhagic cystitis, and gastroenteritis. Meningoencephalitis or unilateral deafness Coincident with nasopharyngeal infection arc rare complications in normal hosts; fatal meningoencephalitis was reported in a bone marrow transplant patient. Diagnosis is by isolation of virus from extraneural sites or by serology.

Parvovirus

Acute infection with B19 parvovirus causes the febrile exanthema tons illness fifth disease (erythema infectiosum) in childhood, transient aplastic crises, particularly in immunocompromised and sickle-cell patients, and small joint chronic arthritis in adults. Chronic parvovirus infection has been found in patients with necrotizing vasculitis resembling polyarteritis or Wegener's granulomatosis. Neurological manifestations have included encephalitis with fifth disease, brachial plexitis, abnormal pupillary reflexes, and recurrent paresthesias. Immunocompromised patients should be treated with 1VIG to speed clearance of viremia.

Hepatitis Viruses

The viral causes of hepatitis are hepatitis A, B, C, D (delta), and E viruses. Hepatitis C and occasionally hepatitis B have been associated with a systemic vasculitic disease and mixed cryoglobulinemia, and hepatitis B has been associated with polyarteritis nodosa. Exrrahepatic manifestations of hepatitis C viral infection include cranial and peripheral neuropathies, mononeuritis multiplex, polymyositis, and anterior spinal artery stroke. A brain autopsy specimen of a patient with progressive encephalomyelitis with rigidity yielded hepatitis C viral ON A by RT-PCR, Interferon-a treats liver and renal involvement but has variable effects on the neuropathy. Plasma exchange may be of benefit for patients whose neuropathy is worsened by intcrferon-a.

Other Syndromes with Possible, but Unproven, Viral Etiologies

Viiiuisk Encephalomyelitis

Viliuisk encephalomyelitis is a biphasic illness of the lakut people of Siberia, in whom an acute meningoencephalitis is followed weeks or months later by a progressive dementia with pyramidal, extrapyramidal, or amyotrophic lateral sclerosis-like features. The acute febrile onset, CSF pleocytosis, epidemiology, geographical clusters, and inflammatory neuropathology have suggested an infectious etiology, but no agent has been identified.

Rasmtissen's Encephalitis

Rasmusscn's encephalitis is a rare inflammatory brain disease of unknown etiology that occurs predominantly in children and is characterized by subacute focal encephalitis of one hemisphere. Pathogenetic concepts have considered the role of viral infection, autoimmune antibodies, and autoimmune cytotoxic T lymphocytes as key factors contributing to this syndrome (Bien et al. 2002). Human CMV has been detected by PCR in brain biopsy specimens in some cases, and HSV-1 has been implicated in other cases, based on PCR and in situ hybridization studies. Nonetheless, a viral etiology for Rasmussen's remains unproven, and there are no appropriately designed and controlled studies establishing a benefit for antiviral therapy. Nonviral treatments have been directed toward the immunologic aspects of the disease, such as the presence of glutamatc receptor antibodies in some patients. Neurosurgical approaches, including hemisphcrectomy or subpial intracortical transection, may facilitate seizure control in some cases.

Progressive Encephalomyelitis with Rigidity

Progressive encephalomyelitis with rigidity is a syndrome of limb and trunk rigidity and stimulus-sensitive muscle spasms, cellular spinal fluid, and inflammatory pathology in cervical cord and brainstem. Early descriptions of

progressive encephalomyelitis with rigidity noted clinical and pathological similarities between this syndrome and spinal forms of encephalitis lcthargica described by von Kconomo. The pathology is consistent with either previous viral infection or an immunopathological process. Some cases are paraneoplastic or manifest antineuronal auto-antibodies and have been treated with plasmapheresis and prednisone. The differential diagnosis of progressive encephalomyelitis with rigidity includes other syndromes with involuntary motor symptoms: tetanus, stiff person syndrome, cramps, tetani, and hemifacial spasm. The electromyographic silent period is usually absent in patients with tetanus, but normal in progressive encephalomyelitis with rigidity.

Epidemic Neuromyasthenia (Benign Myalgic Encepbalo myelitis)

Descriptions of epidemic neuromyasthenia (benign myalgic encephalomyelitis) were of a syndrome of protracted fatigue, following an initial "viral'" syndrome that may include respiratory or gastrointestinal complaints, headache, muscle pain, and lethargy. Many of the described patients would meet modem diagnostic criteria for chronic fatigue syndrome. Several viruses have been suggested as etiological candidates, based largely on serological studies, including enteroviruses, herpesviruses, measles, and rubella viruses.

Chapter 59
Infections of the Nervous System

C. FUNGAL INFECTIONS

Madhuri Behari, Manjari Tripathi, and Ashok Verma

There are over 20,000 fungal species identified in the world. They form an integral part of our ecosystem and have been harnessed to make bread, beer, and antibiotics. Among them, over 250 fungal species have been reported to be pathogenic. From the common *Candida* infections to the deadly mucormycosis, fungal infections influence all levels of clinical practice (Luna 2000).

Fungi differ from bacteria in that they have a nucleus that is bounded by an organized membrane, they divide by mitosis, and they usually have a chitinous cell wall. The cell wall and a lack of mobility differentiate fungi from protozoa (Davis 1999). The absence of chlorophyll distinguishes them from most plants. Most pathological fungi are dimorphic and can exist in yeast and filamentous states, depending on growth conditions and temperature. In the yeast state, they are unicellular, are round to elongated, and reproduce by budding or fission. In the filamentous or mold state, they grow by extension of their tips forming tubular structures called hyphae, which often have septae that divide them into many segments. Spores arc the reproductive elements of these hyphae. Spores develop into yeast when infecting humans or animals but remain in the filamentous form when grown in vitro.

Fungi have varying predilection for involvement of the central nervous system (CNS). In general, fungi found in the meninges and the cerebrospinal fluid (CSF) are in the yeast phase (e.g., Cry/)(ococci«), whereas those causing brain parenchymal infection are in filamentous stage (e.g., *Aspergillus).* CNS fungal diseases are often difficult to diagnose and, as a consequence, are misdiagnosed or undiagnosed during life. Although many therapeutic options have been developed to treat superficial fungal infections, invasive and deep CNS fungal infections often prove tenacious to therapy.

EPIDEMIOLOGY AND CURRENT TRENDS

The incidence of CNS fungal infections varies greatly with the geographic location. For example, histoplasmosis is common in areas infested with bats, and cryptococcosis and histoplasmosis are common in patients exposed to birds. Histoplasmosis is commonly seen in the central United States (Ohio River Valley) and in restricted areas of the tropics. *H. dubaisii* is frequently found in West Africa. Coccidioidomycosis is mainly found in the southwestern United States (San Joaquin Valley) and in Central America, where it resides in the soil. Blastomycosis is endemic in Ohio ,uul Mississippi IVIMIIS in IIIL- United Si.; us. Oihci" fungi such as *Cryptococcus, Aspergillus,* zygomycetes *(Mucor),* and *Candida* species are more universally distributed. With respect to clinically recognized fungal CNS illnesses, *Cryptococcus* and *Candida* infections arc the most common, followed by *Coccidioides, Aspergillus,* and the zygomycetes. Fortunately, other fungi involve the CNS rarely. *Candida* and the zygomycetes rarely invade the deep viscera or CNS in the normal host and are therefore considered to be opportunistic in nature in immunocompromised hosts.

Recently fungal disease of the CNS has become increasingly common as a consequence of the acquired immunodeficiency syndrome (AIDS) epidemic and the use of

aggressive immunosuppressive regimens for cancer, and for solid organ and bone marrow transplantations. A study from the San Francisco Bay area found that more than 75% of patients who had invasive mycoses had serious underlying medical conditions that affected their immune systems (Rees et al. 1998). Only 9% were thought to be healthy at the time of the systemic fungal infection. The authors reported an overall incidence of invasive mycotic infections at 178 per million per year in 1992 to 1993, but the rate climbed to 5000 per million per year in individuals who were infected with the human immunodeficiency virus (HIV). The study found that the rates of invasive fungal infections per million per year for individual fungi were highest for *Candida* followed by *Cryptococcus* {73% and 66%, respectively). In another study from Australia, the two most common strains of *Cryptococcus* had different epidemiological features. *C. neoformans, var. neoformans* primarily caused meningitis in immunosuppressed patients, whereas C. *neoformans, var. gatti* infected healthy hosts. The reason for this difference is unclear. There is no specific epidemiological data available from the developing countries (Bharucha et al. 1999).

PATHOGENESIS

fungi produce disease by direct invasion, allergic phenomenon, or liberating toxins (e.g., ergotism resulting from rye ergot, which thrives on cereals, especially groundnuts, and trichothecene mycotoxins, which are misused in aerosol form as "yellow rain" in biological warfare to produce an illness characterized by weakness, ataxia, hypothermia, and shock).

Fungi are generally not invasive unless there are predisposing factors. They gain entry into the body mainly by inhalation of spores. This causes a localized lung infection, which may be asymptomatic or produce mild respiratory symptoms and is usually successfully terminated by a functional immune system. Failing this, the infection reaches the bloodstream and produces fungemia. If the fungemia overcomes the liosi's reticuloi'iicnilidi.i!, cellular, and humoral defense systems and penetrates the blood-brain or blood-CSF harrier, it reaches the brain parenchyma or the meninges. Fortunately, in the healthy individual, this seldom happens. Indwelling arterial or venous catheters can also he infected *(Candida),* forming a direct source for fungemia. Less common routes of infection are from the skin (sporotrichosis), the mouth, the gastrointestinal tract *(Candida),* and the nasal sinuses *(Aspergillus* and zygomycetes). Finally, direct inoculation of fungi into skull fractures or during neurosurgical procedures that place indwelling devices such as intraventricular shunts also predisposes to CNS infection. Certain conditions predispose a patient to infection with a particular fungus (Table 59C.1).

CENTRAL NERVOUS SYSTEM FUNGAL SYNDROMES

Myriad clinical presentations of the CNS fungal infections occur. Meningitis, meningoencephalitis, cerebral abscess, CNS granuloma, rhinocerebral necrotic mass, and base of skull lesions are the common modes of presentation. Cerebrovascular accidents or epidural fungal abscess are rare. The manner in which fungal CNS disease manifests is largely determined by the growth characteristics of the particular fungal species during systemic invasion. Fungi that are true yeast when invasive (e.g., *Cryptococcus)* most often present as chronic meningitis. Fungi that are pseudohyphae (e.g., *Candida]* often present with encephalitis as a consequence of multiple intraparenchymal microabscesses. Those that are true hyphae {e.g., *Aspergillus)* can present as strokelike illness because of their propensity to invade blood vessels. Clinicians must remain aware that these presentations are not mutually exclusive and that it is not uncommon for the various forms of clinical illness to coexist (Miszkiel et al. 1996).

INDIVIDUAL FUNGAL PATHOGENS

The True Yeasts

Cryptococcus

Cryptococcus is by far the most common cause of fungal meningitis and meningocerebral syndromes. Cryptococcosis is a systemic infection caused by the encapsulated yeast fungus, C. *neoformans,* which has a ubiquitous distribution in soil and pigeon excreta. Infection occurs by inhalation. Occasionally a mild pulmonary clinical infection occurs at the time of invasion. Meningitis is the most common neurological presentation, though multiple small cryptococcomas or a single large granulomatous lesion and abscess may also occur, presenting with symptoms of a mass lesion, seizures, or focal neurological deficits. Cystic lesions or hydroecpb.ilus may develop in patients who survive. Rarely, chronic infection presents with a dementia-like syndrome. The progression of the disease depends on the degree of immunosuppression. A papular or ulcerative skin lesion, lytic bone lesions, prostatitis, pulmonary, and renal involvement occur in disseminated systemic cryptococcosis.

Histoplasma

Inhalation of infectious spores found in soil containing bird excreta causes histoplasmosis. The primary infection may be subclinical, and many cases are diagnosed by chest radiography done for another reason. Acute pulmonary histoplasmosis may result in an influenza-like illness that may be accompanied by erythematous skin eruptions. The disease, often mistaken for miliary tuberculosis, presents

as an acute or chronic febrile illness with diffuse pulmonary infiltrate, abnormal liver function, mucosal ulceration, and less often with neurological involvement (10-20%) in the form of a basilar meningitis, focal cerebritis, or CNS granuloma. Headache, fever, and neck stiffness are seen in about half of the cases. Manifest disease may occur even after leaving an endemic /one indicating the importance of taking a travel history. Diffuse-disease is seen in immunocompromised hosts and at the extremes of age. Approximately 50% of patients who have a CNS infection develop subacute meningitis, whereas 40% have cerebral abscess. The meningitis usually occurs in the setting of disseminated infection but may occur by itself.

Blastomyces

Blastomycosis is a systemic disease caused by *B. dermatitidis,* which proliferates as a saprophyte in soil, and it typically infects healthy individuals. Inhalation of the mycelial form results in the disease. Both systemic and cutaneous forms of blastomycosis may follow pulmonary infection. Neurological involvement occurs in 6-35% of individuals with disseminated blastomycosis and is characterized by intracranial or spinal abscesses or meningitis. Meningitis is often accompanied by rapid deterioration. Infection of vertebrae may lead to osteolytic lesions, which are often painless and may spread to the contiguous soft tissue. For some reason, blastomycosis is not significantly more frequent in HIV/AIDS, and it is not identified as an AIDS-defining infection.

Coccidioides

Inhalation of airborne spores of C. *immttis* found in soil results in coccidioidomycosis. Although the majority of the cases are self-limiting, chronic pulmonary, skin or disseminated disease occurs in approximately 1% of patients. The male gender, extremes of age, non-Cauc.]-.i.iu MCC, pregnancy, and immunosuppressed state are known to predispose to disseminated coccidioidomycosis. Lytic skull and vertebral lesions are seen in approximately one third of patients with disseminated disease. The vertebral arch is most frequently involved initially. Involvement of the vertebral body and disc space classically seen in tuberculosis is uncommon. Meningitis may be the presenting feature and usually occurs within 6 months of symptomatic or asymptomatic primary infection. Nonspecific signs and symptoms of headache, fever, malaise, and weakness are common, but seizures, cranial nerve palsies, and focal neurological deficits may also occur. The meningitis, if present, is more intense than cryptococcal meningitis. Prominent basilar meningitis frequently leads to the development of obstructive hydrocephalus, and meningeal vasculitis may cause occlusions of arteries, leading to cerebral infarcts. If untreated, nunv ilian iO.'•<. (it p.ckiio, \utli coccidioidal meningitis die within 8 months.

Paracoccidioides

Paracoccidioidomycosis is endemic in Central and South America, particularly Brazil, where it resides in soil and chiefly affects laborers in rural areas. Pulmonary infection is usually self-limiting. Dissemination occurs in immunosuppressed patients. Progressive pulmonary disease and extrapulmonary involvement of skin, lymph nodes, and the CNS are common clinical manifestations. Cerebral and cerebellar masses are also seen.

The Pseudohyphae

Candida

The *Candida* species are normal commensals of the human respiratory, gastrointestinal, and genitourinary tracts. Although *Candida* is the fourth most common organism isolated from blood, CNS infection is uncommon in normal hosts. In the immunodeficient host it causes nosocomial and disseminated infection. C. *albicans* is the most important pathogenic species causing neurological involvement. Patients with malignancies, debilitation, those receiving corticosteroids or broad-spectrum antibiotics, transplant recipients, critically ill neonates, and post-operative neurosurgery patients are predisposed to *Candida* infection. Involvement of multiple organs, including the brain parenchyma, meninges, and eye is often seen in disseminated disease. Intracranial abscesses, small vessel thromboses, and microinfarcts occur in areas of vasculitis and tend to have a predilection for the middle cerebral artery. Hemorrhage may occur from rupture of a mycotic aneurysms. Coexistence of ophthalmological and dermatological infection provides a helpful clue to the diagnosis. Patients with endophthalmitis often report blurred vision, eye pain, or scotoma. White, cotton-like exudates ate seen in the retina on funduscopic examination.

] he 1 rue 1 lyphae

Aspergillus

Aspergillus has a predilection for growing on stored grain and decaying vegetation. It mainly affects the paranasal sinuses and causes a hypersensitivity pneumonitis. CNS disease results from direct extension and invasion or embolization. Dissemination from a primary pulmonary focus occurs in immunosuppressed patients, particularly transplant recipients. The posterior circulation is particularly vulnerable, resulting in vertebrobasilar strokes. A strokelike syndrome occurs from direct vessel wall invasion

resulting in vasculitis or from rapidly progressing parenchymal granuloma or brain abscess. *Aspergillus* sinusitis may infiltrate intracranially causing a rhinocerebral syndrome. Pulmonary infection may invade the thoracic vertebrae and then the epidural space, causing spinal cord compression. Meningitis is generally rare, but may occur after transsphenoidal surgery and in intravenous drug abusers.

Zygomycetes (Mucormycosis)

The Zygomycetes belong to a group of saprophytic fungi growing on decaying vegetation or food of high sugar content. Infection is usually sporadic with a worldwide distribution. Diabetes and acidosis are the most frequent predisposing conditions; however, malignancies, high-dose corticosteroids, renal transplantation, and iron chelation therapy in hemochromatosis also predispose individuals to this infection. Mucormycosis causes pulmonary and cutaneous manifestations, Rhino-orbito-ecrebral invasion and cerebral mucormycosis occur after head or orbital trauma. *Mucor* invades through vascular channels producing occlusive ischemic lesions in single or several anatomically related sites. Within the CNS, /.ygomycosis causes an acute necrotizing tissue reaction and thrombosis of neighboring vessels. Cavernous sinus and internal carotid artery thromboses are common. A black regional discharge, such as from the nose, indicates necrosis of the underlying tissue and should suggest the diagnosis of mucormycosis, Ocular manifestations occur due to ischemia and present with loss of vision, optic nerve pallor, corneal ulcer, ocular gangrene, choroidal infarction, and central retinal or ophthalmic artery occlusion.

OTHER **FUNGAL** PATHOGENS

Sporotrichosis is caused by infection by *S. schenkti.* Cutaneous sporotrichosis presents as single or multiple chronic ulcers, spreading along regional lymphatics. Disseminated infecrion affects the CNS (meningitis), joints, and lungs. *Pseudallescheria boydii* is another uncommon opportunistic pathogen, it characteristically presents as neutrophilic meningitis or multiple brain abscesses. Factors predisposing to CNS infection by *I', boydii* include immunosuppression or aspiration of contaminated water (near drowning).

DIAGNOSIS

Fungal infections of CNS may challenge physicians' diagnostic skills. In order to diagnose them early, a physician must have a high index of suspicion in any case presenting as chronic meningitis. The chronic nature of fungal infections often results in patients being anemic with elevated total leucocyte counts and erythrocyte sedimentation rate. Renal involvement results in presence of red blood cells, white blood cells, casts, and protein in urine. Urinary sediment may demonstrate fungal hyphae or yeasts, depending on the load of infection. Culture of urine in fungal media often shows growth, especially in cryptococcosis. Chest x-ray may be useful in cases of concomitant lung infection. Patients with chest x-ray showing infiltrates or abscess should undergo sputum cultures and bronchoscopy and, if needed, a biopsy. Complaints of localized bone pain should always be subjected to bone scan because the lesion can be biopsied or aspirated. Joint radiographs are helpful if fungal arthritis is present.

Neuroimaging in the form of contrast-enhanced magnetic resonance imaging (MR!) or computerized tomography (CT) of the brain is important in identifying the involvement of ncuraxis, MR1 is superior to CT m its higher sensitivity and resolution. Meningeal enhancement, especially in the basal cisterns (Figure 59C.1), is commonly seen and suggests the presence of subacute or chronic meningitis. Infections such as cryptococcal meningitis may have multiple small cerebral abscesses due ro fungal invasion of the Virchow-Robin spaces around the meningeal vessels penetrating the brain parenchyma.

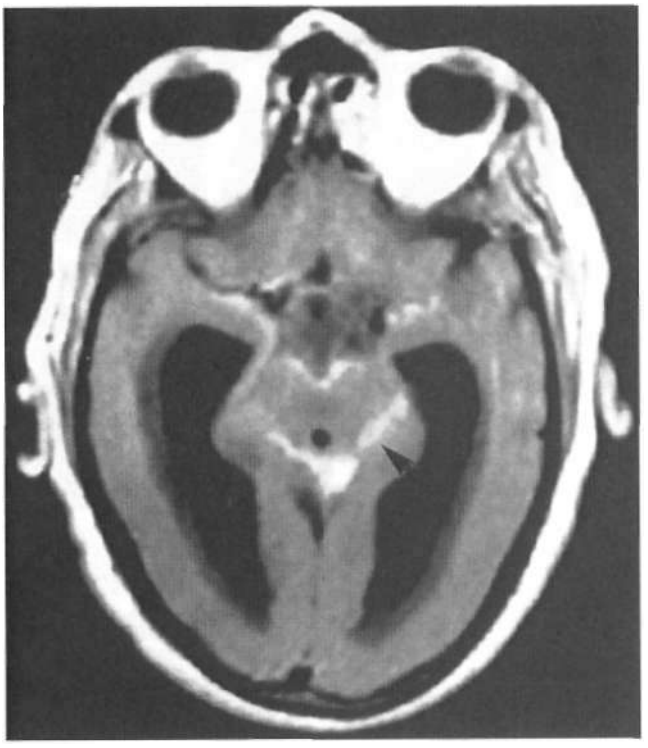

FIGURE 59C.1 Cryptococcal meningitis. Postgaddinium axia [[W-MKI shown is" . i: 111 c s 111! a' lept< IUICIUIIL;NII enhancement i>ee around midbrain *arrow]* and in suprasellar cistern) and ventricular dilatation from obstructive hydrocephalus Courtesy Dr. S. K. Gaekwad.)

Hydrocephalus resulting from blockage of CSF flow at the level of the basal cisterns ot at the outflow pathways from the fourth ventricle by arachnoiditis may also be observed. If the fungus directly invades the brain, neuroimaging often demonstrates an enhancing localized cerebral mass with variable surrounding edema (Figure 59C.2 and Figure 59C.3). Large space-occupying abscesses or granulomas are associated generally with *Aspergillus, Mucor, Blastomyces,* and *Vseudallescherla.* Bland or occasionally hemorrhagic cerebral infarcts may be seen if meningitis causes vasculitis with thrombosis of arteries or veins. In suspected rhinocerebral syndromes, sinus and orbit imaging must be reviewed. Mucosal thickening, air-fluid levels or erosion of bone in the walls of the sinus or orbit suggests rhinocerebral infection.

Lumbar puncture and analysis of the CSF is the most crucial test in establishing the diagnosis of fungal meningitis. The cerebrospinal pressure is often elevated. The fluid is

usually clear and colorless unless either the white blood cell (WBC) count or the protein concentration is significantly elevated due to other associated infection in an immuno-compromised host. The leucocyte count may range from 50 to 1000 cells/mm' with a lymphocytic predominance. A neutrophilic predominance should raise the suspicion of aspergillosis, mucormycosis or *Pseudallescheria* infection. An eosinophilic pleocytosis suggests coccidioidal infections. CSF glucose levels are usually, but not always, decreased and range from 10-39 mg/dL. Very low glucose levels (<1() mg/dL) are unusual and suggest the possibility of coexisting bacterial infection. CSF ptotein levels are elevated and range from 50-1000 mg/dL. A suspicion of a subarachnoid block must arise if the protein level is very high. Gram's stain of CSF is unhelpful unless concomitant bacterial infection exists. Rarely hyphae of *Aspergillus* and *caccidioides* may be seen on microscopic examination of the CSF sediment. India ink examination is useful for *Cryptococcus.* An identifiable capsule and budding yeasts may be seen (Figure 59C.4 and Plate 59C.I). A negative control of India ink should be examined to exclude the possibility of contamination of the ink with the fungus. CSF test fot cryptococcal antigen latex particle agglutination is more sensitive than the India ink preparation. Other tests arc still in the process of development for fungi (e.g., the polymerase chain reaction (PCR) to detect fungal nucleic acid in fluids). Fungal culture growth, except in crypto-coccal infection, is time consuming and does not always isolate the organism. Coccidioidomycosis, histoplasmosis, and blastomycosis yield a growth in only 50% of cases. The yield is even lower for other fungi. The sensitivity and specificity of CSF smear and cultute increase with repeated examinations of large volumes of CSF, centrifuging the CSF, and subjecting the sediment to cultute. The isolation of fungus is important because drug sensitivity patterns can be determined. However, one must also be aware of the possibility of contamination, especially in the case of *Candida* and *Aspergillus.*

Serologic tests can be carried out on blood and CSF. CSF serologic tests may be difficult to interpret. In the early stage, the ptesence of low titers could indicate an acute infection, an immunosuppressed state, or a past infection that is inactive. A high antibody titer suggests an active systemic infection.

If biopsy of a lesion is obtained, it should be subjected to culture in addition to the histopathologic a I investigations. Often a biopsy is the only way to identify infection due to

THERAPY OF FUNGAL INFECTIONS

Antifungal Agents

Amphotericin B is the treatment of choice for most fungal infections of the CNS (see Table 59C. 1). This agent is a polyene compound that binds to the ergosterol component of fungal cell membranes. It acts by increasing the permeability of the cell membrane resulting in the leakage of intracellular contents and lysis of the cells (Patel 1998). The serum half-life of amphotericin B is approximately 12 to 24 hours with peak serum levels lasting 6 to 8 hours. Excretion is chiefly in the urine. Depending on achievable concentrations, it is either fungistatic or fungicidal. It has no effect on other classes of pathogens.

Limitations of amphotericin B include its poor penetration of the blood-brain barrier, making it difficult to achieve effective fungicidal levels in brain. The drug also has renal toxicity (up to 80%), and it causes electrolyte wasting (K^+ and Mg^{++}), normochromic—normocytic anemia and a flulikc allergic reaction after intravenous (IV) use. CNS toxicity limits its intrathecal use. Occasionally life-threatening reactions such as anaphylaxis, acute hepatic failure, seizures, ventricular fibrillation, and cardiac arrest may occur. Premedication with diphenhydramine, hydrocortisone, and ihuprofen for the fever and chills, antiemetics for nausea, and oral potassium supplement to guard againsr hypokalemia reduce adverse effects. Renal toxicity of amphotericin B is related to its peak serum concentrations and the cumulative dose. Patients should be monitored by frequent urinalyses for detection of red blood cell (RBC) or WBC casts, serum creatinine levels, and creatinine clearance. Inability to use this dtug orally limits its use in therapy. Idiosyncratic reactions may fotce stoppage of medication. Amphotericin B should be avoided in patients who are hypersensitive to the drug unless it is the only possible therapy in the face of a life-threatening fungal disorder. In spite of all these limitations, it is the initial choice in induction therapy for most CNS infections, particularly those that are life threatening. New lipid formulations of amphotericin B (vide infra) have been developed to overcome the toxic it}', and though they are expensive, they are as effective as the original drug,

Flucytosine, which was initially developed as an antineoplastic agent, is commonly given as an adjunct to amphotericin B to patients with invasive infections by *Ci-yptnctiLLiis, Ciimi'uh,* and *Aspergillus.* The drug interferes with the metabolism of fungal nucleic acid and disrupts its genetic code. It is rapidly absorbed from the alimentary tract, has minimal protein binding, and is excreted unchanged in urine. CSF concentrations reach 75% of serum. The serum half-life is 3-5 hours. When given alone, flucytosine has few side effects, which include rash, cosinophilia, diarrhea, and hepatic dysfunction; however, in com hi nation with amphotericin B, bone marrow suppression is the major side effect. Blood levels exceeding 100 ug/ml, are associated with increased incidence of these complications. Existing renal failure calls for adjustment of dosage. A twice weekly leukocyte count and platelet count is mandatory in these cases. Flucytosine blood level estimations are done in reference mycology laboratories and are important in patients with azotemia. Blood levels for flucytosine should be drawn 2 hours after the last flucytosine dose and just before the next dose once or twice a week and should be between 50 and 100 (.tg/mL.

Fluconazole and itraconazole are synthetic broad-spectrum antifungal agents that belong to the triazole (azoles) class. They act by inhibition of the synthesis of ergosterol and cause accumulation of substituted sterols, which interfere with the permeability of the fungal cell membrane. Fungal cell membranes are far more sensitive to these agents than mammalian ones. Azole antifungals are generally considered to be fungistatic rarher than fungicidal. The advantage of these drugs is that they are less toxic, can be administered orally, and have good blood-brain barrier penetration. The disadvantage is a lower cure rate, The cure rate is low for cryptococcosis and still lower for aspergillosis with azoles alone. In vitro and animal studies have suggested that concomitant administration of amphotericin B and azole drugs may show antagonistic effects, The use of azoles is hence limited for maintenance therapy to prevent recurrences of coccidioidal, cryptococcal, and bistoplasmal meningitis. Itraconazole has properties similar to fluconazole except for its poor penetration of the blood-brain barrier. Adverse effects of azoles are uncommon but include nausea, abdominal pain, headache, dizziness, rash, reversible alopecia, pedal edema, and transiently increased liver enzymes. Physicians must watch for drug interactions of antifungal azoles with other drugs to prevent side effects or lack of effectiveness of the primary medication.

Newer Agents

Lipid amphotericin preparations (liposomal amphotericin B, amphotericin B cholesteryl, and amphotericin B lipid complex) have the advantage of lower toxicity and infusion-related side effects. The half-life of these preparations varies, and the larger particles are mostly cleared by the reticuloendothelial system faster. The disadvantages of lipid formulation are higher cost and lower CNS permeability compared to the original drug. The CSF/plasma concentration at steady state for amphotericin B is typically

less than 25% and lower for lipid formulations. Doses of lipid formulations range from 3-5 mg/kg per day. There seems to be no major difference in the overall efficacy between the two preparations. A favorable initial response of amphotericin B may permit a switch to a less toxic antifungal preparation after a period of time. Voriconazole, a new triazole derivative, has broad-spectrum antifungal activity and is especially useful for aspergillosis and candidiasis. Doses vary from 50-200 mg per day. SCH59562 is another triazole with apparently greater potency than voriconazole and is currently under investigation. Agents that boost the immune system, which is often deranged in patients with fungal infections, may help in treating invasive fungal infection. Cytokines and gamma interferon are being tried in CNS fungal infections and continue to remain experimental at this stage (Stevens 1998).

Surgery

Surgical procedure may be critical for CNS fungal treatment, especially in cases of invasive rhinocerebral fungal disease. Surgical biopsy may also be essential for establishing the diagnosis. Among the procedures of therapeutic relevance are exenteration of infected facial, nasal, and intracranial tissues in cases of mucormycosis and aspergillosis, extirpation or drainage of fungal cerebral abscess, repair of rare mycotic aneurysm, and surgical drainage of hydrocephalus complicating fungal meningitis. Hydrocephalus can occur in any fungal meningitis and is seen in as many as 15% of cases of cryptococcal meningitis. Acute hydrocephalus may require emergent ventricular drainage, and chronic hydrocephalus may require a ventriculopcritoneal shunt. Ventricular shunt in the face of active fungal meningitis may produce venrriculitis. In cryptococcal meningitis with communicating hydrocephalus, daily lumbar puncture may also alleviate symptoms. However, lumbar puncture is contraindicated in patients with intracranial mass lesions, such as fungal abscess and intracranial shifts on imaging studies. With elevated intracranial pressure, lumbar puncture should be performed cautiously, especially in patients with low-lying cerebellar tonsils, to avoid tonsillar herniation. The later has even been observed following lumbar puncture in the absence of focal mass brain lesion.

TREATMENT OF SPECIFIC INFECTIONS

Cryptococcal Central Nervous System Infection

Practice guidelines by the Infectious Diseases Society of the United States of America (Saag et al. 2000) have suggested therapy beginning with amphotericin B in the dose of 0.5-1 mg/kg per day plus flucytosine 100 mg/kg per day for 6-10 weeks in immunocompetent hosts with CNS cryptococcal disease. An alternative regimen is to use this combination for 2 weeks followed by fluconazole 400 mg per day for 10 weeks or more, especially if the patient develops amphotericin B toxicity. The consolidation therap\ with fluconazole mai be continued for d months to a year, depending on the clinical and CSF response. In patients with HIV infection, induction with amphotericin B (0.7-1 mg/kg per day) plus flucytosine (100 mg/kg per day) for 2 weeks followed by fluconazole 400 mg per day is recommended. The fluconazole dose can later be reduced to 200 mg per day but generally has to be continued for life in HIV/AIDS patients. An alternative regimen consists of amphotericin B in dosage of 0.5-1 mg/kg per day plus flucytosine 100 mg/kg per day for 6-10 weeks followed by fluconazole maintenance therapy. If the patient does not tolerate amphotericin B, fluconazole 400-800 mg per day with flucytosine 100-150 mg/kg per day for 6 weeks can be used. Renal function must be monitored, and serum flucytosine blood levels must be kept between 50 and 100 ug/mL. Neutropenia requires that the treatment be halted. Repeat lumbar puncture evaluation at 2 weeks of therapy to obtain CSF for antigen titers and fungal culture is needed to ensure the response to treatment. Relapse rates may be as high as 50%. An important predictor of final outcome in patients with HIV is the CSF culture sterility 14 days after the initiation of treatment. Patients likely to have poor response are those with a high cryptococcal antigen level, low CD4 count, and low serum albumin level. Mass lesions greater than 3 centimeters may require surgery. Prophylaxis with fluconazole in AIDS is important as about 5-10% of patients develop cryptococcal meningitis, especially when their CD4 count falls below 100 cells/mm (Van der Horst et al. 1997).

Coccidioidal Central Nervous System Infection

Prolonged treatment is usually required for coccidioidal CNS infections. Recent reports suggest that long-term oral fluconazole is as effective as amphotericin B and is now the treatment of choice. Its use in the dose of 400 mg per day orally for 4 years has been shown to result in improvement in 75% cases. Occasionally higher doses of 600-800 mg per day may be required. Signs of improvement may come only 4 to 8 months after beginning the treatment, Intrathecal administration of amphotericin B in the dose of 0.25-1.5 mg/dose 3 times per week for several weeks with a gradual tapering to biweekly and then monthly to a total cumulative dose of 35-100 mg may be given in difficult to control infections. Intrathecal drug is given in conjunction with IV amphotericin B 0.5 mg/kg per day, up to a total cumulative dose of 3 g. The duration of treatment may need to be extended to up to 1 year (Stevens 1995). As many as 78% cases may relapse when the therapy is discontinued. This is especially so in immunocompromised

patients. Hence, lifelong maintenance with fluconazole (200 mg per day) may be required.

Histoplasmal Central Nervous System Infection

IV Amphotericin B (0.7-1.0 mg/kg per day) for a total cumulative dose of at least 30 mg/kg or 1.5-2 g) is used in most cases. Intrathecal amphotericin B in a dose of 0.25—1.0 mg/dose on alternate days can be given if there is no contraindication. Four to 12 weeks of induction therapy is required. Maintenance therapy is required because many patients show relapse following induction therapy alone (Wheat et al. 1990).

Central Nervous System Mucormycosis

Mucormycosis generally occurs in rhino-orbito-cerebral form in patients with diabetic ketoacidosis or other associated illnesses (see Table 59C. 1). Surgical debridement is required, diabetes should be controlled, and in patients with hemochromatosis, desferoxamine should be discontinued. Amphotericin B should be administered in rapidly increasing doses of 1—1.5 mg/kg per day, with an anticipated dose of 2.5-3 g. Hyperbaric oxygenation has been suggested by some investigators. The prognosis is generally poor.

Therapy of other major CNS fungal diseases is summarized in Table 59C.1. Cure rate for cryptococcal meningitis is about 75%, coccidioidal meningitis 50%, *bistoplasyna* meningitis 40%, and for aspergillosis and zygomycetes approximately 25%. Outcome in immunosupprcsscd patients is less favorable, and many of these patients die due to concomitant infections. Shott- and long-term complications in CNS fungal infections are as high as 40-75%, and these include hydrocephalus, infarction, cranial nerve palsies, seizures, and dementia (del Brutto 2000).

Chapter 59
Infections of the Nervous System

D. PARASITIC INFECTIONS

Madhuri Behari, Sumit Singh, and Ashok Verma

Parasites are a group of organisms that thrive on or in the body <ł other organisms, deriving protection and nutrition from them. Whereas protozoa arc microscopic single-celled organisms, helminths arc macroscopic, multicellular organisms ranging from few millimeters to several meters in size. i hanges ill social, technical, political, behavioral, and economical factors have resulted in a dramatic increase in the incidence of some human parasitic infections in recent decades. At least 10% of world population is infected by *Entamoeba histolytica,* a common gut pathogen. It is estimated that one third of the world population harbors helminthic infestations. *Plasmodium falciparum,* the species responsible for 40% to 60% of the 200 million annual cases of malaria and 95% of malarial deaths, remains one of the top infectious disease killers in the world. Of the 1 to 2 million annual deaths caused by malaria, most are the result of cerebral malaria (WHO 1999), Parasitic infections are not restricted to the tropical regions alone. Migrations of individuals across the continents and increasing travel have enabled them to spread all over the globe. Emergence of the pandemic of acquired immunodeficiency syndrome (AIDS) has caused an exponential inctease in the number of individuals affected by certain parasites {Lanjewar et al. 1998). Apart from an absolute increase in the incidence, altered immunity of patients with AIDS has resulted in atypical presentation of these diseases. Parasites that are well tolerated by the human body do not elicit inflammatory response. On the other hand, parasites that are not well tolerated develop intense inflammatory reaction around the larvae or the adult worms, resulting in a multitude of symptoms.

Protozoan infections are responsible for acute meningitis or meningoencephalitis *[Naegleria,* African trypanosomiasis), encephalopathy *(Plasmodium* spp.), chronic meningitis *(Acanthamoeba, Toxoplasma),* space-occupying lesions of the brain *(Toxoplasma, Entamoeba histolytica),* neuropathy (Chagas' disease, filariasis), myositis *[Trichinelia,* cysticercosis), and chorioretinitis *(Toxoplasma).* Helminths cause nervous system involvement due to their size, mobility, and challenge to the host immune response. Helminths can cause meningoencephalitis *(Taenia solium, Trichinelia, Angiostrongylus, Gnathostoma, Toxocara, Strongyhides, Schistosoma,* etc.), encephalopathy *(Trichinelia, Loa loa),* cerebral mass lesions *(Taenia, Echinococcus, Gnathostoma, Schistosoma),* and ocular involvement *(Taenia, Angiostrongylus, Gnathostoma, Eoa loa, Toxocara)* (Table 59D.1). Invasion through the foramina of skull and vertebral column and of tissues surrounding nerves can cause features of nerve or nerve root compression or compressive myelopathy *(Schistosoma).* Ectoparasites do not invade the tissues of the host but release toxins that may affect the nervous system.

It would hardly be possible within the confines of this chapter to discuss with any degree of completeness

Table 59D.1: Parasitic infections of the central nervous svstem

Parasite	*Range*	*Neurological ma infestations*	*Treatment of choice*
Protozoans			Guided by local resistance pattern (see text)
Plasmodium falciparum	Africa, South America, Southeast Asia, Pacific Islands, Haiti	E, Sz	Oral: Chloroquinc phosphate 600 mg base (1 g), then 300 mg base (500 mg) at *6*, 24, and 48 h (if resistance, quinine sulfate plus pyrimethamine-sulfadiazine, nr plus tetracycline, or plus clindamycin) Parenteral: Quinine dihydrochloride 20 mg/kg ioading (maximum 600 mg) over 1/2 hr followed by 10 mg/kg every 8 hour IM or PO for 7 days
Naegleria fowleri	Southern United States, Australia, Europe	ME	Amphotericin R 1 mg/kg/d IV for uncertain duration
Acantbamoeba spp.	Europe	ME, E, O	Amphotericin B 1 mg/kg/day TV plus vitampin for uncertain duration
Entamoeba histolytica	Tropics worldwide	M	Metronidazole 750 mg IV q8h for 10 days followed by iodoquinol 650 mg tid lor 20 days
Trypanosoma brucei rbodesiense	Africa	ME	Mclarsoprol 2-3.6 mg/kg/day IV for 3 days, after 1 week 3.6 mg/kg/day IV for 3 days, repeated after 10-21 days; or eflornithine 100 mg/kg qid for 14 days, then 300 mg/kg/day for 3-4 weeks
Trypanosoma brucei gambiense	Africa	ME	Mclarsoprol 2-3.6 mg/kg/day IV for 3 days, after 1 week 3.6 mg/kg/day IV for 3 days, repeated after 10-21 days; or eflornithine 100 mg/kg qjd for 14 days, then 300 mg/kg/day for 3^t weeks
Trypanosoma cmzi	Central and South America	ME, M, St	Nifurtimox 8-10 mg/kg/day in 4 doses for 120 days
Toxoplasma gondii	Worldwide	ME, Sz, M, O	Pyrimethamine 25-100 mg/day plus sulfadiazine 1-1.5 g qid plus folinic acid 10 mg/day for 3-4 weeks
Helminths			
Ccstodcs			
Taenia solium (cysticercosis)	Worldwide	ME, Sz, M, Sp.O	Albendazole 15 mg/kg/day in 2 doses for 8-28 days, or praziquantel 50 mg/kd/day in 3 doses for 14 days or repeated as necessary, with concurrent glucocorticoids for CNS disease

Echinococcus granulosus	Worldwide	Sz, M, Sp, O	Surgical excision if possible and albendazole 400 mg once; or albendazole 15 mg/kg/day for 40 days, repeated after 2 weeks	—
Echinococcus multilocularis	Arctic	Sz, M	Surgical excision	—
Taenia multiceps (Coenurosis)	Worldwide	M, O	Surgical excision	—
Spirometra spp. (Sparganosis)	Worldwide, mainly Asia, Africa	ME, Sz, M, St	Surgical excision	—
Diphyllobothrium latum	Worldwide	E, Sp, O, N (vitamin B_{12} deficiency)	Praziquantel 10 mg/kg 1 dose, vitamin B_{12}	—
Hymenolepis nana	Worldwide	E, Sz	Praziquantel 25 mg/kg 1 dose	—
Nematodes				
Trichinella spp.	Worldwide	ME, E, Sz, St	Glucocorticoids (for severe symptoms) plus mebendazole 200–400 mg tid for 3 days, then 400–500 mg tid for 10 days	—
Angiostrongylus cantonensis	Asia, Africa, Pacific, Caribbean	ME, Sz, O	Supportive therapy and glucocorticoids as needed	—
Gnathostoma spinigerum	Asia, Israel	ME, Sz, M, St, Sp, O	Surgical removal plus albendazole 400–800 mg/d for 21 days	—
Onchocerca volvulus	Africa, Central and South America, Yemen		Ivermectin 150 μg/kg/day once, repeated every 3–12 months	—
Loa loa	Africa	E, O	Diethylcarbamazine, day 1: 50 mg, day 2: 50 mg tid, day 3: 100 mg tid, days 4–21: 9 mg/kg/day in 3 doses	—
Toxocara spp.	Worldwide	ME, Sz, O	Thiabendazole 25 mg/kg bid for 5 days, supportive therapy and glucocorticoids	Diethylcarbamazine 2 mg/kg tid for 7–15 days, or mebendazole 100–200 mg bid for 5 days, or albendazole 400 mg bid for 3–5 days
Baylisascaris procyonis	Worldwide	ME, Sz	Thiabendazole 25 mg/kg bid for 5 days, supportive therapy and glucocorticoids	Mebendazole 100–200 mg bid for 5 days, or albendazole 400 mg bid for 3–5 days
Strongyloides stercoralis	Worldwide	ME, St	Thiabendazole 25 mg/kg bid for 3–7 days or longer if host is immunosuppressed	Ivermectin 200 μg/kg/day for 1–2 days, or albendazole 400 mg bid for 3 days
Ascaris lumbricoides	Worldwide	Sz	Mebendazole 100 mg bid for 3 days, or piperazine 75 mg/kg (max 3.5 g) for 2 days	Pyrental pamoate 11 mg/kg (max 1 g) or albendazole 400 mg once
Wuchereria bancrofti	Coastal areas in tropics and subtropics	N	Diethyl carbamazine 6 mg/kg/day in 3 divided doses for 12 days	Surgical resection

ME, meningoencephalitis; E, encephalitis; Sz, seizures; St, stroke; Sp, spinal cord; N, nerve.

the innumerable rare parasitic infections that affect the central nervous system (CNS). Rather, we will introduce some general clinical approaches to parasitic CNS infections and deal in greater detail with important or relatively common parasitic CNS diseases. A summary of patasitic CNS infections is given in Table 59D. 1. The interested reader is referred to a number of texts (Gorbach ct al. 1997; Scheld et al. 1997), comprehensive reviews, and references listed at the end of this chapter.

CLINICAL APPROACH TO PARASITIC CNS INFECTION

Because of the diversity of parasitic organisms that may infect the human CNS; a number of factors are important in the assessment of a possible parasitic etiology for a patient's complaints. These factors include issues related to the patient's work, travel and recreational history, immune sratus, and presenting neurological and orher systemic symptoms. The specific laboratory tests required, ranging from standard blood biochemical assays to brain imaging and cerebrospinal fluid (CSF) analysis, are dictated by the nature of the patient's illness.

Geographic, Travel, and Other Exposure History

The cornerstone for the diagnosis of parasitic infections is a thorough history of the patient's illness. Epidemiological aspects of the illness are particularly important because the risk of acquiring many parasites is closely related to occupation, recreation, or travel to areas of high endemicity. A history of travel to, residence or work in, or immigrarion from areas of the world in which various parasites occur offers a clue to the possible parasitic-etiology of a patient's disease. Some parasitic infections may become manifest early after a traveler's return to home; most important among them in terms of mortality is malaria. For patients with history of recent travel, the onset of gastrointestinal symptoms only after return suggests protozoan diseases. Diseases that may become manifest some years after an individual leaves an endemic region include schistosomiasis, some form of filatiasis, strongyloidiasis, echinococcosis, and cysticercosis. Consumption of contaminated or undercooked food may be associated with trichinosis, cysticercosis, Toxocariasis, or eosinophilic meningitis *{Angiostrongylus cantomnsis).* Other relevant exposure history includes blood transfusion (malaria, filanasis, Cliagas' disease) and wading or swimming in freshwater lake or pond *{Naegieria* meningitis, schistosomiasis), Residence in an institutional setting, in which fecal-oral hygiene may he lacking, raises the possibility of exposure to gut parasites, such as *Y.nlamoeba* and *Strongyloides.*

Immune Status

In patients infected with human immunodeficiency virus (HIV), especially those with low CD4(T cell counts, specific protozoan diseases, such as toxoplasmosis or trypanosomiasis, may develop opportunistically. Patients who are asplenic are ar risk not only for overwhelming infections due to encapsulated bacteria, but also for fulminant intra erythrocytic protozoa, including malaria. In patients developing symptoms of enterocolitis while receiving corticosteroids, the possibility of exacerbation of iri--,ii-|-ivi(r -,;ni-i,:.vloi..f,;-.h, •... .niiivlin ^ihiis should In-considered.

Laboratory Investigations

Most protozoa and helminths are excreted from the body in the feces. Stool samples, therefore, should be collected and examined for ova and parasites in appropriate clinical settings. Because of cyclic shedding of most parasites in rhe feces, a minimum of three samples collected on alternate days should be examined. Microscopic examination of feces is not complete until direct wet mounts have been evaluated.

Eosinophilia in blood may offer a hematologic clue to the presence of parasites. Protozoan infections restricted to the CNS, however, do not cause eosinophilia. Thus eosinophilia in the face of CNS parasitic infection mandates a consideration of the multicellular helminthic parasites that characteristically elicit this abnormality. Helminth-elicited eosinophilia, however, may be suppressed by glucocorticoid therapy or by intercurrent bacterial or viral infections. The magnitude of eosinophilia generally correlates with the extent of tissue invasion by the helminths. Marked eosinophilia (more than 2500 eosinophils per microliter) develops during early tissue migration of nematodes. Eosinophilia is also marked in the early stages of trematode infections, including schistosomiasis (Katayama fever), paragonimiasis, and fascioliasis; during the stage of muscle invasion (trichinosis); during tissue migration of adult worms {loiasis and gnathostomiasis); and with heavy infections in visceral larva migrans. Eosinophilia persisting for more than a year may be indicative of strongyloidiasis, visceral larva migrans, filarial infection, trematode infections, or cysricercosis. Leakage of fluid from echinococcus cysts can cause intermittent eosinophilia. Eosinophilia may be the only clue to the presence of helminthic infection, and it should prompt an evaluation for such infection.

Laboratory procedures may detect parasites in body fluids. The most common parasites detected in Gicmsa-stained blood smears are the *Plasmodium* spp., microfilariae, and African trypanosomes. The diagnosis of malaria and the critical distinction between the various *Plasmodium* spp. is made by the microscopic examination of stained thick and thin blood films.

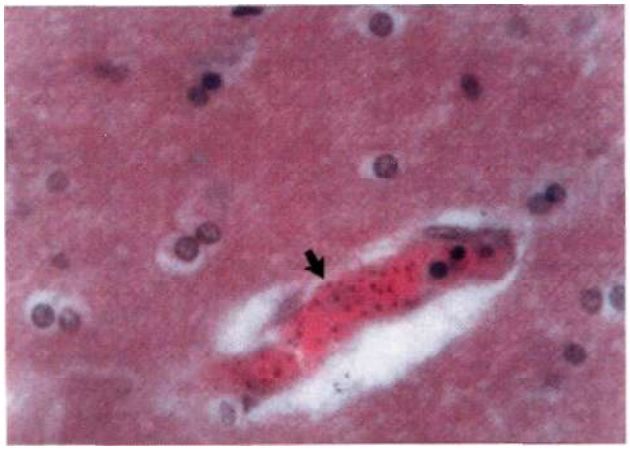

PLATE 59D.I A capillary in brain parenchyma showing RBCs filled with hemozoin pigmenr *(arrow)* in a case of cerebral malaria. (H & E x 100)

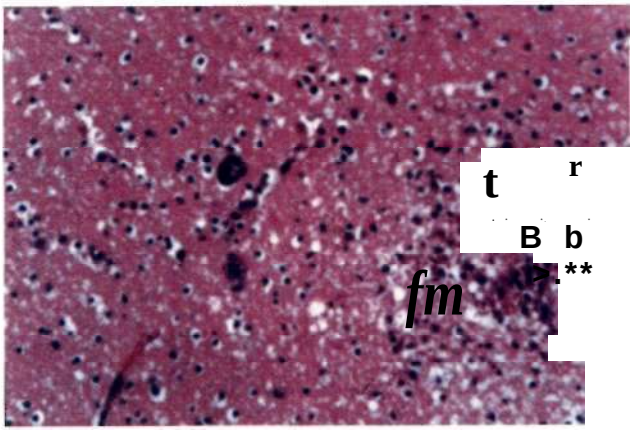

PLATE 59D.11 *F.ntamoeba histolytica* cysts *(arrow)* in a case of cerebral amoebic abscess. (H 6c E x 100)

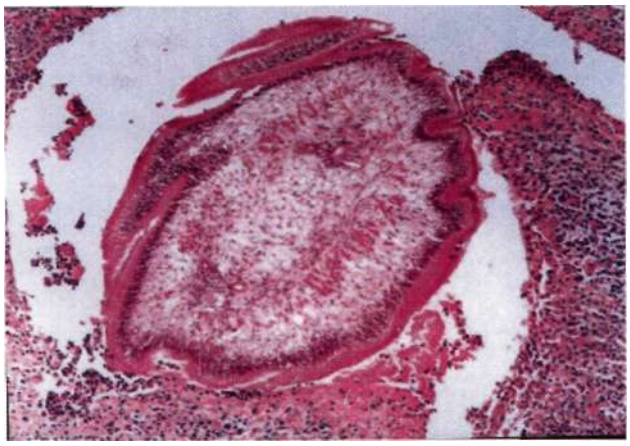

PLATE 59D.1I1 Cysticercus cyst showing scolex in a case with solitary cyst in brain parenchyma. (H & E x 100)

The value of serum antibody assays is generally limited in parasitic CNS infections. The detection of serum antibody to *Plasmodium* is primarily an epidemiologic tool and is of limited use for establishing the diagnosis of malaria in an individual patient. Filarial antigens cross react with those from other nematodes, and antibody assay cannot distinguish between past and current infections. Despite these specific limitations, the restricted geographical distribution of many of the tropical parasites increases rhe usefulness of antibody deteuinii as a means (it establishing diagnosis in travelers from industrialized countries who have returned from the tropics. The presence of a specific IgM antibody in CSr indicates active CNS disease, such as in CNS toxoplasmosis. Polymerase chain reaction (PCR) for the detection of *Plasmodium* DNA is now available.

Imaging Studies

Contrast-enhanced magnetic resonance imaging (MRI) or computed tomography (CT) studies of the brain and spinal cord can identify meningeal enhancement (parasitic meningitis), para meningeal infections (including parasitic granulomas), or inrraparenchymal lesions (cysticercosis, echinococcosis) (Chang and Han 1998). Imaging studies are also useful to localize areas of meningeal or parenchymal disease prior to meningeal or brain biopsy or lesion resection.

Cerebrospinal Fluid Analysis

Once the clinical syndrome is recognized as a potential manifestation of parasitic CNS infection, lumbar puncrure (LP) and CSF analysis are essential. However, if the possibility of raised intracranial pressure (ICP) exists, a brain imaging study should be performed before LP. In patients with communicating hydrocephalus caused by impaired absorption ol (.Sl', I I' is gcneralh safe and may lead ro temporary improvement. However, if ICP is elevated because ol a mass lesion or a blink in ventricular CSF ourflow (obstructive hydrocephalus), then LP carries the potential risk of brain herniation and death. Acute obstructive hydrocephalus usually requires direct venrricular drainage of CSF.

The CSF pressure should be measured and samples sent for cell count and differential, measurement of glucose and protein, microbial stain, and orher investigations. When eosinophils predominate or are present in limited numbers in a primary mononuclear cell response in the CSF, parasitic disease must be considered *(Angiostrongylus cantonensis, Gnathostoma spinigerum, Toxocara cants, Toxoplasma gondii,* cysticercosis, schistosomiasis, and echinococcal disease). Centrifugation of CSF and wet mount preparation with Giemsa stain may reveal parasites in African trypanosomiasis and *Naegleria fowl en.* IgM antibodies against T. *gondii* in blood or CSF suggest recent infection. Other specific CSF rests should be ordered as indicated on the basis of the clinical picture.

Meningeal or Brain Biopsy

A diagnostic brain biopsy should be considered in patients who are severely disabled, who need chronic ventricular decompression, or whose illness is progressing rapidly. Targeting regions rhar enhance with contrast on MRI or CT scan can increase rhe diagnostic yield of biopsy. Single symptomatic lesions *{Cysticercus, Echinococcus)* can be resected for both diagnosis and treatment. The activities of surgeon, pathologist, microbiologist, and cytologist should be coordinated so that adequate sample is obtained and appropriate histological and molecular srudies, including PCR, are performed.

PROTOZOAN INFECTION OF THE CNS

Cerebral Malaria

Malaria caused by genus *Plasmodium* is one of the oldest and most dreaded protozoan diseases affecring more rhan 500 million people throughout the world (WHO 1999). The endemic zones for malaria, sub-Saharan Africa, Asia, and Central and South America, account for the majority of cases. In hyperendemic areas most children acquire infection with *Plasmodium* before they reach 5 years of age. Infants under 6 months enjoy immunity inherited from their mothers. World Health Organization (WHO) defines cerebral malaria as unexplained unconsciousness lasting 30 minurcs or more in a patient with asexual forms of *Plasmodium falciparum* in rhe peripheral blood smear. It occurs in about 0.5-1% of infections with *Plasmodium falciparum.* Though a large majority of cases are due ro *P. falciparum,* few case reports of cerebral malaria due to *P. vivax* are recorded.

Natural transmission of all species of *Plasmodium* occurs by the female *Anopheles* mosquito. Accidental transmission occurs through blood transfusion, laboratory accidents, experimental infection, and zoonotic infection. The female *Anopheles* mosquitoes inject the sporozoites form of *Plasmodium* into the host body during a blood meal. Sporozoites undergo successive developmental stages of trophozoites, schizonts, and merozoites that are liberated into the circulation by rupture of erythrocytes, thus ending the asexual cycle.

Pathogenesis

Pathogenesis of cerebral malaria is ill understood. Evidence based on animal models suggests that the fundamental process in cerebral malaria is the increased cyroadhcrance

due to formation of knobs on parasitized red blood cells (pRBC) containing schizonts. Other endothelial factors such as leucocyte differentiation molecule (LD36), intercellular adhesion molecule-1 (ICAMi) and thrombospondin, ap extracellular matrix protein, may help in the process of cytoadherence (Lou et al. 2001). Additionally, immune mediated ptoinflaminatory response due to tumor necrosis factor-cc (TNF-r*), interleukin-1 and other cytokines may aggravate cytoadhesion, leading to cerebral microvascular occlusion, cerebral anoxia, and ischemic cerebral damage (Singh et al. 2000). Activation of nitric oxide synthetase and the complement cascade induced by prostaglandins and glycophosphatidil inositol, leading to inflammation, may also be contributory. Hypoglycemia and acidosis, common complications of cerebral malaria, produce or worsen encephalopathy and neurological deficit.

Pathology

Pathological description in cerebral malaria is necessarily based on severe cases, which are eventually fatal. Grossly, the brain is heavy, and the meningeal vessels are congested, giving a pink hue to the brain. Microscopically, engorged blood vessels containing pRBCs with asexual forms of parasite can be seen (Plate 59D.I). Petechial hemorrhages showing engorged blood vessel in the center and a surrounding ring of extravasated red blood cells (RBCs) are called ring hemorrhages and are a characteristic finding in cerebral malaria. "Durks nodules" are granulomas consisting of central dcmyelinated core with inflammatory cells in the ring hemorrhage. Immunohistoehemical staining shows amyloid precursor protein in ring hemorrhages indicative of axonal damage (Medana et al. 2002).

Clinical Features

The incubation period depends to a large extent on the immune status, species of *Plasmodium,* dose of inoculation, and prctrcatment with prophylactic drugs (Warrell 1997). In *P. falciparum* the mean incubation period is 12 days but may be 6-12 hours in children and if a massive dose is inoculated. The prodrome consisting of lassitude, myalgia, headache, and chills usually precedes the acute attack, High-grade fever (104= to 105°F), shaking chills, and rigors with diaphoresis announce the presence of malaria. Rarely, patients may have hypothermia due to shock and endotoxemia. The periodicity of fever in *P. falciparum* malaria is once every third day, but it may not be obvious because of multiple exposures and several cycles of parasitemia. Malaria being a systemic disease, symptoms such as nausea, vomiting, abdominal pain, cough, tachycardia, arthralgia, myalgia, and weakness occur commonly. Most patients have enlarged liver and spleen with chest rales and muscle tenderness.

Cerebral symptoms start with seizures (generalized or partial), acute onset delirium, or coma. In children, seizures are more common (70%) as compared to adults (20%), and one third of patients may present with status epilepticus. Other CNS manifestations include headache, meningismus, focal neurological deficits (aphasia, ataxia, hemiplegia, chorea, and tremor), ncuro-opbrhalmological signs (conjugate gaze disturbance, oculomotor palsies, ocular bobbing, and nystagmus), retinal hemorrhages (up to 15%), and rarely papilledema (<1%). In endemic areas, rhe presence of febrile encephalopathy with nearly normal CSF findings warrants a diagnosis of cerebral malaria. Systemic effects of severe malaria often complicate the clinical picture and **adversely iliecl '.hi-** prognosis I'he -.ystemic etlecls include severe anemia, renal complications with oliguria/anuria and azotemia, jaundice, pulmonary edema, adult respiratory distress syndrome, resistant hypoglycemia, secondary infections, and septicemia (Kochar et al. 2002).

Cerebral malaria carries a mortality of 20-50%, it being higher in children. Important prognostic factors are level of consciousness at the time of presentation and the presence of complications. Additionally, recurrent seizures, absent corneal reflex, decerebrate rigidity, retinal hemorrhage, age less than 3 years, high degree of parasitemia, peripheral schizontemia, red cell mass less than 20%, peripheral leucocytosis, lactic acidosis, elevated CSF lactate, elevated serum transferases, and low antithrombin III levels are associated with a poor prognosis. Though complete recovery occurs in the majority who survive, sequelae are reported in 10-18%, being higher in children. Ataxia, hemiparesis, memory disturbance, neuropsychological deficits, visual field defects, vertigo, cognitive impairment, behavioral abnormalities, and psychosis are common sequelae, which are mostly reversible in 4-8 weeks (Rozc et al. 2001). A postmalaria neurological syndrome characterized by acute onset confusion, seizures, ataxia, myoclonus, tremor, and aphasia is described in patients successfully treated for cerebral malaria in the absence of parasitemia. The pathogenesis of this syndrome is not understood, but immunologic mechanism seems to be involved as the condition is responsive to corticosteroids (Nguyen et al. 1996).

Diagnosis

Diagnosis and species identification tequire examination of thick and thin smear of peripheral blood stained with Giemsa or Field's stain for the presence of ring-shaped trophozoites. Cerebral malaria usually occurs when more than 10% of peripheral RBCs are parasitized. Absence of trophozoites in the peripheral smear may occur due to sequestration of RBC in the cerebral circulation or earlier treatment with antimalarial drugs, as it is a common practice in endemic areas to treat all fevers with antimalarial drugs. If the initial smear is negative, two or three smears 6-8 hours later should be repeated (at least three sine.its should he declared negative before **excluding llie** diagnosis of malaria).

CSF examination is necessary to exclude other causes of febrile encephalopathies (meningitis, encephalitis, enteric encephalopathy, yellow fever, viral hemorrhagic fever, relapsing fever, leptospirosis, and heat stroke). In cerebral malaria, the CSF is largely normal. However, mild lymphocytic pleocytosis (10-50 cells/a!.), and mildly elevated protein {up to 200 mg/dL) may be seen. Neuroimaging with CT and magnetic MRI in cerebral malaria is usually normal or it shows edema or cortical or subcortical infarcts in the watershed zones in a small number of cases (15-20%). Recently, a dipstick antigen capture assay for malarial antigen PfHRPi has shown 75-96% sensitivity and 87-100% specificity (Craig et al. 2002). However, its cost prohibits its use where it is maximally needed. Immunochromatographic tests and PCR for malarial parasite in the CSF and blood are also available (Craig et al. 2002). Electroencephalography (EEC) shows a number of abnormalities such as diffuse slowing of background, burst suppression or spike and wave discharges, but is nonspecific for diagnostic purpose (Crawley et al. 2001). Cerebral malaria may occur with negative blood smears. A high index of suspicion in endemic areas is the key to successful treatment in a case of high fever, rigors, encephalopathy, seizures, anemia, jaundice, diarrhea, hemorrhages, renal failure, and respiratory distress. In such cases with a history of malaria exposure, treatment with antimalarial drugs should be initiated even before evidence of parasitemia becomes available.

Treatment

Mortality in cerebral malaria is 20-50% and virtually I 00",) if untreated for 48 hours. In endemic areas if cerebral malaria is suspected, treatment should be started without waiting for laboratory confirmation.

In most tropical and endemic countries the parasite has developed resistance to chloroquine due to its widespread use. Quinine dihydrochloride is the drug of choice. Due to alteration in the pharmakinetics of quinine related to the volume of distribution and renal clearance in severe malaria, an intravenous loading dose of 20 mg/kg of quinine dihydrochloride in dextrose or saline over 30 minutes is advocated to achieve rapid therapeutic concentration in severe cases. The loading dose can be omitted if the patient has already received quinine. Maintenance dose is 10 mg/kg infused over 2-8 hours. The maximum daily dose is 1800 mg. This dose can be used for all age groups. Therapeutic minimal parasiticidai concentration after oral treatment is achieved in about 4 hours. Once patients regain consciousness oral treatment with quinine in 10 mg/kg, every 8 hours can be started. Total duration of treatment is 7 days. Alternatively, 600 mg of quinine can be given orally thrice a day in an adult. In patients who do not tolerate quinine due to scwiv •. oriiitmg, h\ pcrseiisitivin, <r hypoglycemia, quinidine gluconate in doses of 10 mg/kg base can be infused intravenously over one hour under cardiac monitoring, followed by continuous intravenous infusion at the rate of 0.02 mg/kg per hour for 7-10 days or longer. Concurrently or immediately following quinine dihydrochloride, tetracycline 250 mg every 6 hours or pyrimethamine (25 mg)-sulfadiazine (500 mg) every 8 hours should also be administered. In multi-drug-resistant malaria Artemisia derivatives (derived from traditional Chinese medicine *ginghaosu),* artcmether, and artesimate are used. The dose of artemether is 3.2 mg/kg intramuscularly as a loading dose followed by 1.6 mg/kg intramuscularly every day for 4 days plus mefloquine 750 mg orally on the last day of treatment; or artcsunatc 2.0 mg/kg intravenous loading dose, followed by 1 mg/kg intta-venously at 4 hours and 24 hours, then daily for *6* days (Faiz et al. 2001). In children, mefloquine solution given by nasogastric tube in a single dose of 25 mg/kg has been found to be as effective as intravenous quinine.

Treatment of Complications

Hypoglycemia, resulting from consumption of glucose by parasites, malabsorption, and increased pancreatic secretion of insulin induced by quinine, may be severe in young children and pregnant women and is an important prognostic factor. It should be suspected in patients who show deterioration despite adequate treatment and is treated by infusion of 50% dextrose. Anemia can be severe, with hematocrit falling by 8-10% in 48 hours in severe parasitemia. Blood transfusion sin mid be given to keep the hemoglobin at 7 g/dL. In children exchange transfusion is safe as it also clears the parasite load and does not alter hemodynamics. Raised ICP is also common in children and requires intracranial pressure monitoring. Use of corticosteroids has been reported to be associated with increased risk of seizures and gastrointestinal hemorrhages in patients with cerebral malaria. However, there is insufficient evidence to contra indicate the use of corticosteroids in cerebral malaria (Prasad and Garner 2000). Other complications such as renal failure, lactic acidosis, disseminated intravascular coagulation, shock, gastrointestinal hemorrhage, pulmonary edema, and gram-negative septicemia need to he managed as they appear. Adjuvant therapy with vitamin A, immunoglobulins, and monoclonal antibodies has been used without change in morbidity or mortality,

Prevention

Area-specific guidelines for malaria control can be obtained from the regional WHO centers. Chemoprophylaxis with adequate drugs can be used for prevention of transmission of the disease. It should be given to all individuals traveling to malaria endemic zones (Table 59D.2). Vector control is difficult due to resistance of mosquitoes to various insecticides. Recently, the entire genomes of P. *falciparum* and *Anopheles* mosquito have been decoded, and this may help in finding ways to better control malaria.

Table 59D.2: Prophylaxis of malaria

Sensitivity of malaria parasite	*Drug used for chernapropbylaxss*	*Doses*
Sensitive to chloroquine	Chloroquine	300 nig base/week Beginning 2 weeks before departure and up to *6* weeks after return
Resistant to chloroquine	Mefloquine	250 mg/week 2 weeks before departure and 4 weeks after return
	Chloroquine + proguanil or chlorproguanil	Chloroquine as described, proguanil 100-200 mg/day ehlorproguanil 20 mg/day as described above
	Chloroquine or amodiaquine -+ sulpha doxine pyrimethamine (Fansidar) combination, or 4- pyrimethamine alone	Chloroquine as above and Fansidar one tablet/ week, pyrimethamine 50 mg/week as described above

African Trypanosomiasis

African trypanosomiasis or sleeping sickness *(malaise du sommeil)* is caused by *Trypanosoma brucei gambietue* (Gambian trypanosomiasis) or *Trypanosoma brucei rhodesimse* (Rhodesian trypanosomiasis).

African trypanosomiasis occurs in a wide belt of African continent between latitude of 10° north to 25" south. Gambian trypanosomiasis is more widely distributed in western and central Africa, whereas Rhodesian trypanosomiasis is limited to cast and southeast Africa. The official incidence of about 20,000-50,000 cases per year is probably an underestimation, as a large number of cases are not reported due to nonavailability of medical facilities. In the wild, reservoir hosts arc pigs and dogs for *T. b. gambiense* and antelope, wild hogs, and cattle for T. *b. rhodesiense.* It is spread by tsetse fly of the genus *Glossina.* Humans contract the disease by the bite of tsetse fly when they go hunting or searching for water and food in areas in which the infected reservoirs and vector abound. About 25-50 million people in sub-Saharan Africa live in the endemic zone, wherein more than 200 hyperendemic /ones are recognized. Other causes of spread include laboratory accident, blood transfusion, transplacental spread, and perhaps by bites of other insect vectors (Enanga et al. 2002).

Pathogenesis and Pathology

The pathogenesis of CNS trypanosomiasis is poorly understood. Inoculation of the parasite by the tsetse fly is followed by formation of a nodule due to an inflammatory response and parasitic replication (stage 1). Recurrent bouts of parasitemia follow thereafter, resulting in the hemolynipliatic stage (stage 2). The parasites gain access to the brain and meninges through the choroid plexus and Virchow-Robin spaces (stage 3). African trypanosomes are densely coated with a glycoprotein called the variant surface glycoprotein (Magcz et al. 2002), which keeps changing its antigenic character with each new population of trypanosomes. This may result in letting the trypanosome escape immunological control even after the mounting of IgM antibodies against a large number of antigenic subtypes. Mechanism of damage to the host tissue is unknown.

The characteristic pathological finding of CNS trypanosomiasis is meningoencephalitis, with infiltration of perivascular and Virchow-Robin spaces by dense lymphocytic and plasmacytic inflammatory infiltrate, accompanied by glial proliferation. The meninges are covered by a milky white exudate, especially in the region of vertex where the meninges are adherent to each other and the skull. The choroid plexus shows inflammation, round cell infiltration, and edema. The brain is swollen with cerebral vascular congestion. Perivascular demyelination of the subcortical white matter is seen in most cases. Hemorrhagic leukoencephalopathy with fibrinoid necrosis of parenchymal vasculature may also occur.

Clinical Features

Characteristically the disease can be recognized as occurring in stages. The first stage is characterized by formation of chancre at the site of fly bite, second stage is hemolynipliatic stage, and the third stage is systemic stage with involvement of the CNS. A firm, tender nodule (chancre), 2-5 cms in size develops in 20-50% of patients 10-14 days after the bite of tsetse fly. This may ulcerate with enlargement of regional lymph nodes, lasting for 1-2 weeks. This is followed within 1-5 weeks by the hemolymphatic stage characterized b) high grade inter mittent fever, sweating, nausea, vomiting, general malaise, arthralgia, and generalized lymphadenopathy, often coinciding with bouts of parasitemia. Other symptoms are headache, dizziness, tachycardia, debility, amenorrhea, and sterility as parasitemia worsens. During this stage each bout of parasitemia is associated with the liberation of successive generation of parasites with slightly different surface antigens. Treatment, if commenced at this stage, is associated with good prognosis. The hemolymphatic stage can lead to the systemic stage with CNS involvement or several cycles of hemolymphatic stage may occur before the CNS is involved. The pace of disease is rapid in Rhodesian trypanosomiasis, whereas it is more chronic and indolent

in Gambian disease with easy identification of different clinical stages.

The systemic stage is also associated with liberation of a new generation of parasites lasting 1-6 days at several-week intervals. The systemic stage is characterized by serous effusions, pancarditis, deep hyperesthctic pain out of proportion to injury (Kerandel's sign), and lymphadenopathy particularly of the posterior cervical lymph nodes (Winterbottom's sign) in the Gambian form. CNS involvement is indicated by the presence of psychological and behavioral changes. Initial symptoms of lethargy, apathy, indifference, euphoria or depression give way to insomnia (10%), daytime hypcr-somnolence, disturbance of circadian thythm, chorea, rigidity, tremors, ataxia, and hemiplegia. Less commonly, seizures, cranial neuropathies, and altered mentation occut. Eventually patients develop increasing drowsiness and finally coma. Untreated patients with *T. rbodesiense* generally die in 6-9 months aftet the onset of the disease.

Diagnosis

Diagnosis is made by demonstration of parasites in the peripheral blood, lymph node aspirate, bone marrow, or CSF. Examination of wet peripheral smear of blood stained with Giemsa stain can demonstrate motile parasites. Repeated examination is necessary because parasitemia is intermittent. Using thick smear, microhematocrit ccntri-fugation, anion exchange, or huffy coat preparation can increase the chances of parasite detection. CNS involvement is confirmed by demonstration of the motile trypanosome in the CSF, though it occurs in only 17% of severe cases of sleeping sickness. CSF examination shows lymphocytic pleocytosis and elevated protein, IgM levels, oligoclonal bands, and morular or Mott's cells, which are modified plasma cells containing large eosinophilic inclusions. Although, these cells are not pathognomonic of trypanosomiasis, their presence in large numbers is fairly characteristic of the disease. Nenroimaging with CT scan shows meningeal, choroidal, or parenchymal enhancement, hut is not specific. EEC shows diffuse nonspecific generalized slowing of background activity, especially in the later stages.

The elevation of IgM in both serum and CSF can be used as a screening test in endemic regions. Serological techniques such as indirect hemagglutination and immunofluorescence to detect trypanosomal antigen is reported to be sensitive, but high antigenic variability of these parasites poses a major diagnostic problem. Enzyme-1inked immunosorbent assays and immunofluorescent antibody tests allow detection of antibodies in the CSF. Animal inoculation technique, though sensitive, is time consuming, expensive, and impractical in field conditions. The disease should be differentiated from febrile disorders with lymphadenopathy, headache, sleep disorders, malaria, infectious mononucleosis, arboviral cnccphalitides, leukemia, lymphoma, tuberculosis, syphilis, brucellosis, relapsing fever, toxoplasmosis, and onchocerciasis (Enanga et al. 2002).

Treatment

Before initiating therapy, confirmation of the diagnosis is essential because most of the drugs used fot the treatment of trypanosomiasis are highly toxic. T. *b. gambiense* in the hcmolymphatic stage is treated with intramuscular pentamidine at 3 mg/kg per day for 10 days. For *T. b. rbodesiense* in the hcmolymphatic stage, intravenous suramin in the dose of 20 mg/kg per day with a maximum o[I ;-,m per day is s;iven on days I, 3, , 14. and 21. A suramin test dose of 200-300 mg is essential because a severe idiosyncratic reaction presenting with shock is not uncommon. Suramin is nephrotoxic; hence, it cannot be given to patients with pre-existing renal disease. Prolonged use of suramin results in an axonal sensorimotor neuropathy. Both suramin and pentamidine do not cross the blood-brain barrier and therefore are not effective in the meningocncephalitic stage of the disease.

For meningocncephalitic trypanosomiasis cflornithine (difluromethyl ornithine, DFMO), a polyamine synthetase inhibitor has shown promise but is expensive. A 14-day course of DFMO in the dose 100 mg/kg intravenously every 6 hours for primary meningocncephalitic trypanosomiasis, and a 7-day course for treating relapses are recommended. Because the response of T. *b. gambiense* to DFMO is variable, organic arsenicals continue to be the mainstay in the treatment of Gambian trypanosomiasis {Enanga et al. 2002).

Melarsoprol {an organic arsenical) is given intravenously three to font times per day, 200-500 mg (maximum 3.6 mg/kg) per injection. The treatment is given for 3 days, and 3 such treatment cycles are given with an interval of 7 days in between two cycles. Arsenical encephalopathy is a dreaded complication, occurring in about 15-20% of cases. It is characterized by recurrent seizures, cognitive impaitment, and progressive coma, occurring between the first and fifteenth day of treatment. It is fatal in about 10% of cases. A high CSF pleocytosis and simultaneous use of thiabendazole increase the risk of arsenical encephalopathy. Premedication with corticosteroids, nutritional supplementation for malnourished patients, and prophylactic anticonvulsants are recommended before commencing melarsoprol therapy. MRI may assist ro distinguish arsenical encephalopathy from relapse. Focal bilateral high signal areas in white matter on T2- weigh red MRI indicate recurrence of infection or incomplete treatment [Burchmore et al. 2002).

Continuous surveillance for 2-3 years is essenrial as relapses are common. Relapses are indicated by headache, fever, worsening of neurological signs, seizures, and worsening of CSF profile. Relapses in T. *b, gambiense* are treated with eflornithine and in T. *b. rbodesiense* with melarsoprol. Eradication of infection is achieved in about 90% of cerebral cases. However, sequelae in the form of insomnia, irritability, and poor impulse control may occur.

Prevention

Preventive measures include eradication of the tsetse fly, use of protective clothes, reservoir control, regular medical surveillance, and treatment of early cases in endemic areas.

American Trypanosomiasis

Existing as an acute or chronic disease American trypanosomiasis or Chagas' disease is caused by the hemoflagellate protozoa, *Trypanosoma cruzi.* The disease occurs in Centra! and South America. Chagas' disease causes cardiac and gastrointestinal tract autonomic de-efferentation years aftet primary infection. CNS involvement, though tare, should snidest ctincunvnr I IIV infection.

Chagas' disease is a zoonotic disease, transmitted by reduvid bug of the genus *Triatoma.* The trypanosome inhabits the gut of the bug. The bug bites at night and defecates at the time of biting. The infection is transmitted by rubbing the fecal matter containing the metacyclic stage of the parasite into the tiny skin punctutc, other abrasions of the skin, or by rubbing the eyes or orher mucosal surface with infected fingers. The infection can also be transmitted transplacental^, by blood transfusion, or from organ transplant.

Clinical Features

Acute Chagas' disease, mostly in children, is a flulike illness occurring about 1 week after inoculation with fever, lymphadenitis, malaise, hcpatosplenomegaly, facial edema, tachycardia, and, rarely, meningoencephalitis. The portal of entry may show nodular or ulcerative swelling (chagoma) in about 25% of cases. In 50% of cases the primary site is the outer canthus of the eye, with unilateral palpebral edema and periauricular lymph node enlargement (Romana's sign). Early myocarditis, meningoencephalitis, or reactivated Chagas' disease suggest concurrent I IIV infection. CNS involvement manifests as seizures, tremors, rigidity, paralysis, and altered mentation. Death in the acute stage is caused by acute myocarditis, congestive cardiac failure, or meningoencephalitis.

Chronic Chagas' disease develops years or decades after initial infection with clinical features suggesting involvement of heart, gastrointestinal tract, and nervous systems. Cardiac involvement is commonest in chronic disease with congestive cardiomyopathy, syncopal attacks, and systemic and CNS embolization from mural thrombi of a left ventricular apical aneurysm. Destruction of autonomic ganglion in the heart tcsults in postural hypotension, dizziness, and rhythm disturbance, whereas similar involvement of the gastrointestinal tract results in megacolon and megaesophagus. CNS involvement in chronic Chagas' disease is due to embolization of cerebral vessels from intramural cardiac thrombi or from formation of mass lesions with seizures, hemiparesis, cerebellar ataxia, or other focal deficit.

Transplacental transmission of T, *cruzi* results in congenital Chagas' disease with premature birth and developmental delay in the survivors.

Diagnosis

In the acute stage the diagnosis can be established in about 90% of patients by the presence of parasites in thick or thin smears of peripheral blood or buffy coat during febrile episodes. Aspiration of spleen, liver, lymph nodes, and bone marrow may show the parasites in macrophages. Serological tests include hemagglutination, immunofluorescence and compliment fixation tests, which become positive after about 1 month and remain so for life. Chronic Chagas' disease is diagnosed serologically. False positive serology can occur in syphilis, leishmaniasis, malaria, leprosy, or collagen vascular disease.

Treatment

Treatment for Chagas' disease is unsatisfactory as it only reduces the duration of symptoms and mortality. As soon as infection with T. *cruzi* is suspected, treatment should be started without waiting for laboratory confirmation (Urbma 2001). In acute Chagas' disease, nifurtimox in a dose of 8-10 mg/kg for adults, 12.5-15 mg/kg for adolescents, and 15-20 mg/kg for children {1 to 10 years) is recommended in four divided doses for 90-120 days. Adverse effects include abdominal pain, anorexia, nausea, vomiting, weight loss, and neurological side effects (restlessness, disorientation, insomnia, neuritis, and seizures). Alternatively, benzimidazolc 5 mg/kg per day orally for fit) Jays may be used. Side effects include peripheral neuropathy, granulocytopenia, and rash.

Prevention

Vector control by spraying insecticides, improving housing, and screening of donated blood may check transmission of the parasite. Mosquito nets, insect repellents, and the use of protective clothing provide additional protection. Tourists traveling to endemic areas should avoid sleeping in dilapidated houses. Laboratory workers should wear gloves and eye protection.

Amoebic Infections of the CNS

Protozoan free-living amoebae are widely distributed in nature and are particularly found in moist soils and in warm fresh waters {Marshall et al. 1997). Amoebic infections of the brain are extremely rare, but they have a very high mortality. Two climcopathological syndromes are recognized: "primary amoebic meningoencephalitis"

(PAM) and "granulomatous amoebic encephalitis" (GAE). Amoebae from the genera *Naegleria* cause PAM, and those from the genera *Acanthamoeba* cause GAE. *Naegleria fowleri* exists in three forms: trophozoites, flagellates, and cysts. The trophozoite and flagellate forms are highly motile and transform into cystic form under nutritionally deprived conditions. The parasite excysts when the conditions become favorable through the pores in the cyst wall. The most potent stimulus for the excystment is the presence of molecular carbon dioxide in the environment. *Acanthamoeba* lacks the flagellate stage, and the trophozoites are larger than *Naegleria,* The cysts are stellate and have a small opening at one end from which the excystment occurs. *Leptomyxida,* another free-living amoeba, has been recently identified as a cerebral pathogen, and the genus *Balamuthta mandrillaris* is a rare cause of GAE.

N. *fowleri* has been isolated from puddles, pools, mud, rivers, and sewage disposals. They have also been isolated from air conditioners and thermal effluents from factories. Children acquire PAM as they swim or play in water com miniated h) thes< free living amoebae. I'lie disease has a male:female ratio of 2:f for *Naegleria* and 5:1 for *Acanthamoeba.* PAM is more common in children. Granulomatous amebic meningitis can be seen at any age. *Acanthamoeba* causes GAE in immunocompromised hosts, such as patients with AIDS, those on long-term antibiotics or corticosteroids, or transplant recipients on immunosuppression. CNS invasion is generally through the nasopharynx or respiratory tract. The incubation period of the disease is not known hut is probably long.

Pathogenesis and Pathology

The parasites enter the brain by passing through the cribriform plate along the fila of the olfactory nerve to enter the frontal lobes and cause a necrotizing inflammation with extensive destruction. *Acanthamoeba* can also invade the CNS through this route, through the bloodstream, or through a primary corneal infection acquired by using contact lenses stored in contaminated saline solution. A large number of proteolytic enzymes are produced by the amoebae, which destroy the tissues around the area of invasion (Marciano-Cabral et al. 2000).

The meninges in PAM are hypcremic with diffuse superficial hemorrhages and are ensheathed in purulent basal exudates, most intense around the olfactory bulbs. There is extensive necrotizing destruction of the cerebral parenchyma, more so in frontal and temporal lobes. Histopathology reveals polymorphonuclear inflammatory infiltrate with interspersed trophozoites in and around the subarachnoid space. The inflammatory infiltrate is devoid of cysts and flagellate forms. Extracerebral tissues are usually spared but pulmonary and myocardial infiltration has been reported. GAK is characterized by formation of small necrotic abscesses.

Clinical Features

PAM presents with acute onset of fever, headache, vomiting, and photophobia with altered mentation. In the acute phase, the disease closely resembles acure pyogenic meningitis; however, seizures and focal neurological deficits are more common in PAM. Patients may complain of anosmia or cacosmia as the olfactory bulbs are involved early in rhe course of the disease. Rapid deterioration occurs, as patients do not respond to antibiotics, which are often given for the suspected bacterial meningitis. The common preterminal event is raised intracranial pressure and consequent cerebral herniation.

GAE has a slow and insidious course suggestive of an intracranial space-occupying lesion and, rarely, as insidiously progressive meningoencephalitis. The lesions in GAE are most commonly localized in the posterior fossa. The patients gradually deteriorate and eventually die after two to three weeks. *Acanthamoeba* keratitis has been reported in patients who use soft contact lenses kept in contaminated saline solutions. Rarely the corneal infection spreads intracranially (Marciano-Carbal et al. 2000). *Balamuthia* meningitis affects the cortex more frequently, especially the temporal lobes.

Diagnosis

CSF examination reveals polymorphonuclear leukocytosis, with hypoglycorrhachia, and increased protein, but the Gram's stain and the culture are negative. Rarely, their typical sluglike movements in a wet drop preparation of fresh CSF can identify the actively motile trophozoites. I hi (.SI- picture <>l patients with GA1 *i*--. suggestive oJ granulomatous infection, with moderately raised protein, a near normal or slightly low CSF glucose, lymphocytic CSF pleocytosis, and absence of motile trophozoites.

The majority of patients with PAM has normal CT and MRI scans of the brain. In GAE cerebral lesions resembling spaec-occupyiug lesions are seen (Kidney and Kim 1998). PAM needs to be differentiated from acute bacterial meningitis or brain abscess rupturing into the subarachnoid space. The differential diagnosis of GAE is chronic meningitis of fungal or tuberculous origin, brain abscess, neoplastic lesions, and encephalitis. A similar clinical syndrome may occur in CNS vasculitis, PAM and GAE are so rare and with so high mortality that these ate usually-diagnosed postmortem, unless diagnosed and treated very early.

Treatment

Diagnosis is usually delayed in amoebic CNS infections, and the therapeutic response is poor to available drugs. Many drugs, including amphotericin B, misonidazole, rifampin, trimethoprim, phenothiazines, and ginghousu, have been tried. *Acanthamoeba* is more resistant to

treatment than *Naeglena.* As there are no established guidelines for treatment due to the rarity of the disease, the treatment is individualized. The best response has been observed with a combination of chemothcrapeutic agents, which includes amphotericin B given by intrathecal and intravenous routes, in maximal possible doses.

Cerebral Amoebiasis

Entamoeba histolytica, the commonest intestinal parasite colonizing the large bowel in man, causes local ulceration of the wall of the colon and presents as amoebic dysentery. It is endemic in Southeast Asia, India, and South America. Man is the primary host and gets infected by consuming water and food contaminated with infected feces. The amoebae entet the bloodstream and colonize in distant organs causing metastatic abscesses. Liver is affected in about 10%, resulting in amoebic liver abscess. Cerebral involvement is seen in about 0.1% of all cases. Cerebral abscess is almost always associated with hepatic abscess.

Pathogenesis and Pathology

The abscesses are located at the junction of gray and white matter in the cerebrum or cerebellum. Proteolytic enzymes of the amoebae cause tissue destruction locally with gtanulomatous inflammatory infiltrate. The brain appears edematous, with patchy meningeal exudates. The cut surface reveals a necrotic and hemorrhagic center surrounded by poorly differentiated rim with perifocal edema. The rim consists of dense inflammatory infiltrate comprising of mononuclear cells and RBCs. Amebae or tissue cysts can be identified in the tissue sections (Plate 59D.II).

Clinical Features

The disease affects predominantly young adults, with male: female ratio of 10:1, Clinical features are not specific. Intestinal complaints usually predominate initially. Febrile encephalopathy and focal neurological signs should raise the possibility of this disease. Cerebral abscesses have been reported in patients without clinical amebic colitis. An invasive amoebiasis is usually evident in other organs like **ihr** li\ ;**! ,'nul** Inn;--,, l-'ot.il iii-Lin Mimical sie.ns, lever, lethargy, seizures, and varying degree of altered mental status are common symptoms.

Diagnosis

Isolated cerebral abscesses arc rare. Imaging of liver and brain are helpful. CT scans show single or multiple abscesses especially in frontal lobes or basal ganglia, which appear as low attenuating, ring-enhancing lesions with marked perifocal edema. Tl-weighted MRI shows the abscess as a central hypointensity surrounded by an isointense rim, enhancing on gadolinium. On T2-weighted images they are hypcrintensc with a hypointense rim. Antiamebic antibodies are detected in most cases.

Treatment

Medical therapy consists of metronidazole 1 g, followed by 500 mg 6 hourly intravenously or 750 mg intravenously three times a day for 10 days, followed by iodoquinol 650 mg three times a day for 20 days. In children the dose of metronidazole is 30-50 mg/kg per day in divided doses. Emetine in dosage of I mg/kg per day to a maximum of 60 mg per day can also be used. Chloroquine has also been tiled in do',.t!.v u: iiOO iiisJ, per **day** tor 2 days lol owed by 300 mg per day for 2-3 weeks. The result of medical treatment is universally poor. Combining surgical resection of the abscess with antiamoebic therapy may improve survival (Shah et al. 1994). The results of all forms of treatment are poor, and the mortality is 90%,

Toxoplasmosis

Toxoplasmosis is caused by *Toxoplasma gondii,* an intracellular protozoa first described by Janku in 1923 in the retina of a child. Common manifestations of toxoplasmosis are chorioretinitis and meningoencephalitis. After the pandemic of HIV/AIDS beginning in the 1980s, toxoplasmosis has acquired the dubious distinction of being the commonest cause of cerebral mass lesion in AIDS patients. Cerebral toxoplasmosis in HIV/AIDS is covered in Chapter 59E.

The only definitive hosts for T. *gondii* are domestic cats, which are infected by eating infected rodents, ot oocysts passed in the feces of cats that harbor the parasite in their intestines. The tissue cysts of the patasite in these animals infect the intestinal epithelial cells and develop into merozoites. The sexual cycles starts when some of the merozoites develop into gametocytcs, which fuse and form diploid oocysts, which are excreted in the feces. Under favorable conditions (i.e., warm and humid climate) sporogony occurs in the oocysts. Sporulated oocysts are infective *A\K* if ingested by rodents, cats, or other small animals, they release large numbers of sporozoites in the small ir.iestiiie. Spurn/ones penetrate the gui wall, replicate, and spread hematogenously to most mammalian tissues. Once in a cell, spotozoitcs undergo fission until the host cell ruptures and liberates sporozoites that infect the surrounding cells. Over time, tissue cysts are formed containing a large number of parasites, which arc now called bradyzoites as they divide slowly. The tissue cysts are immunologically inert and remain so for years, failing to elicit an inflammatory response. Reactivation of tissue cysts occuts if cell-mediated immunity wanes as occurs in patients with cancer, organ transplant, chronic corticosteroid use, and AIDS. Most human infections are acquired by ingesting

oocysts contaminating food, hands, or soil or tissue cysts contained in raw or undercooked meat. Transplacental transmission is also common. Rarely, organ transplantation and blood transfusion may the routes of entry of the parasite.

Pathogenesis and Pathology

The toxoplasma gains entry into the host macrophages and occupies a "parasitophorous vacuole." Whereas, activated macrophages destroy the parasite with clearance of parasitemia, resting macrophages allow intracellular replication of patasite. The mechanism by which toxoplasma survive the tissue macrophages is not known. As the disease is mild and not fatal in the immunocompetent host, pathological reports are scanty. The lesions are found in eyes, brain, and other organs. In the brain they are present in both gray and white matter and appear as moth-eaten, necrotic honeycombed areas, infiltrated with inflammatory cells, especially in the perivascular area with pyknotic nuclei. In congenital toxoplasmosis the lesions are most intense in cortex, basal ganglion, and periventricular area (Figure 59D.1). Calcification within the areas of necrosis is common. Hydrocephalus occurs as a result of obstruction of aqueduct of Sylvius or foramen of Monroe by active ependymitis or deposition of necrotic debris in the ventricles. Periventricular and periaqueductal vasculitis and necrosis are almost pathognomonic of congenital toxoplasmosis {Kristennson et al, 2002).

Clinical Features

Primary infection in an immunocompetent host is usually asymptomatic. Acute infection is associated with fever and lymphadenitis in 10-20% of patients, 1-2 weeks after ingestion of cysts. A maculopapular rash similar to infectious mononucleosis occurs in a small number of patients. Rarely, immunocompetent hosts develop disseminated toxoplasmosis with CNS involvement, Meningoencephalitis, seizures, drowsiness, confusion, and coma are often the presenting symptoms. The CSF in CNS toxoplasmosis shows lymphocytic pleocytosis, mildly elevated protein with normal sugar. Acute chorioretinitis may precede or follow CNS toxoplasmosis.

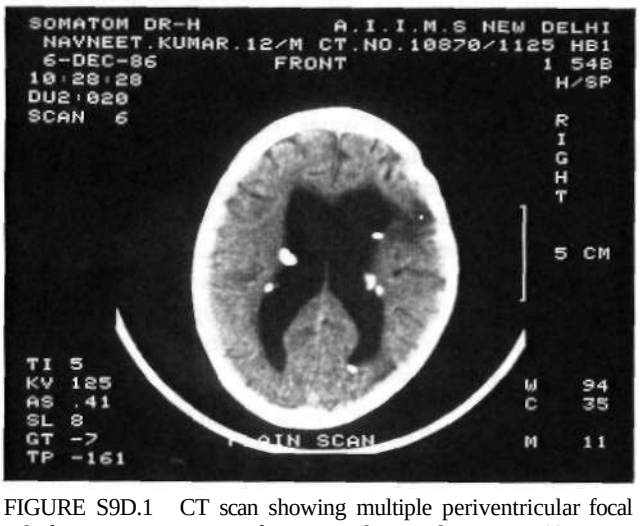

FIGURE S9D.1 CT scan showing multiple periventricular focal calcifications in a case of congenital toxoplasmosis. (Courtesy Dr. S. K. Gaekwad.)

Congenital toxoplasmosis is transmitted transplacentally when a woman acquires *Toxoplasma* infection during pregnancy (Wallon et al. 1999). The infant may be born with bilateral chorioretinitis (blindness and strabismus), CNS involvement (epilepsy, psychomotor retardation, microcephaly, periventricular calcification, hydrocephalus, pituitaty insufficiency), or systemic effects (jaundice, hepatosplcnomegaly, anemia, low birth weight, lymphadenitis, and pneumonitis) (Lowichik and Siegel 1995).

Ocular toxoplasmosis occurs during primary infection, when it is usually unilateral, during congenital infection, when it is usually bilateral, and during reactivation of previous infection in an adult, *'toxoplasma* chorioretinitis usually involves the posterior pole near the macula. Pain in the eye, photophobia, and diminution of vision occur in the acute stage. Focal yellow-white patches of necrotizing retinitis along with retinal edema and exudates give way to darkly pigmented scars after healing. Uveitis, scotoma, defect in central vision, photophobia, glaucoma, cataract, microphthalmia, and strabismus may be associated. Papilledema may occur due to CNS involvement.

Diagnosis

Serodiagnostic tests for toxoplasmosis are available. Antitoxoplasma IgG antibody detection done by Sabin-Fieldman dye test is useful in *Toxoplasma* encephalitis up to 8 weeks as the titers decline slowly after that. Titers above 1:1024 are indicative of acute infection. The test is 93% sensitive but lacks specificity. IgM antibody detection by double sandwich enzyme linked immunosorbent assay (EL1SA) is sensitive and indicates infection in the p.iM 2 .; months. Acute congenital toxoplasmosis is diagnosed by finding high or rising IgG titers or positive IgM titers. Negative IgG in an immunocompetent host with chorioretinitis almost excludes toxoplasmosis. CSF examination in a patient with encephalitis shows monocytic pleocytosis, raised protein and DNA sequences of *T. gondii,* which can be detected by PCR (Montoya 2002). Plain x-rays of skull may show characteristic spotty intracranial calcifications, which are localized in the periventricular area on CT scan (sec Figure 59D.1). In acute stage *Toxoplasma* abscesses are seen as multiple round, nodular, or ring-enhancing lesions with intense edema in the immunocompetent hosts. MRI is mote sensitive (than CT) in detecting these lesions. Differential diagnoses of such lesions on neutoimaging arc tuberculomas, lymphoma, metastases, and pyogenic

abscesses (Kornbluth and Destian 2000). Tissue diagnosis by biopsy of the intracranial lesion is the gold standard but is seldom indicated. It is indicated only if the condition worsens after initiation of therapy, if there is a solitary, large lesion on MR I, or if a patient develops these lesions while on prophylaxis of *Pneumocystis carinii* pneumonia. Differential diagnosis of neonatal toxoplasmosis includes human cytomegalovirus, herpes, rubella, and syphilis or *Escherichia colt* meningitis, sepsis, and erythroblastosis fetalis.

Treatment

A combination of pyrimethamine (a dihydrofolate reductase inhibitor) in a loading dose of 200 mg followed by 50-75 mg per day (or 1 mg/kg per day up to maximum of 100 mg per day) in three divided doses and sulfadiazine (a dihydrofolate synthetase inhibitor) 4-6 g per day (or 100 mg/kg per day, up to maximum 8 g per day) for 3–4 weeks is recommended. Immunocompromised hosts require lifelong prophylaxis. Supplement of folinic acid (10 mg per day) prevents hematological complications. The drug is effective against tachyzoir.es (in active macrophages) but ineffective on the cystic stage. Alternatively, clindamycin 600 mg orally or parenteral ly every *6* hours is recommended. It has poor CSF penetration, and side effects include neutropenia, rash, pseudomembranous enterocolitis, myositis, and elevated CK levels. Another drug atovaquone, a hydroxynephthaquinone derivative, in doses of 750 mg four times a day has shown promise. Patients that cannot tolerate standard therapy may be treated with azithromycin, roxithromycin, or clarithromycin (Derouin, 2001).

Immunologically competent adults and children with only h mphadenopathy do noi require specific Lhcrapv unless the symptoms are severe. Ocular toxoplasmosis should be treated with pyrimethamine plus either sulfonamide or clindamycin for 1 month. Congenital toxoplasmosis is treated with pyrimethamine (0.5-1 mg/kg) and sulfadiazine (100 mg/kg) orally for 1 year. Additionally, spiramycin (100 mg/kg) plus prednisolone (1 mg/kg per day) has shown good results. The choice of antiparasitic agent for its safety and efficacy profile for congenital toxoplasmosis remains unsettled.

Prevention

Prevention requires clean habits while handling pet cats and dogs. Stray dogs and cats should be avoided, and meat should be properly cooked and stored at -20°C. Immunocompromised hosts, especially those with AIDS, require lifelong prophylaxis with 25-50 mg pyrimerhamine and 1-2 grams of sulfadiazine per day after recovery from toxoplasmic encephalitis. Patients intolerant to sulfadiazine should receive clindamycin 1200 mg per day in three divided doses.

HELMINTHIC INFECTIONS OF THE CNS

Twenty different species of the helminths affect the CNS in man. Of these, cystieereosis and echinococcosis arc by far the commonest.

CESTODES

Cystieereosis

Cystieereosis is invasion of tissues by the larval stage of pork tapeworm, *Taenia solium.* Neurocysticercosis (NCC) by larvae is an important public health problem particularly in developing countries. NCC has worldwide distribution and is endemic in Latin America, the Indian subcontinent, China, and most of the African and Asian countries. It is absent in Israel and certain Asian countries in which pig rearing is unacceptable for religious reasons. In the United States and European countries, NCC is becoming more common due to infected immigrants. Seroprevalcnce in villages of Mexico, Guatemala, Bolivia, Peru, and Ecuador is between 4.9-24%. In India it is between 2-3% in the general population. The high incidence of epilepsy in Latin America is attributed to rampant NCC. According to the Commission on Tropical Diseases of International League Against Epilepsy, age-adjusted prevalence of epilepsy in tropical countries is 10-15 per 1000 population and is largely due to NCC. Seizures in people above 25 years of age in endemic areas are due to NCC in 50-70% of cases. Globally, it causes about 50,000 deaths annually. In India 40% of focal seizures arc due to NCC, calcified NCC and granuloma, or single-enhancing CT lesion consistent with cysticercal granuloma (Padma et al. 1994; Pal et al. 2000).

The disease is most common where there is close contact with pigs and where poor sanitation and personal hygiene exist. Man, the definitive host, harbors the adult tapeworm in the intestines. Gravid proglomds containing highly infective fertile eggs are shed in the feces. NCC is acquired iIn ongh the feco-oral route by consuming contaminated food (raw vegetables or water) or even through infected fingers of self or food handlers. On the other hand, tapeworms are acquired by eating raw or undercooked infected pork. After ingestion, the eggs hatch into invasive larvae, which penetrate the gut wall and lodge in various tissues, including brain, muscles, subcutaneous tissue, liver, eyes, and spinal cord, through hematogenous spread. In tissues they mature into the larval form, the cysticercus, with an invaginated scolex.

Pathogenesis and Pathology

By necessity the survival of cysticerci in pigs depends on absence of significant inflammatory response on the part of the host. Cysticerci appear as ihir.-wnLed oval cysts, aboui

1 cm m diameter, with an in vagina ted scolex, which appears as a white nodule, attached to one side of the cyst, The cyst wall consists of an outer smooth white eosinophilic layer, an inner cellular layer, and an innermost layer of loose connective tissue (Plate 59D.IH). The parasite escapes the host's immune surveillance mechanisms by secreting a serine protease inhibitor called teniastatin, which inhibits complement activation, lymphocytic migration, and cytokine formation. The presence of cysts is not always associated with symptoms. Approximately 3-8% of individuals dying of other causes show viable cysticerci in their brains on autopsy in endemic areas. It is only when the cysticerci undergo degeneration that the inflammatory response starts and symptoms like seizures occur. This is especially true for patients with single-enhancing CT lesions. On the other hand, when the infection load is high, patients present with features of raised intracranial pressure and deteriorating mental status.

Different stages of natural evolution of cysticerci are described. Viable cysts have minimal associated inflammatory response (vesicular stage). Inflammation, especially by the mononuclear cells around the cyst, results in the colloidal stage, which i^ followed bj gradual replacement by fibrotic tissue and collapse of cyst wall (granular nodular stage). Finally, replacement by fibrotic tissue and mineralization of the parasite results in the calcific stage. Whereas, parenchymal cysts are small (about 1 cm diameter) in the enrticosuhorned area, larger IMI,I|\I-renchymal cysts may be present in the ventricles or the Mili;ir:u-hiioid space, ['.irenchvinal cysts are generally associated with seizures, raised intracranial pressure, and deteriorating mental status. When parasite load is high, inflammation around the cysts gives rise ro a fulminant meningoencephalitis picture. Subarachnoid cysts generally attain large size with lobulations (grapelike appearance, the racemose variety), lose the scolices, and are usually seen at the base of brain or Sylvian fissure. Intraventricular *NCC.* results in persistent or intermittent raised intracranial pressure due to blockage of aqueduct of Sylvius or foramina of Lushka and Magendie. Inflammation of these cysts results in cpendymitis and arachnoiditis with resultant meningitis, communicating hydrocephalus, or vasculitis with stroke.

Clinical Features

The clinical symptoms occur 1-35 years after exposure and several years after CNS infestation by cysticerci. NCC has protean clinical manifestations depending on number, site, stage, duration of the cysts, and whether inflammatory response is present or not. Seizures, both generalized and partial, are the commonest symptoms, occurring in about 92% of patients with parenchymal NCX; in the active (colloidal and nodular-granular) and inactive (calcific) stages. The acute encephalitic form, common in children, is associated with rapid deterioration in neuropsychological status, recurrent seizures, intracranial hypertension, and coma. This form of presentation is usually seen in patients with high infection load with inflammatory response. Focal neurological signs, such as hemiplegia and cerebellar ataxia, usually occur following the inflammatory reaction (meningoencephalitis), vasculitis, and stroke due to NCC in the subarachnoid space. NCC is a common cause of stroke in young patients in Latin American countries. The infarcts may be small (lacunar) or large involving middle cerebral artery. The clinical picture of raised intracranial pressure with headache, vomiting, cognitive dysfunction, neuropsy-**JualriL. deeiine. j:kl papilledema** liiairs **with** multiple parenchymal NCC, with or without acute meningoencephalitis, with intraventricular cysts causing obstructive hydrocephalus, or with subarachnoid cysts causing severe meningitis and CSF outflow obstruction. Patients harboring cysts in the brainstem present with corresponding focal neurological deficit. Involvement of spinal cord is associated with compressive myelopathy. Downward migration of subarachnoid cyst from the posterior fossa may cause extramedullary compression, whereas intramedullary cysticercosis occurs from hematogenous spread. Root pain occurs in about 1-5% of patients. Ocular cysts occur in about 1 % of cases with retro-orbital pain similar to migraine, proptosis, ptosis, and diplopia. Retinal, vitreous, or subconjunctival cysts present with visual loss, scotoma, floaters, orbital abscess, and panophthalmitis, which occur spontaneously or after initiating specific cysticidal therapy. Patients with cysticerci in muscles can present with painful muscular hypertrophy and weakness, especially of the proximal group of muscles. Subcutaneous nodules may provide a clue to the etiology of epilepsy {Figure 59D.2A).

Diagnosis

In endemic areas, diagnosis of NCC should be considered in almost all cases with neurological or psychiatric complaints. Presence of nodules in subcutaneous or subconjunctival tissue helps in the diagnosis. Definite diagnosis depends on demonstration of latval forms of T. *solium.* Del Bruno et al, have proposed diagnostic criteria of NCC based on clinical, neuroimaging, serological, histopathological, and epidemiological criteria. Absolute criteria include histopathological demonstration of parasite in brain or spinal cord lesion, neuroimaging consistent with NCC (cystic lesion showing scolex), or direct visualization of subretinal parasite by funduscopy. Major criteria include neuroimaging highly suggestive of NCC (cystic lesion without scolex, enhancing lesion, or typical parenchymal brain calcification), resolution of intracranial cystic lesions after cysticidal therapy, or spontaneous resolution of small, single-enhancing lesion. Minor criteria include lesions compatible with NCC on neuroimaging (hydrocephalus, abnormal leptomeningeal enhancement, myelogram showing multiple filling defect in the column of contrast medium), clinical manifestations suggestive of NCC,

positive CSF ELISA for detection of anticysticercal antibodies or cysticercal antigens, and cysticercosis outside CNS (histological diagnosis of subcutaneous or muscle nodule, x-ray films showing "cigar-shaped" soft tissue calcification, direct visualization of cysticerci in the anterior chamber of eye). Epidemiological criteria are evidence of household contact with T. *solium* infection, individuals living in or coming from endemic area, and history of frequent travel to disease-endemic area. The presence of one absolute criterion or two major, one minor, and one epidemiological criterion is required for definitive diagnosis. On the other hand, one major plus two minor, one major plus one minor plus one epidemiological or three minor plus one epidemiological criteria constitute probable diagnosis (Carpio et al. 1994; Del Brutto et al. 2001).

Among the serological tests, more widely used ELISA shows 50% sensitivity and 65% specificity in CSF. More recently, enzyme-linked immuno-electrotransfer blot (F.ITB) assay has been shown to be 98% sensitive and *\00%* specific. This test is, however, positive in only 28% with single-enhancing lesion. Patients with calcified lesions and single-enhancing CT lesions are often serologically negative. A monoclonal antibody-based antigen detection assay is highly specific for viable and degenerating cysticerci (Sako et al. 2001).

Plain radiography of soft tissue may show classical cigar-shaped calcifications (Figure 59D.2B). NcLiroimaging with CT scan is more sensitive in detecting calcified lesions. When there are numerous calcified lesions, it gives the appearance of "starry night" (Figure 59D.2C). Vesicular

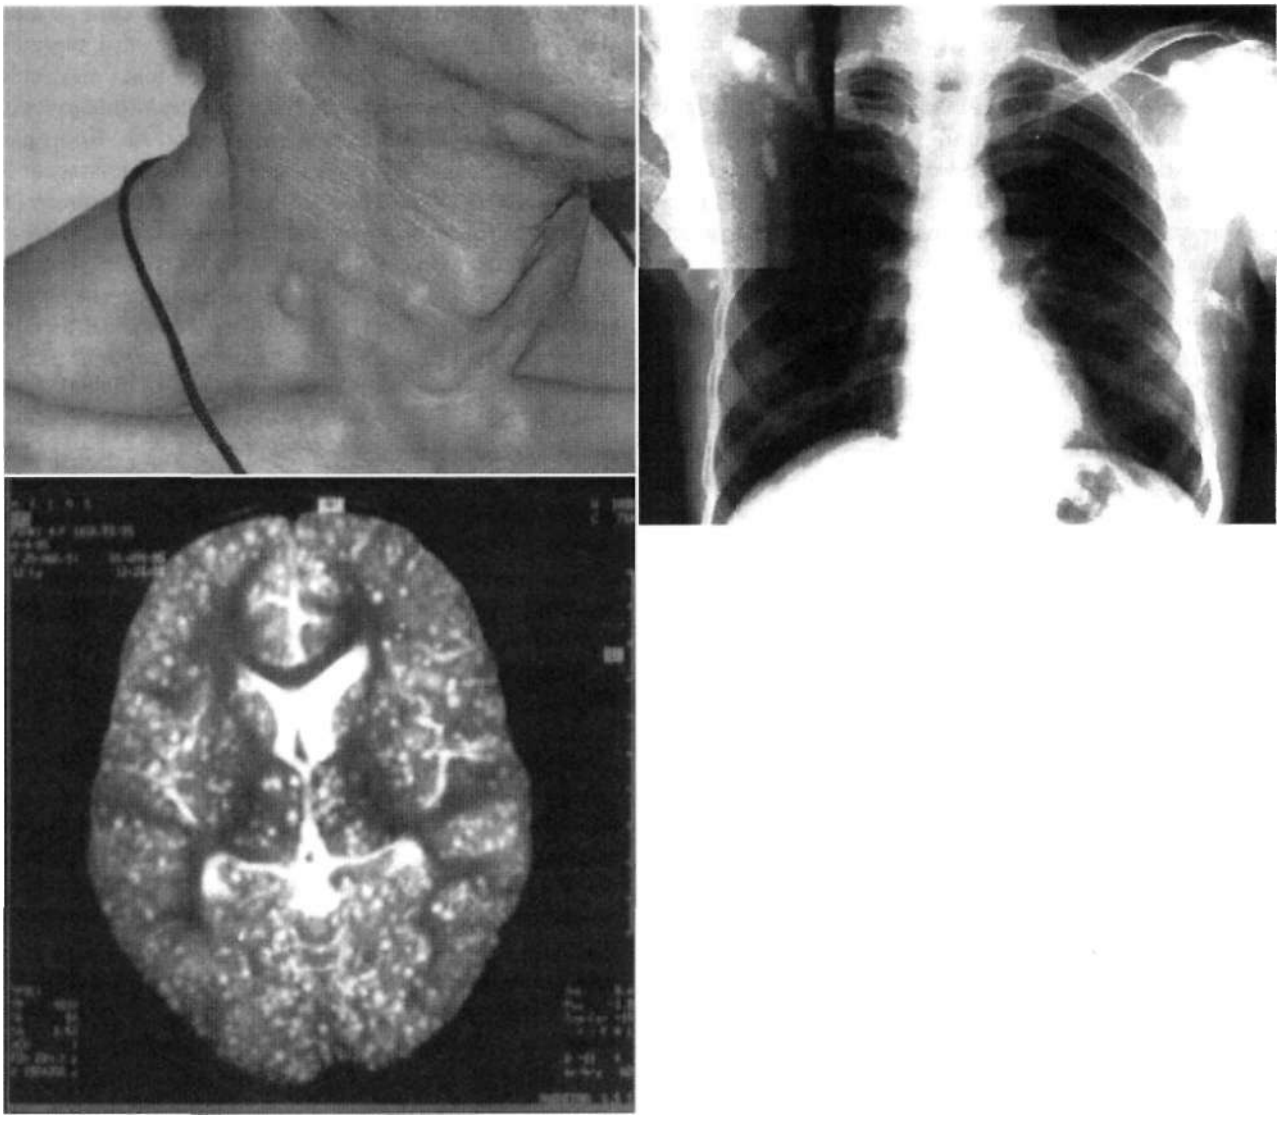

FIGURE 59D.2 Patients with neuroeysticereosis and seizures presenting with multiple subcutaneous nodules (A) and asymptomatic cigar-shaped calcifications in soft tissue (B), and CT brain showing innumerable cystieerci (starry-night appearance, C). (Courtesy Dr. S. K. Gaekwad.)

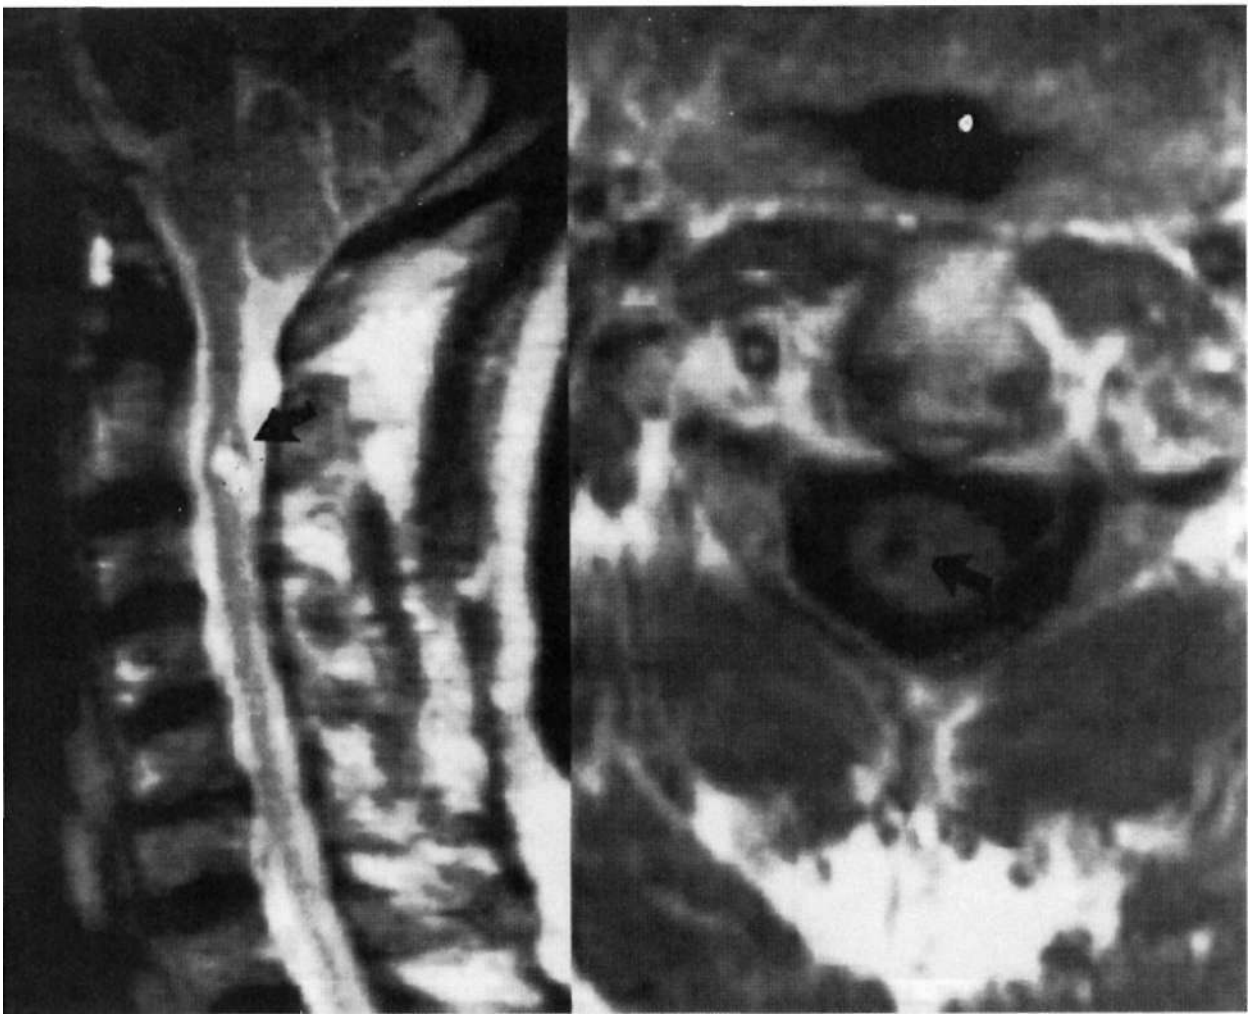

FIGURE 59D.3 MRI scans in cases with neurocysticercosis showing cysricercus cysts in the cervical spinal cord (A, *arrow)* midbrain (B), cerebellum (C), and intraconal compartment of the right orbit (D). (Courtesy Dr. S. K. Gaekwad.)

cysts appear as hypointense lesions with an eccentric intramural nodule representing the scolex in MRI scan. In the colloidal stage the cysts show ring enhancement with edema, whereas in the granular-nodular stage they show disc-enhancing lesion with perilesional edema (Figure 59D.3). The racemose form of the neurocysticerci appears as bunch of grapes in the MRI.

CSF examination is usually nonspecific and shows mononuclear, lymphocytic, or eosinophilic pleocyrosis and positive cysticercal antibody titers. Differential diagnosis includes tuberculosis, echinococcosis, paragonimiasis, sparganosis {Kudesia et al. 1998), cryptococcosis, and cysiic .istnicyloin.i for parenchymal N((and ixhinocoe cosis, coenurosis, CNS tumors, epidermoids, and arachnoid and colloid cysts for extra-axial cysts.

Treatment

NCC is treated with antiparasitic drugs along with symptomatic therapy. Patients with inactive parenchymal NCC with evidence of calcified lesions or degenerating parasites on neuroimaging do not require antiparasitic treatment. As seizures are common symptoms in these patients, chronic anticonvulsant therapy is required. Patients with inactive disease and hydrocephalus due to prior subarachnoid or ventricular infection also do not require antiparasitic treatment, but vcntriculoperitoneal shunt may be required. Shunt failure is uncommon in this group.

Patients with active parenchymal disease are treated with albendazole, a benzimidazole anthelminthic agent, or praziquantel (Garcia et al, 2002). Albendazole is preferred because it is cheaper, has better penetration into subarachnoid cysts, and is unlikely to have pharmacological interference with corticosteroids and other anticonvulsant agents (Salinas et al. 2000). The dose of albendazole is 15 mg/kg per day divided in two oral doses for 8 to 28 days along with dexamethasone. Recent reports of treatment with praziquantel in three oral doses of 25 mg/kg separated by 2 hours, followed 5 hours later by dexamethasone 10 mg

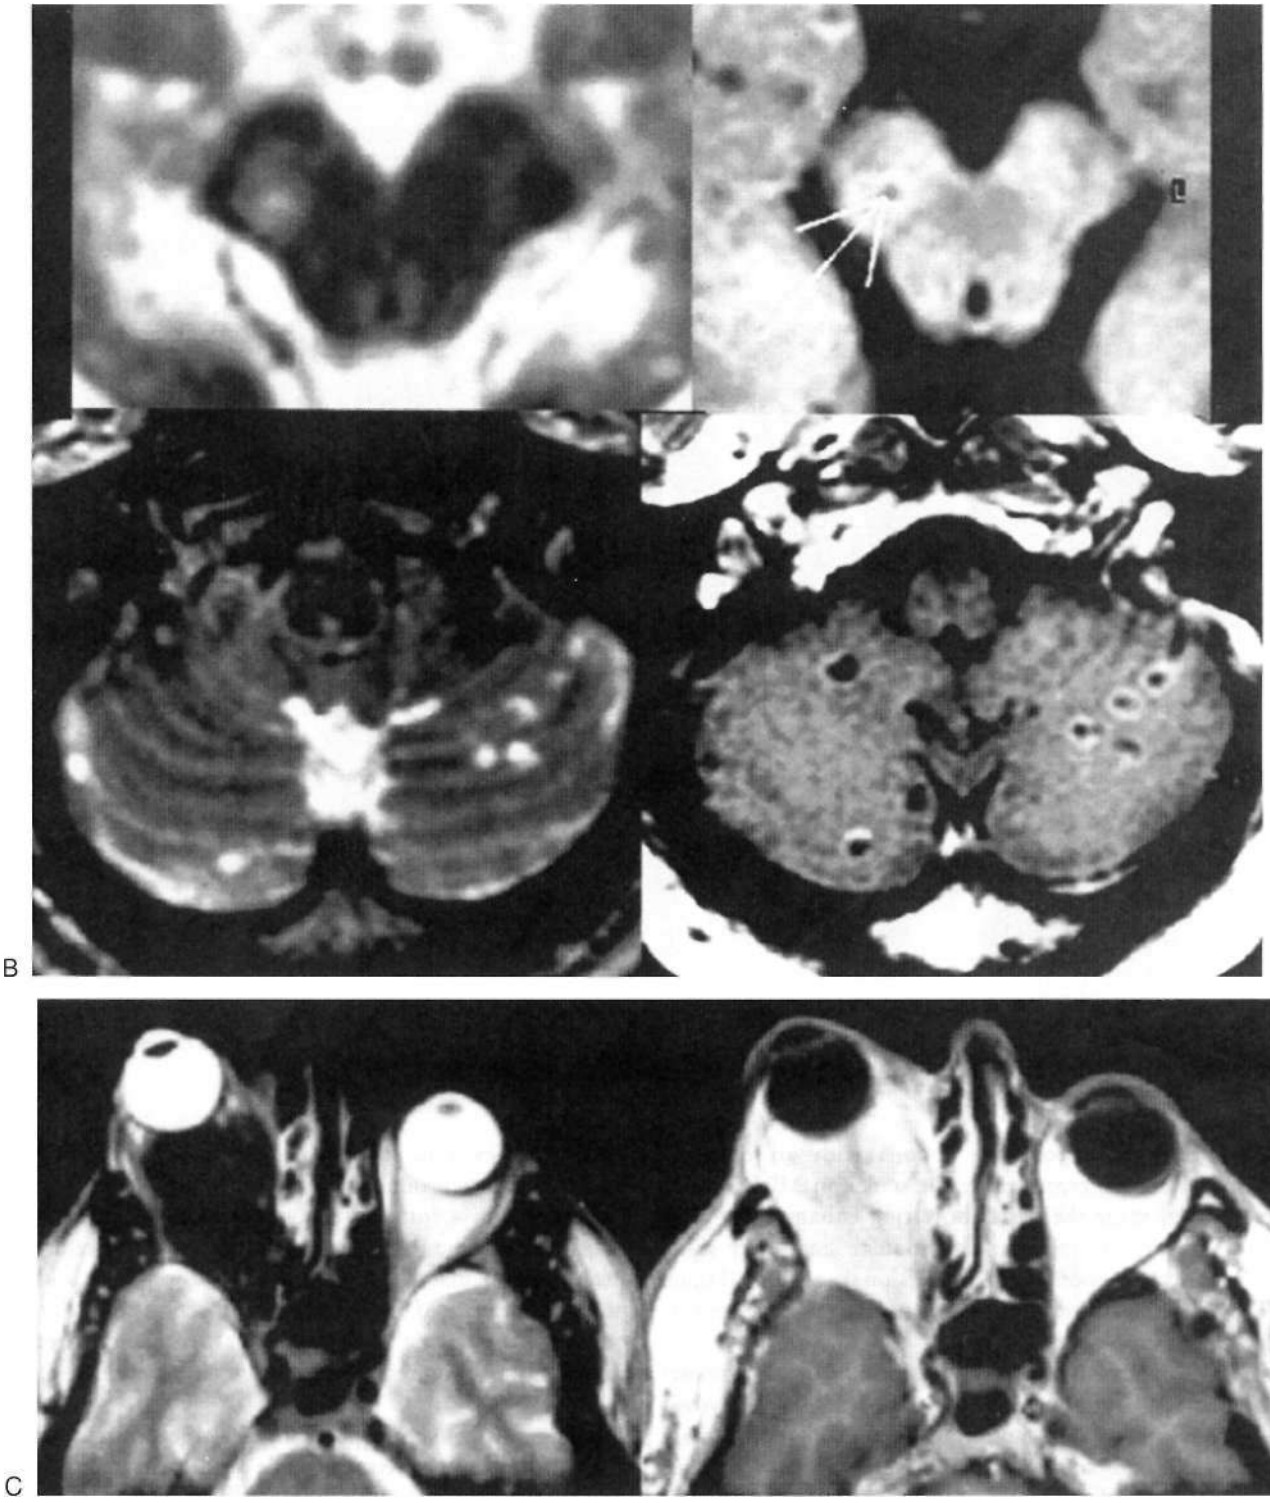

FIGURE 59D.3, cont'd.

intramuscularly, then 10 mg intramuscularly on next 2 days, has also shown good results. Administration of dexamethasone a few hours after praziquantel allows uptake of the drug hy the cyst. Earlier, praziquantel was given otally in doses of 50 mg/kg per day in three divided doses for 14 days. Adverse effects of antiparasitic drugs are worsening of neurological status (headache, vomiting, di/.ziness, seizures, coma, and increased ICP) and are believed to be due to host inflammatory response to dying parasites. Many cysts resolve spontaneously over

time. There is no consensus regarding treatment of active extraparenchymal NCC. Until recently, surgical removal of intraventricular NCC was done with or without ventriculoperitoncal shunt. Ventriculopcritoneal shunt in this group is complicated with frequent shunt failures. Neuroendoscopic removal of intraventricular NCC as an alternative method is less invasive. In patients with single-ring-enhancing CT lesions presenting with epilepsy, treatment with anticonvulsant drugs alone is advocated as most of these resolve spontaneously. Treating them with anthelmintic agents does not improve the resolution of these lesions.

Prevention

Improving sanitation, elimination of intestinal tapeworms, improving sewage disposal system, surveillance of pork farming, preventing pigs from entering human dwellings, and eating properly cooked clean vegetables and pork are some of the methods to prevent the occurrence of NCC.

Echinococcosis

Hydatid disease is caused by the cestode of genus *Echinococcus,* found in the intestines of canines. The disease is common in people who live in close contact with dogs and cats. The highest incidence of echinococcal disease is seen in Greece, Lebanon, and Turkey. It is also reported from Australia, South Africa, East Africa, Canada, North America, Asia, and parts of Russia. The larval cysts of the parasite, the metacestodes, cause the hydatid disease in the intermediate hosts. Common sites are liver (.50-70%), lungs (20-30%), bones, heart, and the spleen. CNS involvement is seen in less than 2% of cases and involves brain parenchyma and intraventricular and subarachnoid spaces.

Human hydatidosis can be caused by four different species, causing different types of cysts. E. *granulosus* infection is the commonest, and it causes simple hydatid cyst. Dogs, cats, and other canines are the definitive hosts. The eggs, containing the *Echinococcus* larvae, are excreted in the feces of the host, which are accidentally ingested by the intermediate hosts (humans). The larvae penetrate the intestinal wall and are spread hematogenous I y to liver, brain and other sites where they develop into the hydatid cysts.

Clinical features

The latent period is 2-20 years. Involvement of liver and lungs causes abdominal pain, hepatosplenomegaly, or cough. Rupture of cyst causes an acute abdomen syndrome, dyspnea, hemoptysis, or hypersensitivity reaction (60-70%). In the brain, cysts grow at a rate of about 1 cm per year. Patients with CNS cysts generally present with focal neurological deficits, seizures, or signs of raised KT. T:ic rupture of the cysts can cause an acute allergic response (Khalidi et al. 2000). Rarely, involvement of basal ganglia, cerebellum, cavernous sinus, and intrasellar and intra-orbital spaces can be seen. Other sites of involvement are intraventricular, subdural, or spinal canal. Cord compression also occurs due to vertebral collapse caused by hydatid bone disease (hydatid Pott's disease).

Diagnosis

The first clue to the diagnosis comes from plain x-ray abdomen showing a calcified lesion or peripheral or CSF eosmophilia. X-ray of the skull is normal, or it shows evidence of bone erosion due to a large cyst. Neuroimaging with CT and MRI reveals a large spherical, smooth cystic lesion filled with fluid of CSF intensity with ventricular distortion and midline shift (Figure 59D.4). The cyst wall is isodense or hyperdense to the brain tissue and does not show contrast enhancement unless ruptured or infected. On MRI, the cyst appears hypointense on Tl-wcighted images with a slightly byperintense rim. On T2-weighted images the cyst wall appears hypointense and the fluid hyperintense. Daughter cysts usually accompany the main cyst (Kornbluth ct al. 2000). E, *granulosus* gives rise to single solitary cyst, whereas *E. multilocularis* is associated with multichambered complex cysts. The Casoni's test is now obsolete, hut the serological tests such as hemagglutination test and ELISA using arc-5 antigen of the parasite are more sensitive.

Treatment

The treatment of choice is surgical resection of the cyst. During the resection, care must be taken to not to spill the contents of the cyst because this causes anaphylaxis and the formation of innumerable daughter cysts in the surrounding tissues. Intracystic instillation of 20% saline, formalin, cetrimide or silver nitrate, and topical applications of 20% saline or silver nitrate to the surrounding tissues avoid this complication. The size of the cyst can he shrunk hy prctrearment with albendazole (1.5 mg/kg per day for 40 days) or mebendazole (50 mg/kg) for 3 months. In those patients where only partial resection of the cyst is possible, lifelong treatment is required.

NEMATODES

Angiostrongyliasis

Angiostrongylus, or the rat lung worm, can cause eosinophilic inciungiris or meningoencephalitis in humans. The parasite is widespread in distribution and has been reported from practically every part of the world including Asia, the Pacific region, Africa, and the Caribbean.

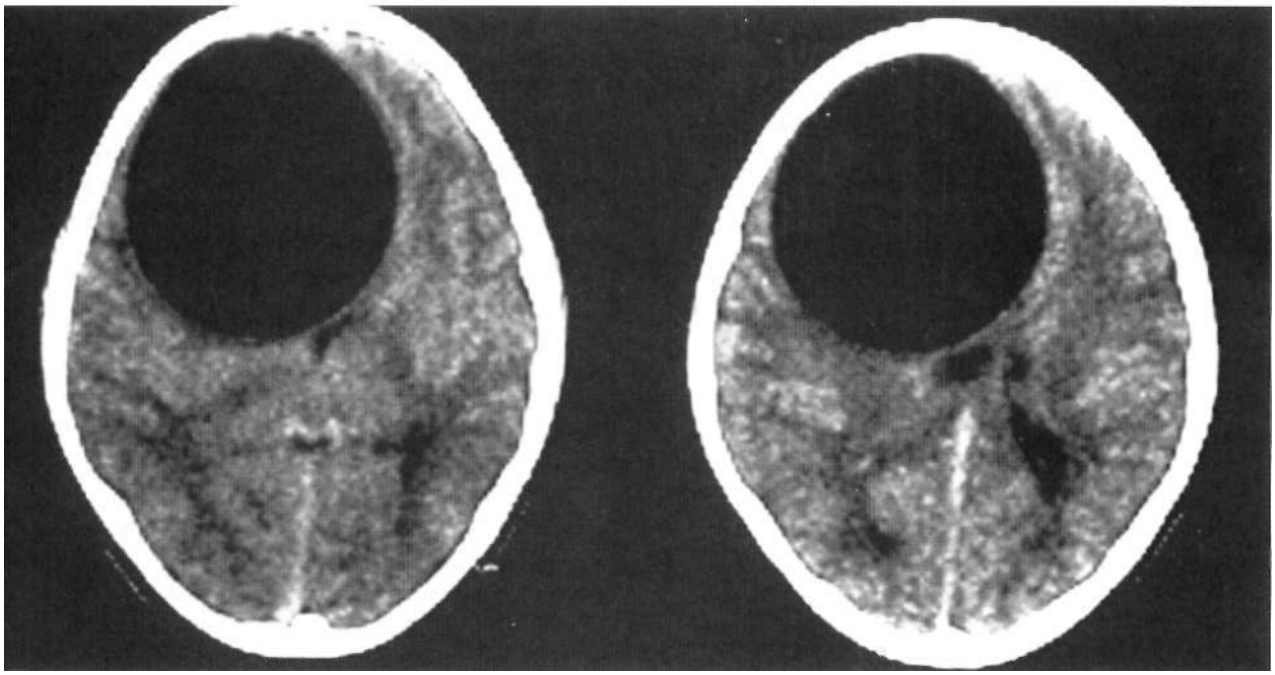

FIGURE 59D.4 CT scan in a patient with raised intracranial pressure and epilepsy showing large well-defined hypodense mass in right frontal lobe (Hydatid cyst). (Courtesy Dr. S. K. Gaekwad.)

Transmission and Pathogenesis

Rats arc the definitive hosts for the parasite *Angiostrongyius cantonensis,* and the parasite is present in their pulmonary circulation. The intermediate hosts are freshwater snails including grand African snail *(Achatina julica),* prawns, and crabs. Humans become infected if they consume molluscs containing the third-stage larvae. Once the larvae gain entry into the human brain, spinal cord, meninges, eyes, and other tissues, the parasites die and result in eosinophilic meningitis. The leptomeninges are more intensely affected with dense eosinophilic infiltrates along with mononuclear cells and neutrophils.

Clinical Features

The latent period is 1-36 days. Severe headache, neck rigidity, varying degrees of altered mentation with vomiting, papilledema, optic neuritis, cranial nerve deficits, brisk reflexes, and seizures are common clinical features, Paresthesia, impaired vision, and generalized weakness are other common symptoms.

Diagnosis

Hie (ST ;s liclptul ir. ;li.i;',i!i-.-,is ami roi'.tls r.ux'il IC l\ pleocytosis between 150-2000/uL with predominantly eosinophilic leucocytosis, raised protein, and near-normal sugar levels. Rarely, larvae can be seen on CSF examination. Ncuroimaging findings on MR images include prominence of Virchow-Robin spaces,'Subcortical enhancing lesions, and abnormally high T2 signal lesions in the periventricular regions.

Treatment

Treatment is generally supportive and analgesic and anti-inflammatory drugs are used. Corticosteroids have no significant role. Larvicidal drugs are generally avoided because they exaggerate CNS symptoms (Chotmongkol and Sawanyawisuth 2002).

Gnathostomiasis

Gnathostomiasis (Yangtze river edema, Shanghai's rheumatism, nodular eosinophilic panniculitis, consular disease, woodhury bug) is caused by *Gnathostoma spinigerum,* a nematode found in the gul oi dogs and cats, li usual!) causes cutaneous larva migrans and orbital masses, hut rarely, CNS involvement in the form of eosinophilic meningitis and radiculomyelopathy can occur (Lo Re and Gluckman 2002). Larva migrans refers to a condition of protracted migration of larvae in tissues. The disease is common in Southeast Asia, Japan, Thailand, and Israel.

Dogs and cats are the primary hosts, and freshwater fish and cyclops arc the intermediate hosts. The eggs passed in the feces contaminate fresh water whete cyclops and other aquatic animals ingest them. Consuming an undercooked intermediate host infects humans. The larvae migrate actively through various tissues producing symptoms.

Clinical Features

Patients present with firm, red, itchy subcutaneous nodules or urticarial rash, fever, and eosinophilia about 3 weeks after exposure. At times the parasite pierces the skin and appears externally on the skin surface where it can be removed for diagnosis and treatment. CNS involvement is the most serious complication and presents with meningoencephalitis, headache, cranial nerve palsy, depressed consciousness, subarachnoid and intracerebral hemorrhage, focal neurological deficits, and spinal cord involvement. Painful myeloradiculopathy with segmental pain and paraparesis is one of the most characteristic presentations. The CNS involvement may occur in isolation without concomitant skin involvement. Eosinophilic meningitis occurring in gnatbostomiasis has a more serious course than that caused by *Angiostrongylus,* Orbital involvement results in uveitis, retinal hemorrhage, and detachment.

Diagnosis

The diagnosis is based on the typical clinical picture, CSF findings, and history of exposure. CSF is hemorrhagic or xanthochromic with eosinophilic pleocytosis. CT and V1RI reveal ring or disc-enhancing lesions and evidence of intracerebral or subarachnoid hemorrhage. Serological tests are unreliable. Hemorrhagic CSF, painful radiculomyelopatby, and diffuse neurological involvement help differentiation from angiostrongyliasis.

Treatment

The treatment is symptomatic with analgesics forming the mainstay of treatment. Albendazole in doses of 400-800 mg per day for 21 days has been tried with variable results. Recently ivermectin is used in single dose as an effective alternative. Systemic corticosteroids can be given in severe cases. The prognosis is not good, and mortality is between 8-25%. About one third are left with permanent neurological deficits. Surgical removal of the worm is possible if it migrates to accessible locations.

Trichinosis

Trichinosis or trichinellosis is caused by the nematode *Tricbinella spiralis.* Other species known to cause the disease are T. *nativa* (of Arctic bears) and T. *nelson* (of scavengers of Africa). Trichinosis is seen all over the world except Australia. *Tricbinella* cysts have been found in Egyptian mummies from 1200 BC.

The adult worm is an intestinal inhabitant, but the larvae localize in the skeletal muscles eliciting an eosinophilic inflammatory response, and they transform there into cysts. Eating undercooked pork (T. *spiralis),* bear, or walrus in Arctic regions and "bush meat" in the tropics causes trichinosis. CNS involvement results in intense inflammatory reaction by the parasite. The meninges in the fatal cases are intensely hyperemic with dense eosinophilic infiltrate in the perivascular regions. The CSF remains free of significant inflammatory response. Inflammation of the vessels causes endarteritis and infarctions or hemorrhages in the involved regions of brain.

Clinical Features

Gastrointestinal symptoms with fever are the first symptoms occurring 1-2 days after ingestion of infected pork. Dissemination of the larvae by the hematogenous route causes fever, muscle pain, conjunctival chemosis, periorbital edema, subconjunctival hemorrhage, and eosinophilia about 5 days after infection. Localization of larvae in muscles leads to pain, swelling, and weakness of extraocular, neck, diaphragmatic, intercostal, limb, and paraspinal muscles. The larvae can invade heart, lungs, brain, and meninges. Involvement of brain occurs in about 10% of patients with eosinophilic meningitis, meningoencephalitis, seizures, delirium, coma, brain infarction, hemorrhage, and venous thrombosis. Peripheral neuropathy, necrotizing arteritis with mononeuritis multiplex are reported in less severe cases. Death is rare and occurs due to respiratory failure or massive involvement of myocardium with cardiac failure.

Diagnosis

In the appropriate clinical setting, eosinophilia, raised muscle enzymes, and raised serum IgG levels clinch the diagnosis. Muscle biopsy is diagnostic, and a fresh muscle sample can reveal the larvae. Serological tests are available. The differential diagnosis includes inflammatory myopathies, eosinophilic myalgia syndrome, and systemic vasculitis.

Treatment

Oral mebendazole 20 mg/kg given in 6 hourly doses is the treatment for the intestinal nematode, which also prevents the larval stage. The efficacy of this drug against tissue invasive form is not established. The allergic symptoms secondary to tissue invasion can be managed by corticosteroids, analgesics, and antipyretics.

Strongyloidiasis

S. stercoralis is a free-living nematode found in warm and moist climates all over the world. Adult worms are passed in human feces and are found in soil where they lay eggs, which hatch to liberate rhabditiform larvae. In the indirect cycle, the rhabditiform larvae, under favorable conditions,

transform into infective filiform larvae, pierce the skin of the host, and gain access to lungs by the hematogenous route. Adult worms develop in the lungs, travel to the trachea from where they make their way into the gastrointestinal tract. Occasionally rhabditiform larvae transform into infective filiform larvae and gain entry into the systemic circulation. The parasite lodges in the lungs, lymph nodes, spleen, muscle, heart, and brain. J ligh-risk individuals are (1) residents and immigrants from countries where strongyloidiasis is common, (2) residents of the Appalachian region of the United States, and (3) institutionalized individuals. The parasite has capacity of multiplying in the host, especially by an auto infection cycle. This is called hypcrinfection,

Clinical Features

Gastrointestinal symptoms include epigastric pain, tender-ness, anorexia, nausea, vomiting, diarrhea, and malab-sorption. Lungs are affected in the migratory phase and result in bronchospasm, cough, and hemoptysis. Inflammatory reaction at the site of skin penetration causes cutaneous larva migrans. Gram-negative septicemia and disseminated strongyloidiasis arc serious manifesta-tions. CNS involvement is in the form of polybacterial pyogenic meningitis and meningoencephalitis caused by gram-negative enteric bacteria, which ensheathe the sur-face of the parasite during its transit from the gastro-intestinal tract. The commonest organisms involved in these cases are *Klebsiella, E. colt,* and *Serratia.* Other manifestations arc eosinophilic meningitis, encephalitis, vasculitis, and infarcts. The worms are identified in the CSF only on rare occasions.

Diagnosis

The disease is difficult to diagnose antemortem but should be suspected in immunocompromised individuals wirh features of sudden febrile encephalopathy or frank poly microbial meningitis. Rarely, patients have eosinophilic meningitis. The CSF shows polymorphonuclear or eosino-philic pleocytosis with hypoglycorrhachia and raised protein. Diagnosis is based on finding adult worm, larvae, or eggs in stool.

Treatment

If diagnosed in time, treatment for immunocompetent host is with albendazole 400 mg once or twice daily for three days, ivermectin in a single dose of 200 mg/kg or thiabendazole 25 mg/kg twice a day for 3 days. Bacterial meningitis and septicemia associated with the disease should be managed with appropriate antibiotics. In the immunocompromised host treatment with thiabendazole 50 mg/kg twice a day for 2-4 weeks is recommended (Zaha et al. 2000).

Toxocariasis

Toxocariasis is caused by larvae of T. *cams* (dogs), T. *catis* (cats), and *Baylisascaris procyonis* (raccoons). Larva migrans (K.vurs in skip., \iscer..i, and neural tissue.

Ingestion of food contaminated by eggs from the feces of cats and dogs results in human infection. It is common in children with history of pica and geophagia. It is also contacted on beaches where cats and dogs deposit their feces. The larvae hatch from the eggs in the small intestine, penetrate the intestinal wall, and migrate to various tissues.

Clinical Features

Cutaneous larvae migrans show serpiginous creeping tracts, which are itchy and get secondarily infected. Visceral larva migransischaracterizedbypronouncedeosinophilia(100%), hepatomegaly (85%), pulmonary symptoms (50%), and fever. Involvement of the nervous system causes encephalitis, meningoencephalitis, and spinal cord compression resulting in headache, disturbance of consciousness, seizures, child-hood dementing v\ minim s, lri.nvl^ n oin \ .IMILII :-., c< iv.nu phil ic granuloma, and paraplegia or quadriplegia. Ocular larva migrans rcsulrs in retinal inflammatory mass.

Diagnosis

Diagnosis of neural larva migrans is suspected by history of exposure to dogs or cats and peripheral eosmophilia in a child with an encephalitic or a dementing illness. CSF shows eosinophilic pleocytosis, normal sugar, and protein. HI ISA and Western blot technique to detect IgG against larval secretory and excretory antigen can confirm the diagnosis. The differential diagnosis of neural larva migrans includes loiasis, gnathostomiasis, and strongyloi-diasis. Ocular larvae migrans must be differentiated from retinoblastoma, toxoplasmosis, histoplasmosis, optic neuritis, and Coat's disease.

Treatment

Anthelminthic agents, including thiabendazole (25 mg/kg twice daily for 5 days), mebendazole (100 mg three times a day for 7 days), or albendazole (15 mg/kg per day for 5 days) are useful, Diethylcarbamazine also shows good results. Laser photocoagulation to kill the larvae can be used if they are away from the macula or disc in the retina.

TREMATODES

Schistosomiasis

Schistosomiasis, caused by the trematode *Schistosoma mansoni,* is seen in Africa, Brazil, and the West Indies. The adult worm infects humans. Ova of different

schistosomes are passed in urine *(S. hematobium)* or feces *(S. japonicum* and *S. mansoni)* of the infected mammals. They gain access to fresh water, hatch, and penetrate freshwater snails and Cyclops. The larvae pierce the infected host and are liberated into the water. Humans are infected by bathing in or wading through the infected water. After entering the human body, larvae reach the circulation where they develop into adult worms that produce eggs. Oviposition takes place in the urinary venous plexus in 5. *hematobium* and in the mesenteric and hepatic venous system in *S. japonicum* and *S. mansoni.*

Clinical Features

A pruritic papniar rash or swimmer's itch develops after exposure, and signs of acute toxemic schistosomiasis in the form of fever, myalgia, headache, urticaria, and lymphadenopathy (Katayama fever) develops I 1-50 days later. At this stage a mild transient meningoencephalitis or generalized vasculitis may occur in infection with *S. mansoni.*

The chronic stage of disease occurs when the worms complete intravascular migration and settle in the venules of mesentery, portal system, and bladder, depending on the species. At this stage symptoms are related to portal hypertension, hepatic cirrhosis, hcpatosplenomegaly, variceal bleeding, intestinal polyps, diarrhea, cystitis, and hematuria.

Involvement of spinal cord, cauda equina, and conus medullaris, resulting in cord infarction, transverse myelitis and granulomatous cauda equina compression is associated with *S. mansoni* and *S. haematobium.* These are thought to be due to ectopic eggs or worms in the spinal canal or cord parenchyma via arterial egg embolization or through the valveless intra vertebral venous plexus causing cord infarction or inflammatory granuloma. Cerebral involvement commonly occurs with S. *japonicum* (60%), and it may be in the form of cerebral inflammatory masses or vasculitis resulting in seizures, confusion, coma, focal neurological signs (hemianopic field defects, hemiplegia, ataxia, etc.), and papilledema.

Diagnosis

In endemic areas or in individuals with a history of travel to endemic areas schistosomiasis should be considered in the differential diagnosis of painful cauda equina or spinal cord syndromes. Examination of stool and urine for ova and peripheral cosinophilia are not helpful. Liver or rectal biopsy may show granuloma with a centrally located ovum. CSF examination may show eosinophilic pleocytosis with CNS involvement. CT and MR! scans may demonstrate granuloma with edema in the brain and enlargement of the spinal cord with granulomatous cord disease. Multiple serological tests ate described to detect antibodies to eggs, larvae, or adult worm, but they lack sensitivity and specificity. ELISA using keyhole limpet hemocyanin is helpful to distinguish acute from chrome antibody responses.

Treatment

Praziquantel is effective against all species of schistosomes. A single oral dose of 40 mg/kg is sufficient for 5. *japonicum, S. mansoni,* and *.S. hematobium. S. mckongt* requires three doses of 20 mg/kg separated by 4 hours. Corticosteroids are needed during the treatment with antiparasitic therapy to reduce reaction and edema. Metrifonate and oxamniquine arc effective against *S. hematobium* and *S. mansoni,* respectively. Neurological involvement during the acute phase is self-limiting and does not require treatment. Masses in Lite brain ami spinal cord require surgical decompression.

Paragonimiasis

The causative agent is the oriental lung fluke of the *Paragonimus* spp. The adult worms inhabit lungs but rarely do the larvae gain entry into ectopic sites, of which the brain is the most common leading to meningoencephalitis, seizures, and focal neurological syndromes.

The parasite is found in the Southeast Asian countries (Japan, Taiwan, Philippines, India, and China), America, and West Africa. The most common etiological agents arc *P. westermant. P. mexicanus,* and /'. *miyazakii.* The intermediate hosts are freshwater fishes, snails, and crabs. Humans get infected by consuming infected and partially cooked crabs and fishes, contaminated water, or contaminated water plants. Adult worms migrate from the gastrointestinal tract to the lungs. The brain is affected when the parasite passes through the sheaths around the jugular veins, internal carotid arteries, or the nerve trunks.

Clinical Features

Acute infection is characterized by cough, fever, pleural effusion, and hcpatosplenomegaly. The chronic stage is associated w'ith a cough productive of brown sputum, chest discomfort, recurrent hemoptysis, and night sweats. Migrating larvae and worms localize in the brain or spinal cord and present as a space-occupying lesion, taiscd intracranial pressure, epilepsy, meningitis, subacute encephalitis, infarction, headache, cranial nerve paresis, focal neurological deficits, papilledema, optic atrophy, mental retardation, and depressed consciousness.

Diagnosis

Diagnosis is made by examination for eggs in the sputum, ELISA, intradermal test, chest x-rays and peripheral cosinophilia. CSF findings are nonspecific. CT or MRI scans reveal characteristic conglomerate, multiple ring-shaped contrast enhancing lesions, 1-3 cm diameter located most commonly in temporal or occipital lobes

(Nomura et al. 1999). In chronic stages the CT and the plain radiographs of the skull may show evidence of characteristic soap bubble appearance and dilated ventricles.

Treatment

The most widely used drug for the treatment of paragonimiasis is praziquantel in doses of 25 mg/kg thrice daily for 2 days. Longer treatment may be required in resistant cases. Niclofalan in a single dose of 2 mg/kg is an alternative. Cerebral and spinal masses require surgical decompression, Corticosteroids or ventriculo peritonea I shunt maybe indicated in some cases.

Diseases Caused by Ectoparasites

Tick paralysis is an ascending flaccid paralysis caused by a large number of species (Greensrein 2002). These are *Dermacentor andersoni* {Korrh American wood tick), *D. variabilis* (dog tick), *Amblyomma macttlatum* in North America, *Omithodoros laborensis* in the Russian Republic, *Otobius megnini, Ixodes rubicundus,* and *Kbipicephalus simus* in South Africa; *Ixodes tancitarus* in Mexico, *Ambiyomma cyprium aeratipes* in the Philippines, and *Ixodes holocyclns* in eastern Australia. The tick is removed by pulling it out from the point of attachment with the help of forceps; it is induced to release its hold by paralyzing it with chloroform or lighter fluid. Tick paralysis may be severe and fatal. The agent injected by the tic that produces paralysis has yet to be fully characterized. Paralysis resolves within a few hours of removing the tic.

Chapter 59
Infections of the Nervous System

E. NEUROLOGICAL MANIFESTATIONS OF HUMAN IMMUNODEFICIENCY VIRUS INFECTION IN ADULTS

Ashok Verma

EPIDEMIOLOGY AND CURRENT TRENDS

Acquired immunodeficiency syndrome (AIDS) was first recognized in the United States in the summer of 1981 when unexplained occurrences of *Pneumocystis carom* **and** Kaposi's sarcoma were reported in cohorts of previously-healthy homosexual men. Within months, the disease became recognized in intravenous drug users (IDUs) and soon thereafter in recipients of blood transfusions and blood product including hemophiliacs. As the epidemiological pattern unfolded, it became clear that a microbe transmitted by sexual (homosexual and heterosexual) contact and through blood and blood products was the most likely etiologic agent of the epidemic. In 1983, human immuno-deficiency virus type-1 {HIV-1, henceforth called HIV) was isolated, and in the following year it was demonstrated clearly that it was the causative agent of AIDS. In 1985, a sensitive enzyme-linked immunosorbent assay (ELISA) test was developed, which led to the recognition of the scope of HIV infection among cohorts of individuals in the United States and elsewhere. As the disease spread, scro-prevalence studies revealed the enormity of the global pandemic, with cases reported ftom virtually every country.

According to **the Joint** United Nations Program on HIV/AIDS (http://www.mednav.com), as of the end of 2002, 42 million people were living with HIV/AIDS worldwide. Of these, 38.6 million are adults, 19.2 million are women, and 3.2 million are children under 15. An estimated 5 million people acquired the HIV infection in 2002, including 2 million women and 800,000 children under 15. During the year 2002, AIDS caused the deaths of an estimated 3.1 million people, including 1.2 million women and 610,000 children under 15, Three fourths of the world's AIDS population is currently in sub-Saharan Africa and Asia; 45% of cases are women. In certain sub-Saharan African countries, such as Zimbabwe and Botswana, available seroprcvalence data indicate >25% of adult population aged between 15 and 49 is HIV infected. The epidemic in Asian countries, particularly India and Thailand, has lagged temporarily behind that in Africa; however, the number of new cases in these countries is accelerating rapidly (Anonymous 2002).

In the United States, the cumulative number of AIDS cases reported to the Centers for Disease Control and Prevention (CDC) as of December 2001 was 816,149. Adult and adolescent AIDS cases were at 807,075, with 666,026 males and 141,048 females, and 9074 were children under age 15. The total number of AIDS deaths reported during this period is 467,910, including 462,653 adults and adolescents, 5257 children under age 15, and 388 persons whose age at death is unknown. It is estimated that between 650,000 and 900,000 adults and adolescents in the United States are living with HIV infection, including 120,000 to 160,000 women. This estimate results in an overall nationwide prevalence of HIV infection of approxi-mately 0.3%. The number of new infections per year is estimated to be approximately 40,000, and this number has remained stable for several years (Fauci 1999). Following the use of the highly active anti retroviral therapy (HAART), the death rate from AIDS declined 40% from 1996 to 1998, and it has further declined over the subsequent years. It is currently the fifth leading cause of

death among Americans aged 25 and 44, having dropped from first within the past six years.

The high prevalence and striking diversity of neurological disorders complicating AIDS were recognized early in the epidemic (Snider et al. 1983). Neurological opportunistic infections (OIs} and malignancies predominated in early reports, but it became also clear that AIDS was associated with distinct neurological syndromes, such as dementia, myelopathy, and painful neuropathy, that appeared to result from the HIV itself. It also became recognized that the risk of neurological complications increased with the progression of the HIV infection and decline of the CD4" T cell counts. Clinically apparent neurological disease develops in approximately one half of HIV-infected patients. Neuropathological abnormalities arc nearly universal in patients dying with AIDS, suggesting subclinical disease, underdiagnosis, or both. Neurological disorders cause significant morbidity and mortality, and they may be the AIDS-defining illnesses in previously asymptomatic HIV disease or, occasionally, hetald unrecognized HIV infection. Nervous system complications may directly lineal en life, as well as impair ability to comply with complex HA ART regimens necessary to manage HIV disease optimally. These disorders affect every level of the neuraxis, and a given patient may suffer more than one HIV-associated neurological disease. Familiarity with the common HlV-telated neurological syndromes (Tables 59E.1 and Tables 59E.2) facilitates their recognition, even in the medically complex patient with several medical and neurological diagnoses.

Spinal epidural or intradural lymphoma (metastatic)
HTI.V-1-associated myelopathy

The stage of systemic HIV infection influences both the risk of neurological disease, .is well as likely ecologies, and hence $CD4^+$ T cell count provides critical information that helps guide the evaluation (Figure 59E.1). In early infection, corresponding to $CD4^+$ T cells greater than 500/jiL, autoimmune disorders, such as demyelinating neuropathies, may develop. During midstagc infection, or $CD4^+$ T cell levels of 200-500/uL, ptimary HIV-reiated disorders, such as dementia, may become symptomatic, as may some infections such as varicella-zoster virus (VZV) radiculitis (shingles). In advanced HIV infection, defined as CD4' T cell count less than 200/uL, the risk of dementia, myelopathy, and painful neuropathy increases further, and patients become vulnerable to major OIs such as cerebral toxoplasmosis, progressive multifocal leukoencephalopathy (PML), and cryptococcal meningitis, as well as to neoplasms such as primary central nervous system lymphoma (PCNSL).

NATURAL HISTORY OF HIV INFECTION AND NEURO-HW DISEASE

The clinical consequences of HIV infection encompasses a spectrum ranging from an acute syndrome associated with primary infection to a prolonged asymptomatic state to advanced disease. It is best to regard HIV disease as beginning at the time of primary infection and progressing through various stages. In most patients active viral replication and progressive immunological impairment occur throughout the course of HIV infection. With some exceptions, HIV disease in untreated patients inexorably progresses, even during the clinically latent stage. Accumulating clinical and laboratory observations clarify that the brain is infected early at the time of primary HrV infections, the infection and low-grade inflammation of brain continue through the latent phase of HIV infection, and significant central nervous system (CNS) morbidity and mortality are due to the continued CNS infection in the late stages of the HIV disease. In this context, the CNS serves as a parallel compartment to the systemic HIV disease. The CNS manifestations relate principally to the continued infection in the CNS compartment, the interaction of the virus with the systemic immune system, and the consequent failure of the immune defense system,

The Acute **HIV** Syndrome

It is estimated that 50-70 % of individuals with HIV infection experience an acute clinical syndtome

Tabic 59E.2: Classification of HIV-associated neuromuscular disorders

Peripheral neuropathies
Early stages (immune dysregulation)
- Acute inflammatory demyclinating polyradiculoneuropathy (AIDP)
- Chronic inflammatory demyelinating polyradiculoneuropathy (CIDP)
- Vasculitic neuropathy
- Brachial plexopathy
- Lumbosacral plexopathy
- Cranial mononeuropathy
- Multiple mononeuropathies

Mid- and late stages (HlV-rcplieation driven)
- Distal sensory polyneuropathy
- Autonomic neuropathy

Late stages (opportunistic infection, malignancy)
- CMV poiyradiculomyelitis
- Syphilitic poiyradiculomyelitis
- Tuberculous poiyradiculomyelitis
- Lymphomatouspoly radiculopathy
- Zoster ganglionitis
- CMV mononeuritis multiplex
- Nutritional neuropathy (vitamin Bij, BJ
- ?AlDS-cachexia neuropathy
- ?AI.S-like motor neuronopathy

AH stages (toxic neuropathy)
- Nucleoside reverse transcriptase inhibitors (ddl, ddC, d_4T)
- **Other drugs (vincristine, INH, ethambutol, thalidomide)**

Myopathics
- Polymyositis
- Pyomyositis
- PInclusion body myositis
- **Toxic (Zidovudine) myopathy**
- AlDS-cachexia myopathy

approximately 1-6 weeks after the primary infection. The syndrome is typical of an acute viral syndrome and has been likened to acute infectious mononucleosis. Fever, erythematous or maculopapular rash, headache, nausea, anorexia, lethargy, arthralgia, sore throat, and lymphade-QOpathy occur in different combinations in this syndrome.

Neurological manifestations occur in approximately 10 % of cases at the time of initial HIV infection. Several general principles of this early interaction are apparent. First, the neurological complication, as also the seroconversion syndrome, usually occurs 1-6 weeks after the exposure and primary infection. Second, the neurological presentation frequently involves multiple parts of the nervous system, although one part is usually dominant. Third, the illness is monophasic, with the majority of patients recovering within weeks. Meningitis, meningoencephalitis of varying severity, seizures, myelopathy, and cranial and peripheral neuropathies have all been linked to the primary HIV infection or seroconversion. Occasionally, opportunistic CNS infections have been reported during this stage of infection, reflecting the temporary immunodeficiency that results from the reduced number and the likely-dysfunction of CD4"""" T cells. In a review of 139 published cases of primary HIV infection, encephalopathy and neuropathy were each reported in 8% of the cases (Clark ct al. 1991). Meningitis and less severe symptoms, such as headache, have been reported in up to 30-45% of patients. Laboratory analysis at this stage (with or without neurological disease) reveals cerebrospinal fluid (CSF) abnormality with mild mononuclear pleocytosis and moderate rise in protein. Imaging of the brain is usually normal, whereas the electroencephalogram (EEC) may be diffusely or focally slow in brain-symptomatic cases. The diagnosis of these neurological syndromes can be difficult because they are indistinguishable from other acute vital or postinfectious syndromes, most of which are self-limiting and never achieve specific diagnoses.

Most patients recover spontaneously from these acute systemic and neurological HIV syndromes in one to several weeks and are left with only a mildly depressed $CD4^h$ T cell count that remains stable for a variable period of time. In most cases, primary infection with or without the acute HIV syndrome is followed by a prolonged period of clinical latency.

The Asymptomatic or Latent Stage

Although the length of time from initial infection to the development of clinical AIDS varies greatly, the median time for untreated patients is approximately 10 years. During this asymptomatic phase the virus is actively replicating, and the disease is gradually progressing. The rate of disease progression is directly correlated with HIV RNA levels (viral load). Patients with high vital load in the plasma progress to symptomatic disease faster than do patients with a low viral load. During asymptomatic HIV infection, the average rate of $CD4^+$ T cell decline is approximately 50/uL per year. When the CD4~ T cell count falls to <200/uL, the resulting state of immunodeficiency is severe enough to place the patient at high risk of OIs and neoplasms.

Evidence indicates that the CNS continues to harbor and mount a host reaction to the HIV through the asymptomatic or latent stage, yet without apparent immediate clinical sequelae. The CSF in patients with latent HIV infection generally shows abnormalities, including abnormal cell count, protein and immunoglobulin, and local synthesis of anti-HIV antibodies within the CNS compartment; the intact virus can be recovered from the CSF (Price 1 996). Pathological studies have shown evidence of inflammatory reactions in the CNS, with perivascular mononuclear cell infiltrations, although the HIV RNA burden, as evident by polymerase chain reaction (PCR) from CSF and brain samples, appears to be negligible at this stage. Neither overt nor subclinical cognitive or motor dysfunction appears to be common in the early latent stage. From a practical standpoint, the risk of isolated cognitive decline in asymptomatic individuals is sufficiently small as to provide no

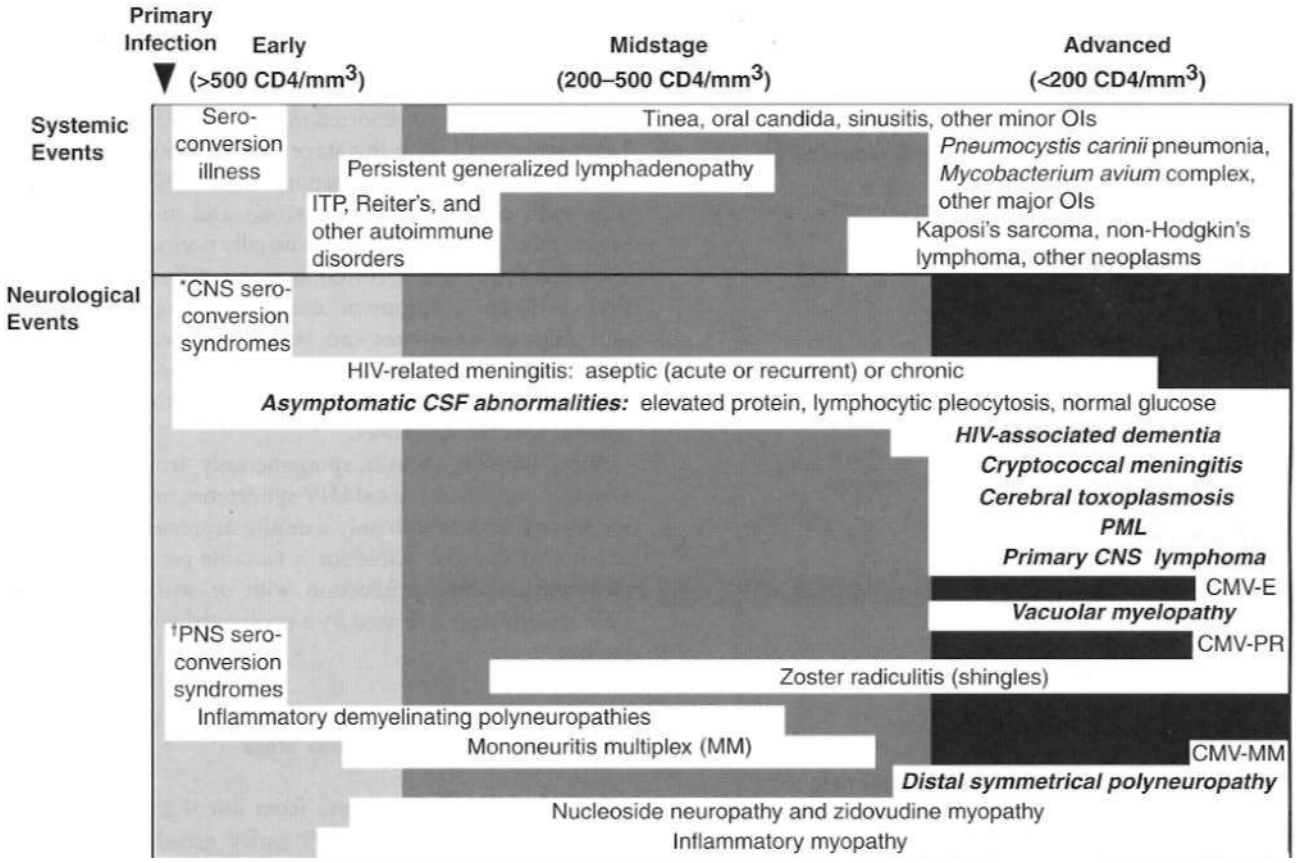

FIGURE 59E.1 Systemic and neurological events in human immunodeficiency virus (HIV) infection. Temporal sequence is ^ppni^iin.iv: ;md indicates the increasing risk oi systemic and neurological complications as HIV infection advances. [CMYT — Cytomegalovirus encephalitis; CMV-PR = CMV polyradiculitis; CNS = central nervous system; CSF = cerebrospinal fluid; ITP = idiopathic thrombocytopenic purpura; Ols = opportunistic infections; PML = progressive multifocal leukoencepbalopathy; PNS — peripheral nervous system.) 'Includes, in addition to HIV-related meningitis and asymptomatic cerebrospinal fluid abnormalities, meningoencephalitis, acute demyelinating syndromes, myelopathy. Includes, in addition to acute inflammatory demyelinating polyneuropathies, sensory ganglioneuritis, brachial plexitis, and rhabdomyo lysis. Common neurological syndromes are in bold italics.

basis for disability or disqualification from work based simply on HIV-positive status.

Some patients who are termed "long-term nonprogressors" show little if an\ decline in (1)-1 ! I cell comic-, over a prolonged period of time (Samson et al. 1996). These patients generally have extremely low levels of HIV RNA, Certain other patients remain entirely asymptomatic despite the fact that their CD4 h T cell counts show *a* progressive decline to extremely low levels. In these patients, the appearance of a systemic or CNS opportunistic infection may be the first manifestation of HIV disease. The length of asymptomatic stage is determined by the viral and host factors.

Symptomatic Stage

Following the initial burst of viremia during primary infection, HIV-infected individuals generally mount a robust immune response that usually curtails the level of viremia and likely contributes to delaying the ultimate clinically apparent disease. The host immune response is directed against multiple antigenic determinants of the HIV virion as well as against viral proteins expressed on the surface of infected cells. Ironically, those $CD4^+$ T cells with T cell receptors specific for HIV are the cells most likely to bind to the virus, be infected, and themselves be destroyed. Thus, the early consequence of HIV infection may be dysimmune in the face of persistent high antigenemia, and the late consequence is an immunocompromised state, through the elimination of HIV-spccific $CD4^+$ T lymphocytes.

HIV-associated neurological complications in late-stage HIV infection include primary manifestations, secondary complications related to the Ols and neoplasia, and complications arising from antiretroviral or prophylactic therapy. The primary neurological complications include HIV-associated dementia (HAD) or its less severe form,

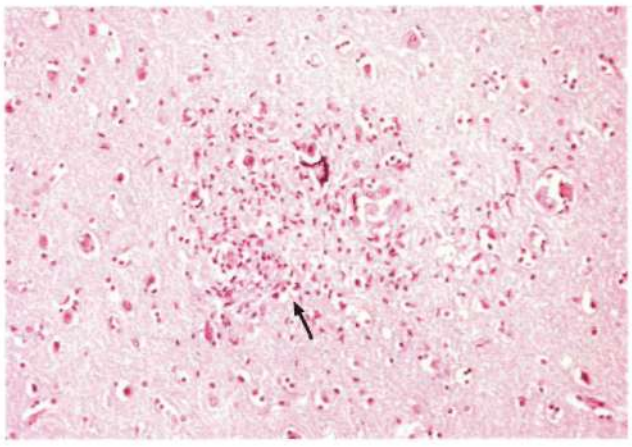

PLATE 59E.1 HIV encephalitis. Microglial nodule (*arrow*) containing multinucleated giant cells. (H & E × 200)

minor cognitive motor dysfunction (MCMD), vacuolar myelopathy (VM), and distal sensory polyneuropathy (DSP). Generally, the nature and severity of illnesses (systemic and neurological) that one observes change as the $CD4^+$ T cell count progressively declines. The frequent and life-threatening complications of HIV infection occur in patients with $CD4^+$ T cell count <200/uL. Although the causative agents of the secondary infection are characteristically opportunistic organisms such as cryptococcus, cytomegalovirus (CMV), and other microorganisms that do not ordinarily cause disease in the absence of a compromised immune system, they also include common bacterial and micobacteriai pathogens. Secondary complications (systemic and neurological) are of great importance because they are rather common. Timely and appropriate therapy is critical and potentially Ufesaviug in many of them. Approximately 80% of deaths among AIDS patients are as a direct result of an infection other than HIV.

PATHOGENESIS OF NEURO-H1V DISEASE

HIV-infected individuals can experience a variety of neurological abnormalities due cither to direct effects of the HIV or its products or to opportunistic infections or neoplasms. With regard to the direct effects of HIV, the main cell types infected in the brain in vivo are those of the monocyte/macrophage iineage. These include monocytes that have migrated into the brain from the peripheral blood, as well as resident microglial cells (Sabri et al. 2003). Although there have been reports of infrequent HIV infection of astrocytes and neurons, there is no convincing evidence that brain cells other than those of monocyte/macrophage lineage can be productively infected in vivo. Nevertheless, in vitro infection of a neural cell line can occur (Klein et al. 1999), and it appears that galactosyl ceramide on neuronal surface is an essential component of the HIV gpl20 receptor, and that antibodies to galactosyl ceramide inhibit the entry of HIV into the neural cell lines.

HIV enters the brain during viremia of primary infection and remains there for the life of the HIV-infected individuals. The viral entry is due, in part, to the ability of virus-infected and immune-activated macrophages to induce adhesion molecules such as vascular adhesion molecule-1 (VCAM-1) on brain endothelium. Other studies have demonstrated that HIV gpl20 enhances the expression of intercellular adhesion molecule-1 (1CAM-1) in glial cells; this effect may facilitate entry of HIV-infected cells into the CNS and may promote syncytia formation (Plate 59E.1). HIV isolated from the brain is preferentially of the R5 strain, as opposed to other strains; in this regard, HIV-infected individuals who are heterozygous for CCR5delta32 {a mutation of HIV $GD4^+$ T cell receptor) appear to be relatively protected against the development of HIV encephalitis (Weiss et al. 1999). Distinct HIV envelope sequences are also linked with the clinical manifestation of HAD.

HIV-infected individuals may manifest white matter changes as well as neuronal loss. Given the relative absence of evidence of HIV infection of neurons either in vivo or in vitro, it is unlikely that direct infection of these cells account for this cell loss. Rather, the HIV-mediatcd effects on brain tissue arc thought to be due to a combination of direct effects, either toxic or function-inhibitory, of virus or viral antigens on neuronal cells and effects of a variety of neurotoxins released from the infiltrating monocytes, resident microglial cells, and astrocytes. In this regard, it has been demonstrated that HIV-1 antigens, for example, Nef and Tat (viral core antigens), can induce chemotaxis of leukocytes, including monocytes, into the GNS. Neurotoxins can be released from monocytes as a consequence of other HIV-associated infections or immune activation. Activated monocyte-derived neurotoxic factors have been reported to injure neurons via the N-methyl-D-aspartate (NMDA) receptor. Additionally, HIV gp!20 shed by virus-infected monocytes, and a variety of cytokines, including tumor necrosis factor-alpha (TNF-tx), IL-1, IL-6, rnterferon-a (IFN-a), and endothelin, can contribute directly or indirectly to the neurotoxic effects in HIV infection. Further, infection or activation of monocyte-lineage cells can result in increased production of cicosanoids, nitric oxide, and quinolinic acid, which may also contribute to the neurotoxicity.

Astrocytes may play diverse roles in HIV neuropathogenesis, Astrocytosis and reactive gliosis occur in brains of HIV-infected individuals, and TNF-ur and II.-6 have been shown to induce astrocyte proliferation. In addition, astrocyto-derived IL-6 can induce HIV expression in infected cells in vitro. Furthermore, it has been reported that HIV-infected older individuals and individuals with the E4 allele for apo-lipoprotein E (Apo E) are at increased risk of HIV encephalitis and polyneuropathy (Gordcr et al. 1998). The fact that neuropsychiatric abnormal ides may undergo remarkable and rapid improvement on the initiation of antiretroviral therapy, particularly in HIV-infected children, indicates that it is virus driven, that the 111V or its products are involved in the neuropathogenesis of primary HIV neurological disorders, and that the dominant changes are either structural or functional at the synapses.

ANTIRETROVIRAL THERAPY AND ITS IMPACT ON NEURO-HIV DISEASE

Combination antirctroviral therapy or HAART is the cornerstone of management of patients with HIV infection (Fauci 1999; Arendt and von Giesen 2002). Following the widespread use of HAART in the United States from 1996, dramarie declines have been noted in the incidences of most AIDS-defining conditions, including neurological

diseases (see earlier). Successful HA ART with rcconsritution of immune defense can even enable some patients to discontinue secondary prophylaxis against certain CNS pathogens, which had not been possible in the pre-HAART era. It appears also that certain primary neurological diseases, where the disease processes are driven by the HIV burden, can be prevented or delayed by successful HAART (Geraci and Simpson 2001), although the evolution of drug-resistant viral strains may eventually limit the sustained benefits of HAART (Power et al. 2002; Samuel ct al. 2002). It is currently unknown if in the future, as patients develop increasing drug-resistant HIV mutations, the incidence of neuro-HIV diseases would begin to rise (Anonymous 2002; Sacktor 2002; Kandaneararchi et al. 200.'5). Moreover, some anriretroviral drugs have significant neurological side effects. Additionally, there are numerous drug-drug interactions that one must take into consideration when using these drugs. It is desirable that neurologists caring for HIV-infected patients have a broad understanding of the principles and practical guidelines of modern antirettovirai therapy.

Treatment decisions must take into account the fact that one is dealing with chronic infection that can only be controlled; eradication of HIV infection has not yet been possible. Although early therapy is generally the rule in infectious diseases, immediate treatment of every HIV-infected individual on diagnosis may not he prudent, and the decision to treat must balance risks and benefits. Early use of antiretroviral drugs in the latent stage, for example, may select resistant HIV strains and preclude theit use in later stages when viral suppression is even more important. Unfortunately, some of the most impottant questions related to the treatment of HIV disease currently lack definitive answers. Among them are the questions of when should the HAART be started, what is the best initial regimen, and when should a given regimen he changed. Notwithstanding these difficulties, the physician and patient must come to a mutually agreeable plan based on the best available data. Given the complexity of this field, decisions regarding antiretroviral therapy are best made in consultation with experts. At present, a reasonable course of action is to initiate therapy in anyone with the acute HIV syndrome; HIV meningitis or meningoencephalitis; patients with asymptomatic disease with $CD4^+$ T cell counts <400/uL or with >20,000 copies of viral RNA per milliliter; and patients with HAD, VM, or DSP. In addition, one may wish to administer a 6-week course of therapy to uninfected individuals immediately following a high-risk exposure. Currently licensed drugs for the treatmenr of HIV infection are summarized in Table 59EJ.

Once the decision has been made to initiate therapy, the physician must decide which drugs to use as the first therapeutic regimen. Initial choice of drugs will determine the immediate response to therapy, and it will have implications regarding options for future therapeutic regimens. The two options for initial therapy most commonly in use today are a three-drug regimen from two different antiretroviral classes (see Table 59E.3). The first regimen utilizes two nucleoside analogues (one of which is ptefetably 1 amivudine) and a protease inhibitor. The second regimen utilizes two nucleoside analogues and a non-nucleoside reverse transcriptase inhibitor. Unfortunately there are no clear data at present on which to base a distinction between these two approaches.

For HIV-associatcd brain disease, one must use drugs tli at have good blood-bra in barrier penetration (sec Table 59E.3). Following the initiation of therapy, one should monitor virological (HIV RNA levels) and immunological ($CD4^{"1"}$ T cell counts) responses periodically. The HIV RNA levels in serum generally reflect viral levels in CSF, at least until late stages of the HIV disease. In terminal stages, the CNS compartment may harbor slightly different and divergent HIV strains, with different degrees of drug susceptibility (Antinori et al. 2002). In an attempt to determine an optimal therapeutic regimen, antitetroviral drug susceptibility through genotyping or phenotyping of HIV quasi species has been attempted, although its practicality[7] for general use is questionable. Maximal suppression of viral replication is the goal of therapy, not just to prevent the disease progression but also to prevent the appearance of drug-resistant HIV quasi species. The principles of thetapy for HrV infection arc well articulated in publications of the U.S. Department of Health and Human Services (CDC 1998, see updates at www. hivatis.otg). There are a scries of excellent sites on the V/orld Wide Web that are frequently updated, and they provide the most recent information on a variety of topics, including epidemiological data (www.cdcnpin.org) and consensus panel reports on treatment of HIV infection (www. cc.nih.gov/phar/hiv-mgt).

MAJOR HIV-ASSOCIATED NEUROLOGICAL SYNDROMES

The neurological complications of HIV infection are both common and varied, and they occur at all stages of the HIV disease {Price 1996; Simpson and Berger 1996; McArthur 1997). Disorders of both the CNS and peripheral nervous system (PNS) can complicate HIV infection from the period after initial infection through the end stages of the severe immunosuppression. These neurological complications can be classified in a number of ways. A classification based on the underlying pathophysiology and HIV disease stages is summarized in Figure 59E.1. At the time of initial HIV infection or soon after seroconversion, when the immune defense mechanism is generally robust, dysimmune diseases of the CNS and PNS are encountered. In later stages of HIV disease, when HIV RNA burden is high and the immune system is compromised, primary neurological diseases, OIs, and neoplasia are frequently encounteted. Tables 59L. I and Tables 59E.2 present classification based

Tahle 59E.3: Currently approved antiretroviral drugs tor HIV infection

Drug	*Duse*	*i • i.v/iV/i*	*Ri-injrki*
NRTIs			
Abacavir (Ziagen)	300 mg bid	Rash, CI, LA	Abacavir-resistant HIV strains are typically also resistant to 3Tc, ddl and ddC
Cornbivir (Zidovudin f Lamivudine)	Zidovudine 300 mg + lamivudine 150 mg, bid	GI, HA, P, LA, BM, rash	May cause myopathy, pancytopenia
Didanosinc (ddl, Videx)	200 nig bid or 400 nig qd	PN, GI, P	Pancreatitis can be fatal
'] anm ndiiiL- ⋮ 1'c. hpivin	150 mg bid	HA, GI, P, LA	May cause hepatic steatosis
*Stavudine (d_4T, Zerit)	20^t0 mg bid	PN, HA, GI, LA, rash	May cause fatal lactic acidosis
*Trizivir (Zidovudin + Lamivudine + Abacavir}	Zidovudine 300 mg + Lamivudine 150 mg + Abacavir 300 mg, bid	GI, HA, P, BM, LA, rash	May cause myopathy, pancytopenia
Zalcitabin (ddC, Hivid)	0.75 mg tid	PN, GI, P, oral ulcers	Low potency, rarely used
'Zidovudine (Retrovir)	300 mg bid	CI, FIA, BM, rash	May cause myopathy, pancytopenia
NtRTIs			
Tinofovir (Viread)	300 mg qd	P, LA	
NNRTls			
Delavirdine (Rescriptor)	400 mg bid	Rash, (J, fatigue	
'Efavircnz (Sustiva)	600 mg qd	K isli, sli .p J:-.: .:rb:i-\ • . CNS symptoms	
*Ncvirapinc (Viramune)	200 mg qd *x2* wk then 200 mg bid	Rash, GI	Close monitoring first 2 weeks (severe rash, hepatic steatosis)
Pis			
Amprenavir (Agenerase)	1200 mg bid	Rash, HA, GI, metabolic changes	Contra indicated in pregnancy, <4 yr age
'Indinavir (Crixivan)	800 mgtid	Nephrolithiasis, diabetes, GI	
Kaletra (Lopinavir + Ritonavir)	Lopinavir 133..3 mg + Ritonavir 33.3 mg, (400/100 mg, 3 capsules) bid	GI, perioral paresthesia, metabolic changes	Lower dose blocks metabolism of ritonavir
Neifinavir (Viracept)	750 mg tid	Rash, GI, diarrhea	
Ritonavir (Norvir)	600 mg bid	GI, perioral paresthesia	Lower dose blocks metabolism of other Pis
Saquinavir (Invirase)	1200 mg tid	GI	

'Indicates good CNS penetration

NRTIs = nucleoside reverse transcriptase inhibitors; NtRTIs = nucleotide reverse transcriptase inhibitors; NNRIs = nonnucleosidc reverse transcriptase inhibitors; Pis = protease inhibitors; BM = bone marrow suppression; CNS = central nervous system toxicity; GI = gastrointestinal toxicity; HA = headache; LA = lactic acidosis; I^1 — pancreatitis; PN = peripheral neuropathy,

on neuroanatomical localization, following the classic proven methods of the neurologist. Clinicians must be aware that more than one site of neural axis can be involved in the same HIV-infected patient at the same time. Further, the clinical deficits from one site may be masked by another lesion higher in the neuraxis; appropriate investigations may be necessary to delineate the complete clinical diagnosis. One example is peripheral neuropathy in the face of HIV-associated VM. The clinician must be vigilant also for common conditions that are not necessarily associated with the HIV or AIDS.

Experience in large HIV clinics indicates that the diagnosis of the neurological complications of HIV infection and AIDS is far from an academic exercise. Rather, precise diagnosis is critical, and it frequently leads to specific therapy with resultant reduction in morbidity, mortality, and preservation of meaningful function and quality of life.

Diffuse Disorders of the Meninges and Brain

Aseptic HIV Meningitis

Diverse clinical forms of meningitis, without other evident cause, may develop during HIV infection. Although the seroconversion-rclatcd illness may be accompanied by headache and meningeal irritation, this clinical syndrome, in less severe and protracted form, is more frequent in the later course of HIV infection. It occurs more commonly in patients undergoing progressive HIV disease with decline in CD4'" T cell counts and clinical manifestations of HAD. Isolated persistent headache is common in HIV-infected patients and often occurs in the same setting as aseptic meningitis. The headache can be severe and intractable. In some patients, it may be precipitated or aggravated by a concomitant systemic infection, such as *Pneumocystis carinii* pneumonia (PGP) and hence may be

related in part to the systemic release of vasoactive cytokines.

Included among HlV-rclatcd mcningitidcs is acute aseptic meningitis, which occasionally accompanies or follows the flulike, febrile illness frequently associated with I1IV seroconversion (Price 1996). By definition, preserved alertness and cognition accompany headache and other symptoms of meningeal inflammation. A similar illness with signs and symptoms of parenchymal cerebral dysfunction suggests meningoencephalitis related to the HIV, a relatively rare seroconversion syndrome. The typical CSF profile consists of elevated protein (<100 mg/dl.) and lymphocytic plcocytosis (<25/uL), with normal glucose. Meningeal exposure to HIV can occur early in systemic infection, as inferred by recovery of HIV from CSF and evidence of intrathecal anti-1 NV IgG synthesis. The practical consequence of the CSF abnormalities routinely observed in HFV infection is that they can complicate interpretation of CSF obtained to diagnose other neurological disorders.

HIV-related meningitis is principally a diagnosis of exclusion, and hence evaluation for other causes of aseptic or chronic meningitis, such as parameningeal infection, other infections (syphilis, tuberculosis, *Listeria,* fungi, among others), lymphomatous or carcinomatous meningitis, other noninfectious etiologies (sarcoid, Behcet's syndrome, among others) or medications (nonsteroidal antiinflammatory agents, among othets) is usually undertaken (Marinac 1992). Patients suspected of having acute HIV meningitis with an initially negative HIV test result tequire repeat testing in Mveral months, because HIV antibodies may not be detectable in early infection. The prognosis in acute HIV meningitis is generally good, and it requires no specific therapy.

HIV-Associated Dementia and Minor Cognitive Motor Dysfunction

HAD, called also AIDS dementia complex (ADC) or HIV encephalitis, is characterized by cognitive, motor, and behavioral dysfunction, usually developing later in the course of infection. HAD and its less severe form, MCMD, are the most common complications of late untreated HIV disease. An alternative terminology, HIV-assoeiated cognitive/motor complex, has also been proposed to encompass the full constellation of this syndrome. Characteristically, this syndrome manifests after patients have developed AIDS-dehning systemic illnesses. However, a small number of patients present with HAD at a time when they do not yet fulfill formal diagnostic criteria of AIDS, although they show significant immunosuppression by laboratory criteria. Recognition of this early presentation was instrumental in the addition of HAD to the diagnostic criteria of AIDS.

Clinical Features. Patients' early symptoms usually consist of difficulties with attention and concentration. Manv complain of slowness of thinking. Complex tasks become more difficult and take longer to complete, and forgetfulness and difficulty in concentration lead to missed appointments and the need to keep detailed lists outlining each day's plan. The HAD is recognized early if patients require a high level of concentration and organization in their occupation or at home, because impaired performance becomes obvious in such situations. In many instances, an employee, friend, or family member may be the first to notice subtle cognitive and personality changes as the patient begins to withdraw socially and appears apathetic and uncharacteristically quiet and forgetful. An agitated organic psychosis and dysphoria are rare as presenting or predominant aspects of this illness. Psychological depression and fatigue are not uncommon in HIV-infected individuals and require differentiation from early HAD.

The second major component of HAD syndrome is psychomotor dysfunction. Although cognitive dysfunction usually appears earlier than motor symptoms and continues to predominate, motor manifestations in the form of poor balance and incoordination may be an initial presentation. Fine and skilled hand movements are affected early, resulting in deterioration of handwriting. Cait incoordination may result in frequent tripping or falling or a need for extra caution in walking. The later may impart a slow and somewhat rigid character to the gait. Usually, these patients also have VM pathologically. Even if not symptomatic, motor abnormalities can usually he detected on examination early in the course of the disease.

Initially, formal mental staus testing may be normal. As the disease progresses, patients begin to perform poorly on tasks requiring concentration and attention, such as digit and word reversals and serial sevens. Later, a large array of mental status tests becomes abnormal, affecting multidomains of cognitive function. However, mental slowing continues to remain a prominent feature, and afflicted individuals often appear apathetic with poor insight, and even indifferent to their illness. Parallel to cognitive deterioration, ataxia, which at first affects only rapid tutns ot tandem gait, may become disabling. Associated HIV VM causes worsening of leg weakness, and paraparesis limits walking. Postural tremors are common, and on occasion, patients may exhibit choreiform movements and myoclonic jerks (Cardoso 2002). Bowel and bladder disturbances are common in the latet stages of the disease. In the end stage, patients become almost vegetative, lying in bed mute with vacant stare, unable to ambulate, and incontinent. Characteristically, the course is notable for the absence of focal or lateralizing neurological deficit, such as hemiparesis or aphasia.

Laboratory Investigations

Neuropsychological Tests. Formal neuropsychological testing can be useful in diagnosis, management, and clinical monitoring of individual patients and in clinical research

studies. Appropriately chosen neuropsychological tests that target the same cardinal cognitive dysfunction delineated by the AIDS-directed clinical assessment provide a formal, quantitivc means of monitoring patients serially. These assessments focus chiefly on motor speed, concentration, and motor manipulation. However, the neuropsychological test findings are not disease specific and should always be interpreted in the clinical context. Nor do the neuropsychological tests substitute for the clinical neurological examination. Clinicians should be vigilant because some patients with MCMD perform within the population norms, and some without HAD/HMCD perform poorly on testing for other reasons.

Neuroimagmg. Neuroimaging procedures arc often essential in i-valuaLon ot *ihc* AIDS patients with cognitive dysfunction. Hirst, neuroimagitig is particularly helpful in ruling out other conditions such as primary CNS lymphoma. Second, neuroimaging often reveals abnormalities that are characteristic, although not pathognomonic, of HAD. Diffuse cerebral atrophy on cither CT or MRl is an almost universal finding in HAD (Figure 59F.2). In some patients, MRI shows abnormalities in the hemispheric white matter and, less commonly, in basal ganglia and thalamus, with patchy or diffusely abnormal signals, most apparent on FLAIR images. Children with AIDS-related dementia often have basal ganglia calcification in addition to atrophy. Results of metabolic imaging, such as single-photon emission computed tomography (SPECT) and MRI spectroscopy have also been reported, although their utility in clinical diagnosis remains undefined.

Cerebrospinal Fluid Analysis. CSV examination is used chiefly to exclude other diagnoses. The results need to be considered in the context of the nonspecific changes found in clinically normal HIV-infected individuals (discussed earlier). Routine examination of CSF in patients with HAD reveals nonspecific findings of mild mononuclear pleocytosis and mildly elevated protein in approximately 60% of the cases. Specialized CSF examination may also reveal abnormalities in immunoglobulin, including evidence of intrathecal IgC synthesis and the presence ol oligoelonal bands, but because these abnormalities are also detected in patients who do not have HAD, their diagnostic utility is uncertain. HIV can be isolated directly or HIV DNA be amplified from the CSF sample in many of these patients, but this finding is common also in infected patients who are asymptomatic or who have HIV meningitis. Similarly, detection of HIV antigens in CSF is of limited practical utility.

Several surrogate markers of virological and immune-eel 1 activation in CSF have been investigated in patients with HAD. Quantitative HIV PCR to assess the CSF viral burden is perhaps the best parameter that relates to HAD; effective suppression of HIV in the CNS compartment is demonstrated to improve the clinical status in HAD (Antinori et al. 2002). However, there is no absolute correlation of the CSF HIV burden with the clinical severity of HAD among all patients. Other CSF surrogate immune-activation markers, including ^-microglobulin, neopterin, quinolinic acid, and cytokines, have been reported but their practical utility is currently uncertain (Letendre et al. 1999).

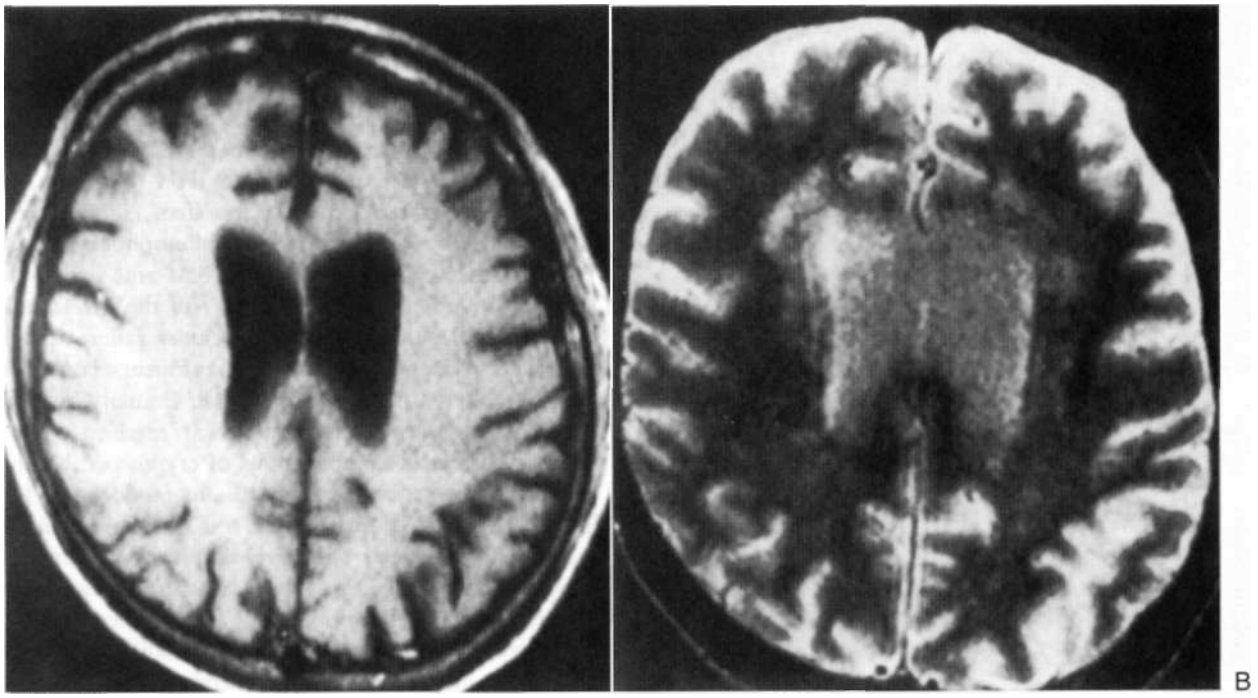

FIGURE 59E.2 Human immunodeficiency virus-associated dementia. Gadolinium-enhanced (A) Tl and (Bl T2 magnetic resonance images, obtained from a patient with acquired immunodeficiency syndrome and progressive cognitive impairment, show marked cerebral atrophy and diffuse white matter abnormalities.

Neuropathology. Histopathological abnormalities in HAD include white matter pallor, multinucleated-cell encephalitis (Plate 59E.1), and vacuolar myelopathy. Other findings include vacuolar changes in the brain, focal necrosis, and neuronal loss. These abnormalities are most common in the subcortical structures: the hemispheric white matter, basal ganglia, thalamus, brainstem, and the spinal cord. The cerebral cortex is relatively spared, at least on routine examination. There is good clinicopathological correlation in the sense that these pathological findings relate to the subcortical character of dementia in AIDS patients.

Management. Accumulating evidence indicates that HAD can be treated and even prevented, at least to some extent, by effective antiretroviral therapy (Clifford 2002; Arendt and von Giesen 2002). Initial case reports and small case series have been supplemented by controlled studies showing that HAART improves neuropsychological performance in patients with HAD. With a growing list of HIV therapies in several classes of drugs (described previously; sec Table 59E.3), many combination regimens are potentially availabc.

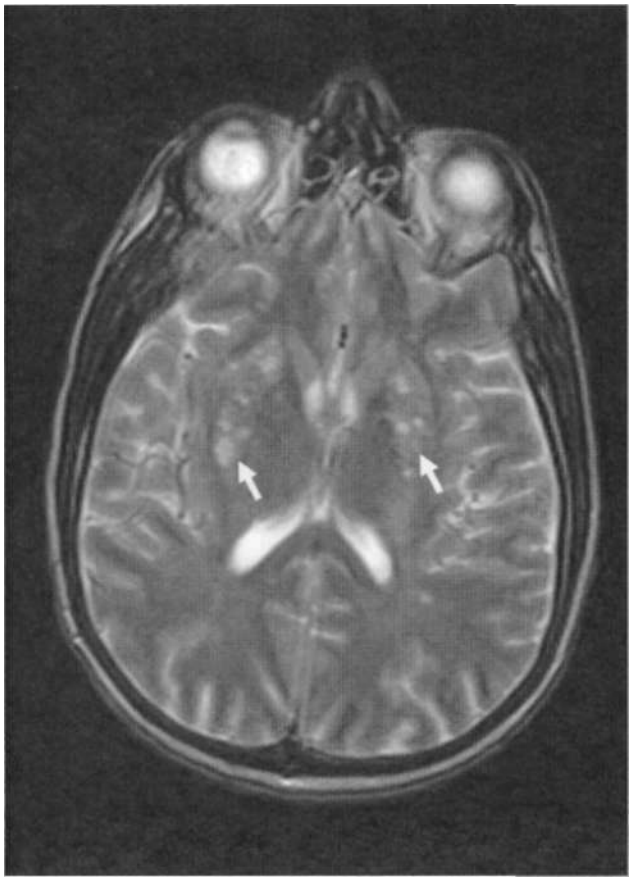

FIGURE 59E.3 Cryptococcai meningitis in AIDS. Axial T2-W-MR1 showing multiple small gelatinous pseudocysts in basal ganglia *{arrows).* [Courtesy Dr. S. Ouanouuou.)

For successful management of patients with HAD, HAART should be designed to enhance the probability of a patient's adherance to the therapy, fly the nature of the disorder, adherance to complicated treatment schemes might be particularly difficult. Simpler regimens with the least number of drug side effects arc important to enhance the adherance to therapy. For example, a once daily dose of cfavirenz is possible, and a combination formulation {combivir or kaletra; see Table 59E.3) may be easier for patient compliance. Adherence may also be enhanced by the patient entering a living facility with greater assistance and supervision, active support of family and close friends, and careful organization of medications (timers, pill boxes, etc.). Directly observed treatment is desirable in later stages of HAD.

Although the data are scanty, selecting retroviral drugs that enter the CSF and brain optimally can be an advantage in patients with HAD (Aminoh et al. 2002). The relative CNS penetranon of different antiretroviral drugs is summarized in Table 59E.3. The possible neurotoxic role of viral antigens, cytokins, and other substances in HAD and strategies to counteract these neurotoxicities are currently under active reasearch, Patients must be encouraged to participate in clinical trial research that may provide the patient the best available therapy and also assist future development of therapy. Treatment trials and a listing of health providers with expertise in this area may be accessed through the Neurological AIDS Research Consortium Web site at http://www.ncuro.wustl.edu/narc.

Cryptococcai Meningitis

Cryptococcai meningitis is covered in Chapter 59C. Approximately 10% of patients with AIDS develop cryptococcai meningitis, a neurological OI by the encapsulated yeast *Cryptococcas neoformans* {Zeind et al. 1996). This complication of advanced HIV infection, with CD4~ T cell counts generally less than 200/uE, presents as headache, fever, stiff neck, and photophobia (Powderly 1996). However, meningeal symptoms and signs may be minimal or absent in over one half of the cases, and the rather broad clinical spectrum includes failure to thrive, personality change, cognitive impairment, cranial neuropathy, altered mentation, or coma. Cranial CT or MRI, typically obtained to exclude focal cerebral disorders, sometimes reveals complications of cryptococcai meningitis, such as hydrocephalus, gelatinous pseudocysts, infarction, or cryptococcoma (Figure 59E.3}. More commonly, neuroimaging reveals only cerebral atrophy related to the advanced HIV disease. The CSF profile ranges from striking protein elevation, mononuclear plcocytosis, and hypoglycorrhachia to minimal abnormalities that overlap with those attributable to HrV infection alone. Fungal CSF culture is the gold standard, but the weeks that may pass before a positive result is obtained limit its clinical utility. India ink smear is helpful when positive, but is too

insensitive to exclude the diagnosis if negative. Fortunately, CSF cryptococcal antigen (CrAg) testing is a rapid, specific test with a sensitivity exceeding 90%. The rather diverse clinical presentations of cryptococcal meningitis may indicate that CrAg be performed routinely in patients with AIDS undergoing diagnostic CSF examination.

A typical acute regimen for cryptococcal meningitis consists of amphotericin B (0.5-0.7 mg/kg per day} with or without flucytosine (75-150 mg/kg per day) for 2-3 weeks. Renal insufficiency, hypokalemia, and Hypomagnesemia may complicate amphotericin B therapy, and the hematological toxicity of flucytosine sometimes precludes its use in patients with AIDS, in whom pancytopenia is common. Patients who are doing well can be switched to fluconazole, 200 mg twice a day for 8-10 weeks (Simpson and Bergcr 1996; Apisarnthanarak and Powdcrly 2001), and then placed on maintenance therapy of 200 mg daily to prevent relapse. Although fluconazole therapy may be as effective as amphotericin B for acute therapy of cryptococcal meningitis, delayed CSF clearance of the fungus and a trend toward poorer outcomes among fluconazole-treated patients suggest this approach be reserved for patients with mild disease.

Poor prognostic features at presentation include altered level of consciousness, CSF cell count less than 20 cells/uL, and CSF CrAg greater than 1:1024, Acute mortality approaches 30% and is related to increased intracranial pressure (ICP) at presentation. Medical management with corticosteroids or acetazolamide and CSF drainage with repeated lumbar punctures or ventriculostomy can be used to lower ICP, although none of these interventions has been subjected to clinical trial (Zeind et al. 1996). Optic nerve sheath fenestration has been MI^.MUI as .m ..kfunu *u*> these measures when increased ICP threatens vision. Focal cerebral signs accompanying cryptococcal meningitis may suggest stroke from cryptococcoma or infectious vasculitis, Other complications include cranial neuropathies and obstructive or communicating hydrocephalus. Without chronic suppressive therapy, relapse rates exceed 50%. As noted, first-line maintenance therapy is fluconazole, 200 mg daily; second-line agents include weekly amphotericin B or itraconazole. In patients who escape early complications, cryptococcal meningitis is compatible with long-term survival in patients who tolerate and adhere to HAART.

Neurosyphilis

Neurosyhilis is covered in Chapter 59A. Diagnosis and management of neurosyphilis in I [IV-infectcd patients pose some complex challenges. Syphilis and HIV infection often coexist, as the disorders share risk factors. Moreover, both infections are characterized by diverse neurological syndromes affecting brain, meninges, spinal cord, and nerve roots. CNS invasion in early syphilis appears to occur at similar rates in patients with and without HIV infection (Rolfs et al. 1997; Pao et al. 2002). Individuals without HIV infection frequently clear *Treponema pallidum* from CSF even without antibiotic therapy. Whether the same is true in HIV-infected patients is less certain. Meningeal disorders characteristic of early neurosyphilis dominate case reports of HIV infection and neurosyphilis, perhaps implicating impaired CSF clearance of T, *pallidum* in HIV-infected patients, even with adequate therapy for early syphilis. Other clinical syndromes described in association with HIV infection include syphilitic eye disease, gumma, and myelopathy.

Several factors complicate the diagnosis of neurosyphilis, particularly asymptomatic forms, in the setting of HIV infection. Individuals coinfected with HIV and *Treponema pallidum* may demonstrate unusual serological responses. When clinical suspicion of neurosyphilis is high and syphilis serology results are negative, repeat testing to exclude the prozone effect and darkfield examination or immunofluorescence staining of the biopsied lesion may be necessary (Bergcr and Levy 1997). Assuming an atraumatic lumbar puncture, CSF Venereal Disease Research Laboratory test is quite specific, but not particularly sensitive, for diagnosing neurosyphilis (see Chapter 59A). Moreover, relying on CSF pleocytosis and protein elevation to make the diagnosis, as is done for HIV-negative individuals, is complicated by the high frequency of these CSF abnormalities caused by HIV infection alone. Treponerne-specific tests in CSF are quite sensitive, but not specific, for neurosyphilis. Hence negative CSF fluorescent treponemal antibody or microhemagglutination-7". *pallidum* excludes the diagnosis of neurosyphilis, but a positive result does not establish the diagnosis. The CDC recommends that HIV-infected patients with late latent syphilis or syphilis of unknown duration undergo CSF examination before therapy, regardless of whether there are associated ophthalmic, vestibular, or neurological symptoms (CDC] 199S).

Regardless of HIV status, recommended treatment for neurosyphilis consists of a 10- to 14-day course of either aqueous crystalline penicillin G, 3-4 million units intravenously every 4 hours, or procaine penicillin, 2.4 million units intramuscularly daily, with oral probenecid, 500 mg four times a day. Because alternative agents, such as doxycycline and tetracycline, are of uncertain efficacy in neurosyphilis, desensitization should be considered in patients allergic to penicillin. The CDC recommends CSF examination every 6 months after therapy for all patients with neurosyphilis, regardless of HIV status, until pleocytosis, if initially present, resolves. Whether this is appropriate for patients with HIV infection and neurosyphilis remains uncertain. Treatment failures may occur more commonly in the serting of HIV infection, and neurological status and serum serologies should be carefully monitored as well.

Cytomegalovirus Encephalitis and Ventriculaenccphalitis

Unusual causes of global cerebral dysfunction in advanced AIDS ($CD4^{P}$ T cell <50/pL), CMV encephalitis and

ventriculoencephalitis often cause death within weeks to months (McCutchan 1995; Williams 19991. Prior or active disseminated CMV disease, such as retinitis, esophagitis, or colitis, may provide important clues to the neurological diagnosis. CMV encephalitis typically presents as a confusional state evolving over weeks and can resemble HAD. In addition to a course that is more subacute than chronic, focal cerebral signs, hyponatremia, and cranial MR1 showing periventricular enhancement are other factors that favor a diagnosis of CMV encephalitis over HAD. CSF abnormalities are typically nonspecific, and CMV PCR is positive in less than one half of cases. Pathological findings include microglial nodules and cytomegalic cells in cortical and subcortical gray matter, thought to be consistent with hematogenous spread of CMV to brain. By contrast, CMV ventriculoencephalitis may reflect dissemination from CSF and presents more acutely than CMV encephalitis, often on a background of CMV retinitis or concurrently with polyradiculomyelopathy. Brainstem signs and neuroimaging studies revealing dilated ventricles also suggest the diagnosis. CSF abnormalities tend to be more striking than CMV encephalitis, revealing elevated protein, polymorphonuclear or lymphocytic plcocytosls, and normal or low glucose. Identifying CMV DNA in CSF by PCR helps confirm the diagnosis. Pathological features include epei:dym.i! uci:(isi.s ,i:ul M ; K peiu:\ in.'il : M O V , V. nil cytomegalic cells, but no microglial nodules. CMV viremia is quite common in late-stage AIDS, and hence detection in this setting by culture, antigen testing, or PCR from blood does not help establish the diagnosis of CMV-related neurological syndromes. Prospective data are needed to confirm the impression that CSF PCR for CMV DNA is specific and reasonably sensitive for these and other CMV-related neurological disorders. Clinical trial data for the efficacy of ganciclovir, foscarnet, cidofovir, or combination therapy for CMV encephalitis and ventriculoencephalitis are lacking, though a trial of empiric therapy is probably appropriate given the poor prognosis (Table 59F..4).

Other Meningitis and Meningoencephalitis Syndromes

Odier causes of meningitis complicating HIV infection include neoplasm, other rare infections, and meilic.itions. Patients with AIDS are at increased risk for systemic lymphoma, which can cause lymphoma tons meningitis. Additional infectious causes of meningitis include bacteria *{Salmonella typhi, Pneumococcus pneumonae, Mycobacterium tuberculosis,* syphilis, *No card ia aster aides, Listeria monocytogenes, Bartonella henselae)* and fungi *[Htstoplasma capsulatum* and *Coccidioides immitis* in individuals who have lived in endemic regions, *Candida albicans, Blastomyces dermatidis, Sporothrix schenckii).* Medications are often overlooked as a cause of meningitis; implicated agents in common use for HIV infection include nonsteroidal anti-inflammatory drugs, trimethoprim/sulfamethoxazole (TMP/SMX), and intravenous immunoglobulin. Causes of meningoencephalitic syndromes include VZV and the parasites *Toxoplasma gondii, Trypanosoma cruzi,* and *Acanthamoeba* spp. (Ambroise-Thomas 2001).

Focal CNS Disorders

Four disorders account for most HlV-related focal CNS dysfunction: cerebral toxoplasmosis, PCNSL, PML, and VM. All are disorders of advanced HIV infection, when $CD4^+$ T counts decrease below 200/uL. Although they share focal hemisphcral and, less commonly, brainstem and cerebellar or spinal cord symptoms as a prominent clinical feature, other aspects of the history, supplemented by neuroimaging studies, response to therapeutic trial, and occasionally brain biopsy, usually allow each to be diagnosed quickly and accurately (Skiest 2002).

Cerebral Toxoplasmosis

CNS toxoplasmosis is described in Chapter 59D. Toxoplasmic encephalitis (TE) is the most frequent of the CNS OIs in AIDS (Porter and Sande 1992; Hill and Dubey 2002); it complicates the course of 10% patients or more, depending on the geographic origin. The varying incidence relates principally to the likelihood of earlier environmental exposure to the etiological parasite, T. *gondii.* It is most common in patients from the Caribbean and from France. Cerebral toxoplasmosis in AIDS almost always occurs from recrudescence of previously acquired infection and relates to the loss of the immune defenses that maintain *T. gondii* in an inactive, encysted form. It is 10 times more common in patients with antibodies to the organism than in patients who are seronegative. It is generally a late complication of HIV infection and usually occurs in patients with $CD4^1$ T cell counts <200/uL. The incidence has declined where TMP/SMX has been used as prophylaxis for PCP, because this regimen is also effective in reducing the development of TH. More recently, incidence of cerebral toxoplasmosis is further decreasing in the HAART era.

The most common clinical presentation in TF is headache and focal neurological deficit with or without fever. Patients may present with seizure, hemiparesis, or aphasia as a manifestation of these focal lesions or with a picture more influenced by the accompanying cerebral edema characterized by confusion, mental torpor, and lethargy, which can progress to coma. Diagnosis is usually suspected on t:ie basis ot (. T or MR! findings ol nuiltipie icsk>rs in multiple locations, although in some cases only a single lesion is seen. Pathologically, these lesions generally exhibit inflammation and central necrosis and, as a result. demonstrate ring enhancement on contrast CT or MR1 (Figure 59E.4). There is usually surrounding edema. In addition to toxoplasmosis, the differential diagnosis of multiple mass lesions in the HIV-infected patient include primary CNS lymphoma (see following) and, less

Table *59EA:* Selected therapies of HIV-associated neurological complications

E tio logy idiso rder	*Therapy*	*Major side effects*	*Primary prophylaxis*
Qryptococcus neoforma ns (meningitis, meningoencephalitis, abscess)	Amphotericin B (0.7 mg/kg/day IV) for >3 wk; adjust for renal status, plus Flucytocin (induction: 25 mg/kg/day po q6h for x3 wk Or Fluconazole 400 mg po qd x3 wk, then 200 mg po qd	Renal toxicity, chills, hepatic toxiciry (amphotericin B) IUme inarrow suppression (flucytocin) Hepatotoxicity (fluconazole)	(If prior documented disease elsewhere and CD4* Tcell <100VuJL) Fluconazole 200 mg po qd
Toxoplasma gondii (encephalitis, abscess)	Sulfadiazine (induction: 1.5 g po q6h *x6* wk; maintenance: 0.5 g po qid), plus Pyrimethamine (200 mg po one day, then 75 mg po qd), plus Folinic acid 10 mg po qd, or Clindamycin (induction: 600 mg/day IV or po qd; maintenance up to 450 mg po qid)	Rash, bone marrow suppression, crystalluria (sulfadiazine) Rash, leukopenia (pyrimethamine) Rash, diarrhea, pseudomembranous colitis (clindamycin)	(If IgG antibody seropositive and CD4+T cell <100/ul.) Trimethoprim/ Su 1 fa methox a zo 1 e DS po qd, or Trimethoprim/ Sulfamethoxazole SS po qd, or Atovoquone 1.5 g po qd, ot Dapsone 50 mg po qd, plus pyrimethamine 50 mg po weekly, plus lciieoYonii 25 mg po weekly
I ytomeg.llovirus (encephalitis, polyradiculomyclitis, tnononcl.inipathy multiplex)	Ganciclovir (induction: 5 mg/kg/day IV qSh x2 wk; maintenance: 5 mg/kg/day IV 5 days/wk) Foscamet (induction: 60 mg/kg IV q8h x2 wk, adjust for renal function; maintenance: SO mg/kg/day IV) Cidofovir (5 mg/kg IV! weekly *x2* wk, then every 2 wk	Bone marrow toxicity (ganciclovir) Renal toxiciry, hypocalcemia (foscamet) Renal failure, neutropenia, iriris, uveitis, ocular hypo tony (cidofovir)	(If prior cytomegalovirus retinitis) Ganciclovir 5 mg/kg/day IV 5 days/wk, or Foscamet 90 mg/kg/d IV, or Cidofovir 5 mg/kg IV every other wk
JC virus (progressive mulrifocal leukoencephalopathy)	Inter feron-ur (3 million U/day sc) Cidofovir (.5 mg/kg IV wkly x2 wk, then every 2 wk	Flulike syndrome (interfere n-nr) Renal failure, neutropenia, iritis, uveitis, ocular hypotony (cidofovit)	
AIDP	IVIG 0.4 g/kg/day IV x5 days	Flulike syndrome, renal failure, headache

commonly, tubercular, fungal or bacterial abscesses (Minamoto and Rosenberg 1997). Resolution of lesions on antitoxoplasma therapy confirms the clinical diagnosis. The definitive diagnostic procedure is brain biopsy, but it carries morbidity and therefore is reserved for the patient who has failed 2—4 weeks of empirical antitoxoplasma therapy.

Standard therapy in TE is sulfadiazine (0.5-1.5 g by mouth every 6 hours) and pyrimethamine (200 mg loading day 1, then 75 mg by mouth every day). Folinic acid 10 mg a day is given to counteract pyrimethamine bone marrow toxicity. Clindamycin (600 mg intravenously or by mouth every day) can be substituted for sulfadiazine in sulfa-allergic patients. Long-term suppressive therapy is generally

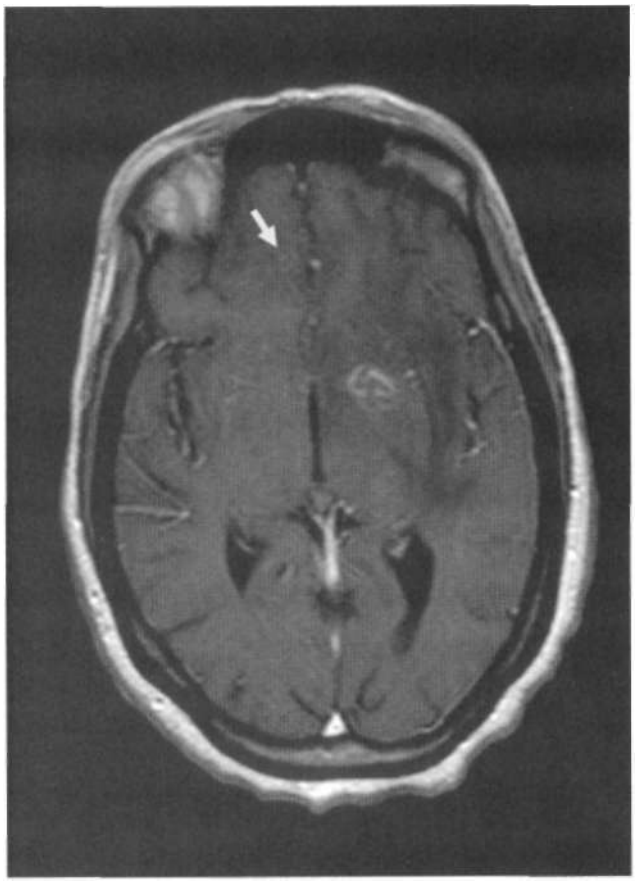

FIGURE 59H.4 Cerebral toxoplasmosis in AIDS. Post-gadolinium axial Tl-W-MRI demonstrating ring-enhancing lesions in tlie left basal ganglia and right parasagittal frontal region *(arrow).* Courtesy Dr. S. Ouanounou

required, but doses may be tapered to pyrimethamine 2.5 mg per day and sulfadiazine 2 g per day. Relapses are common, and it is recommended that patients with a history of TE receive lifelong maintenance therapy with sulfadiazine, pyrimethamine, and folinic acid. In patients who do not tolerate sulfa drugs, clindamycin (300-450 mg three or four times daily po) can be substituted. The patients who show immune reconstitution on successful HAART with CD4~ T cell counts >100/uL may not require continued prophylaxis after 3-6 months prophylactic therapy. Rarely, toxoplasmosis manifests as acute meningoencephalitis, variably accompanied by muscle involvement (Gherardi et al. 1992), In the even more unusual circumstance in which the diagnosis is made premortem, antiroxoplasma therapy may be lifesaving.

Patients with $CD4^1$ T cell counts <100/uL and IgG antibodies to *Toxoplasma* should receive primary prophylaxis against toxoplasmosis. HIV-infected patients who are seronegative for *Toxoplasma* should be counseled about ways to minimize the risk of primary infection, including avoiding consumption of undercooked food and careful liaiul w:i~li::ii', after contact with **soil** or chansiinj; **ifc oil** litter box.

Primary CNS Lymphoma

Primary CNS lymphomas (PCNSL) of B-cell origin arc considered opportunistic neoplasms that complicate the course of AIDS in up to 5% of patients. The incidence of PCNSL in HIV-infected individuals appears to be incteasing because of their increased longevity following the efficacy of both prophylactic and therapeutic measures against OIs and HAART. Patients with PCNSL present with progressive focal or multifocal neurological deficits similar to those seen with toxoplasmosis and PML (DeAngclis 2001). The tempo of disease evolution in PCNSL is generally slower than in toxoplasmosis and faster than in PML, with patients presenting after several days or a few weeks after the onset of symptoms. These symptoms may include headache, hemiparesis, aphasia, ataxia, behavioral changes, and altered mentation. Fever and constitutional symptoms arc absent except in patients with associated systemic infection.

The diagnosis of PCNSL is generally considered following review of neuroimaging in appropriate clinical setting. MRI is more sensitive than CT scan, and it characteristically shows one or more lesions (Thurnher et al. 2001); PCNSL microscopically is multicentric. The location is typically deep in the brain, adjacent to the lateral ventricles and often in white rather than gray matter; MRI may show characteristic subependymal extension (Figure 59E.5). Mass effect may be present, but there is usually little contrast enhancement or surrounding edema. CSF cytology is frequently unhelpful, although the presence of monoclonal B-lymphocyres by flocytometry, if demonstrated, indicates PCNSL. PCR amplification of Epstcin-Barr virus DNA in CSF corroborates the diagnosis of PCNSL (Cinque et al. 1997). The definitive diagnosis of PCNSL generally requires brain biopsy. Most often, brain biopsy is undertaken after a therapeutic trial for cerebral toxoplasmosis. Thallium-201 SPECT may be useful in supporting the diagnosis of PCNSL and prompting early biopsy. The use of stereotactic biopsy techniques has increased the access to these tumors and reduced the morbidity of biopsy.

Before HAART era, the outcome of AIDS-associated PCNSL had been dismal, with medial survival of approximately 80 days. As with PML, the prognosis in PCNSL is improved by successful HAART and immune reconstitution, and vigrous attempts to supress HIV replication are recommended in all patients. Mass effect is treated by high-dose corticosteroid therapy. Palliative whole brain irradiation therapy is reasonable, at least to buy time for HAART regimen to work. Use of chemotherapy remains controversial outside a clinical trial setting (Forsyth and DeAngelis 1996).

Progressive Multifocal Leukoencephalopatby

JC virus, a human papilloma virus that is the etiological agent for PML, is an important opportunistic pathogen in

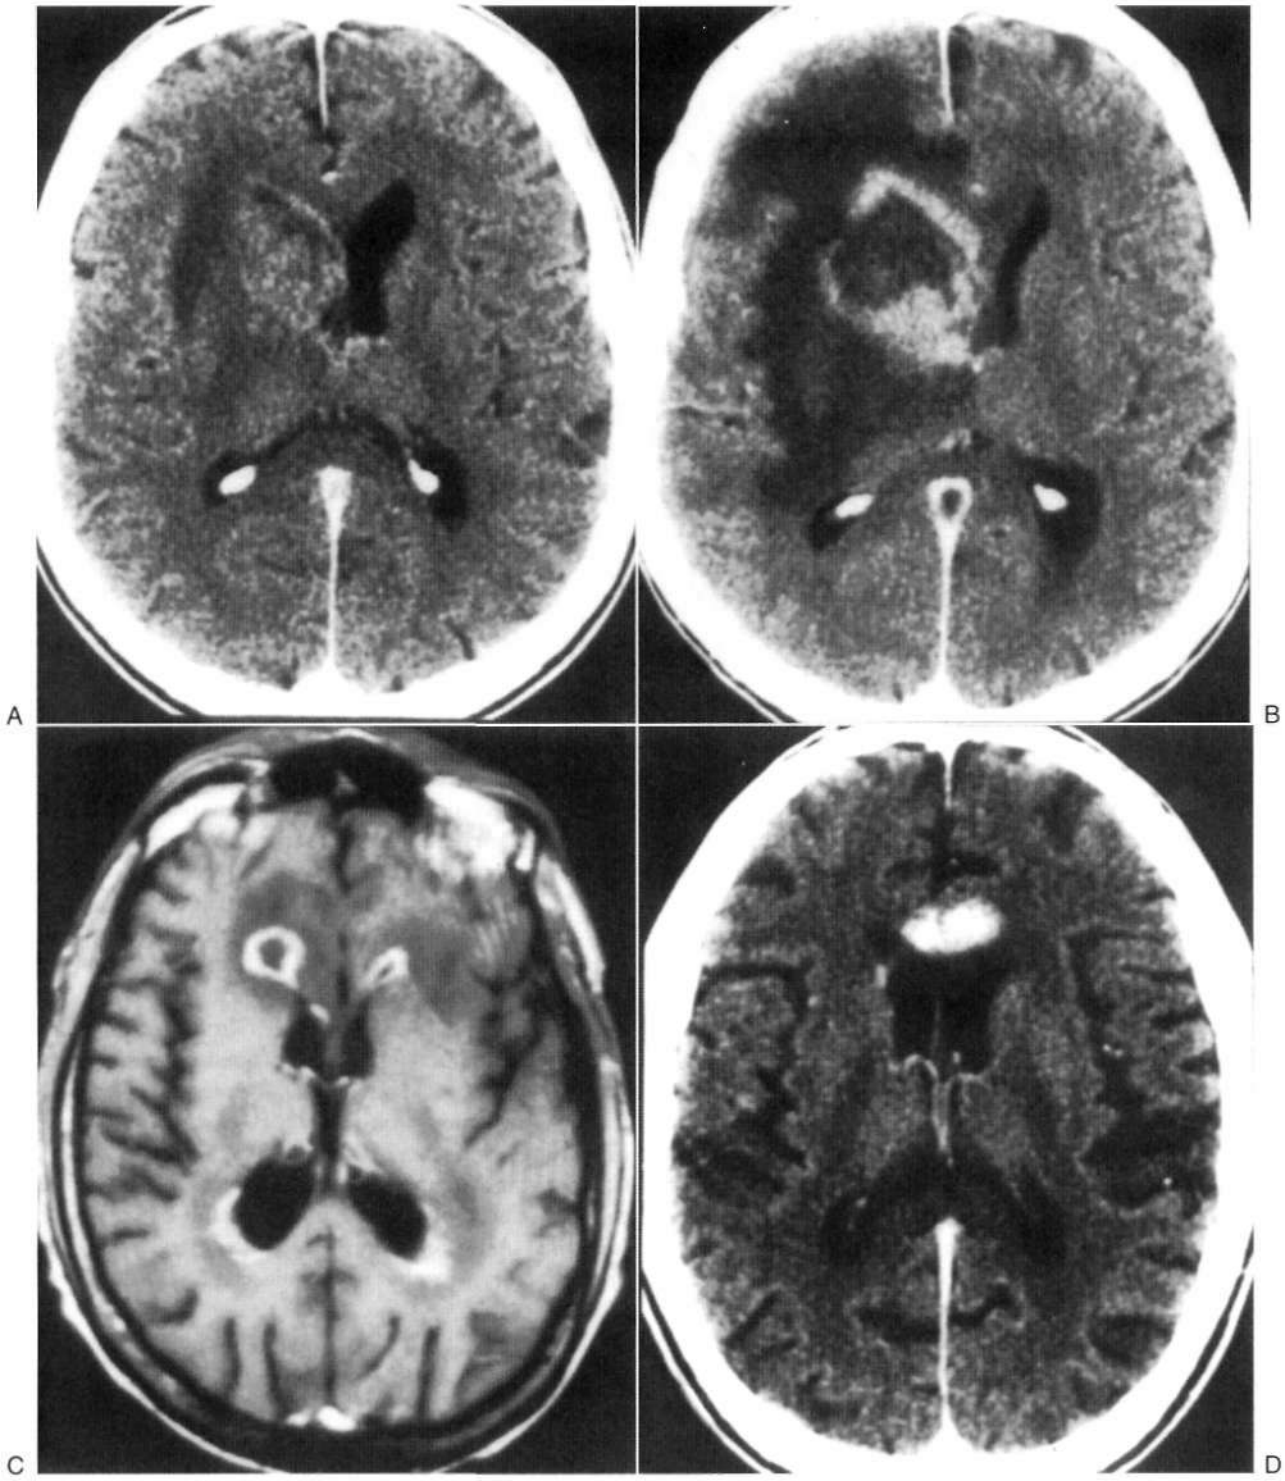

FIGURE 59E.5 Primary central nervous system lymphoma. (A) Contrast-enhanced computed Tomographic scan shows a solitary, enhancing lesion adjacent to the right frontal horn with edema and mass effect. (Bl Repeat contrast-enhanced computed tomographic scan after empiric antitoxoplasma therapy shows increased lesion size, enhancement, edema, and mass effect, consistent with lymphoma. Images train two additional patients show involvement of subependymal regions on (C) gadolinium-enhanced Tl magnetic resonance imaging and (D) corpus callosum on contrast-enhanced computed tomographic scan. (Courtesy Dr. Alisa D. Gean.)

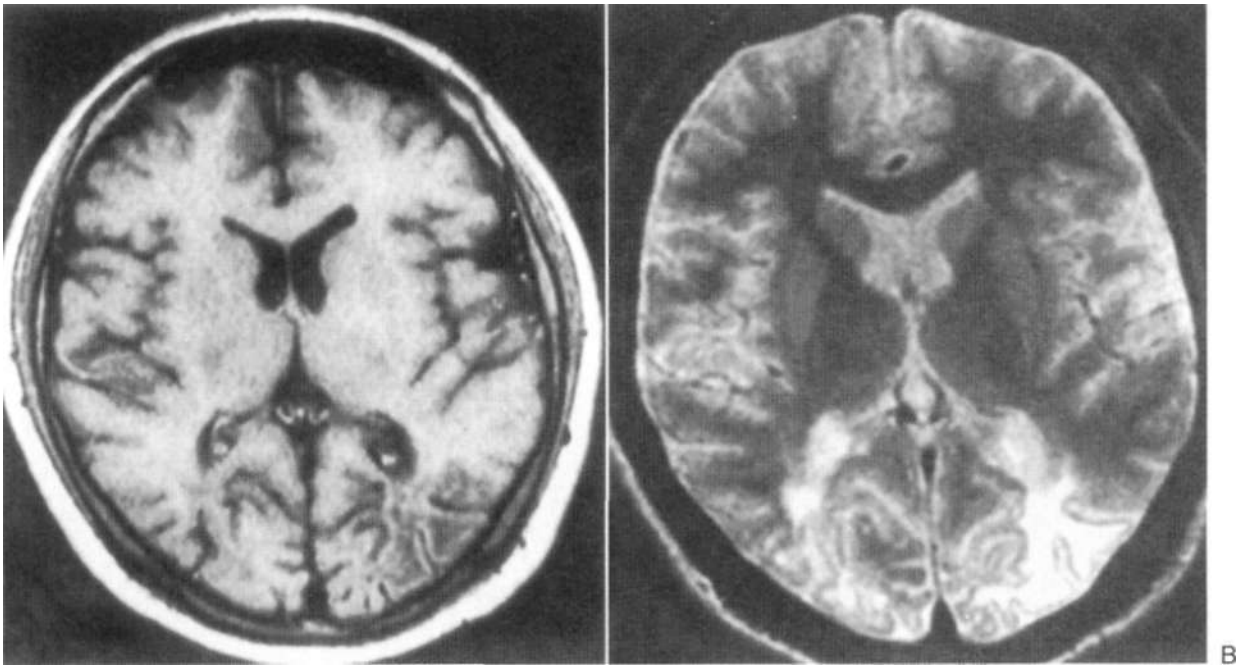

FIGURE 59E.6 Progressive multifocal leukoeiiecphalopathy. (A) TL and (B) T2 cranial magnetic resonance images show bilateral lesions in occipital white matter without mass effect.

patients with AIDS (Dworkin 2002). Approximately 70% of the general population has antibodies to JC virus, indicative of prior infection, hut less than 10% of healthy persons show any evidence of ongoing viral replication. PML is the only known complication of JC virus infection. It is a late manifestation of AIDS and is seen in approximately 4% of patients with AIDS. The lesions of PML begin as small foci of demyelination in subcortical white matter, often in the parietooccipital area, that eventually coalesce. The cerebellum, the brainstem, and very rarely the spinal cord can be involved in PML. Patients typically have a protracted course with focal neurological deficit, with or without changes in mental status. Visual field defects, hemiparesis, aphasia, sensoty defects, and ataxia may occur. MRI typically reveals multiple, nonenhancing white mattet lesions that may coalesce and have a predilection for occipital or parietal lobes (Figure 59E.6). CSF is usually normal or shows nonspecific changes, hut the viral DNA can be amplified from the CSF sample. CSF PCR for JC virus DNA appears to be more specific than sensitive for the diagnosis of PML, but eventually may decrease the need for brain biopsy {in positive cases) in practice and in clinical trials. In cases in which viral DNA is not detected in CSF, a brain biopsy is necessary to confirm the diagnosis. Brain biopsy reveals bizarre giant astrocytes with pleomorphic hyperchromatte nuclei, altered oligodendrocytes with enlarged nuclei that contain viral inclusions, and myelin loss.

There is no specific therapy for PML. Mean survival is 2^1 months; approximately 8% of patients experience spontaneous remission (Simpson and Berger 1996). Despite anecdotal evidence describing benefit from intrathecal or intravenous cytosine arabinoside therapy, a controlled study showed no benefit. Regression of the lesion and prolonged survival for more than 2.5 years have been recently reported in patients with **PML** treated successfully with HAART for their HIV disease (Clifford et al. 1999). Factors influencing a favorable outcome include CD4' T cell counts >100/uL at baseline and the ability to maintain an HIV viral load of less than .500 copies per milliliter. Baseline viral load docs not seem to have independent predictive value of survival. Unfortunately, immune reconstitution takes considerable time, in some cases longer than the survival expectation from PML and, hence, the necessity to develop therapy directed against the JC virus. Cidofovir, a drug used for cytomelovirus in AIDS patients, topotecan, a topoisomerase inhibitor, and IFN-a have been tried in AIDS-related PML with varying, generally unsatisfactory, results (Gasnault et al. 2001; Dworkin 2002).

HIV-associated Vacuolar Myelopathy

VM is the most common cause of spinal cord dysfunction in patients with AIDS, apparent pathologically in 25-55% of AIDS autopsy series (Dal Pan et al. 1994; Dt Rocco and Simpson 1998). VM complicates late HIV infection and frequently coexists with HAD and DSP. Affected patients develop gait difficulty, caused by spasticity, leg weakness, and impaired proprioception, often accompanied by sphincter dysfunction, evolving over several months. Back pain is not a prominent feature. Examination reveals spastic paraparesis with Babinski's signs and hyper-reflexia, unless concomitant neuropathy is severe. Sensation in the legs,

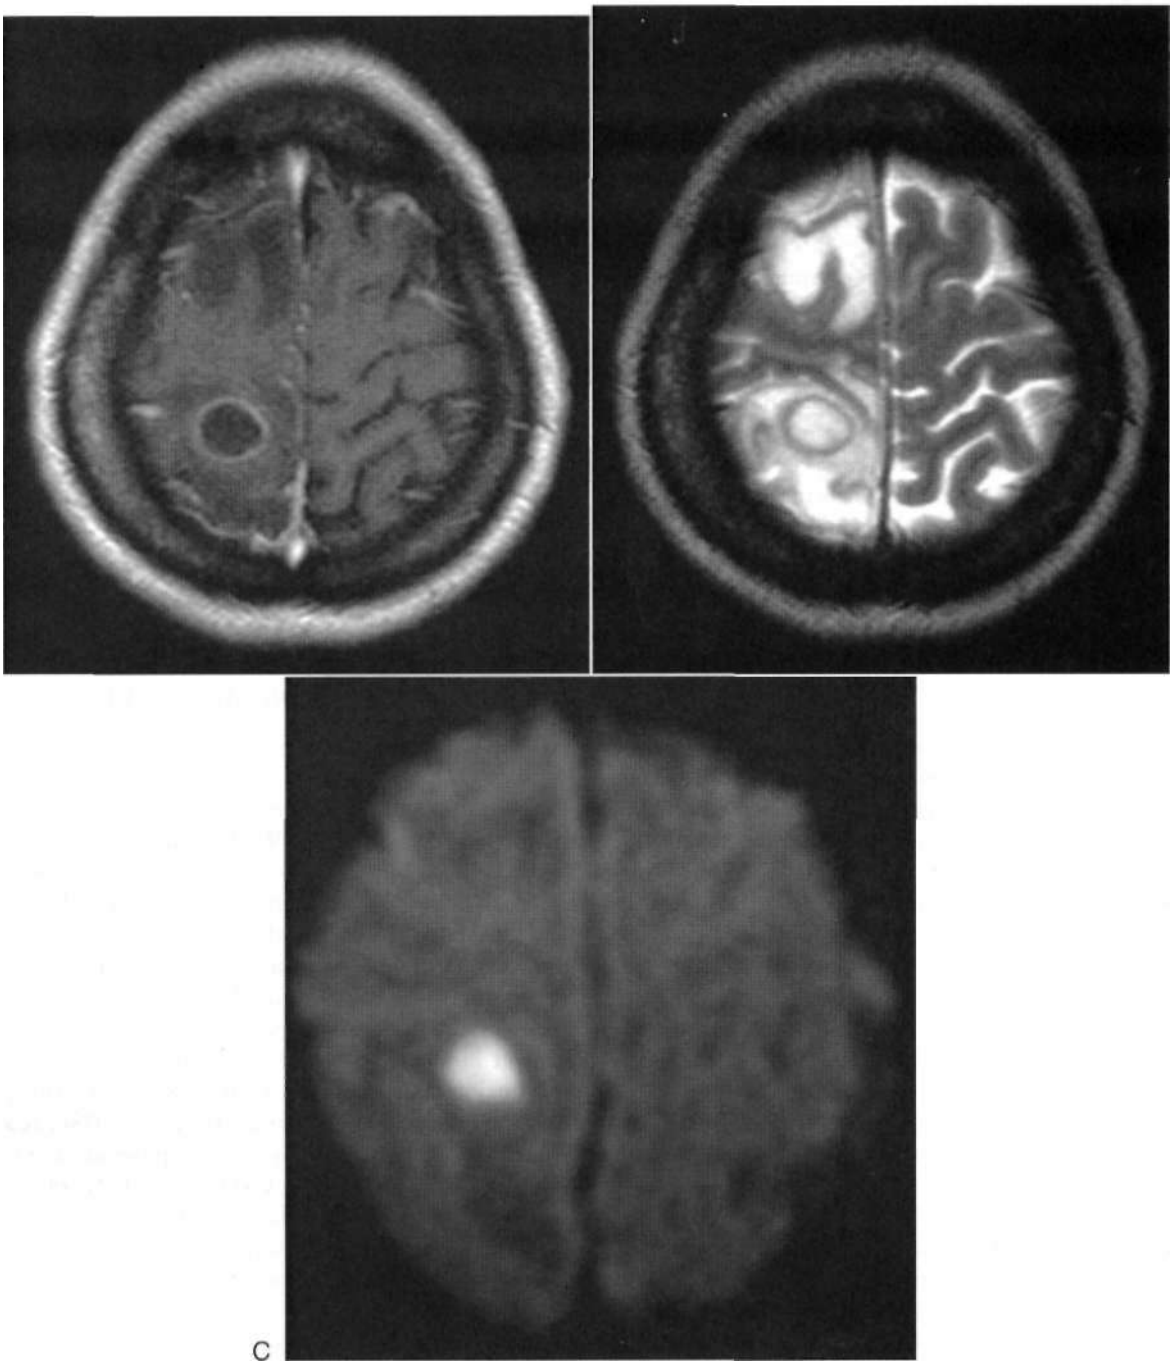

FIGURE 59E.7 Pyogenic brain abscess in AIDS. Postgadolinium axial T'l-W-MRI showing ring-enhancing lesion (A) with surrounding edema best seen in T2-W sequence (B) and with associated intralesional diffusion restriction (DW-MRI, C). (Courtesy Dr. S. Ouanounou.)

particularly proprioception and vibratory sense, is usually impaired, but a clear sensory level on the trunk is unusual. The arms are typically spared until VM is advanced. MRI may occasionally reveal cord atrophy, but usually is unremarkable. Pathological findings are most striking in the dorsolateral thoracic cord and include vacuolar changes in myelin sheaths with relative preservation of axons. Despite the clinical and pathological resemblance to combined systems degeneration, vitamin Bi_2 levels are typically normal in affected patients. HIV-induced release of neurotoxic cytokines or abnormalities in vitamin B12 utilization may contribute to the development of VM.

Evidence that viral control can result in unproved neurological function is not well documented in VM, but there are such reports, making the effort to control the infection important. Additionally, VM is often associated with HAD, in which improvement following HA ART and virus control is better documented. One should construct a

potent and toletahle regimen individualized to the patient's virus and medical history (discussed previously, principles of antiretroviral therapy). Patients with myelopathy and paraplegia require considerable assistance, comparable with that fot multiple sclerosis patients with severe spinal cord demyelination. Care of the neurogenic bladder, bladder infection, management of limb spasticity, prevention of skin breakdown and dccubiti, and assist devices to improve mobility are the issues that tequire individualized attention,

Numerous other infectious, neoplastic, and metabolic disorders occasionally cause myelopathy in patients with HIV infection, and they need to be differentiated from VM. Compared with VM, these disorders may progress more rapidly, often with associated back or radicular pain. CMV, VZV, and herpes simplex virus may cause myelitis. Helpful diagnostic tests include spinal MRI, which may teveal cord swelling with intramedullary enhancement and T2 signal changes, and CSF PCR testing for viral DNA. Because HIV shares risk factors with human T-cell lymphotropic virus I and II, cotnfection with these retroviruses ;iko may cause myelopathy ill the HIV-infected patient. Othet causes of myeloneuropathy complicating HIV infection include neurosyphilis and vitamin B_{12} deficiency. HIV-infected parenteral drug users may develop spinal epidural abscess, a neurosurgical emergency whose clinical manifestations do not appear to be significantly modified by HIV infection (Heary et al. 1994). Rarer infectious causes of myelopathy include M. *tuberculosis* and *T. sioiulii.* Patients with AIDS arc susceptible to systemic lymphoma, which can cause myelopathy ftom epidural metastases.

Stroke

Cerebrovascular disease also causes focal brain dysfunction in HIV infection. Ischemic and hemorrhagic stroke have been reported in up to 4% of clinical series and up to 34% of autopsy series (Pinto 1996). Whether HIV infection itself elevates stroke risk remains uncertain. Thrombocytopenia, coagulopathy related to liver disease or disseminated intravascular coagulation, PCNSL, metastatic Kaposi's sarcoma, and rarely, toxoplasmosis, may be associated with cerebral hemorrhage. Causes of ischemic stroke include bacterial endocarditis, particularly in IDUs, as well as nonbacterial thrombotic endocarditis, vasculitis, and procoagulant states. Granulomatous angiitis of the nervous system has been reported in AIDS. VZV, tuberculous meningitis, and meningovascular syphilis can cause infectious vasculitis, as can the angioinvasivc fungi *Aspergillus* and *Mucar.*

Other Focal CNS Disorders

Numerous other infections have been reported to cause focal cerebral dysfunction in HIV-infected patients. Bacteremia from indwelling catheters needed to manage other aspects of HIV infection or from parenreral drug use predisposes to bacterial brain abscess (Figure 59E.7). Other bacterial causes of focal cerebral dysfunction include *Mycobacterium tuberculosis* abscess, syphilitic gumma, *Bartotiella henselae* (Marra 1995), and *Nocardia asteroides.* Fungal causes of focal brain disease, in addition to the angioinvasive fungi discussed previously, include cryptococcoma, *Blastomyces dermatitidis,* and *Histoplasma capsulatum* (Minamoto and Rosenberg 1997}. Among parasites, relevant diagnostic considerations in patients who have lived in or traveled through endemic areas arc cysticercosis and intracerebral Chagas' disease *{Trypanosoma cruzii)* (Gluckstein et al. 1992). VZV can cause a demyclinating syndrome with lateralmng fearures (Gray et al. 1994), and CMV has been reported to cause mass lesions (Moulignier et al. 1996). Interestingly, HIV infection docs not appear to increase significantly the risk for herpes simplex virus encephalitis.

H1V-ASSOCIATED NEUROMUSCULAR DISORDERS

Neuropathies

Peripheral neuropathies are common in HIV infection (Sadler and Nelson 1997; Wulff et al. 2000; Verma 2001; Sacktor 2002). Peripheral neuropathies complicate all stages of the HIV disease and cause considerable morbidity and disability in HIV-infected individuals and AIDS patients. Although symptomatic neuropathy occurs in approximately 10 to 15% of HIV-infected patients overall, pathological evidence of peripheral nerve involvement is present in virtually all end-stage AIDS patients. There are five major clinical types of HIV-associatcd neuropathies that are regularly seen in large HIV clinics: DSP, acute and chronic inflammatory demyelination polyradiculoneuropathies (AIDP and CIDP), CMV-associated polyradiculomyelopathy, and nucleoside-associated toxic neuropathies. A vasculitic neuropathy is less common but often responds well to corticosteroid treatment.

Distal Sensory Polyneuropathy

Of the various peripheral nerve syndromes that complicate HIV infection, the most common is DSP, also called HIV-associated neuropathy or AIDS neuropathy. This axonal, predominantly sensory, length-dependent polyneuropathy develops in approximately one third of patients with AIDS, becoming more prevalent as the CD4~ T cell count decreases (Sadler and Nelson 1997; Childs et al. 1999). Depressed or absent ankle jerks and mild pain, Temperature, and vibratory sensory loss in the feet, with or without associated foot parcsthesiae and numbness, may be the only evidence of the disorder, and probably make up the more common clinical syndrome. Less frequently, severe burning

pain and parcsthesiae develop in the feet, often disrupting sleep in a manner reminiscent of diabetic or nutritional sensory polyneuropathies. Symmetrical involvement is a characteristic clinical feature, and the hands are usually spared until the disorder is advanced. F.ven though DSP typically spares motor function and proprioception, walking may be impaired because of severe pain. The pathogenesis of DSP is not well understood. Cytokine upregulation in advanced infection has been proposed, as have dorsal root ganglion toxicity of HIV antigens and the effects of chronic, multisystemic illnesses.

The rather typical clinical features usually obviate the need for electromyography and nerve conduction studies. Exposures to neurotoxins, including ethanol, should be reviewed. Neurotoxic drugs commonly used to manage HIV infection include the nucleoside analogs didanosine, zalcitabine, and stavudine (see Table 59H.3), in addition to isoniazid, pyridoxine, dapsone, metronidazole, and vincristine. Screening for vitamin B_{12} deficiency and diabetes mellitus is important. Goals of treatment include minimizing neurotoxic exposures, virus suppression by HAART, and management of pain. Tricyclic antidepressants and anticonvulsants ameliorate neuropathic pain in DSP. When there is coexisting dementia or other cerebral disease, the anticholinergic effects of amitriptylinc may be poorly tolerated. Using very low doses or switching to a less anticholinergic tricyclic antidepressant such as nortriptyline, plus addition of a selective serotonin reuptake inhibitor, may facilitate tolerance. With regard to anticonvulsants, the high rate of adverse reactions and drug interactions with carbamazepine in patients with AIDS limits its utility for the management of neuropathic pain, The favorable side effect and drug interaction profile of gabapentin makes it the treatment of choice for managing neuropathic pain in AIDS. Mexiletine, selective serotonin reuptake inhibitors and topiramate have been tried with variable success, A recent trial with nerve growth factors failed to show clinically significant improvement. Topical capsaicin is an appealing choice for select patients with DSP. but is rarely dramatically beneficial. Other occasionally useful adjuncts include nonsteroidal anti-inflammatory drugs, transcutaneous electrical nerve stimulator units, and acupuncture, but some patients may require chronic narcotic therapy.

Nucleoside Analogue-Associated Toxic Neuropathy

A painful polyneuropathy that closely resembles DSP is the major dose-limiting toxicity of the nucleoside analogue antiretroviral agents didanosine, zalcitabine, and stavudine (Verma 2001; Sacktor 2002). Two clinical features can help distinguish nucleoside neuropathy from DSP. First, nucleoside neuropathy typically evolves over weeks following initiation of therapy, in contrast to DSP, which progresses over months or even years. Second, stopping the offending agent eventually leads to regression of nucleoside neuropathy over several months, although *coasting,* in which symptoms worsen for several weeks before improvement, may complicate the evaluation of this strategy for diagnosis. Although pre-existing DSP increases the risk for nucleoside neuropathy, many patients with DSP tolerate neurotoxic anciretrovirals, particularly if the dose is kept low. Similarly, many patients who develop nucleoside neuropathy can resume therapy at a lower dose or may tolerate a different neurotoxic drug. Other aspects of the evaluation and treatment are similar to DSP.

inflammatory Demyel'mating Polyradiath>!u-itrojhHk'w<,

Less common than the painful neuropathies related to HIV or nucleoside antiretrovirals are the inflammatory demye-Imaring polyradiculoneuropathies (IDP), AIDP, and CIDP {Wulff et al. 2000). These disorders resemble the syndromes seen in individuals without HIV infection with regard to pathogencsi* and men cluneal features. 1 he precise prevalence is unknown, but case series from the United States and Africa suggest that the IDP often develops during early HIV infection, sometimes around the time of seroconversion. Before the frank immunosuppression of AIDS, viral antigenemia and immune dysregulation are presumed to cause autoimmune disorders, such as the IDI[J], in early HIV infection. AIDP or the Guillain-Barre syndrome typically presents as rapidly progressive ascending weakness with areflexia, variably accompanied by respiratory failure and dysautonomia. The Miller-Fisher variant, in which cranial nerve dysfunction, areflexia, and ataxia are more prominent than limb or respiratory weakness, also has been described during HIV infection. In CIDP, neuropathic weakness and sensory loss occurs in a more indolent and episodic manner than in AIDP. Cranial nerves may be involved in CIDP, but respiratory failure or autonomic dysfunction are unusual. In both AIDP and CIDP, electrophysiological studies reveal slowed conduction, temporal dispersion, multifocal block, and ptolonged F waves, indicating demyelination. CSF from seronegative patients with IDP typically reveals only elevated protein, sometimes with oligoclonal bauds on Immunoelectrophoresis, without associated pleocytosis. In HIV-infected patients with IDP there is often lymphocytic pleocytosis (10-50 cclls/nl.) in addition to increased protein. Clinical experience suggests that intravenous immunoglobulin, plasmapheresis, and corticosteroids {only CIDP) are beneficial.

Lumbosacral Folyradiculomyelitis

Subacute lumbosacral polyradiculomyelitis is an uncommon HIV-relatcd syndrome that results from a variety of infectious agents, most notably CMV, Clinical manifestations suggest a cauda equina syndrome, with leg weakness and later paralysis, sphincter dysfunction, sacral and leg paresthesiae and sensory loss, and areflexia, typically

evolving over several days. When such a syndrome develops in a patient with a CD4' T cell count less than 50/|iL, and CSF reveals marked polymorphonuclear pleocytosis, elevated protein, and low to normal glucose, CMV infection of the nerve roots, with subsequent inflammation and necrosis, is the likely cause. CMV PCR or branched DNA assay in CSF is a helpful confirmatory test, but treatment should not be delayed pending these results. Intravenous ganciclovir (see Table 59F.4) can arrest and reverse the deficit in CMV polyradiculomyelitis, which is fatal without treatment (McCutchan 1995; Wulff et al. 2000). Polyradiculomyelitis caused by ganciclovir-rcsistant CMV has been reported and may respond to foscarnet, either alone or with cidofovir. Other causes of polyradieulomyelopathy in AIDS include tuberculosis, neurosyphilis, and lymphomatous meningitis.

Other Neuropathies and Neuronopathies

Mononeuritis multiplex (MM) is a relatively rare peripheral nerve syndrome of HIV infection that manifests clinically as multifocal, asymmetrical peripheral nerve lesions that may include cranial nerves. When the syndrome develops in early or mid-stage HIV infection, it often responds well to corticosteroid therapy, though it may be self-limited, not requiring immunosuppressive therapy (Bradley and Verma 1996). MM complicating advanced HIV infection, with $CD4^+$ T cell count less than 50/uL, may be caused by CMV and responds to intravenous ganciclovir. An ALS-like syndrome (Moulignier et al. 2001) and brachial plexus and lumbosacral plexus (Benatar and Eastman 2000) neuropathies have also been reported in HIV disease.

Myopathics

Myopathic symptoms in HIV-infected individuals can arise from toxic (zidovudine) or dysimmune (polymyositis) causes or from AIDS cachexia (muscle wasting syndrome) (Lange 1994; Sheikh et al, 1999). In HIV-associated polymyositis, patients develop proximal weakness and, less commonly, myalgia, both of which are ascribed to a dysimmune response following 1IIV infection. On occasion it may occur with immune restoration following HAART (Sellier et al. 2000). Serum creatine kinase is elevated in most cases, and electrophysiological studies often reveal myopathic motor units and increased insertional activity and spontaneous activity typical of an inflammatory myopathy. Muscle biopsy reveals fiber size variability, fiber degeneration, and endomysial infiltrates. Cytoplasmic bodies and nemaline rod bodies are other common histological features. HIV does not appear to directly infect muscle fibers, but rather induces them to express major histocompatibility complex I, triggering cell-mediated muscle fiber injury. Even so, inflammatory myopathy is among the few HIV-related neurological disorders that develop at any time during HIV infection. Despite the potential risks of corticosteroid therapy in the setting of HIV infection, such treatment is often well tolerated. Prednisone has helped in motor recovery and pain improvement in HIV-associated polymyositis. Starting with dose of 1 mg/kg per day, the dose is titrated downward as strength improves. Inclusion body myositis also has been reported in association with HIV infection (Cupler et al. 1996).

Zidovudine myopathy is a toxic mitochondrial disorder that presents with the insidious onset of proximal weakness and myalgia, making it difficult to distinguish clinically this condition from HrV-associated inflammatory myopathy (Grau et al. 1993). Though first described in patients raking zidovudine in doses of 1000 mg per day or more (Dalakas et al. 1990), zidovudine myopathy also develops on lower dose regimens in current HAART regimen. Affected patients typically have taken zidovudine for at least *6* months. Serum creatine kinase may be normal or elevated, .uul iiiusclr :iiojv-\ slunv, hivolniuV,!! leanre[1]. v.ii',i',iMmi>, mitochondrial dysfunction, with no or scanty inflammation, Clinical response to a drug holiday or reduction in zidovudine dose often obviates the need for muscle biopsy.

Pyomyositis, a focal suppurative bacterial muscle infection, was more common in the tropics but rare in developed nations, before the AIDS epidemic (Medina et al. 1995; Hossain et al. 2000). Clinical features include fever accompanied by local muscle pain and swelling evolving over several weeks. A source of bacteremia may be evident by history or general examination. Typically, the affected area is swollen, hot, and indurated, but not fluctuant, Peripheral white count and serum creatine kinase are usually normal, prompting consideration of cellulitis or deep venous thrombosis as the initial diagnosis. Ultrasound, CT, or MRI of the affected area establishes the diagnosis. Blood cultures may reveal the causative organism, usually *Staphylococcus aureus* or, less commonly, *Salmonella typhi* or other gram-negative bacilli (Medina et al. 1995). Empirical intravenous antibiotic therapy should be given to cover these pathogens. Surgical drainage may be required. Intravenous therapy for 1-2 weeks is usually followed by oral antibiotic therapy for up to 8 weeks. Disseminated infection with C. *twoformans*, *T. gondii*, M. *tuberculosis*, *Mycobacterium avium-intracellulare*, and Microsporidia occasionally may involve muscle also. HIV infection has also been associated with adult-onset nemaline rod body myopathy. Rhabdomyolysis may occasionally occur at the time of seroconversion.

Chapter 59
Infections of the Nervous System

F. NEUROLOGICAL MANIFESTATIONS OF HUMAN IMMUNODEFICIENCY VIRUS INFECTION IN CHILDREN

Ashok Verma and Anita L. Belman

EPIDEMIOLOGY AND CURRENT TRENDS

Epidemiology of human immunodeficiency virus type-1 (HIV-1, called henceforth HIV) infection and acquired immunodeficiency syndrome (AIDS) in adults is covered in Chapter 59E. The epidemiological consideration of pediatric HIV infection must take into account HIV-infected women and children together because the worldwide increase in the number of children with vertically acquired HIV infection parallels the increase in number of HIV-infected women of childbearing age. The exact number of HIV-infected children is unknown because surveillance systems in the past have relied on identification of children younger than age 15 years who had clinical manifestations of AIDS. According to the United Nations Program on HIV/AIDS, as of the end of 2002 out of 42 million people estimated to be living with HIV infection, 19.2 million arc women and 3.2 million are children under 15. An estimated 5 million people acquired HPV in 2002, including 2 million women and 800,000 children under 15. During 2002, AIDS caused the deaths of an estimated 3.1 million people, including 1,2 million women and 610,000 children under 15 (United Nations: www.unaids.org/epidemic update),

The cumulative number of AIDS cases in the United States reported to the Center for Disease Control and Prevention (CDC) is 816,149, and children under age 15 account for a total of 9074 AIDS cases {CDC: www.hivatis.org). Total deaths of persons reported with AIDS reported to the CDC are 467,910, including 5257 children under age 15. The incidence of perinatally acquired AIDS peaked in the United States in 1992 and then decreased in the ensuing years (Figure 59F.1). In April 1994, the United States Public Health Setvice released guidelines for the use of zidovudine (ZDV) to reduce perinatal HTV transmission, and in 1995 recommendations for HIV counseling and voluntary testing for pregnant women were published. Highly active antiretroviral therapy (HAART) was introduced in 1996. Since then, the percentage of perinatally HIV-exposed or HIV-infected children who received antiretroviral therapy (postnatally) and whose mothers received IIAART (parapartum) has increased steadily and significantly. As a tcsult, in 2000 only 196 children were reported to CDC with AIDS, a decrease from 263 in 1999. Over 90% of HIV-positive children acquire the infection pctinatally, that is, from their mothers before or during the birth or from breastfeeding.

The prevalence of neurodevelopmental abnotmalities in children with HIV is high. Approximately 50% of HIV-infected children who have not received antiretroviral therapy have abnormal neurodevelopmental findings: abnormal motor function, reflexes, and cognition. The frequency with which HIV-rclated progressive encephalopathy (HPE) is reported as an initial AIDS-defining illness is much higher in children (12-67%) than is reported in adults. Particularly noteworthy is the finding that more than half of these children are not severely immunosuppressed at the time of the HPE diagnosis: 26% of the children do not demonstrate CD4+ T cell depletion at all;

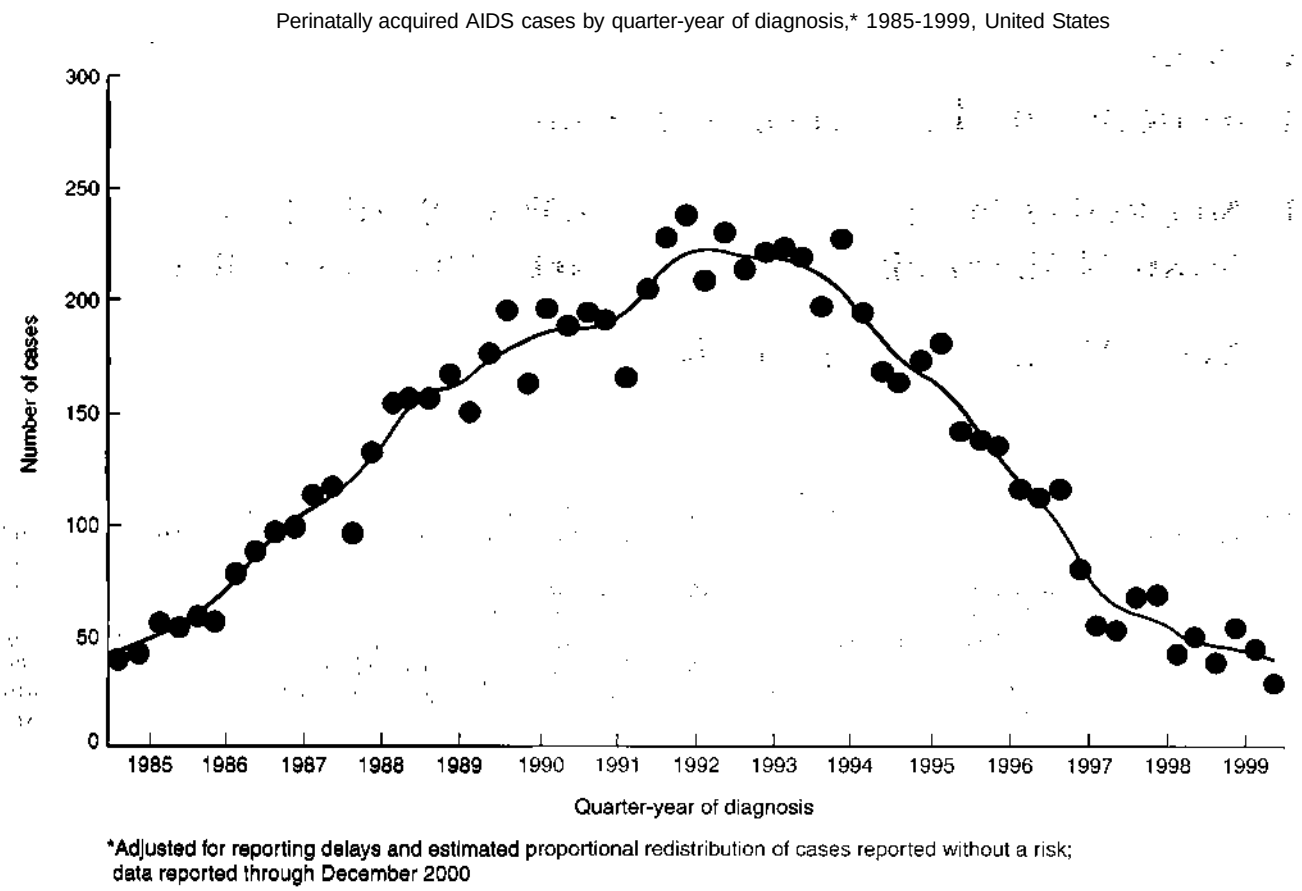

FIGURE 59F.1 Notified cases of pediatric AIDS in the USA from 1985 to 1999. Source: CDC Atlanta (http://phil.cdc.gov/phil/).

approximately 30% have moderate suppression; and only 44% are severely immunosuppressed.

TIMING AND MODE OF HIV INFECTION IN CHILDREN

Vertical Transmission

Most mother-to-child transmissions of I NV occur in utcro in intrapartum, or in postpartum period via breastfeeding The true frequency of in utero versus peripartum transmis sion is not known. A healthy placenta generally protects the fetus in utero from HIV in the maternal blood for most of the gestation. The integrity of the placental protection against HIV may rarely be breached by infections and drugs (e.g., *Toxoplasma).* In a nonbreastfeeding population, modeling backwards from the earliest detection of HIV DNA by polymerase chain reaction (PCR) in the infant's blood in the first days or weeks of life has suggested that the majority of transmissions occur around the time of delivery, with the remainder mostly late in the third trimester. For breastfeeding, the risk of transmission extends beyond delivery and throughout the breastfeeding period. The overall risk of transmission of HIV from the untreated mother to child is about 20-30% for nonbreastfeeding mothers and 30-45% for breastfeeding mothers.

Although infection during or near the time of birth has become rare in industrialized countries following the use of antirctroviral therapy, it continues to be rampant in the underdeveloped nations. It is estimated to be 19-24% in Thailand and 25-45% in Africa. Factors associated with increased transmission risk include low maternal CD4+ T cell count, high viral load, advanced HIV disease or AIDS, low vitamin A level, placental membrane inflammation, premature rupture of membranes, increased infant exposure to maternal blood, premature delivery, and breastfeeding.

Parenterally Acquired Infection

Before routine blood donor screening for HIV, recipients of HlV-contaminated blood or blood products included children with hemophilia or other coagulation defects and children with illnesses that required blood transfusions

(e.g., children with leukemia, sick neonates). Virus transmission also occurred through the use of contaminated injection equipment. Although hlood screening and preventive medical practices have significantly improved the risk of contracting HIV infection through blood transfusion, the risk of contact with unsterile skin-piercing instruments still remains for children, particularly for children living in areas where blood supplies are not properly screened and universal preventive precautions are not observed.

Sexually Transmitted Infection

Sexual abuse during childhood and adolescence in the home or community or by exploitation is a well-documented problem that affects all societies. Sexual abuse of children takes two forms: (1) commercial sexual exploitation (a clandestine trade in certain parts of the world) and (2} sexual abuse in the home and community. Most sex industry children are girls aged 13-18 years. Although not a new phenomenon, childhood sexual abuse has recently been recognized by the World Health Organization as a major worldwide concern. Ir is unknown how many child sex workers exist in the world and how frequent is the sexual transmission of HIV in these young individuals.

CLINICAL APPROACH TO CHILDREN WITH HIV DISEASE

The diagnosis of pediatric HIV infection and the associated neurological disorder requires experience, clinical skills, and major neurodiagnostic investigative tools. A careful medical and developmental history, HIV systemic disease history (see following), current immunological and virological status, neurological examination, neuropsychological assessment, and neuroimaging studies arc often required to diagnose accurately the HIV-associated neurological diseases in children.

The diagnosis is straightforward if a previously known seropositive child is found to have cognitive and motor impairment and the clinical assessment documents the new onset of, or progression of, these deficits. Serial assessments of untreated children with HPE reveal progressive neurological deficits (other causes excluded). The diagnosis of opportunistic infections (OIs), neoplasia and Hl'K is often straightforward if the child has been followed prospectively. The infant may show impaired head control, speech deterioration, axial hypotonia, or upper motor neuron signs. The toddler or older child may have a change in gait, become hyperreflexic, refuse to walk, and over time may develop progressive corticospinal tract (CST) signs.

Diagnostic difficulties arise when the youngster who has not been followed prospectively is found to have a neurological deficit. Because of the relatively high frequency of neurological and developmental impairments in this population, it is often difficult for the clinician to ascribe these findings to ! NV-associatcd central nervous system (CNS) disease. A careful history is paramount. If no other risk factors are identified, the diagnosis of HIV-associated disease is likely. Neuroimaging studies are critical. If calcification of basal ganglia is present (see following), it is probable that the child's neurological deficits arc related to HIV infection. If cerebral atrophy is present in the absence of documented perinatal complications or other known causes of atrophy, the diagnosis is also very likely. Head circumference measurements are invaluable (Belman 1990). A careful review of medical records will document at least one or two past head circumference measurements, allowing serial measurements to be plotted. If a pattern of downward deviation and acquired microcephaly is present, the diagnosis is likely. Thus neuroimaging evidence of atrophy accompanied by acquired microcephaly clearly strengthens the diagnosis 01 Hl'K. 1 ol;ow-Lip neimi'oL'.ival, pv> chonu-tric, and neuroimaging studies help confirm the clinical diagnosis.

Laboratory Monitoring of HIV Infection in Infants and Children

Plasma viral load data from prospective cohorts followed from birth demonstrate the difference in response to infection in infants and young children compared to adults. Within 4-8 weeks of birth a peak viremia is reached in perinatally HIV-infected infants, and this may take many years to decline to a baseline. The HIV RN'A copies at the peak are higher and the subsequent decline is much slower in children than that seen in newly infected adults (Abrams ct al. 1998; Dickover et al. 1998). In one cohort *[n* - 106), HIV was not detected in most infants at birth, consistent with very recent intrapartum infection, and the median viral load at one month was 318,000 copies/uL. The median base line level of 34,000 copies/ul. was not reached until around 24 months of age. Infants with rapidly progressive disease generally have higher levels of viremia in the first days of life and during the first 2 months.

The HIV plasma viral load has also been measured in cohorts of children presenting with symptoms of disease and who had not been followed from birth. The relative risk of death during follow-up increased if the HIV RNA load was higher. In a time-independent model, the relative risk of death was 2,8 per $h>g_m$ increase in HIV RNA copy number. HIV RNA viral loads were highest in the young infants, and the greatest decline in viral bad occurred by *2-4* years, giving an average yearly decline of approximately 0.29 logio/year, unrelated to any interventions. Similar findings were demonstrated in a retrospective analysis of HIV RNA load in 70 children

(median age 3.5 years) entered in a study of immediate versus deferred ZDV monotherapy. The majority of these children (76%) were asymptomatic (stage N, see following) at enrollment, and the HIV RNA load was significantly higher in those <3 yrs (median 5.23 logio), and it fell to a nadir of 4,25 logio at 6 years; the decline was most rapid in the first 2 years of life. The predictive value of baseline viral load and its relation to the age of the infant/child was also demonstrated in another cohort. The risk of progression with elevation of viral load in the older children in these cohorts was similar to that seen in adults (CDC 1998).

A recent meta-analysis of more than 3000 untreated children from cohorts in the United States and Europe demonstrated that for children over 6 months of age progression to AIDS or death increased sharply for viral loads over 10" copies/uL, and at 2 years of age the risk of progressing ro AIDS was 5% with a viral load $<10^5$ copies/uL, 24% at 10^6 copies/uL, and 66% at 10^7 copies/uL (Lyall 2002).

CD4+ T cell Count and Progression of HIV Disease in Infants and Children

Assessment of a CD4+- T cell count in a child must be in relation to the appropriate count for age, the 50th percentile CD44- T cell count at age 6 months being 3000/pL, compared to 1,000/uL for a 6-year-old, by which time the CD4+ T cell count range approaches that of adults (Comans-Bitter et al. 1997). Further, for an individual child the CD4+ T cell count varies and is often depressed with intercurrent infections. Therefore, this parameter should be measured when the child is in a stable clinical condition. The CD4+ T cell percentage varies less with age and other factors than the absolute count and may be a more useful measure of immune function in children.

Although CD4+ T cell count may be less helpful in infants, overall the baseline CD4+ T cell count along with the plasma viral load are predictive of progression of HIV disease in children. Fot example, in one cohott, if the CD4+ T cell count dropped to < 15% the relative risk of death was 2,8 (95% CI 1.6-4.9). In a time-in dependent model the relative risk of death per 5-point decrease in CD4+ T cell percentage was *13 (95%* CI 1.2-1.5). In this cohort both HIV RNA levels and CD4-I- T cell counts were significantly and independently associated with mortality in the follow-up period.

In a recently reported meta-analysis, in children over 2 years of age the 12-month risk of developing AIDS was 6% for a CD4+T cell count of >20%, increased to 18% with a CD4+ T cell count of 10%, and 34% with a CD4+ T cell count of 5%. The CD4+ T cell count was less predictive of progression of disease in infants than that in older children in this meta-analysis.

CLINICAL FEATURES OF HIV INFECTION IN CHILDREN

Clinical features of HIV infection in a pediatric population differ from those in adults in a number of ways. First, up to 20% of children with HIV present with severe symptoms or they die in infancy (fast progressors). Whether their poor prognosis is related to a greater inoculum of HIV, earlier infection in the face of an immature immune system, the acquisition of immune escape HIV mutants from the mother, or a combination thereof is not completely known. Second, mononucleosis-like seroconversion illness with or without acute aseptic meningitis or meningoencephalitis described in some adults does not occur in infants. Third, the spectrum of neurological and non-neurological manifestations m I llV-infected children is somewhat different from adults. For example, hepatosplenomegaly and bone marrow failure, lymphocytic interstitial pneumonia (LIP), chronic diarrhea and failure to thrive, acquired microcephaly, cerebral vasculopathy and basal ganglia calcification are unique to or occur more frequently in children. Fourth, OIs that represent recrudescence of previously acquired infections in adults (e.g., cerebral toxoplasmosis, ptogressive multifocal leukoenceph.ilopathy) are obviously rare in infants. Fifth, absolute CD4+ T cell counts as a parameter of disease stage is less helpful in infants and young children as previously described. A high number of CD4+ T cells can be associated with a higher HIV load in infants and children than in adults, and infant fast progressors usually harbor higher plasma HIV RNA levels. Sixth, in an infant anti-HIV antibody in the serum may be of maternal (transplacental) origin and therefore is not diagnostic of infection (Blanche et al. 19fi^{L}>). The current gold standard test for HIV infection in infancy is HIV-DNA PCR on peripheral blood lymphocytes. Because most infants are infected intrapartum and circulating HIV levels may still be very low, HIV DNA cannot be amplified from the plasma in all infected infants at birth. Indeed a positive HIV-DNA PCR result within 48 hours of birth has been taken as evidence of intrauterine transmission. Finally, 1 iPE, clinical equivalent of HIV-associated dementia (HAD) in adults, is more frequent in children and is generally more amenable to treatment with HAART.

The current classification system of infection used for children was revised in 1994 prior to the availability of measurements of HIV plasma viremia. This classification is based on clinical signs and symptoms, giving a clinical score (Table 59F.1), as well as age-related CD4+ T cell count, giving an immunological score (Table 59F.2). Clinical signs and symptoms are allocated to four categories: N (none), A (mild), B (moderate), and C (severe). OIs and other conditions associated with an AIDS diagnosis are all category C. Originally, LIP was an AlDS-defining diagnosis, despite its good prognosis, but it is now listed as a category B condition (see Table 59F.1).

Table 59F.1: Symptom categories of HIV disease in children

Category N: Not symptomatic
No signs or symptoms considered to be the result of HIV-1 infection or only one of the conditions listed in category A.

Category A: Mild symptomatic
Two or more conditions listed following, but none of the conditions listed in categories B and C:
Lymphadenopathy (0.5 cm or greater at more than two sites; bilateral = one site)
Hepatomegaly
Splenomegaly
Dermatitis
Parotitis
Recurrent or persistent upper respiratory infection, sinusitis, or otitis media

Category B: Moderately symptomatic
Symptomatic conditions other than those listed for categories A or C that are attributed to HIV infection. Including:
Anemia (<8 g/dL), neutropenia (< 1,000/uL), or thrombocytopenia (< 100,000/uL) persisting at least 30 days
Bacterial meningitis, pneumonia, or sepsis (single episode)
Candidiasis, oropharyngeal (i.e., thrush) persisting for >2 months
Cardiomyopathy
Cytomegalovirus infection with onset before age I month
Diarrhea, recurrent or chronic
Hepatitis
Herpes simplex virus stomatitis, recurrent (i.e., *>2* episodes within I yr)
Herpes simplex vims bronchitis, pneumonitis, or esophagitis with onset before age 1 mo
Herpes zoster (i.e., shingles) involving at least two distinct episodes or more than one dermatome
I i-iomj nsarcoma
Lymphocytic interstitial pneumonia or pulmonary lymphoid hyperplasia coinpleN
Nephropathy
Nocardiosis
Fever lasting > 1 month
Toxoplasmosis with onset before age 1 month
Varicella, disseminated (i.e., complicated chickenpox)

Category C: Severely symptomatic
Any condition listed in the 1987 surveillance case definition of AIDS, with the exception of lymphocytic interstitial pneumonia (which is a category B condition).

Adapted from Centers for Disease Control and Prevention. 1994, "Revised classification system for human immunodeficiency virus infection in children less than 13 years of age," MMWR, vol. 43, no. 12, pp. 1-10.

AIDS-RELATED NEUROLOGICAL DISORDERS

Neurological disorders associated with HIV may be divided into two major categories: (1) HIV-associated primary neurological diseases (e.g., HPE, a syndrome complex with cognitive, motor, and hehavioral features related to primary HIV CNS infection), and (2) HIV-associated secondary neurological complications (e.g., disorders related to immunosuppression). The secondary complications include CNS neoplasms, CNS infections caused hy pathogens other than HIV, and strokes. The child's nervous system may also be adversely affected by complications related to systemic HIV disease and its therapy and metabolic and toxic complications associated with and retro viral therapy. These conditions are not mutually exclusive, and coexisting pathological conditions are common at the same or different anatomical levels of the nervous system in HIV-infected children. Ncurodevelopmental status may also be affected by non-HIV-related comorbid conditions. Some of these conditions relate to maternal high risk factors during pregnancy (malnutrition, drug abuse), complications in the perinatal period (premature birth), as well as postnatal psychosocial stressors. OIs, neoplasia, neuromuscular i:i.im\-.uiiiiM.v and antircu-m iral i:ui\ip\ ivhuo compli cations associated with HIV infection arc described in Chapter 59E.

HIV-ASSOCIATED PROGRESSIVE ENCEPHALOPATHY (HPE)

Neurological involvement associated with pediatric AIDS was reported early in the AIDS epidemic. Longitudinal follow-up of HIV-infected children showed several patterns

Table 59F.2: Immune categories of 1 IIV disease in children

	CD4+- *T ceil: No./fiL(%)*		
Immune category	*< 12 months*	J-5 *years*	*6-12 years*
Category L(no suppression, Nl)	> 1,500 (>25)	> 1,000 {> 25)	>500(>25)
Category 2:(modcrate suppression, N2)	750-1499 (15-24)	500-999 (15-24)	200-499 (15-24)
Category 3:(severc suppression, N3)	<750 (<15)	<500 (<15)	<200 (< 15)

Source: Centers for Disease Control and Prevention. 1994, "Revised classification system for human immunodeficiency virus infection in children less than 13 years of age," *MMWR,* vol. 43, no. 12, pp. 1-10.

of neurological dysfunction and deterioration, now known under the rubric of **HPE.** It was also observed that by the time HIV infection had advanced to "full-blown" AIDS, HPE was extremely common, and in the majority of cases (in contrast to adult cases) there was no evidence of concomitant CNS OIs or neoplasms. Furthermote, clinical and research studies documented that the CNS was infected by HIV in the early stage. Morphological and generic similarities were documented between HIV and *visna* virus, an ovine retrovirus with well-known neurotropic properties in the developing brain. The clinical syndrome of HPE in children is similar to the adult counterpart, HAD, and is related to the primary HIV CNS infection. Following its recognition, HPE in infants and children was added to the CDC's list of pediatric AIDS-defining conditions.

Cognitive impairment, poor brain growth (acquired microcephaly), and progressive CST signs are the frequent manifestations of HPE (Belman 1990). Disorders of movement, usually superimposed on spasticity, and cerebellar signs are less frequent. Mood and behavioral problems are common. Rate and pattern of disease progression show variations. Neurological deterioration is rapidly progressive in some infants and young children (rapid processors). Within a few months they develop severe and progressive CNS dysfunction resulting in quadriparesis and mental deficiency. In a subset of children, neurological deterioration occurs over a period of months, followed by a relatively stable period, which then is followed by further deterioration. Cognitive and motor impairment can also be discordant. Some children develop progressive and disabling motor deficits yet maintain relatively stable (albeit impaired) cognitive function. In contrast, other children have more impaired cognitive function than motor function. Finally, some children have relatively minor and stable motor and cognitive deficiencies over a prolonged period of time (slow progrcssors). Clinical HPE syndrome is described according to the age of onset of the clinically apparent disease.

Neonates

HIV-infected newborns are usually well and have generally no recognizable neurological features of HIV-associated CNS disease at birth. Some HIV-infected neonates, however, have or will develop coexisting neurological problems in rhc neonatal period. The developing nervous system in HIV-infected infants, as in non-HIV-infected infants, may be adversely affected by maternal conditions during pregnancy (e.g., inadequate prenatal care and nutrition, AIDS-associated and non-AIDS-associatcd illnesses, premature delivery). Premature delivery is often interlinked with these high-risk conditions, and in turn, the prematurely born HIV-infected infant (as the uninfected prematurely born infant) is at risk for developing perinatal CNS complications.

Infants

The most severe and clearly recognized syndrome in HPE of childhood is rhc "severe infantile" form. Age of onset is usually in the first year of life but may begin in the second to third year. Neurological deterioration results in mental deficiency and spastic quadriparesis, usually by 2-3 years of age. Characteristic features include decline in intellectual and motor milestones, CST signs, and acquired microcephaly. The children look aloof and often have "masklike" facies. They appear alert and wide-eyed but have a paucity of spontaneous facial expression (manifestations of the basal ganglia and subcortical pathology). Pseudobulbar signs with feeding difficulties are frequent. Neuroimaging studies show progressive atrophy, white matter abnormalities, and frequently, calcification ol [he basal ganglia (Figure 59F.2). Magnetic resonance imaging (MRI) is more sensitive for demonstrating the white matter abnormalities, maturational changes of myelination, and structural abnormalities in the CNS. Computed tomography (CT) is more sensitive for demonstrating calcification. Both CT and MRI demonstrate cerebral atrophy. The end-stage picture is an apathetic, withdrawn, often irritable, quadriparetic child with markedly impaired higher cortical functions.

Young Children

A change of gait is often the first sign of HIV-associated CNS disease in toddlers. Children begin to toe walk. They develop hypcr-reflexia and increased tone in the lower extremities. The rate of progression varies. Progression may be rapid in some children who will become wheelchair bound within months; some will progress gradually to quadriparesis. Cognitive decline becomes evident over time. Although the child may gain additional skills, the rate of acquisition of these new skills deviates not onlv from the norm, but also from the child's previous rate of developmental progress. Poor brain growth is common. Some children maintain independent ambulation for years, although they have a spastic gait. Associated impairment of fine motor ability and dexterity is common. Cognitive deficits, although frequent, are not invariable. The degree of impairment ranges from low-average or "borderline" intelligence to mild mental retardation. A subset of children will have a prolonged stable course.

Older Children and Adolescents

Cognitive decline, impaited attention, decreased linguistic and scholastic performance, psychomotor slowing, emotional lability, and social withdrawal are common in older children with HPE, HPE in adolescents is reminiscent of HAD in adults. Hyperreflexia, clumsy and poor fine motor ability, and poor dexterity are noted initially. Progressive

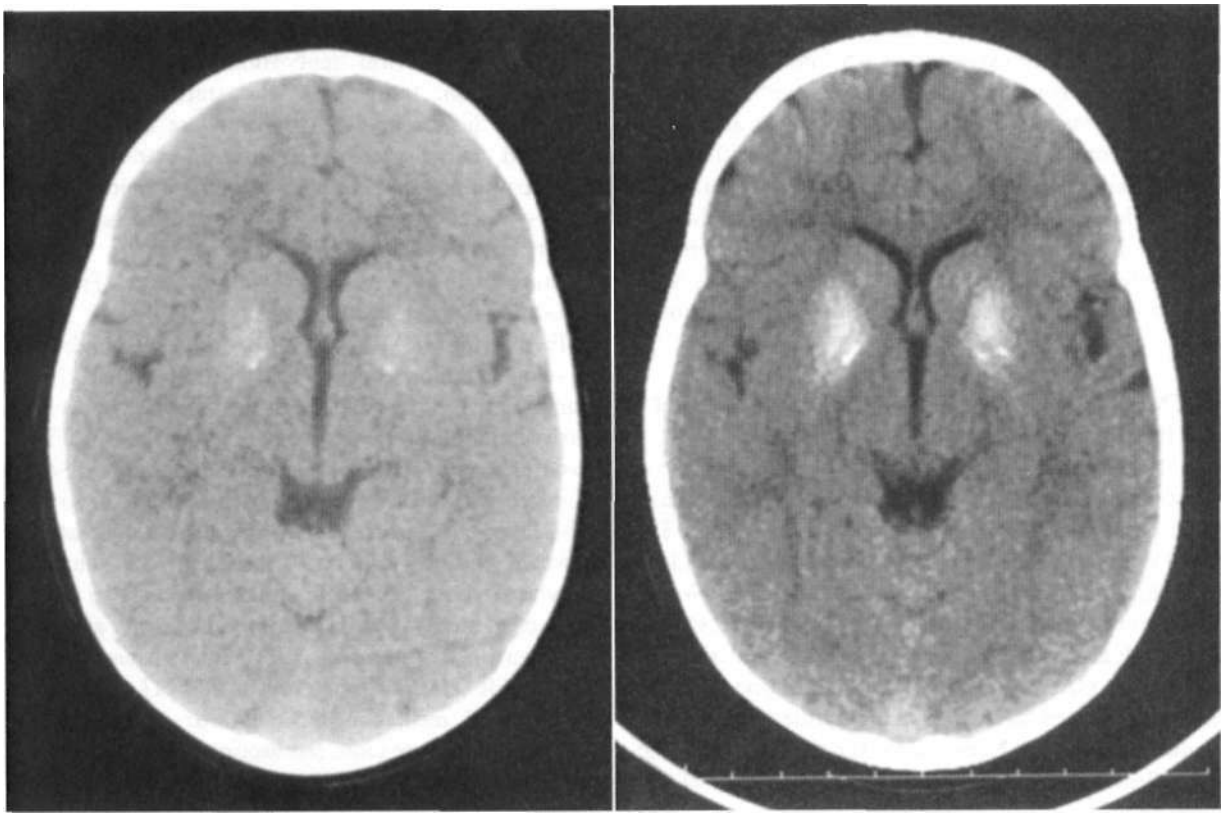

FIGURE 59F.2 (A,B) Serial studies show progressive calcification of the basal ganglia in a child with HIV infection. (From Devita, V. T., Jr., Hellman, S., & Rosenberg, S. A. (eds). 1997, *AIDS: Biology, Diagnosis, Treatment, and Prevention,* 4th ed, Lippincott-Raven, Philadelphia.)

long-tract signs, movement disorders, cerebellar signs, and myelopathy may develop as the disease advances, Progressive cerebral atrophy and white matter abnormalities are commonly seen on neuroimaging, and some children have basal ganglia calcification.

Cerebrospinal fluid (CSF) may be normal or may show mild pleocytosis with or without protein elevation. Presence of HIV antigens, intrathecal anti-HIV antibody production, oligoclonal bands, and cytokines in CSF are also reported. These data come ftom a small numbet of cross-sectional studies of small cohott size; thus, their prognostic significance is uncertain. As with adults, howevet, the data suggest that HIV CNS invasion occurs in the early stage of infection. CSF viral RNA levels have been studied in children and are reported to correlate with cognitive impairment. Electroencephalography shows diffuse mild to moderate slowing of the background rhythms.

STROKE IN HIY-INI ICIED CHILDREN

Acute strokes are the second most common cause of large lesions demonstrated by imaging studies in HIV-infected children (after primary and secondary CNS lymphoma). A 4-10% estimated incidence of stroke (hemorrhagic and ischemic) was reported from clinical series conducted during the early years of the AIDS epidemic, with an even higher rate noted at autopsy. A stroke incidence of 1% per yeat was estimated in children with AIDS. Clinical presentation includes the new onset of focal neurological deficits, most commonly hemiparesis, with or without seizures.

Intracerebral hemorrhage usually occurs in the setting of immune-mediated thrombocytopenia. Hemorrhage into a minor may also occur, as may subarachnoid hemorrhage associated with aneurysmal arteriopathy of major cerebral arteries. Clinical presentation is variable, reflecting the location and severity of the hemorrhage.

Nonbemnrrhagic infarctions are most often associated with pathological changes of cerebral blood vessels, meningeal infections, or cardiomyopathy. Cerebral vascular ectasia, aneurysmal arteriopathy of major cerebral arteries, and thrombosis of these arteries or of small cortical vessels are reported. Aneurysmal dilation of the branch vessels of the circle of Willis is increasingly recognized in HIV-infected children. It may be diffuse and fusiform or focal and saccular. The mechanism by which HIV causes CNS arterial damage is unclear. Possibilities include direct HIV endothelial invasion and exposure to toxic cytokines. Varicella zoster virus (VZV) infection can cause cerebral vasculitis and consequently an ischemic stroke. A fibrosing

inflammatory vasculopathy is also described and is thought to be related to the primary HIV CNS infection.

A subacute necrotizing encephalopathy with cystic encephalomalacia was reported in 8% of cases in an autopsy series. This entity appears to be associated with dilated cardiomyopathy and may be related to an acquired mitochondrial cytopathy or hypoxic-ischemic damage. Multiple ischemic infarcts may also result from leptomeningitis associated with infectious etiologies such as VZV, *Mycobacterium tuberculosis,* and *Treponema pallidum.*

TREATMENT AND PROGNOSIS FOR CHILDREN WITH HIV INFECTION

Treatment and prognosis of HIV-associated OIs, neoplasia, and neuromuscular disorders is described in Chapter 59E. Children with HPE generally harbor a high HIV RNA load, and the encephalopathy illness is related to the vircmia. Effective antiretroviral therapy and viral suppression is therefore a logical strategy in HPE. Recommendations for when to start HAART and which combination to use in infants and children have been made by the United States, the Pediatric European Network for the treatment of AIDS, and the British HIV Association. All children in clinical stage C should receive IIAART. Therapy may be considered in stage B if CD4+ T cell count is low or viral load is high. Treatment is deferred in stage A and N diseases. One circumstance in which it might theoretically be appropriate to treat an asymptomatic infant is where HIV infection is detected within a few weeks, akin to treatment of an adult in acute seroconversion. The HAART regimen for children is similar to that in adults and typically consists of either two nucleoside reverse transcriptase inhibitors (NRTIs) and one protease inhibitor (PI) or two NRTI and one nonnucleoside reverse transcriptase inhibitor (NNRI) (see Chapter 59E, Table 59E.3). Three NRTI can also be considered as a part of HAART if NNRTI or PI cannot be used because of drug intolerance or resistant viral strains. Ideally, drugs with high CNS penetrance should be included in HAART regimen for pediatric neuro-HIV disease (Chapter 59E, Table 59E.3).

To date, most published reports of HAART in children have demonstrated poor maintenance of viral load suppression, with up to half of the children showing viral rebound within a yeat of treatment (Spector et al. 2000; Krogstad ct al. 2002), This is most likely related to the difficulties with adherence to unpalatable liquid formulations, very high viral loads at the base line, and insufficient dosing regimens due to less known pharmacokinetics in infants and children. However, with increasing awareness of these problems, treatment of children is improving with active adherence support, therapeutic drug monitoring, and careful planning and education for families prior ro starting the therapy.

Survival on HAART depends on the fact that effective suppression of viral replication would allow immune reconstitution. Individuals who start treatment in later stages of infection, when the immune system is severely depleted, may have less effective immune reconstitution with continued susceptibility to OIs, despite elevation in CD4+ T cell counts. Children appear to have a greater ability to reconstitute the immune system than adults because of their persistent thymic function (Franco et al. 2000; Gibb et al. 2000).

In the pre-HAART era, up to 50% of children in the developed countries were surviving into later childhood, compared to most children in the African cohort dying in early childhood. Since the beginning of HAART in 1996, progressions to AIDS or death have become rare events in children with HIV in resource-rich settings (Figure 59F. 1). The long-term survival of the currently treated HIV-infected children cannot be predicted, but most should survive at least into their adult years. It also seems that long-term survival on HAART would come at some cost; children on long-term HAART regimen may have cumulative side effects from NRTI, NNRTI, PI, and other HIV-related medications. Long-term effects of HAART in children require close monitoring.

PREVENTION OF HTV INFECTION IN CHILDREN

Pediatric HIV infection is a preventable disease if pregnant women are able to receive interventions to stop transmission of the virus to their children. This, of course, depends on the availability of routine antenatal screening for HIV and availability of antiretroviral therapy. The landmark PACTG 076 study in 1994 demonstrated that use of ZDV monotherapy could reduce vertical HIV transmission by nearly 70%, and this rapidly became standard of care for pregnant women with HIV (Connor er al. 1994). It has since been further documented that the most important factor in terms of an individual woman's risk of transmission is her plasma viral load, hence the importance of the combination HAART (Garcia et al. 1999). In recent years, where women have delivered while on HAART with complete viral suppression, the HIV transmission has been very rare.

As most transmission of HIV occurs around the time of labor and delivery, avoidance of the labor, vaginal delivery, and birth canal exposure with planned prelabor caesarean section also reduces the risk of HIV transmission for woman at all levels of vircmia. Whether planned prelabor caesarean section can have an added effect where there is undetectable plasma viral level is not known. Finally, as the risk of transmission may be doubled for breastfeeding mothers, women should be advised to formula feed their seronegative infants.

Women who are found to be HIV-infected on screening in pregnancy and who commence HAART for their own

health will concomitantly greatly reduce the risk of infant infection. Women who do not yet require treatment for their own health may take a short course of therapy during the third trimester and intrapartum period, with their newborns receiving a postnatal short-term oral prophylaxis. No specific teratogenic effects of antenatal exposure to combination antiretrovira! therapy have been reported to date (Antiretroviral Pregnancy Registry 2000).

Chapter 59
Infections of the Nervous System

G. PRION DISEASES

Marcin Sadowski, Ashok Verma, and Thomas Wisniewski

in accordance with contemporary practice, prion diseases, also called the transmissible spongiform encephalopathies (TSE) or prionoses, are included for discussion with the infectious diseases of the nervous system. It is now clear that the cause of these slow infections is neither a virus nor any nucleic acid-containing particle. During the past 20 years, a comprehensive body of research led by Prusiner and colleagues has presented compelling evidence that the transmissible pathogen for these diseases is a proteinaceous infectious particle, which Prusiner termed *prion,* derived from "proteinaceous and infectious" (Prusiner 1982, 2001). The prion protein (PrP) is encoded by a gene (designated as *PRNP)* on the short arm of chromosome 20. The discovery of mutations in *PRNP* and its linkage to prion diseases in patients with familial Creutzfeldt-Jakob disease (fCJD) and the reports of accidental transmission of CJD (iatrogenic, iCJD) in humans attest to the fact that prion diseases can be genetic, infectious, or spontaneously acquired; in this respect prions are unique among all infectious agents.

The prion diseases affect both human and nonhuman mammalian species (Table 59G.1). All prion diseases result from a conformational alteration of the same host-derived, membrane protein PrP^{c} (C for cellular). The first recognized and documented prion disorder was scrapie affecting sheep flocks about 250 years ago. The word *scrapie* was used as a vivid descriptive term of ataxic sheep that scrape against fences to prevent falls. The first reports of prion diseases affecting humans came from Creutzfeldt in 1920 and Jakob in 192i (Jakob 1921), who independently reported cases of a progressive dementing neurological illness with prominent spongiform changes in the grey matter, although Creutzfeldt's original case does not correspond to what is currently classified as a CJD, In 1928 Gerstmann (Gerstmann ct al. 19.36) described purely familial disease with a clinical course dominated by slowly progressive ataxia, with minimal spongiform changes but extensive amyloid deposits. As the new cases were described and studied, the term Gerstmann-Straussler-.Scheinkcr syndrome (GSS) emerged and the syndrome was found to be caused by mutation in the *PRNP* gene. It has been recognized subsequently that fCJD related to different mutations of this same *PRNP* gene exists as well.

The infectious nature of the prion disorders was first recognized in 1936 by Cuille and Chcllc, who transmitted the disease by intraocular inoculation of scrapie-infected spinal cord (Cuille and Chellc 1939). First transmission of human prion disorder was demonstrated by the Gajdusek group, who transmitted kuru into chimpanzees (Gajdusek et al. 1966). Success of these experiments was followed by successful transmission of sporadic Creutzfeldt-Jakob disease (sCJD) from man to chimpanzee. It was recognized from the beginning that the prion diseases have a very long incubation followed by a relatively short symptomatic period preceding death. This long incubation time, extending up to 24 months for intracerebrally inoculated laboratory animals, explains why these illnesses are sometimes called slow infections. Prusiner demonstrated that the major component of the infectious agent is a protease-resistant 27 to 30 kDa prion protein, PrP^{c} (sc-scrapie, because prions were first isolated as a scrapie infectious agent). PrP^ is a conformcr of PrP with an identical

Table 59G.1: Prion diseases in humans and nonhuman mammalian species

Sporadic Resulting from spontaneous conversion of PrP^{c} to PrP^{SL}, or somatic mutation	Sporadic Crcutzfeldt-Jakob disease (sCJD) Sporadic fatal insomnia (sFI)	Scrapie of sheep and goats Chronic wasring disease (CWD) of mule and white-tailed deer and elk Transgenic mice expressing normal human $PrP^{1"}$
Genetic Dominantly inherited with almost 100% penetrance	Familial CJD (fCJD) Gerstmann-Strauss ler-Schc inker (GSS) syndrome Fatal familial insomnia (FFI)	Scrapie in sheep and goats spread vertically from ewes to lambs Transgenic mice expressing mutated human PrP
Transmissible	Kuru Iatrogenic CJD (iCJD) New variant CJD (nvCJD)	Scrapie among flocks of sheep in the field Bovine spongiform encephalopathy (RSF) Chronic wasting disease (CWD) of mule and white-tailed deer and elk Transmissible mink encephalopathy (TME) Feline spongiform encephalopathy Fxotic ungulate encephalopathy (nyala, oryx, kudu) TSF transmitted to laboratory animals: mice, sheep, goats, monkeys

amino-acid sequence but has an increased j9-sheet content. PrP has the ability to bind to PrP^{c} and induce its conformational change. Therefore PrP uses endogenously produced host PrP^{L} as a template for its own replication. The increase in /?-sheet content is associated with a dramatic change of physical-chemical properties of PrP^{c} resulting in increased proteinase resistance, decreased water •ioluHliu. and *::r.* MK iv.iscd tendency to polymerize, .ill of which ultimately leads co neuronal death.

Although PrP^ has an increased resistance to proteolytic digestion and denaturating agents, the infectivity of prion diseases remains very low. Human-to-human transmissions (iatrogenic or iCJD) have been described in a limited number of cases worldwide. So far these have been related to surgical operations using contaminated instruments, contaminated EEG electrodes, corneal transplantation, contaminated **dura** mater grafts and the use of contaminated cadaver-derived human growth and gonadottophic hormones (P. Brown et al. 2000). Although $PrP^{1"}$ is a phylogenetically conserved protein, slight variations in ammo-acid sequence exist between species. These differences arc responsible for the species barrier limiting spread of this disease from one species to another; however, such spread can occur. Accidental transmission of scrapie to cattle receiving feed containing ground bones contaminated with central nervous system (CNS) tissue from serapie-infected sheep resulted in an outbreak of bovine spongiform encephalopathy (BSE) in the United Kingdom. BSE, in turn, led to the emergence of new variant CJD (nvCJD) {Collinge and Rossor 1996). Although, no effective treatment for the prion disease yet exists, two major approaches are under development focused on vaccination against the prionoses and the development of agents able to inhibit or revert the conformational change from PrP^{c} to $PrP^{5""}$ (Brown 2002; Wisniewski and Sigurdsson 2002).

EPIDEMIOLOGY

The incidence of sporadic CJD is estimated as 1 per million in the general population. The risk of disease is age-related but does not indefinitely increase with age. In populations younger than 50 years the incidence is 1 per 10 million and after the age of 50 years it sharply rises, reaching a peak in the population between 65 and 74 years, with an average of about 5.7 per million. The incidence in the population older than 75 years slowly decreases to less than I per million in subjects older than *85* years.

fCJD is about nine rimes less common than sCJD. There are two ethnic groups, Slovaks from Orava and descendants of Sephardic Jews originally living in territory of current Libya (Gabizon et al, 1991; Hsiao et al. 1991), that have a significantly increased occurrence of *PRNP* mutations resulting in an incidence of CJD 60-100 times greater than in other populations. GSS remains an extremely rare disorder with a yearly incidence of 2-5 cases per 100 million. The most common mutation related to GSS is P102L. This mutation has been found in *M* kindreds living today in nine countries: Austria, United Kingdom, Canada, France, United States, Germany, Italy, Israel, and Japan. Fatal familial insomnia (FFI) has been described in two large kindreds and in several sporadic cases.

There is no significant sex difference among patients with CJD. Cumulative data gathered by the Centers for Disease Control and Prevention (CDC) indicated a slight preponderance for sCJD in women younger than 60 years and in men older than 60 years. An exception is kuru, in which mainly women and children were affected; this is related to this group eating body parts with a higher prion concentration such as the brain, whereas males ate more muscular portions.

To date about 250 cases of iCJD have been described, both among older and younger subjects. The biggest

clusters were related to the use of contaminated dural grafts in Germany (about 60 cases) and contaminated cadaver-dcHved human growth hormone therapy in France *(55* cases). Rare sporadic cases of kuru arc still described in New Guinea, and these are linked to its extremely long incubation time, which can extend to 40 years.

Since the original report in 1995 a total of 139 confirmed cases of nvCJD have been diagnosed, 128 in the Great Britain, six in France, and one each in Italy, Ireland, Hong Kong, Canada, and the United States. The patients from Canada, Ireland, Hong Kong, and the United States resided in the United Kingdom during a key exposure period of the UK population to the BSE agent. It has been difficult to predict the expected future numbers of nvC]D. Mathematical analysis has given a range from 5 thousand to about 136 thousand individuals who will eventually develop the disease. This broad range reflects a lack of knowledge regarding the time of incubation and the number of patients who could be infected from a given dosage of BSE agent. Because the nvCJD agent is present at high levels in the lymphatic tissue, screening for $Pr?^{Sl\eta}$ was performed on sections from lymph nodes, tonsils, and appendices archives in the United Kingdom. One out of 8300 randomly selected cases showed evidence of subclinical infection, leading to a prediction that the total 55 million population of the United Kingdom will ultimately have about 8000 nvCJD cases. However, because this predication is based only on one report, it should he viewed with caution. The initially predicted epidemic of nvCJD does not seem to be materializing, as the number of cases in the United Kingdom has declined from a peak of 28 in 2000 to 17 in 2002 (Tvler 2003). The estimated risk for new cases of nvCJD in other European countries looks more optimistic. In the United Kingdom, 200,000 cases of BSE were reported (it is estimated that four times this number entered the food chain), compared to about 500 BSE cases in other European countries. This suggests a significantly lower exposure of these populations to BSE prions. A few cases of BSE have also been reported in other parts of the world, such as japan and Canada.

PATHOGENESIS OF PRION DISEASES

Genetics

The gene *PRNP* coding for the prion protein has been mapped to the short arm of the human chromosome 20 (murine *PrP* gene is located on chromosome 2) (Spnrkcs etal. 1986; Westaway, Cooper etal. 1994). The whole gene is translated within a single-reading frame (Plate 59G.IA). Human *PRNP* shows limited nonpathogenic polymorphism of *PRNP,* which includes an octapeptide deletion from the repeat region, methionine/valine polymorphism at codon 129 and a glutamine/lysine polymorphism at codon 219 (Table 59G.2). The methionine/valine 129 polymorphism is of special importance because 129 homozygotes are more susceptible to prion infection than hetcrozygotes. The 129 codon M/M, V/V, and M/V allelic frequency in Caucasian populations is 37%, 12%, 51%, respectively (Collinge et al. 1991). The incidence of the M/M allele is significantly increased among patients who died from sCJD, being 72% (V/V—17%, M/V—12%) (Palmer etal. 1991; Parchi etal. 1996; Parchi, Giese et al. 1999). All genotyped patients who died with nvCJD so far were M/M homozygotes. Of subjects with iCJD related to hC.H, 50% were V/V homozygotes and 31% were homozygotes for M/M (Collinge et al. 1991).

Of interest ovine *PRNP* shows more extensive polymorphism than the human gene, having nine allelic variants. Of these, A/V136, R/H154, and QH/R171 arc linked to susceptibility to disease. Increased susceptibility is associated with the presence V136, R154, and Q171; VRQ/VRQ homozygotes being the most susceptible (Westaway, Zulani et al. 1994). In contrast, arginine in the position 171 seems to increase resistance to scrapie infection, and no disease has been detected in carriers of the ARR/ARR allele (Eaplanche et al. 1993; Belt et al. 1995; Clouscard et al. 1995; Bosscrs et al. 1996; Hunter et al. 1996).

Pathogenic *PRNP* mutations are autosomal dominant with near 100% penetration (sec Table 59G.2). Great variability in clinical phenotype, age of onset, and the length of disease course related to different mutations of this same gene is one of the most astonishing aspects of inherited prion disorder. The fCJD phenotype is linked to either octapeptide repeat insertions equal to or less than 168 base pair (Owen et al. 1989), or missense mutations located mainly in regions of a-helices B or C (Gabizon et al. 1991; Hsiao ct al. 1991). The GSS-phcnotype is associated with either longer octapeptide repeat insertions (192 or 216 bp) or missense mutations in the region preceding oc-helix A (Hsiao, Baker et al. 1989; Hsiao, Doh-ura et al. 1989). - Three other missense mutations, namely, at 145 codon resulting in a stop codon and truncation of the *PRNP* product (Dlouhy et al. 1992), F189S (Piccardo et al. 1996), and Q217R also result in a GSS phenotype. The rare FFI phenotype is a result of the coexistence of a D178N mutation and methionine at the polymorphic position 129 (Gambetti et al. 1992; Medori et al. 1992). Coexistence of the same D178N mutation and valine in position 129 produces a picture of fCJD (Goldfarb et al. 1992; Gambetti etal. 1995).

Biology of Prion Protein

PrP ' is expressed in many types of cells; however, the highest level of expression is found in the CNS neurons (Kretzsehmar ct al. 1986; jendroska ct al. 1991). The molecular anatomy of PrP is crucial for understanding its malfunction in prion diseases. The whole protein is located on the outer surface of the cell anchored to the cell

Table S9G.2: Genetic forms of prion diseases

Disease phenotype	*Mutations*	*Comments*
Nonpathogenic *PRNP* polymorphism	Octapcptidc deletion from the repeat region (— 8)	
	MTV 129	Increased susceptibility for nvCJD and iCJD in homozygotes
	E7K219	
Mutations producing fCJD phenotype	Octapcptidc repeat insertions of 168 or base pair (24, 48, 96, 120, 144, 168)	Protracted clinical course (4-13y)
	D178N (V129)	The same mutation associated with M at 129 produces FFI
	VI801	
	T183A	
	E200K	fCJD associated with peripheral neuropathy
	H20SK	50% penetrance
	V210I	50% penetrance
	M232R	
Mutations producing GSS phenotype	Octapeptide repeat insertions of 192 or 21 6 base pair	
	P102L	The most common ataxic form with NFTs

membrane by phosphatidylinositol glycolipid (GPI) attached to its C-terminus. The C-terminus contains two ot-helical domains B and C, which are interconnected by a disulfide bond between serines at residues 179 and 214. Two oligosaccharide chains attached to the ot-helical regions additionally stabilize the structure of the C-terminus. The C-terminus is the site of binding protein-X (see following), which plays a role in maintaining oc-helical structure and preventing transmissibility of the disease. The central portion of the peptide contains one short oc-helical segment (ct-hdix A) flanked by two short ^-strands. The N-tcrminns is unstructured and extends into the intracellular space. Positively charged arginine and lysine residue at the N-tcrminns give it a potential to interact with negatively charged moieties on the cellular surface or with sialic acid residues in the two asparagines—linked oligosaccharides. This allows for significant mobility and possibly for a certain degree of conformational plasticity. The N-terminus harbors five octapeptide repeats. 1 listidincs located within the octapeptides bind copper ions (Brown et al. 1997). It has been postulated teceiuly that the possible function of PrP^c is in capture, storage, and presentation of copper to the neuron (Brown et al. 1997; Qin et al. 2000, 2002). The exact function of PrP^c remains yet to be elucidated. The protein is not essential because *PRNP* knockout mice (Bueler et al. 1992) did not show a significant disease phenotype. Minor abnormalities in synaptic physiology (Collinge et al, 1994) and in circadian rhythm (Tobler et al. 1996) using more detailed methods have been described in these knockout mice.

The prion diseases belong to a broader category of conformational diseases. The etiology of each of the conformational IKIMM'S IS ivi.ued (o a specific protein thai can exist in at least two distinct forms associated with either health or disease. The most common conformational disorder is Alzheimer's disease (AD), in which the disease state is associated with the accumulation of an endogenously expressed peptide, the amyloid-/8 peptide, in a ,8-shcet structure within neuritic plaques. The pathological conformer of PrP ' is PrP* , which due to its increased ,8-shect content demonstrates increased resistance to proteolysis and the abilin to aggregate and polymerize isec Plate .590,1). Although the insolubility of PrP has prevented performing crystallographic conformational studies, less exact structural methods such as circular dichroism and Fourier transform infrared spectroscopy indicate a *0*-sheet content as high as 45% (compared with 3% in PrP) and oc-hclix content of 30% (40% in PrP^c) (Aucouturier et al. 1999). Understanding the mechanism that convetts PtP into PrP""- is another intriguing aspect of the prion disease. This conversion may happen spontaneously in sCJD, be induced by the introduction of exogenous PrP in

transmissible forms, or be induced by *PRNP* mutations (Gabizon et al. 1996). The spontaneous conversion of PrP^{1} into PrP^ has been demonstrated in sheep and probably is the major cause of scrapie and sCJD. A high rate of spontaneous conversion has been also shown in transgenic mice ove rex pressing human $PrP^{(}$ on a murine PrP knockout background (Westaway, DeArmond et al. 1994). It has been postulated that the PrP molecule exists in two forms, PrP*' and PrP^, able to change conformation between these two by spontaneously unfolding and refolding. Neuronal PrP has a half-life of approximately 3 hours. The mechanisms that maintain the PrP molecules in $PrP^{1,}$ state have not been fully elucidated. Protein X has been hypothesized to exist, having the role of binding to PrP and increasing the energy threshold needed for the conformational shift to PrP^{s}\ It has been also demonstrated thai binding copper to tile \-termmus significantly change-; tin: seeondan structure of PrP^{c}, increasing its /S-sheet content and resistance to proteinase K (Qin et al. 2000). Furthermore, a copper imbalance has been implicated in early stages of the disease.

One of the most crucial features of PrP^{v} allowing for the mmsmissibility of prion diseases is the ability of PrP^{c} to bind to PrP , initiating a self-perpetuating vicious cycle (Prusincr et al. 1998). It has been demonstrated in cellular models that the PrP is transported to the membrane in $PrP^{1'}$ form and that the conversion of PrP^{c} to PrP^ occurs at the cell surface. Neurons produce native PrP (Krctzschmar et al. 1986) and transport it to the cellular surface where it can encounter PrP^{s}\ leading to its conformational change into a high fi-shcer content state. During progression of the disease, the amount of PrP produced remains stable, whereas the amount of $PrP^{K,:}$ increases. Homozygosity of PrP^{c} facilitates prion replication. This has been observed in humans with respect to the codon 129 polymorphism, as well as in sheep with respect to the VRQ/VRQ polymorphisms. Evidence from transgenic animals expressing various segments of PrP indicates that residues 90-150 are required for the interaction with PrP^{s}^ leading to conversion of $PrP^{(}$ into PrP^{Sc}.

Mechanisms of prion-related toxicity require both the conversion of PrP to PrP^{St} and the subsequent accumulation of proteinase resistant, /J-sheet rich $PrP^{Si:}$ (jendroska et al. 1991; Kret/schmar et al. 1997). Animals infected with prion strains demonstrated that accumulation of PrP^ preceded dendritic and synaptic degeneration, which was followed by gliosis and neuronal dropout (Plate 59G.II) (Jeffrey et al. 2000). Two cellular compartments—cell membranes and the endosomal/lysosomal system—show the highest concentration of PrP , and dysfunction of these two compartments is thought to be two separate phenomena responsible for breaking down neuronal homeostasis and subsequent degeneration. The highest cellular concentration of PrP^{St} was demonstrated in caveole-likc domains (CLD) associated with the plasma membrane, which are involved in metabolism of glycolipid-anchorcd proteins. The most commonly accepted scenario assumes that initial accumulation of $PrP^{Si:}$ in the membrane results in early alteration of membrane properties required for synaptic transmission, signal transduction and generation of second messenger, maintenance of ion and water balance, and the responsiveness of neurons to trophic factors necessary for neuronal viability. 1 he appearance ol so-called spongiform changes (see following) is a result of swelling of dendritic processes mainly in the vicinities of synaptic contacts. Accumulation of PrP^{Sc} in the endosomal/lysosomal system follows its accumulation on the cell surface and leads to dysfunction of the cell disposal system. Although PrP is present in many cell lines, symptoms of the disease derive mainly from neuronal degeneration. This probably occurs because of the significantly higher expression of PrP in neurons compared with glial or endothelial cells and the greater sensitivity of neurons to membrane perturbations.

Another aspect of prion-related pathology is amyloidosis characteristic for some but not all prion diseases (see Plates 59G.ID, 59G.III, and 59G.IVB) (Ghetti, Piccardo, Frangione et al. 1996). PrP^{St} purified from diseased brains using proteinase K, which cuts off the N-terminus leaving 143 amino-acid fragment called PrP 27-30 (Ocseh ct al. 1985) and treated with detergents, readily polymerizes in vitro into amyloid. The mechanisms of prion-reiated amyloidosis in vivo and reasons for its occurrence only in certain clinical variants are elusive. sCJD amyloid deposits are only demonstrated in 10% of cases, whereas florid amyloidosis is a hallmark of nvCJD. It has been postulated that this feature is determined at lea si partially by host responses because neither scrapie in sheep nor BSE in cattle is associated with amyloid, whereas significant amyloidosis is found in transgenic mice infected with scrapie or BSE that express either human $PrP^{<}$ alone or a chimeric combination oi human and murine $PrP^{c'}$. The heavy amyloid deposits in GSS consist of truncated 8-11 kDa peptides (Tagliavini ct al. 1991) containing the central portion of the peptide. Recently, a distinct mechanism of amyloidosis has been demonstrated for some, but not all, GSS-related *PRNP* mutations (see Plate 59G.IVB). These mutations result in a specific form oi PrP where the N-terminus is located intracellularly, and the C-tcrminus remains outside the cell, anchored by GPL The central transmembrane PrP^{c} domain is designated ^{Ltm}PrP '. It is postulated that peptidases cut both sides of the transmembrane section of $^{ctl,1}PrP^{c}$, and the remaining short central segment of the PrP protein is endocytosed and then secreted to the extracellular space, where its aggregation and polymerization into amyloid occurs.

Infectivity, Species Barrier, and the Immune System

Despite commonly expressed concerns, the infcctivity of the TSE is relatively low even within the same species. Transmission between species is much less efficient due to species harrier, which is in part explained by differences

in the amino acid sequence of PrP . The gene sequence is highly conserved among mammals with only 28 differing amino acids between human and mouse and two between human and chimpanzee. The exogenous Prl'V has to he similar enough to the host PrP ' to bind and use it as a template for further replication. Moreover, numerous lines of evidence suggest that the propagation of PrP^{L} also involves interactions with prion-associated proteins, such as protein X, which differ among species (Telling et al. 1995). Mice are susceptible to hamster and sheep PrP strains but not to human PrP^. CJD can be transmitted only to the transgenic mouse expressing human PrP (Telling et al. 1994), Transmission of all human forms of prionoses including GSS and FFI (Tateishi et al. 1995) to these transgenic mice strains has been documented (Masters et al. 1981).

Although the existence ot scrapie :us Ixvi documented in Great Britain since the early eighteenth century, no nans-mission to humans has been demonstrated. However, the species barrier between sheep and cows is more limited, resulting in the epidemics of the BSE, also called mad cow disease, once these animals received feed enriched with sera pie-contaminated sheep bone meal. Transmissibiliry of scrapie to cows has been confirmed by transfusion of sheep blood into cattle. The spatial and temporal relationship between the outbreak of BSE and nvCJD, as well as the biochemical and neuropathological similarities between these strains when they are transmitted to transgenic mice expressing bovine PrP' in the absence of mouse PrP, indicates that the species barrier between humans and nonhumans has also been breached.

There is an increasing incidence of the chronic wasting disease (CWD) of mule and white-tailed deer and elks in the Midwestern and Rocky Mountain states. Occurrence of the CJD among three young deer hunters from this same region raised the speculation of transmission of the CWD into humans {Belay er al. 2001). Like BSE, CWD is transmissible to the transgenic mouse expressing human PrP^{c} (Raymond et al. 2000). However, autopsy of these three subjects did not show the extensive amyloidosis characteristic of the nvCJD and CWD (Liherski et al. 2001).

The pathophysiology of prion disease also depends on the distinct isolates or strains of prion. The strains are defined by the production of distinct patterns of incubation time, distribution of CNS lesions, and resistance to proteolytic digestion. PrP^{L} from different strains have variable proportions of monoglyeosylated, diglycosylated, and nonglycosylated PrP^{1m} and a variable length of $PrP^{c,}$ residues following proteinase K digestion. Although, a given strain may show different behavior when first trans-mitted into mice compared to the original species, once a pattern is established the strain can be stably passaged among inbreed mice of the same genotype (Baron 2002). At least 14 different sheep scrapie strains and two human strains PrP-19 and PrP-21 (Parchi et al. 1996) (19 and 21 kDa-main nonglycosylated peptide cleaved either at residue 97 or 82 of PrP ', respectively) have been isolated and passaged into mice. However, the possible number of human strains is higher (Parchi ct al. 1996; Aucouturicr et al. 1999). Because all strains originating from one species have the same amino-acid sequence, according to the Prusmcr protein only theory, it has been hypothesized that PrP^{bc} is able to adopt multiple, distinct pathological con-formations that result in the existence of multiple strains {Telling et al. 1996; Scott et al. 1999).

ReeenlH . recognition *n*\ the role oi tile immune system in the pathomechanism of prion diseases has been steadily growing. This is particularly important for BSE, nvCJD, and iCJD. PrP molecules introduced to the bloodstream or to the alimentary tract ultimately uudctgo endocyrosis by dendritic cells. The proteinase resistance of PrP^{Sc} renders it impossible for the dendritic cells to digest it. Furthermore, PrP^{L} is able to replicate inside dendritic cells. Lymphatic organs like spleen, tonsil, lymph nodes, or lymphatic tissue in the digestive tract mucosa contain high concentration of PrP^{Sc} long before PrP^{Sc} starts replicating in the brain (K. I.. Brown et al. 2000; Hcggebo et al. 2002). Dendritic cells from infected animals are capable to spread the disease (Aucouturier et al. 2001). Splenectomy in infected animals, probably by decreasing the PrP burden, has been shown to increase the incubation period (Fraser and DiDario 1978). The presence of high levels of $PrP^{"c}$ in the lymphatic tissue, such as the tonsil and Peyer's patches, is typical for nvCJD, iCJD, BSE, and CWD, but not for other forms of the disease such as sCJD.

How the prions reach the CNS remains an unanswered question. In light of the important tolc of the lymphatic system, especially dendritic cells, spread from the blood has been considered as the most likely route of CNS invasion. The supportive role of B lymphocytes in hematogenic ncuroinvasion has also been suggested (Klein et al. 1997). An alternative and not mutually exclusive hypothesis suggests that ption invasion of the CNS occurs via the peripheral nervous system (PNS). This has been proposed based on serial observations of intraperitoneal!}' infected animals, the $PrP^{1"}$ entering via the vagus nerve (Beekes et al. 1998) and then spinal cord, brainstem, and eventually the brain. The highest accumu-lations of spongiform changes in BSF cattle and scrapie sheep have been found in the brainstem, including the cuneate nucleus and the dorsal nucleus of the vagal nerve. Following intraperitoneal delivery of prions, disease can be delayed by sympathectomy or accelerated by sympa-thetic hyperinnervation of lymphoreticular organs (Glatzel et al. 2001).

Neuropathology

The gross examination of the brain in prion disease is variable and not specific. The spectrum extends from a lack of recognizable abnormalities to marked atrophy of

cortex, basal ganglia, and/or the cerebellum. The term *transmissible spongiform encephalopathy* (TSE) was coined to emphasize the most characteristic aspect of the microscopic picture of these diseases: vacuolar changes observed in the grey matter neuropil and sometimes within neurons, Intrancuronal vacuoles are typical for **kuru and** sheep scrapie and are also sometimes seen in CJD (Beck et al. 1964), The vacuolar changes seen in the neuropil, are round or oval, arc 5 to 25 urn in diameter, and represent cross sections of swollen dendritic and axonal processes. Most of the vacuoles appear to he in the region of synaptic elements. There is significant degeneration and loss of both axons and synapses (Jeffrey et al. 2000}. Occasionally neuropil vacuoles ma\ he as hig .is 100 jmi in diameta and be surrounded by a meshwork of reactive astrocytes. This picture bears the name of the status spongiosis (Masters and Richardson 1978). In the end stage of certain forms of prion diseases vacuolar changes may disappear from the neuropil, following very extensive neuronal loss. Other typical features of the microscopic picture of prionoses are neuronal loss and astrocytosis (see Plate 59G.I1IB and C) (Dormont et al. 1981). Little inflammatory response or activation of microglia cells is observed. Spongiform degeneration, neuronal loss, and astrocytosis are typical features for all variants of prion diseases. These changes in some types of prion disease may be associated with amyloid deposition (sec Plate 59G.M1B). Differences between particular subtypes include relative intensity of these lesions, their anatomical distribution, presence and type of amyloid deposits, as well as the occasional presence of neurofibrillary tangles (NFTs). A summary of pathological variations found in specific forms of human prionoses is provided in Table 59G.3.

Sporadic, Iatrogenic, and familial Creutzfeldt-Jakob Disease

The histopathological picture of sporadic, iatrogenic, and familial CJD is similar. The spongiform encephalopathy is found mainly in the cerebral cortex, putamen, caudate nucleus, thalamus, and the molecular layer of the cerebellar cortex. Unlike the putamen and caudate, the globus pallidus is usually spared. The brainstem and the spinal cord are affected to a lesser degree. Severe involvement is often found in the suhiculum, hut interestingly the cornu ammonis and the dentate gyrus arc usually spared. Vacuoles can be diffusely distributed throughout the whole thickness of the cortical neuropil or have pseudolaminar distribution, especially in deeper layers. There are variants of sCJD described with more focal intensity of pathology. These are the *Heidenhain variant* with involvement of the visual cortex out of proportion to rest of the brain, the *Broumell-Oppenheimer variant* characterized by predominantly cerebellar involvement, and the *Stern-Garcin variant* demonstrating prominent involvement of the basal ganglia and thalamus. Only 5-10% of CJD cases of sporadic or inherited forms demonstrate cortical amyloid plaques in the cerebrum or cerebellum (Snow et al. 1989, 1990). They are either kuru type or primitive amyloid deposits (see below) (Klatzo et al. 1959; Pearlman et al. 1988). Prion pathology affects mainly the grey matter, however in rare sCJD cases vacuolar myelopathy has been observed. These vacuoles are present wirhin the myelin sheath and are occasionally intra-axonal.

Nv Creutzfeldt-Jakob Disease

The highest intensity of spongiform degeneration and neuronal loss is found in the basal ganglia and thalamus followed by the cerebral and cerebellar cortices. Of interest in BSE and sheep scrapie cerebral cortex, basal ganglia, and thalamus are relatively spared and the highest density of lesions is found in the brainstem, cerebellum, and hypothalamus. Also neuronal vacuoles are much more frequent in scrapie and BSE than in nvCJD.

The most characteristic ncuropathological feature of nvCJD are numerous amyloid plaques consisting of protcinase-resistant prion protein (Collee and Bradley 1997; Will et al. 1997). The amount of these deposits is higher than in other forms of CJD and can be compared only with GSS. Two types of plaques in nvCJD can be distinguished: primitive plaques, which can be stained with specific anti-PrP antibodies but do not show properties of amyloid, and mature amyloid plaques. The latter in addition to reacting with anti-PrP antibodies show the classical properties of all amyloid, such as positive staining with thioflavin, and an appie-green birefringence under polarized light when stained with Congo red. These physical properties reflect a high /J-sheet content. Some of the plaques are found in the center of a vacuole and beat the name of florid plaques. Another charactcrisin. feature is clustering oi primitive and classical plaques. Plaques are distributed throughout the whole cerebral cortex, usually with a predilection for the occipital lobes and the cerebellum. Unlike nvCJD, neither cattle with BSE nor sheep with scrapie develop plaques. Transgenic mice expressing bovine PrP on a murine *PRhiP* knockout background also do not develop plaques when infected with scrapie, but they do when inoculated with BSE or nvCJD. This indicates that each specific histopathological picture results from a combination of the strain of the agent and the host background.

Fatal Familial Insomnia and Sporadic Fatal Insomnia

Fatal familial insomnia (FEI) is a result of a D178N missense mutation in the *PRNP* gene in association with a methionine at position 129 (D178N M129). Interestingly, the same missense mutation, D178N, when associated with a valine at position 129, produces a picture of fCJD. In FFI there is severe neuronal loss and atrophy of the antcroventral and mediodorsal thalamic nuclei not associated

Table 59G.3: Comparison of the most characteristic clinical and pathological features of human prion diseases

Characteristic	*sCJD*	*twCJD*	*fCJD*	*iCJD*	*FFI/SFI*
Average age at onset (yr)	67	28	Variable among kindreds 23-55	All ages	50
Average duration of disease (mo)	7	14	Variable among kindreds 8-96	12	18
Most prominent early signs	Cognitive dysfunction	Psychiatric abnormalities, sensory symptoms	Cognitive dysfunction	Cognitive dysfunction	Insomnia, autonomi instability
Cerebellar dysfunction (%)	40	100	40	40	No
PSW on EEG	Yes in 79%	No	Yes	Yes	No
Amyloidosis	Sparse plaques in 10%	Severe in all cases	Sporadically seen	Sporadically seen	No
Presence of $PrP^{\sim c}$ in the lymphoreticular system	No	Yes	No	Yes	No

CJD = Creutzfeldt-Jakob disease; EEG = electroencephalogram; FFI = familial fatal insomnia; SF1 = sporadic fatal insomnia mo = months; N/A = not available; PSW = positive sharp waves; yr = years,

with spongiosis, along with mild to moderate spongiosis of the cerebral cortex. The neuropathologies! features of sporadic fatal insomnia (SFI) are indistinguishable from FFI (Parchi, Capcllari et al. 1999). Inoculation of transgenic mice expressing human PrP^{c} with brain extracts from either FFI or SFI patients gave the same pathological picture (Mastrianni et al. 1999).

Gerstmann-Straussler-Scbeinker Syndrome

Severe amyloidosis is a hallmark of GSS (Piccardo et al. 1995). Three types of plaques are found: multicentric amyloid plaques (i.e., consist of a large central deposit surrounded by smaller satellite amyloid plaques) (see Plate 59G.IVB), primitive plaques, and kuru-type plaques. GSS plaques are composed of a highly truncated form of the PrP peptide (8-1 lkD) (Ghetti, Piccardo, Frangione et al. 1996). Plaques an abundant in the cerebellar cortex and are also present in the cerebral cortex and in the basal ganglia. Unlike the amyloidosis, spongiform degeneration in many GSS kindreds may be minimal. Some GSS pedigrees show additional histo pathological features. Those with the most common P102L mutation demonstrate severe white matter degeneration resembling that of Friedreich's ataxia. Neuronal loss is scattered throughout brain and cerebellum. In GSS A117V there is severe neuronal loss in the putamen, globus pallidus, and thalamus and somewhat less in the substantia nigra. These lesions in the basal ganglia correlate with parkinsonian symptoms observed frequently in probands expressing this mutation. The F198S mutation is associated with abundant neutofibrillary pathology including intraneuronal tangles composed of paired helical filaments and neuntic plaques (Ghetti et al. 1995; Ghetti, Piccardo, Farlow et al. 1996). As in AD, they show immunoreactivity for abnormally phosphorylated lai: rvn;.: r (Ghetti et al. 1994). Neuronal loss is prominent in the cerebral and cerebellar cortex, substantia nigra, red nucleus, inferior olivary nucleus, and the dentate nucleus. NFTs are also a feature associated with P105L, Q217R, and Y145Stop mutations (Hsiao et al. 1992; Ghetti et al. 1994, 1995). The Y145Stop mutation is unique in that PrP^{St} deposits are present in the vessel wall producing a picture of cerebral amyloid angiopathy (CAA) (Ghetti, Piccardo, Spillantini et al. 1996).

Kuril

In kuru the highest neuronal dropout affects the cerebellum, followed by the medial temporal lobe, basal ganglia, and the medial and anterior nuclei of the thalamus, Isocortical areas show usually mild to moderate spongiform degeneration in the neuropil. Amyloid deposits classical kuru plaques—are found in 75% of cases (Klatzo et al. 1965). These are on average 15—20 pm in diameter and consist of spherical deposits with radiating spicules at their periphery—sometimes called spiked ball plaques. The greatest number of plaques is usually found in the cerebellar granule cell layer.

PrP-relatcd abnormalities might not only be confined to the CNS. The prion protein has been identified in the common age-related myopathy and in inclusion body myositis (Askanas et al. 1998). Overex press ion of PrP in transgenic mice causes age-related necrotizing myopathy (Westaway, DeArmond et al. 1994). Myopathy may also be associated with scrapie in sheep and CWD in mule deer and elk.

CLINICAL FLATURFS

Sporadic Crcutzfeldt-Jakob Disease

The classic sCJD patient is between 50 and 75 yeats with a mean age of 67 years (see Table 59G.3). Subjects as young as 17 years and as old as 83 years have been reported. The disease is characterized by a rapid development of Kyuipioitis and progression to dearh. The clinical course averages 7 months but may vary from 2 months to 2 years. In 15% of cases a subacute course over several days or in rare cases even acute presentations have been described. There is, however, a subgroup of patients (less than 10%) with pathologically confirmed disease, who lived more than 2 years from initial presentation. In rare cases patients in whom the diagnosis was confirmed by the transmission of disease to primates have survived as long as 15 years.

Three stages can be distinguished in typical cases. The first stage is characterised by discrete neurological and psychiatric symptoms. Retrospective questioning can reveal prodromal symptoms weeks to months prior to diagnosis in some patients. These can include asthenia, altered sleep pattern, decreased or increased appetite, and loss of libido. Difficulties with memory, concentration, and problem solving are the usually first symptoms that bring the patient to medical attention. Fpisodes of disorientation also have been described. A variety of personality and behavioral changes are often present in the initial phase of CJD, and these may include apathy, self-neglect, irresponsibility, emotional liability, and inappropriate behavior. The second stage evolves over a period of weeks to months and is characterised by a rapid deterioration of the global cognitive deficit, which in 29% is associated with significant behavioral disturbances. Frank psychiatric symptoms such as hallucinations, paranoia, psychosis, uncontrolled outburst of aggression, or conversely depression also may be present. These symptoms are typically associated with the presence of myoclonus. Cerebellar dysfunction in CJD is present at this stage in one third of cases and develops in roughly 70% of cases during the course of the disease. These symptoms include truncal and limb ataxia, dysarthria, and nystagmus. Prominent visual and/or oculomotor complains are present in 19%,

and these include blurred or distorted vision, altered color perception, held defects, visual agnosia, diplopia, and supranuclear patsies. The second stage of the disease usually has a rapid course; however, either periods of stabilization of symptoms or a slowing of the progression after an acute onset have been reported. In the final stage the cognitive, cerebellar, and visual symptoms progress, resulting in severe dementia. Most patients become bedridden. Myoclonus, choreiform, and/or athetotic movements are ultimately observed in 90% of cases. Other infrequent symptoms include seizure, vestibular dysfunction, lower motor neuron, or pseudobulbar symptoms. The final stage is characterized by akinetic mutism followed by death frequently preceded by a period of autonomic dysfunction. The clinical picture of sCJD is influenced by the anion 12^{L}) genotype and its classification based on the Western blot appearance of the PrP^{L} after PK digestion. In type 1 CJD the molecular mass of the unglycosylated $PrP^{Sl_{m}}$ band is approximately 21 kDa, whereas in type 2 CJD it is approximately 19 kDa. Individuals with an M/M genotype at codon 129 are more likely to show a type 1 Western blot appearance and have a classical clinical presentation as described earlier. Patients with an M/V or V/V genotype are more likely to shovv a type 2 Western blot appearance, which is associated with a younger age at onset and ataxia as a more prominent clinical feature.

The differential diagnosis may be challenging due to variation in the initial presentation; however, as the disease evolves the diagnosis typically becomes obvious. A good history taken from family members and documenting the rate of progression is extremely important. There is no noninvasive biomarker that would definitively diagnose CJD (Plate 59G.V). Abnormalities are observed in several clinical tests (see following), but none of these shows specificity or sensitivity allowing them to be used in isolation. The diagnosis is made by a sum of clinical symptoms, course of the disease, abnormalities on adjunctive tests, and ruling out other dementing illnesses. The diagnosis is confirmed by a brain biopsy.

The speed of progression of the memory disorder m CJD typically allows differentiation from AD. The frontotemporal dementia (FTD) spectrum, including corticobasalganglionic degeneration and dementia lacking distinctive hismpathological features, especially presenting in lobar form associated with occipital predominance, and dementia with Lewy bodies may be more problematic in early stages. Thyroid studies, antithyroid antibodies, syphilis serology, and cyanocobalamin/methylmaloiuc levels should be checked to rule out treatable causes of dementing illnesses. In the differential diagnosis of rapidly progressive neurological disorders, the paraneoplastic syndromes, especially those producing limbic encephalitis, cerebellar syndrome, or myoclonus, have to be taken into account. In such instances evaluation for the presence in the serum of anti-Yo and anti-flu antibodies should be performed. Antithyroid antibodies should be checked when Hashimoto thyroiditis with dementia is suspected (Scipelt ct al. 1999). A spinal tap especially combined with magnetic resonance imaging (MRI) using gadolinium as intravenous contrast is helpful in ruling out brain lymphoma, neoplastic or infectious meningitis, as well as encephalitis, especially caused by herpes simplex,

Iatrogenic Crcutzfeldt-Jakob Disease

Because sCJD before age 50 is extremely rare, the occurrence of this disease in *55* patients between ages 10 and 41 years who received human growth hormone (hGH) strongly suggested an iatrogenic etiology. All the patients received two to three injections per week of cadaver-derived hGH over many years. Similarly, the occurrence of CJD in two young patients with intractable epilepsy, in whom intracerebral electrodes were surgically implanted, suggested an iatrogenic etiology. One case occurred after repair of a perforated eardrum with pericardial graft. Five cases were reported among women receiving human pituitary gonadotropin. Three cases were related to corneal transplantation. The incubation time can vary depending on the route of infection: corneal transplant, '16-20 months; deep brain electrodes, 1 6-20 months; neurosurgical procedure, 15-28 months; dura marer graft, 1.5-16 years; intravenous gonadotropin preparation, 12-16 years; and intravenous growth hormone preparation, 5-30 years. Eighty-one percent of iCJD cases were homozygotes at codon 129. The course of the disease ranged from fi to 18 months. The clinical presentation can be dominated by a primary dementia, cerebellar symptoms, or visual symptoms; however, the course ultimately leads to dementia and death. The differential diagnosis remains the same as for sCJD.

Familial Creutzfeldt-Jakob Disease

I'RNP mutations linked to fCJD are inherited in an autosomal dominant fashion but they do not always show 100% penetrance. The rate of penetrance depends on the mutation and increases with age. The most frequent mutations at codons 208 and 210 have only 50% penetrance. Kindred with the E200K missense mutation have a 1% penetrance at age 40 years, which increases up to almost 100% by the age of 80 years. The onset of disease in fCJD is usually earlier and the course longer than in sCJD. These also greatly depend on the specific mutation. The E200K kindred has an onset at 55 ±8 years, with an average course of 8 months, whereas kindred D178N, V129 has an onset at 46±7 years of age with death occurring in an average of 22 months. Kindreds with octapeptide insertion present at the age 23-25 years and have a protracted course of 4—13 years.

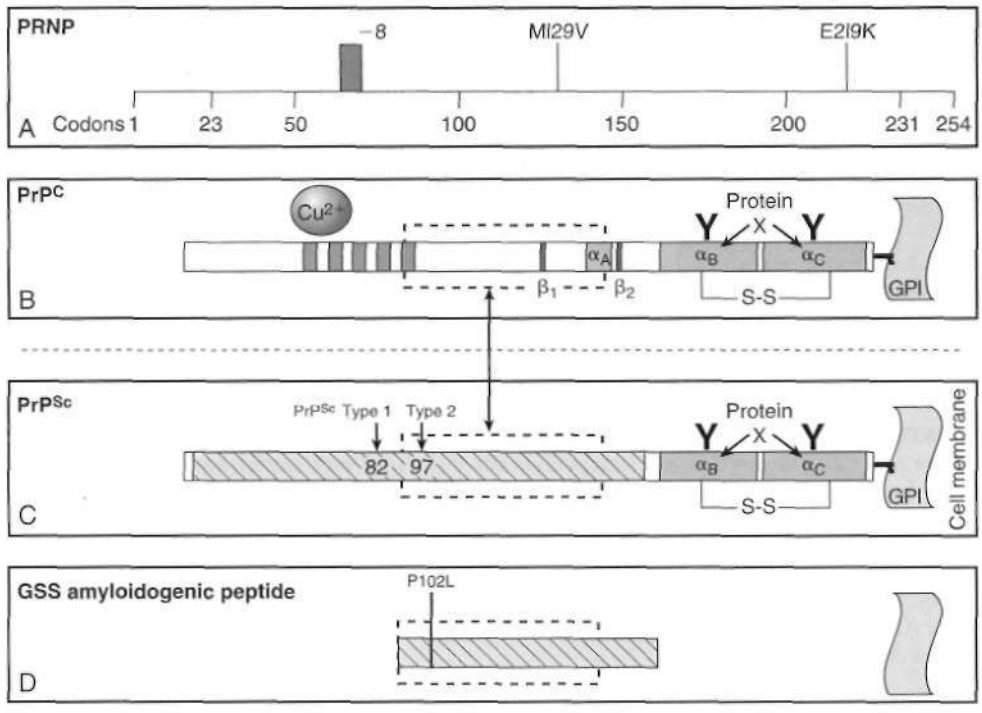

PLATE 59G.1 The Prion protein. (**A**) The prion protein gene *(PRNP)* is located on the short arm of the human chromosome 20. The nonpathogenic polymorphism includes deletion of one of octarepeat segments, methionine/valine polymorphism at the position 129, and glutamine/lysine polymorphism at the position 219. (**B**) Posttranslational modification truncates the cellular prion protein (PrP^C) at positions 23 and 231 and glycosylates (*Y*) at positions 181 and 197. The phosphatidylinositol glycolipid (*GPI*) attached to serine at the position 231 anchors the C-terminus to the cellular membrane. The intracellular N-terminus contains five octarepeat segments P(Q/H)GGG(G/-)WGQ (*blue blocks*) that can bind copper ions. The central part of the protein contains one short ∝-helical segment (∝-helix A encompassing residues 144-157 [*green block*]), flanked by two short β-strands (*red block*): β_1(129-131) and β_2(161-163). The secondary structure of the C-terminus is dominated by two long ∝-helical domains: ∝-helix B (residues 172-193) and ∝-helix C (residues 200-227), which are connected by a disulfide bond. The blue arrows indicate binding sites of the protein X within ∝-helices B and C. The purple, dotted frame marks a segment between positions 90–150 which is crucial for the binding of PrP^C to PrP^{Sc}. (**C**) PrP^{Sc} has increased β-sheet content (*red dashed block*). (**D**) Unlike PrP^{Sc}, which is anchored to the membrane, Gerstmann-Straussler-Scheinker (*GSS*) amyloidogenic peptides are truncated and excreted into the cellular space where they aggregate and fibrilize into GSS amyloid deposits. This example is an 8 kDa PrP fragment associated with the most common GSS/P102L mutation. A synthetic form of this peptide (90–150 residues), exposed to acetonitrile treatment to increase β-sheet content, is the only synthetically generated peptide, which when injected intracerebrally into P102L transgenic mice is able to induce the GSS disease.

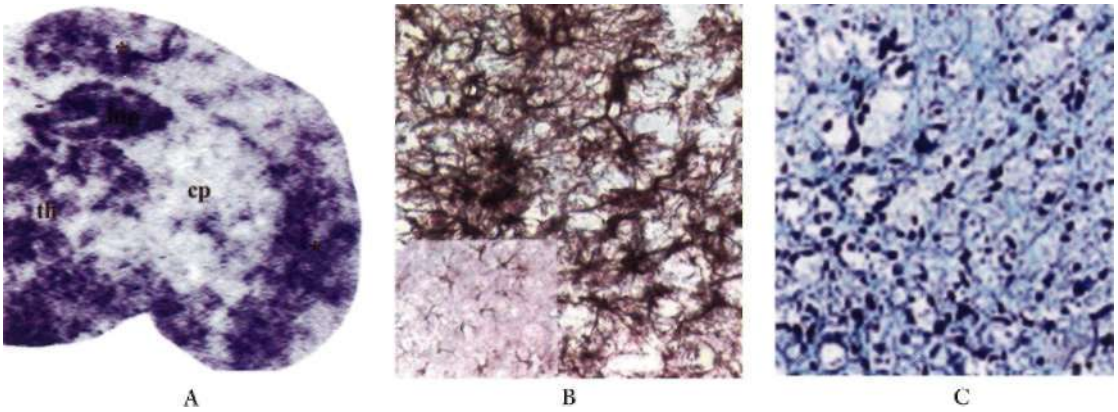

PLATE S9G.II Brain pathology associated with prion diseases. (A) Distribution of PrP^{St} in the brain of a CD-I mouse that was intraperitoneal!)' inoculated with murine-adapted scrapie strain and developed symptoms of disease f 50 days later. The picture shows an imprint of histological section on a nitrocellulose membrane that was treated with proteinase K and immunostamed with anti-PrP antibodies. The highest concentration of PrP^{St} is in the hippocampus (hip), followed by the cortex (*) and the thalamus (th). (B) Marked astrogliosis is associated with prion infection of CNS. Insert shows a control brain. Section was immunostained against glial-fibrillary acidic protein (GFAP). (C) Cresyl violet stained sections demonstrate advanced spongiform state and neuronal dropout.

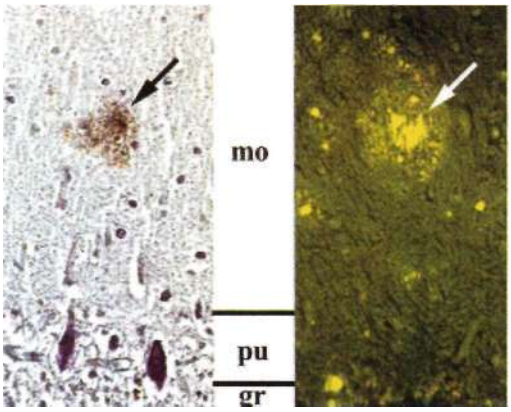

PLATE .S9G.III Amyloidosis associated with GSS. Two section through the cerebellum demonstrating amyloid deposits in the molecular layer (mo). (A) Imrminostaming with anti-PrP antibodies shows a plaque *(black arrow).* (B) Staining with Thioflavin-S, which selectively binds to pS-plcated sheet of PrP^{Sc} and can be detected on fluorescence microscopy *(white arrow).* gr = granular layer; mo = molecular layer; pu = Purkinje cell layer).

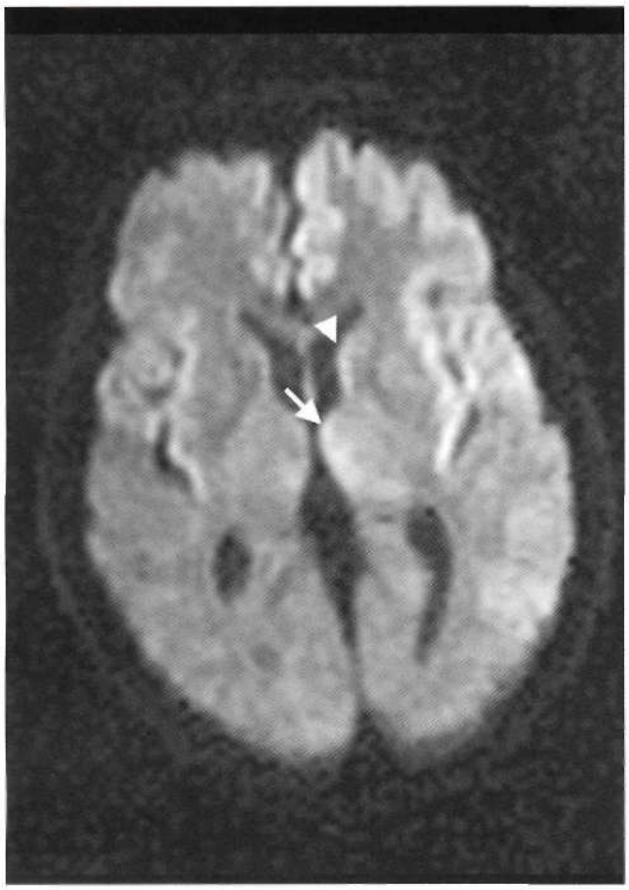
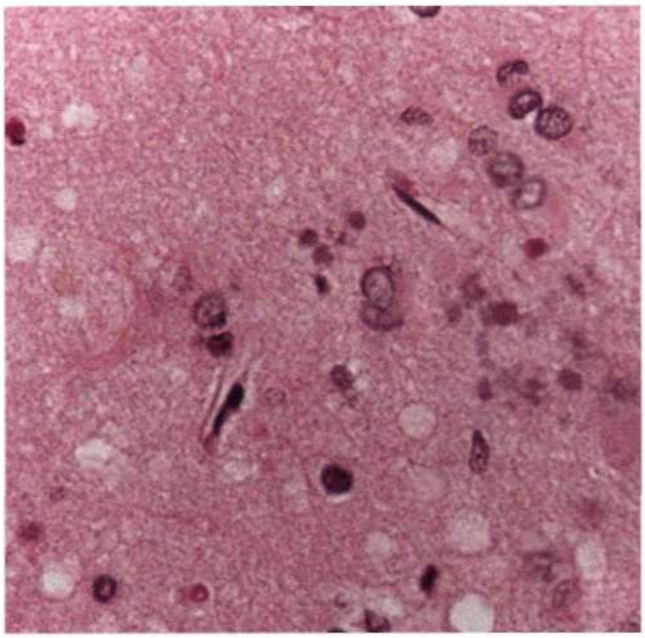
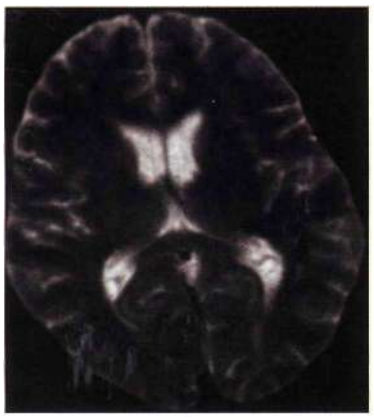
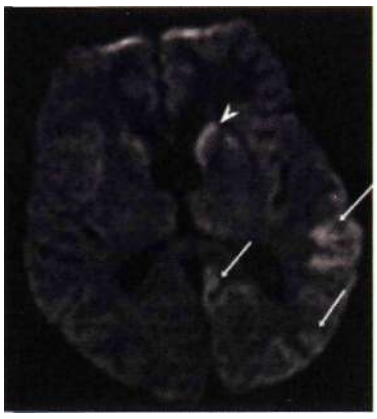


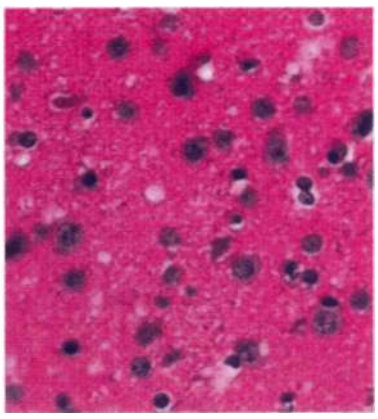


B

PLATE 59G.IV Gerstmann-Straussler-Scheinker syndrome. Axial diffusion weighted imaging showing abnormal signal intensity in cerebral cortex ribbon sign, head of caudate nucleus (*arrowhead*) and thalamus (*arrow*) (A), and multicentric plaques and spongiform changes in brain biopsy (B). (Courtesy Dr. P. Gambetti.)







A B C

PLATE 59G.V A case of sporadic CJD showing normal post-gadolinium Tf- and T2-weighted MR images (A) and mildly increased signal in die cortex *(arrows)* and basal ganglia *(arrowhead)* on diffusion-weighted images (DWI, B). The diagnosis was confirmed by a brain biopsy, which demonstrated spongiform changes, neuronal loss and gliosis (C).

Once a patient is evaluated in the light of an identified familial mutation, the diagnosis is not problematic, unless there is a suggestion of another inflammatory or malignant process. The differential diagnosis for unrecognized families must include familial forms of AD (especially related to presenilin mutations) or FTD. Of interest is the fact that fCJD associated with the E200K mutation has, in addition to a classical rapidly ptogressive dementia, features of a peripheral neuropathy.

Gerstmann-Straussler-Scbeinker Syndrome

This inherited form of ptionoses demonstrates a broad spectrum of clinical symptoms related to diffcrcnr mutation subtypes (Ghetti et al. 1995). Symptoms become apparent usually in the third or fourth decade. The clinical course is the slowest among human TSE and may progress over several years (3-8 year range with an average of 5 years). The largest number of cases has the P102L mutation. This mutation was causative in the original family described by Gerstmann in 1929. The clinical picture is dominated by cerebellar ataxia and dysarthria followed by dementia in the advanced disease stage. Unlike ataxia in P102L mutation, beatcts of A117V mutation ptescut with dementia, associated with dysarthria, rigidity, tremor, and hyper-reflexia. Parkinsonian features including masked face, tremor, and rigidity may be also present. Probands with F198S mutation initially present wirh short-term memory loss and clumsiness, which further progresses to global dementia and ataxia, associated with parkinsonism (Ghetti et al. 1994). The Yl45Stop mutation has the longest clinical course. A Japanese patient, cartying this mutation, presented initially with short-memory disturbance and disorientation at the age of 38 years (Ghetti, Piccardo, Spillantini et al. 1996). Ovet 21 years symptoms progressed toward global dementia. She was initially wrongly diagnosed with AD. Other features associated with GSS include gaze palsies, deafness, cortical blindness, extensor plantar response, or loss of deep tendon reflexes in lower extremities. Unlike CJD, myoclonus is relatively infrequent. The disease, especially in the early stage, may be confused with spinocerebellar ataxias, olivopontocerebellar atrophy, early onset Parkinson's disease, or dystonia. Because many of these conditions can also be inherited, the definitive diagnosis of GSS requires analysis for mutations in the *PKNP* gene.

Fatal Familial Insomnia and Sporadic Familial Insomnia

FFI was first described by Medori and colleagues in 1992 (Manetto et al. 1992; Medori, Montagna et al. *1992;* Medori, Tnschler et al. 1992). The age of onset is between 35 and 61 years and the course ranges from 6 months to 3 years. It is distinct from other prionoses by a progressive intractable insomnia and symptoms of sympathetic system hyperactivity such as hypertension, tachycatdia, hypetthermia, and hyperhidrosis. These may be accompanied by tremor, ataxia, hyper-reflexia, and myoclonus. Mild cognitive symptoms, rather than frank progressive dementia are present. They include decreased attention span and memoty deficit. Disorientation, confusion, or complex hallucinations may also be present. There are endocrine abnormalities consisting of loss of circadian rhythm for the secretion of melatonin, prolactin, and growth hormone. Decrease in adrenocorticotropic hormone secretion and increase in Cortisol secretion were noted. Clinical and pathological data on FFI is derived from two kindteds. Recently sporadic cases fitting this phenotype have been reported (Parchi, Capellari et al. 1999). Clinical features of SFI are indistinguishable from those of FFI; however, no *PRNP* mutation has been found in affected individuals.

Insomnia associated with autonomic instability presents a anique picture. The differential diagnosis is limited, but includes multiple system atrophy with Shy-Draget syndrome or hypothalamic lesions.

Kuru

Kuru is the Fore language word, which connotes trembling associated with feat or cold and describes the major clinical sign of the disease. Once a common cause of death among the Fore women, kuru is being viewed from the historical perspective since etadication of cannibalistic tituals eliminated this disease. Rare cases are still occurring and can be attributed to an incubation period that extends up to 40 years. Clinical symptoms of kutu differ from othei human prionoses. Its course is dominated by ptogressive cerebellar ataxia. Three clinical phases of this disease have been described: (1) an initial phase when affected individuals are able to ambulate with minimal to moderate ataxia. The ataxia is mainly truncal associated with dysarthria and Tremor. (2) A sedentary phase where ambulation become impossible due to progression of ataxia and associated choreoathetosis. There is worsening of tremor and mood instability. (3) A terminal phase characterized by general hyper-reflexia and progression of dysarthria and dysphagia. Muscle strength and the sensorium are usually preserved. Usually the downhill course of the disease takes 12 months from presentation to death. The disease affected mainly women and children, who consumed preferentially the brains of deceased tribal members during cannibalistic rituals.

DIAGNOSTIC **TESTS**

Unfortunately there is currently no single test that with high specificity and sensitivity can diagnose human prion disease, other than brain biopsy. The clinical diagnosis is made based on clinical course, ruling out other

diseases, and the combined results of diagnostic tests. Brain biopsy histology combined with Western blot analysis of proteinase K (PK)-treated brain homogenate still is the diagnostic gold standard.

Cerebrospinal Fluid Evaluation Including Assays of 14-3-3 and Tau Proteins

In the majority of cases routine examination of cerebrospinal fluid (CSF) including measuring opening pressure, glucose, protein, and cell count is normal. In a small fraction of patients, elevated protein and elevated rg/protein ratio, sometimes with oligoclonal hands, have been reported. Performing a spinal tap, however, helps to rule out other causes of dcrncntia. It is recommended to measure the levels of 14-3-3 and tau proteins in the CSF while evaluating for CJD (Green 2002a, 2002b; Van Everbrocek et al. 2002). The 14-3-3 protein is ubiquitously present in the cytoplasm of central nervous system neurons and is thought to play a chaperoning function in a number of phospborylation-dcpcndent intracellular signal transduction pathways. The sensitivity and specificity of the 14-3-3 protein assay has been reported to be up to 94% and 93%, respectively, in patients with sCJD. The assay was found to be less sensitive in nvCJD with a sensitivity of 77% (Green et al. 2002). The 14-3-3 protein is also elevated in most familial forms of CJD but not in FFI and rarely in GSS. The 14-3-3 protein may be elevated after acute stroke, exacerbation of multiple sclerosis, and encephalitis (Zerr and Poser 2002). Some false positive results of the 14-3-3 test can be related to blood contamination of CSF because some anti-14-3-3 protein antibodies can cross react with the light chain of immunoglobulins. Positive assays have also been sporadically reported (in less than 10% of cases) in end stages of slowly progressing dementing illnesses such as AD, FTD, or AIDS dementia. Therefore, the 14-3-3 protein assay is useful for the work-up of rapidly progressive dementias and this clinical setting has been recommended by both the World Health Organization and the American Academy of Neurology (Knopman et al. 2001), but the results need to be closely correlated with the clinical setting. Similarly, the tau protein level is elevated in the CJD. Its elevation may precede elevation of 14-3-3 (Olio ct al, 2002). Unfortunately, testing tor tin: ran protein has similar limitations as testing for 14-3-3. Its level is transiently elevated after acute stroke (Bitsch et al. 2002) and permanently in AD and FTD. Otto and colleagues (Otto et al. 2002) reported that using a cutoff value of 1300 pg/ml, of tau in the CSF allows for a diagnostic sensitivity of 94% and a specificity of 90% because tau protein elevations in FTD and in most AD cases arc below this limit. The level of tau, like the 14-3-3 protein, increases iliirmti the course of the discs;c; hence, repeated testing can lie useful in iiutully negative cases (Brandel el al. 2001; Otto et al. 2002).

Electroencephalogram

Electroencephalogram (KEG) is the oldest clinical test demonstrating some specificity for CJD. Classical recordings demonstrate theta and delta waves with occasional burst-suppression in the background, in association with rhythmical, paroxysmal sharp waves (PSW). They are present in up to 79% of sporadic CJD cases but not in nvCJD. A similar EEG pattern may be associated with lithium toxicity or other toxic encephalopathies; however, PSWs in these conditions typically do not show rhythmic - ity. Rhythmic PSW are also seen in the subacute sclerosing panencephalitis, but with much longer interbursr intervals.

Neuroimaging

There is a growing interest in using MRI to detect CJD. Besides evident atrophy and ventricular enlargement, increased signal on proton density, T2-weigh ted and fluid attenuated inversion recovery images (FLAIR) has been reported in moderately advanced patients in the brain cortex, thalamus, caudate, and putamen nuclei, but not in the globus pallidus (sec distribution of pathology) (Demaerel et al. 1999; Collie et al. 2001; Mirtal et al. 2002). Changes arc frequently asymmetric, and their intensity increases along the course of the disease on serial scans. It has been demonstrated that increased T2 and FLAIR signal may be preceded by increased intensity on diffusion-weighted images (DWI) with colocalizing dropout on the apparent diffusion coefficient (ADC) map (see Plates 59G.TVA and 59G.VA and B) (Murata et al. 2002). The characteristic cortical ribbon sign on DWI (see Plate 59G.IVA} and signal dropout on ADC that extends beyond the two-week period allows its distinction from acute stroke. Bilateral signal increase in the thalami, especially in their posterior parts (the pulvinar complex), is statistically more frequently found in nvCJD (Collie et al. 2001). This so-called pulvinar sign has been described in up to 60% of nvCJD patients. In contrast, abnormalities in the caudate/ putamen are more frequent in sCJD (Murata et al. 2002). The term *hockey stick sign* refers to an axial section through the head of the caudate nucleus and the putamen where increased signal in a distribution resembling a field hockey stick (the putamen) and a ball (the head of the caudate nucleus). Increased signal correlates with accumulation of $PrP^{Sl\text{''}}$ protein in the tissue (Maik et al. 2002). Unlike the grey matter, the white matter usually demonstrates normal signal, which helps to differentiate from vasculitis, encephalitis, lymphoma, demyelinating disease, parasite, or fungal infections. Lesions associated with CJD do not enhance after intravenous administration of gadolinium. Functional imaging has limited utility in TSE. Single-photon emission spectroscopy CT and positron emission tomography (PET) studies have demonstrated a nonspecific pattern of regional hypomerabolism.

Brain, Tonsillar, and Olfactory Mucosal Biopsy

In unresolved cases where the sum of clinical observations and diagnostic test results is inconclusive, a brain biopsy is needed for definitive diagnosis (sec Plate 59G.V}. The area of greatest EEC or MR1 abnormalities can guide the site of the biopsy. The finding of spongiform change is indicative of prion infection. If amyloid plaques are found, they should be confirmed to consist of PrP by immunostaining. A lack of amyloid plaques speaks against but does not rule out the nvCJD. Amyloid deposits are found only in approximately 10% of sCJD patients. In all cases it is advisable to confirm the diagnosis by Western blot analysis of fresh tissue to establish the presence of PK-resistant prion protein. The sensitivity of brain biopsy, comparing to postmortem diagnosis, and perioperative morbidity greatly varies even between academic centers. In a National Institutes of Health series, 52 out of 55 (95%) autopsy-verified cases biopsies were diagnostic for CJD. A report of positive immunostaining for PrP^{c} in the cytoplasm and dendrites of olfactory receptor neurons in postmortem specimens of olfactory mucosa in sCJD (Zanusso et al. 2003), if confirmed, may provide extra-cerebral tissue for definitive diagnosis. If nvCJD is suspected, a tonsillar, lymph node, or rectal mucosa biopsy can be performed, rather than a brain biopsy. The yield and sensitivity is close to 100% in nvCJD patients. However, the level of PrP^ is too low for detection in sCJD; hence, a lymphoid tissue biopsy is only useful for the diagnosis of nvCJD and not sCJD.

I'RI VI NTION

Prevention of prion diseases starred with breeding sheep about 1000 years ago by Moorish Berbers to maintain healthy flocks. By the 1950s extinction of cannibalism among New Guinea Fore people eradicated kuru, Recognition of the routes of prion transmission in iCJD decreased the potential for new cases. These included introducrion of recombinant growth hormone in place of cadaver-derived hypophyseal homogenatc, use of disposable I'IXT electrodes and neurosurgical instruments used to biopsy suspected CJD cases, and the use only of synthetic dura or lyophilized human dura after a special decontamination process. The epidemic of BSE and nvCJD in the United Kingdom resulted in the slaughtering of 4.5 million asymptomatic cattle. No cattle older than 30 months are allowed to enter the food chain in the United Kingdom, and in other European countries they are tested for PK-resistant PrP^{L} prior to slaughtering. In 1996 in the United Kingdom mammalian meat and bone meal residue produced by rendering was prohibited from all animal feed and from fertilizers. To prevent spreading of BSE to humans, the British government introduced in 1989 a ban on specified bovine offal for human consumption, and in 1992 use of head meat collected after the skull was opened was banned. In 1996 production of mechanically recovered meat from the spine (homogenizarion of bones with remnants of meat) w;v; prohibited. In the United States the Eood and Drug Administration restricted bovine source materials for pharmaceutical, dietary supplements, and cosmetic products to BSE-free countries. Because blood can be a potential source of prion infection, currently in the United States all subjects who resided in Great Britain for more than 6 months between 19S0 and 1996 are deferred as blood donors. In the United Kingdom Ieukodepletion of the whole blood is mandated. Restrictions concerning donations of dura, corneas, hematopoietic stem cells, bone marrow, liver, and kidney are debated in the United Kingdom.

Although infectivity of TSE is low, prions are unaffected by routine antiseptic practice. Therefore special measures should be taken when handling infected matetial. All instruments used for spinal tap, brain biopsy, or processing of the histological specimen should be disposable, or if not possible these instruments should undergo prolonged steam autoclaving for 1 hour at 132"C (Budka ct al. 1995; Ironside and Bell 1996). Unautoclavablc instruments can be decontaminated by immersion for 1 hour in 1 M sodium hydroxide (NaOH) or undiluted bleach. All contaminated surfaces should be cleaned with 1 M NaOH or undiluted bleach and during specimen shipment special precautions should be maintained. Brain tissue is the most contagious specimen even after fixation in formalin. Eor complete disinfection, it should be immersed in 100% formic acid for 1 hour (Brown et al. 1990). Direct contact with the patient's skin or mucosa and exposure to body fluids other than blood do not pose any additional risk of infection.

There is no epidemiological evidence that medical personnel are at incfeased risk of developing CJD as the result of direct patient care, performing an invasive procedure, including brain biopsy, or handling a patient's tissue obtained during biopsy or autopsy. On the contrary, the incidence of CJD among health care personnel including neurosurgeons and pathology technicians remains the same as in the general population (Brown et al. 1992). There is one reported case of CJD in a spouse (Brown et al. 1998), and the incidence of CJD among other family members and friends remains similar to that in the general population. Therefore there is no justified reason to keep patients in contact isolation.

In the United States and in Europe, surveillance of patients with CJD is performed. Therefore reporting the diagnosis to these surveillance organizations may be necessary. In particular, any suspected case of nvCJD should be reported. The incubation period of prionoscs is very long. During this clinically silent period, material from the patient, such as blood, is potentially infectious; therefore whether the patient donated blood or other body tissues in the past should be appropriately investigated.

TREATMENT APPROACHES

Currently there is no treatment that would arrest and/or reverse progression of the disease. All forms of prion diseases are ultimately fatal. Patients and their caregivers may, however, benefit from symptomatic treatment. Agitation and outbursts of violence may require antipsychotic agents, especially atypical antipsychotics with a lower incidence of extrapyramidal side effects, and benzodiazepines. Benzodiazepines and other antiepileptic agents can be used for the treatment of seizures and myoclonus. Parkinsonian symptoms can be alleviated by [.-dopa preparations and D_z receptor agonists. Prolonged survival of patients with GSS when treated with antiparkinsonian medications has been demonstrated. This seems to be related to increasing mobility and reducing risk of fatal comorbidities, rather than slowing down the course of the disease. Amantadine has been used with limited efficacy for symptomatic treatment of ataxia associated with spinocerebellar degeneration and CJD with prominent cerebellar syndrome.

The quest for treatment specifically arresting and reversing symptoms of the prion diseases is underway. Several compounds have been proven to be effective at delaying development of prion diseases when given to sera pie-infected hamsters. These included Congo red (Caspi et al. 1998; Demaimay et al. 1998), anthracyclines (Tagliavini et al. 1997), amphotericin B (Adjou et al. 1996, 1999), and sulfated polyanions (Earquhar et al. 1999). Unfortunately, these agents are toxic or have unfavorable pharmacokinetic properties when used in humans. Derivatives of acridinc (Quinacrine) and phenothiazine ((hlorpromazine), commonly used in humans as antimalarial and antipsychotic agents, have been shown in tissue culture to inhibit the conversion of PrP^c into PrP^{Sc} (Korth et al. 2001). Unfortunately, recent reports of anecdotal use of these agents in a limited number of sCJD and nvCJD patients are not encouraging.

Treatment approaches aimed to arrest or reverse the detrimental secondary structure of proteins are under investigation for many conformational disorders including prionoses and AD (Sigurdsson et al. 2000). The sequence between amino acid residues 90 and 150 is critical for PrP^{Sc} binding to PrP^c and the conformational shift. Synthetic peptides corresponding to PrP^c residues 109-141 can reproduce some of PrP^{Sc} properties in vitro, including high jS-sheet content and aggregation to form amyloid-like fibrils (Dc Gioia et al. 1994; Zhang et al. 1995). Short-peptide homologues to PrP^c have been designed to interact with PrP^{Sc} and act as /3-sheet breakers (Wisniewski et al. 1998, 2001). They have been tested and shown to inhibit the murine $PrP^{5'}$ conversion (Soto et al. 2000), demonstrating their therapeutic potential in prion diseases.

Another approach, which may be beneficial for prion diseases, is immunological. Splenectomy has been shown to prolong the period of TSE incubation. Recently some reports have shown that immunization with nontoxic recombinant PrP or amyloid-^ homologous peptides is beneficial for prion diseases and AD animal models, respectively (Sigurdsson et al. 2001). Vaccination of mice with recombinant PrP delayed the onset of disease (Sigurdsson et al. 2002). The delay was longer when mice were vaccinated before exposure, and it correlated with the antibody titer. Similar beneficial effect was reproduced after passive immunization. Reduction in PrP^{St} level without affecting PrP^c level with immunization has been reported in a sera pie-infected mouse model. It is speculated that antibodies binding to PrP^c interfere with the PrP^{St}-mediated conversion of PrP^c into PrP^{Sc} and thereby delay the onset of disease. Epitope mapping of the anti-PrP antibodies produced by immunization is under way to establish which portion of PrP^{St} is essential for prion replications. The ultimate goal of these vaccination studies is either to develop a vaccine or a compound, using peptidomimetic technology, which would interact with PrP^{Sc} molecule to prevent its multiplication. It is hoped that some of these strategies will produce a successful therapeutic approach.

Chapter 60
Multiple Sclerosis and Other Inflammatory Demyelinating Diseases of the Central Nervous System

Michael J. Olek and David M. Dawson

Diseases affecting central nervous system (CNS) myelin can be classified on the basis of whether a primary biochemical abnormality of myelin exists (dysmyelinating) or whether some other process damages the myelin or oligodendroglial cell (demyelinating), Demyelinating diseases in which normal myelin is disrupted include autoimmune, infectious, toxic and metabolic, and vascular processes (Table 60,1). Dysmyelinating diseases in which a primary abnormality of the formation of myelin exists include several hereditary-disorders (see Table 60.1; Chapter 68). Infectious demyelinating disease (progressive multifocal leukoencephalopathy) is discussed in Chapter 59B, toxic and metabolic demyelinating diseases in Chapter 62, and vascular demyelinating disease (Binswanger's disease) in Chapter 57, The present chapter concentrates on multiple sclerosis and "tiicr mllanimalon demyelinating diseases ol myelin (acute disseminated encephalomyelitis [ADEMJ and acute hemotrhagic leukoencephalopathy), as well as other CNS diseases that are presumably immune-mediated (see Table 60.1). The paraneoplastic disorders are discussed in Chapter 58.

Multiple sclerosis (MS) is the most common disease caused by an inflammatory demyelinating process in the CNS, MS is a leading cause of disability in young adults. In the United States the total lifetime cost per patient, including services, alterations to home and vehicle, medications, purchase of special equipment, and loss of earnings, was $2.5 million in 1994 dollars. In 2002 average annual insurance expenditures for MS patients were 1.9 to 3.2 times higher than the average for three different third-party payers, and 1% of the MS patients accounted for 20% of the total costs.

Pathologically, MS is characterized by multifocal areas of demyelination with relative preservation of axons, loss

Tabic 60.1: Diseases of myelin

Autoimmune
Acute disseminated encephalomyelitis
Acute hemorrhagic leukoencephalopathy
Multiple sclerosis
Infectious
Progressive multifocal leukoencephalopathy
Toxic/metabolic
Carbon monoxide
Vitamin B,; deficiency
Mercury intoxication (Minamata disease)
Alcohol/rob a ceo amblyopia
Central pontine myclinolysis
Marchiafava-Bignami syndrome
1 lypi ixiii
Radiation
Vascular
Binswangcr's disease
Hereditary disorders of myelin metabolism
AdrL'iiDk-iikiidj'si'i'iiphy
Metachromatic leukodystrophy
Krabhc's disease
Alexander's disease
Canavan-van Bogaert-Bertrand disease
Pelizaeus-Merzbacher disease
Phenylketonuria
Multiple sclerosis

of oligodendrocytes, and astroglial scarring. Certain clinical features are typical of MS, but the disease has a highly variable pace and many atypical forms. Investigative studies are often needed to confirm the diagnosis and exclude other possibilities. Advances in disease monitoring and treatment hold promise of slowing the progression of disability. Our understanding of the basic nature of the disease remains limited, and true control of the disease and repair of damaged myelin remain as goals for the future.

PATHOPHYSIOLOGY

The symptoms and signs of MS must be the manifestations of the pathological lesions seen in the CNS, namely demyelination with, in general, axonal preservation. However, detailed pathological and magnetic resonance (MR) spectroscopy studies indicate axonal loss of a moderate degree can occur in MS plaques (Trapp et al. 1998). A comparison of the physiological properties of normally myelinated axons and of dcmyclinated axons provides insight into the basis for the symptoms and signs characteristic of MS,

Compacted myelin is the lipid-rich plasma membrane of oligodendrocytes that provides insulation tor electric impulses traveling along axons. Myelinated axons propagate nerve impulses rapidly in a saltatory fashion with a high safety factor for transmission (five to seven times above threshold) (Waxman and Ritchie 1993). Current is induced by the opening of voltage-gated $Na^{\wedge}$ channels found at the nodes of Ranvier. The resultant Na^{+} influx creates a current that then moves toward the *next* node of Ranvier, as current cannot flow outward in myelinated internodal segments (Figure 60.1). K^{l} channel opening terminates current flow and leads to repolarization. Several types of K^{ch} channels exist in the axon. Fast $K^{:}$ channels sensitive to 4-aminopyridine arc located in internodal axonal membrane and contribute to repolarization of demyel mated axons. Slow K channels .-re found a: the nodes of Ranvier and have a role in modulating repetitive firing. The Na^{+}, K^{+}-adenosinetriphosphatase (ATPase) in the axon membrane restores ionic balance following high-frequency firing.

Demyelination interrupts current flow by removing the insulator of internodal axon current flow. For short segments (one or two internodes) demyelination is not critical because of a high safety factor for transmission. However, longer segments of demyelination can result in interruption of current flow, because current must flow by continuous propagation. The low density of internodal Na^{+} channels, at least in the early stages of demyelination, inhibits impulse propagation. If conduction does occur, it is at a much-reduced speed (5-10% of normal). The refractory period of dcmyclinated axons is prolonged, and repetitive volleys may be blocked when encountering an axon segment in a refractory period. Persistent neurological deficits or negative symptoms of MS are caused by regions in which conduction block persists, such as in regions of large plaques, whereas transient worsening of function teflccts a drop below the safety threshold for conduction because of physiological changes involving the partially dcmyclinated axon (Uhthoffs phenomenon, worsening with increased body temperature).

Mechanical stimulation of demyeliuated axons can generate *de novo* action potentials in the axon and may explain Lhermitte's phenomenon, electric shocklike sensations on flexing the neck. Spontaneous action potentials have been recorded from dcmyclinated axons and, if present in the CNS, could explain paroxysmal positive-symptoms of MS such as trigeminal neuralgia, myokymia, and visual phosphencs.

In addition to structural changes, one must consider functional impairment of nerve transmission caused by edema or factors liberated by immunocompetent cells (cytokines, adhesion molecules) in the plaque and peri-plaque regions that may be toxic to cells or axons. Rapid recovery of function may be caused by resolution of edema, pH changes, and reduction of cellular infiltrates, whereas more delayed recovery may reflect use of alternate axonal pathways or an increase of internodal Na^{+} channels.

PATHOLOGY

The pathological hallmark of MS is the cerebral or spinal plaque, which consists of a discrete region of demyelination

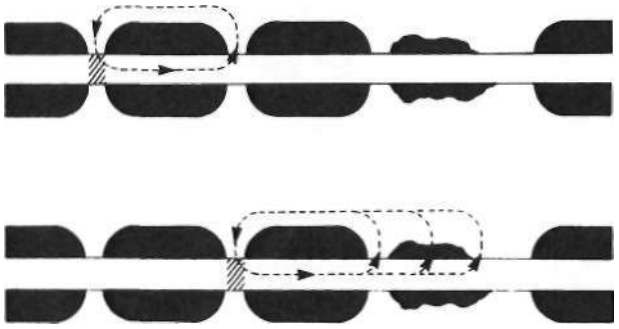

FIGURE 60.1 Schematic diagram of impulse conduction in normal (upper panel) and demyelinated (lower panel) regions of a nerve fiber. The solid arrow indicates the direction of impulse conduction; the shaded area indicates the region occupied by the impulse. Current flow is indicated by the broken atrows. In normally myelinated regions (top), the high resistance, low capacitance directs the majority of action cutrent to the next node of Ranvier. In contrast, in demyelinated regions (bottom), action current is short-circuited Through the damaged myelin sheath or denuded regions of the axon, and hence further propagation of the action potential is blocked. (Reprinted with permission from Waxman, S. G. 1982, "Membranes, myelin, and the pathophysiology of multiple sclerosis," *N Engl J Med*, vol. 306, pp. 1529-1533.)

with relative preservation of axons, although spectroscopic and pathological studies suggest some axonal loss may be an integral part of the demyelinating process.

Gross examination of the brain in MS often reveals variable degrees of atrophy and ventricular dilatation. Plaques may be visible on the surface of the spinal cord on inspection. The cut surface of the brain reveals the plaques, which, when active, appear whitish yellow or pink, with somewhat indistinct borders. Older plaques appear translucent with a blue-gray discoloration and sharply demarcated margins. These plaques often have a hard or rubbery consistency. Individual lesions are generally small (1-2 cm), but may become confluent, generating large plaques. Plaques develop in a perivcnular distribution and are seen most frequently in the periventricular white matter, brainstem, and spinal cord (Figures 60.2 and 60.3), a finding confirmed with magnetic resonance imaging (MRI) studies. However, large numbers of small plaques, often detected only by microscopy, are found in cortical regions affecting intracortical myelinated fibers.

One of the earliest features of acute MS lesions is a disruption of the blood-brain barrier (BBB) as detected by MRI studies. Disruption of the BBB appears to be a critical early step in lesion pathogenesis. The BBB depends on tight junctions between brain endothelial cells. These junctions are not disrupted; rather, a rransendothelial cell vesicular transport system will become active. It can carry water, proteins, antibodies, and cytokines (and gadolinium) into the brain.

Histological examination of active plaques reveals perivascular infiltration of lymphocytes (predominantly T cells) and macrophages with occasional plasma cells. In the plaque, myelin is disrupted, resulting in myelin debris found in clumps or within lipid-laden macrophages. Macrophages, most prominent in the plaque center, appear to have an integral tole in stripping myelin lamellae from axons. Reactive astrocytes ate prominent in plaques. Immunohistochemical studies have found increased levels of cytokines in active plaques indicative of ongoing immimoreactivity.

The fate of oligodendroglia in MS lesions is disputed; consensus opinion is that oligodendroglia number is reduced proportionate to myelin loss in the plaque center, whereas at the plaque edge oligodendroglia are preserved or even increased, suggesting an attempt at remyelination. Remyelination has previously been considered improbable in the CNS (as opposed to the peripheral nervous system [PNS]), yet the finding of shadow plaques (areas of thinly myelinated axons) supports the concept of central rcmyclination (Prineas ct al. 2001). Remyelination may involve either oligodendrocytes that previously produced myelin or maturation of progenitor cells. Such remyelination may explain the clinical finding of slow and delayed tccovcry from an acute attack, whereas rapid clinical recovery presumably reflects the resolution of edema, inflammation, and removal of toxic factots associated with acute plaques in which myelin destruction is minimal.

Studies of plaques with tecurrent demyehnation provide insights into a possible mechanism whereby permanent demyehnation occurs. Evidence of recurrence of activity in old plaques may be demonstrated by gadolinium-enhanced MRI. Chronic demyelinated plaques could thus result not from a single severe episode of demyelination, but rather from recurrent bouts of demyelination at the same site

(Prineas et al. 2001). This could eventually exceed the ability of oligodendroglia to remyelinate or result in tissue changes that eventually prevent remyelination,

Data derived from biopsy as well as autopsy material (I.uccmerti et al. 1999, 2000) has emphasized the heterogeneity of the MS lesion. Some lesions appear to be chiefly inflammatory with retention of active oligodendrocytes, derived from identifiable precursor cells, and evidence of remyelination. In other patients extensive destruction of oligodendrocytes, little replacement, and closer resemblance to a viral or toxic cell apoptosis was found. Because all active lesions from an individual patient were of the same type, the tissue response must clearly be genetically controlled.

The specific target of the immune-mediated injury in MS remains undetermined. A proportionate loss of oligodendroglia and myelin would imply a primary attack against cither oligodendroglia or an antigen present on oligodendroglial cell bodies and myelin. Alternatively, myelin may be the primary target of disease, and the oligodendroglia may survive demyelination, at least in the initial stages of disease.

The active lesions contain T lymphocytes and macrophages in the perivascular regions and parenchyma. Most of the T cells express the *tx/fi* T-cell receptor. Both $CD4^+$ ami I l)N T cells arc present. An apparent increase in $CD8^+$ cells occurs in the CNS, when compared with the prevail me of this subset in the peripheral blood. C D4' cells extend from the periphery of active plaques into adjacent white matter, whereas $CD8^+$ cells predominate in the perivascular regions. Some MS lesions also have an accumulation of T cells expressing the *y/S* T-cell receptor, which may mediate cytolysis of CNS cells expressing heat shock proteins.

Among the lymphocytes are cells specifically sensitized to myelin antigens. **Reports** vary **with** regard to the extent of restriction and the precise profile of the T-cell receptor repertoire of CNS T cells. T-cell sensitization could occur via direct exposure to myelin antigens within the CNS or within cervical lymph nodes, a site to which CNS antigens are transported, or via exposure to exogenous agents sharing antigenic determinants with myelin. The latter has been termed *molecular mimicry.* Microglial cells, endothelial cells, and possibly astrocytes can be induced to express major histocompatibility complex antigens and function as antigen-presenting cells, thus potentially promoting myelin antigen interaction with immune-mediating cells.

Activated T cells and the microglia-macrophages can contribute to tissue injury via nonantigen-restricted mechanisms. Each of these cell types releases an array of soluble factors that can contribute to tissue injury including oligodendroglia. Cytokines characteristic of T cells include imerleukin-2 (I1.-2), interferon-^, and tumor necrosis factor-/* (TNF-£) (lyinphotoxin), A shift toward Th 1 cells expressing IFN-gamma, TNF, and IL-2 and away from Th 2 cells, expressing IL-4, IL-5, IL-10, and IL-13, may be characteristic. Soluble factors released by macrophages **and microglia include** TNF-or, leukotrienes, thromboxanes, proteases, and complement components. Many of these immunologically active substances can result in uprcgulation of adhesion molecules, which can promote or facilitate

nonspecific lymphocyte-macrophage migration to the site of immune injury and immune effector-target cell interactions.

B cells and immunoglobulin are also found in MS lesions. To date, no specific myelinotoxic antibody is identified in MS. Antimyelin antibodies are shown, however, to enhance the disease seventy in the experimental allergic encephalomyelitis (EAE) model, suggesting that both cellular and humoral mechanisms may be needed for full expression of immune injury.

Chronic, inactive plaques display sharp demarcation from surrounding brain and are hypocellular (Figures 60.4 and 60.5). The plaques show astrocytic proliferation with denuded axons and an absence of oligodendroglia. Axonal shrinkage or loss also may be noted to a variable extent. Microglia and macrophages, occasionally with a foamy appearance, are scattered throughout the lesion. The edge of chronic plaques may still exhibit hypercellularity, suggesting continued disease activity.

Pathological differences are described between classical MS and disorders considered as variants of the disease. Balo's concentric sclerosis is characterized by alternating bands of myelinated and demyelinatcd fibers in white matter. Clinically, the illness is more fulminant in onset and course than typical MS and has a more inflammatory cerebrospinal fluid (CSF). Transitional forms exist with typical MS. The affected CNS structures in Devic's neuromyelitis optica show more necrosis, cyst formation, and vascular proliferation than is seen in the usual MS case (Mandler et al. 1993). Large tumor-like plaques, found in the variant of MS known as Marburg variant, may show extensive areas of inflammation and edema.

An important area of investigation, now underway in a number of centers, is to correlate recent concepts of pathological heterogeneity with the pace of the illness and tendency toward recovery, ongoing disability, or axon loss and other clinical features. So far little information in this area is available. With time, different pathological processes may predominate. In secondary progressive MS (defined later), ongoing low-grade demyelination was found at the borders of plaques, associated with C3D, an opsonin coupled with complement activation, and this profile may explain the slow expansion of plaques leading to progressive loss of function (Prineas 2001).

ETIOLOGY

Autoimmunity

Low levels of autoreactive T cells and B cells are present in normal individuals. Presumably they have escaped from clonal depletion during the process of immune development and arc now tolerant of their antigens. Autoimmunity develops when these cells lose tolerance and a complex process of immune reactivity in target tissues begins. One potential way in which tolerance can be broken is by means of molecular mimicry between self-antigens and foreign antigens, for example, viral components. Several viral and bacterial peptides share structural similarities with important proteins of myelin, and a few of them are able to

activate specific T-cell clones derived from patients with MS. Another way in which tolerance can be broken is by CNS infection, causing tissue damage and releasing antigens into the peripheral circulation where they may encounter corresponding autoreactive T cells.

Myelin basic protein (MBP) has long been considered one of the primary candidates for an autoimmune attack. T cells that respond to MBP are found in the peripheral blood in normal persons and those with MS, possibly at higher levels in patients with MS with active disease. MBP can be an antigen for EAE, the primary animal model of MS. MBP accounts for 30% of the protein of myelin.

Several other proteins characteristic of myelin are also candidates for an autoimmune attack. Proteolipid protein accounts for 50% of CNS myelin protein and is an integral membrane protein of the myelin leaflets. In the PNS P0 protein fulfills this role. Myelin-associated glycoprotein, myelin oligodendrocyte glycoprotein, and cyclic nucleotide phosphodiesterase are proteins that account for a few percent of myelin. Myelin oligodendrocyte glycoprotein and cyclic nucleotide phosphodiesterase are not found in peripheral nerve myelin and arc therefore of interest because MS is a disease affecting only central myelin.

Infection

A possible role for viral infection in the causation of MS has been a matter of ongoing debate for decades. The epidemiology of MS (see Epidemiology, later in this chapter) suggests an exogenous or environmental factor of some type. Beyond epidemiology, and much speculation, there is little to support the concept of a role for viral infection. Innumerable efforts to culture a sir LIS from autopsy-derived or biopsy material have yielded no consistent result. Serological data are difficult to interpret because titers may reflect only a nonspecific tendency toward increased immune reactivity. Specific efforts to recover a known viral genome (e.g., that of human T-cell lymphotropic virus type 1 [HTEV-1|) have proven negative. Retrovirus infection is unlikely because reverse transcriptase is absent from the CSF, despite the use of sensitive assay techniques.

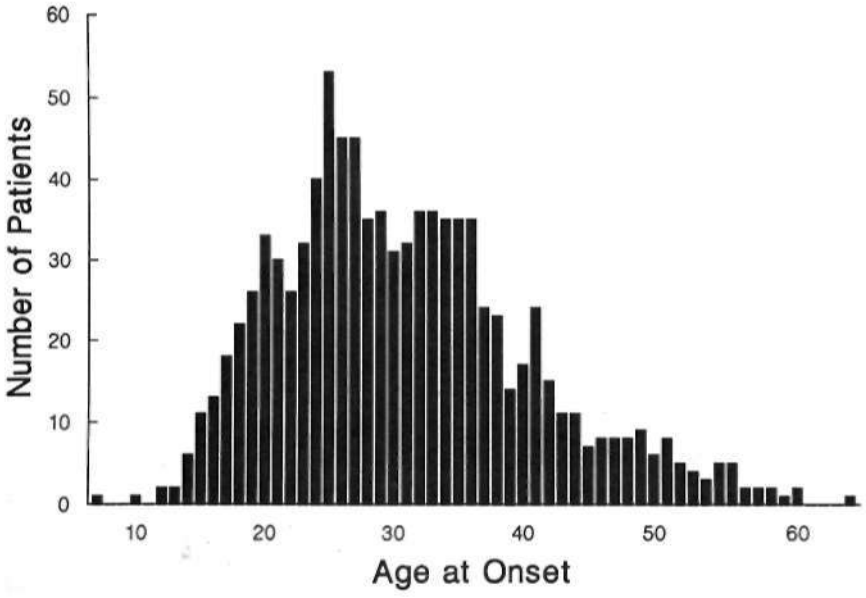
Recently, human hcrpcsvirus-6 (HHV-6), Epstcin-Barr virus (EBV), and Chlamydia pneumoniae have been the focus of intetcst as potential triggers for MS. Several studies of serum and CSF samples have yielded varying results. For example, one early study showed 47% of MS brains were positive for HHV-6, and *H0%* showed elevation in the serum. A more recent study found no HHV-6 DNA in any CSF sample, and the serum antibody titers were comparable to the general population. As has been stated before about viruses and MS, the final word is pending.

Epidemiology

The epidemiology (see Chapter 43) and genetics of MS are complex topics. The interested reader is referred to the articles of Sadovnick and Ebers (1993) and Ebers and Sadovnick (1994).

Age of Onset

Most studies agree that the median age of onset is 23.5 years of age (Figure 60.6). The peak age of onset is approximately 5 years earlier for women than for men. The mean age of onset is 30. Relapsing-remitting MS tends to have an earlier onset, averaging 25-29 years,



KK ;UR1 6!).6 \ge at i inset of (ympti *ns of multiple sclerosis in 940 patients followed at the multiple sclerosis clinic of the Montreal Neurological Institute. Mean age of onset is 30.6 years, median is 27 years, and peak incidence is 25 years.

compared with the relapsing-remirting progressive type with an average of onset of 25-29 years, and a mean age of conversion to progressive MS of 4CM14 years. Primary progressive MS has a mean age of onset of 35-39 years. The onset of MS can occur as late as the seventh decade, although it rarely occurs.

Sex Distribution

Autoimmune diseases in general and MS in particular affect more women than men. In a summary of 30 incidence and prevalence studies, a cumulative ratio of female to male subjects was 1.77 to 1.00.

Mortality

Mortality caused by MS is difficult to ascertain because of poor data collection and reporting. The U.S. Department of Health and Human Services report of deaths in the year 1992 indicates that 1900 U.S. citizens died of MS in that year, giving MS a U.S. mortality of 0.7 per 100,000. The mean age of death of all patients with MS was 58.1 years, compared with a national average of 70.5 for all causes of death. The life expectancy of patients with MS was therefore calculated to he 82.5% of the normal life span, In Denmark, in an exceptionally complete survey of the country, median survival after diagnosis for men was 28 years and for women 33 years, compared with matched population death rates of 37 and 42 years, respectively.

In another study, MS mortality figures were calculated for England and Wales for the years 1963-1990. Over this span of years there was a steady and consistent decline in the death rate attributable to MS compared with the overall death rate. Patients with MS tended to live longer, and other diseases were more likely to be the cause of death. Current estimates indicate that about half of the deaths in MS patients arc directly due to the disease, slightly more than half if accidents and suicide are included as uu'ireci causes.

Geographic and Racial Distribution

More than 250 prevalence surveys have been carried out, serving as the basis for the delineation of geographic risk for MS that is depicted in Figure 60.7. High-frequency

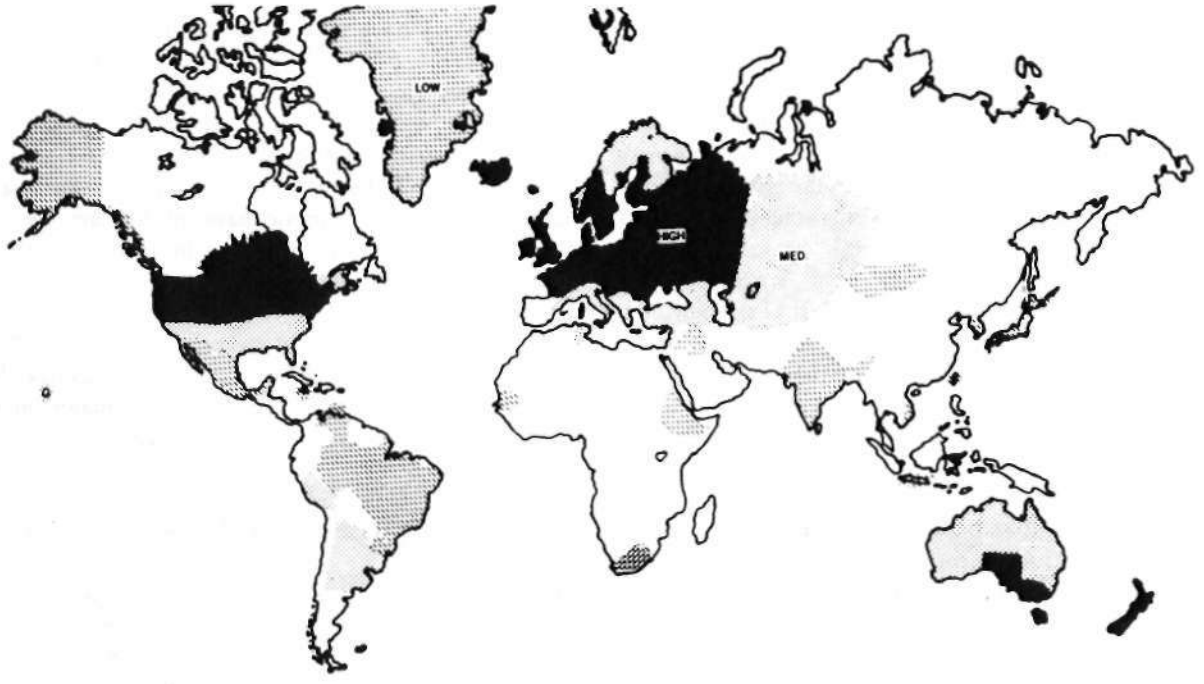


FIGURE 60.7 Worldwide distribution of multiple sclerosis as of 1980. High-frequency areas (>30 per 100,000 population) are indicated in black, medium-frequency areas (5-25 per 100,000) with dots, and low-frequency areas (<5 per 100,000) with diagonal dashes. Open areas are regions without data. South American frequencies are tentative, ['lie low frequency in South Africa is for native South Africans, with medium frequency for persons of European stock native to South Africa. (Reprinted with permission from Kurtzke, J. F. 1980, "The geographical distribution of multiple sclerosis—an update with special reference to Europe and the Mediterranean region," *Acta Neurol Scand,* vol. 62, pp. 65-80. Copyright 1980, Munskgard International Publishers Ltd., Copenhagen, Denmark.)

areas of the world, with current prevalence of 60 per 100,000 or more, include all of Europe including Russia, southern Canada, the northern United States, New Zealand, and the southeastern portion of Australia. In many of these areas the prevalence is more than 100 per 100,000, with the highest reported rate of .500 per 100,000 occurring in the Orkney Islands. In the United States, the prevalence is 0.1 %, or a total of 250,000 persons with MS.

Medium frequency areas comprise most of Australia, the southern United States, the Mediterranean basin (other than Italy), the Asian parts of the former Soviet Union, parrs of South America, and the white population of South Africa.

Low-risk areas include most of South America, Mexico, most of Asia, and all of Africa. One possible conclusion is that MS is a place-related illness, with a latitude gradient. However, notable exceptions then need to be explained. Japan, situated at the same latitude as areas of high prevalence in Europe, is a low-risk area. Second-gene rat ion Japanese in the United States retain their parents' low risk of MS. The white population of South Africa, of medium prevalence of MS, is surrounded by a black population in which the disease is very uncommon. Native North Americans, especially of pure Amerindian background, have a very low prevalence, but are surrounded by a white population with a medium or high risk for VIS.

It seems plausible that race is a determinant of MS risk, with populations of white extraction, especially from Northern Europe being the most susceptible. People of \si;n, African, or Anic'imlian origin have rhc IOWCM v.sk, whereas other groups are variably intermediate.

Migration data have often been used to support the view that a transmissible agent is involved in the pathogenesis of MS. The data indicate that persons migrating from an area of high risk ro an area of low risk after the age of puberty carry their former high risk with them. With migration during childhood, the risk seems to be that of the new area to which the person has migrated. The data are not always clear-cut. Japanese in Japan are at low risk for MS. People of Japanese extraction living in the United States have a higher risk, although less than their neighbors of Northern European extraction. However, those Japanese who migrate to this country do not seem to acquire the risk of their new area. Comparable data are available for persons moving to Israel from Europe (high risk) compared with those arriving from countries in the Middle East.

Genetic and Racial Distribution

The frequency of familial occurrence of MS has varied from 3-23% in different studies. The studies with the higher percentages are those in which ascertainment was more intense; that is, the more one looks, the more one finds. An overall risk in first-, second-, and third-degree relatives of at least *15%* seems a reasonable estimate. The risk is highest for siblings and decreases progressively for children, aunts, uncles, and cousins (Table 60,2). for genetic counseling purposes, it may be stated that the sibling risk is 3-5%, approximately 30-50 times the background risk for this same population. In some studies unaffected family members may have been found to have abnormalities on MRI, implying that the risk may be even higher. The risk applies to blood relatives; only a few studies of adopted children have been done, but they show no increased risk, One unexplained finding is rhe marked deficiency of transmission from father to son.

Table 60.2: Risk of developing MS in family members

Parent with MS	Son	Daughter
Mother	3.8%	3.7%
father	0.8%	2.0%
Sibling with MS	Sister	Brother
Female	5.6%	2.2%
Male	*3,5%*	4.1%
Twin with MS	either sex	
Identical	25-40%	
Nonklentical	4%	

The 95% confidence numbers for these figures range from 0.86 to 1.5.

Source: Modified from Sadovnick, A. D., Baird, P. A., Ward, R. H., et al. 1988, "Multiple sclerosis: Updated risks for relatives," *Am) Med Genet,* vol. 29, pp. 533-541.

Twin studies have shown the familial nature of MS in dramatic fashion. The risk for dizygotic twin pairs is the same as that for siblings, that is, 3-5%. The risk for monozygotic twins is at least 20%, and if the subjects are followed for long periods of time and if various nonclinical data are included, the risk may reach 38.5%. Because the highest rates for the genetic basis of MS are less than 50%, there must be a contribution by nongenetic factors. There arc several candidate genes for MS, including human leukocyte antigen, T-cell receptor, MBP, portions of the immunoglobulin chain, and mitochondrial genes. Three entire genomic scans for MS susceptibility genes have been reported, without an identifiable region of major interest. The data argue for non-Mcndelian polygenic inheritance.

CLINICAL SYMPTOMS AND PHYSICAL FINDINGS

Although the clinical syndrome of MS is classically described as a relapsing-remitting disorder that affects multiple white matter tracts within the CNS, with usual onset in young adults, the disorder displays marked clinical heterogeneity. This variability includes age of onset, mode of initial manifestation, frequency, severity and sequelae of relapses, extent of progression, and cumulative deficit ovet the course of time. The varied clinical features reflect the multifocal areas of CNS myelin destruction (MS plaques), although discrepancies occur between the extent of clinical and pathological findings.

Cognitive Impairment

Data from formal neuropsychological studies indicates that cognitive involvement has been underreported in MS. Neuropsychological test results have shown that 34-65% of patients with MS have cognitive impairment. The most frequent abnormalities are with abstract conceptualization, recent memory, attention, and speed of information processing. Patients refer to memory loss or frustration. The abnormalities are usually not apparent during a routine office visit. In a fast-paced environment with multiple stimuli the cognitive deficit of the MS patient is most obvious. Aphasia, neglect syndrome, cortical blindness, or marked behavioral problems are rare.

Two kinds of recent data have added urgency to the need to assess cognitive deficits: the demonstration by Trapp and colleagues of ongoing axon loss in central white matter beginning at the earliest stages of MS and the demonstration that thinning of the corpus callosum, enlargement of the ventricular system, and other evidences of brain atrophy can be measured accurately by MRI and also begin earlier than previously believed.

Cross-sectional studies have shown some degree of affective disturbance in up to two thirds of patients with MS (Rao et al. 1993). Depression is the most common manifestation and is in part secondary to the burden of having to cope with a chronic, incurable disease. Some data suggest that depression is more common in patients with MS than in others with chronic medical conditions. The lifetime risk of depression a study of 221 patients with MS was 34%, compared with 12.9% in patients' chronic medical conditions in another study. Some data indicate a comorbid association, presumably genetic, between bipolar illness and MS. brontal or subcortical white matter disease may also be a contributory causative factor. Euphoria is usually associated with moderate or severe mental impairment. Patients may manifest a dysphoric state with swings from depression to elation.

On occasion, acute cerebral lesions can manifest as a confusional state. Epilepsy is more common in patients with MS than in the general population, with a cited figure of 3%. Convulsions may be either tonic-clonic in nature or partial complex. They generally respond well to anticonvulsants.

Cranial Nerve Dysfunction

impairment of the Visual Pathways

Optic neuritis (ON) is the most frequent type of involvement of the visual pathways, usually presenting as an acute or subacute unilateral syndrome characterized commonly by pain in the eye accentuated by ocular movements, which is then followed by a variable degree of vision loss (scotoma) affecting mainly central vision. Bilateral ON may occur, but one needs to distinguish whether it is truly simultaneous or sequential. Bilateral simultaneous ON is rare in MS and its occurrence in isolation may suggest another diagnosis such as Leber's hereditary optic atrophy or toxic optic neuropathy (see Chapter 14). In bilateral ON in MS cases, the impairment begins asymmetrically and is usually more severe in one eye. Recurrence is highly variable. In a large ON treatment trial, 15% of placebo-treated patients developed recurrent (ipsilateral or contralateral eye) ON within 6-24 months following the initial bout of ON. Mapping of visual fields teveals a central or cecocentral saiumi.i (antral scotoma involving the physiological blind spot). The finding of a bitemporal hemianopia is rare in MS; if present, it should raise the suspicion of a mass lesion compressing the optic chiasm. Although uncommon, homonymous field defects can be seen in MS caused by involvement of the optic radiations (see Chapters 14 and 40).

Patients with ON have a relative afferent pupillary defect (Marcus Gunn pupil) {see Chapter 40). The afferent pupillary defect is tested by shining a bright light alternately in each eye (the swinging flashlight test), and in the case of unilateral optic nerve dysfunction, the abnormal pupil paradoxically dilates when the light is shifted from the normal to the affected eye. The interpretation of this sign becomes difficult when the degree of optic nerve impairment is similar in the two eyes. When the acute ON lesion involves the head of the optic nerve, one observes disc edema (papillitis), a finding more commonly seen in children than in adults. More often, the lesion of the optic nerve is retrobulbar, and funduscopic examination is normal in the acute stage. Later the optic disc becomes pale as a result of retrograde axonal loss and resultant gliosis. This pallor predominates in the temporal segment of the disc (temporal pallor). After an attack of acute ON, 90% of patients regain normal vision, typically over a period of 2-6 months. Desaturation of bright colors, particularly red, is often reported by recovered patients; some also report a mild nonspecific dimming of vision in the affected eye.

Uhthoffs phenomenon refers to a decrease in visual acuity following an increase in body temperature. This can occur following exercise, a hot bath, or fever. This phenomenon, which reflects subclinical demyclination or pre-existent injury to the optic nerve, may occur without a history of clinical involvement of the optic nerve. A similar phenomenon can occur at other sites of CNS dysfunction with an increase in body temperature.

Impairment of the Ocuiar Motor Pathways

Impairment of individual ocular motor nerves is infrequent in MS. When present, the involved nerves are, in decreasing order of frequency, cranial nerves VI, III, and, rarely, IV. More frequent findings are those that reflect lesions of vestibuloocular connections and internuclear connections. Nystagmus is a common finding in MS (see Chapters 14

and 39), One form of nystagmus particularly characteristic of MS is acquired pendular nystagmus, in which there are rapid, small amplitude pendular oscillations of the eyes in the primary position resembling quivering jelly. Patients frequently complain of oscillopsia (subjective oscillation of objects in the field of vision). This type of nystagmus usually is seen in the presence of marked loss of visual acuity.

Internuciear ophthalmoplegia, defined as abnormal horizontal ocular movements with lost or delayed adduction and horizontal nystagmus of the abducting eye, is secondary to a lesion of the medial longitudinal fasciculus on the side of diminished adduction. Convergence is preserved. When present bilaterally, it is usually coupled with vertical nystagmus on upward gaze. Although most suggestive of MS, a bilateral internuciear ophthalmoplegia can be observed with other intra-axial brainstem lesions, including brainstem glioma, vascular lesions, Arnold-Chiari malformations, and Wernicke's encephalopathy.

Ocular pursuit movements are frequently saccadic rather than smooth. Ocular dysmetria may coexist with other signs of cerebellar dysfunction and other ocular oscillations, such as intrusive saccadic movements (square wave jerks), though these are more common with spinocerebellar degenerations.

Impairment of Other Crantai Nerves

Impairment of facial sensation, subjective or objective, is a relatively common finding in MS, The occurrence of trigeminal neuralgia in a young adult is frequently an early sign of MS. Facial myokymia, a fine undulating wave!ike facial twitching, and hemifacial spasm can be caused by MS, but other causes of a focal brainstem lesion must be excluded. Unilateral facial paresis can occur, but taste sensation is almost never affected. In these syndromes, as with acute oculomotor palsy, the nerve is affected in its course within the neuraxis, rather than peripherally. Vertigo is a reported symptom in 30-50% of patients with MS and is commonly associated with dysfunction of adjacent cranial nerves. Resulting symptoms include hyperacusis or hypoacusis, facial numbness, and diplopia. Complete hearing loss, usually unilateral, is an infrequent complaint. Malfunction of the lower cranial nerves is usually of the upper motor neuron type (pseudobulbar syndrome).

Impairment of the Sensory Pathways

Sensory manifestations are a frequent initial feature of MS and are present in almost every patient at some time during the course of disease. The sensory features can reflect spinothalamic, posterior column, or dorsal root entry zone lesions. The sensory symproms are commonly described as numbness, tingling, pins and needles, tightness, coldness, or swelling of limbs or trunk. Radicular pains, unilateral or bilateral, can be present, partieulatly in the low thoracic and abdominal regions, or a bandlike abdominal sensation may be described. An intensely itching sensation, especially in the cervical dermatomes, usually unilateral, suggests MS.

The most frequent sensory abnormalities on clinical examination are the following: varying degrees of impairment of vibration and joint position sense, decrease of pain and light touch in a distal distribution in the four extremities, and patchy areas of reduced pain and light touch perception in the limbs and trunk. A bilateral sensory level is a more frequent finding than a hemisensory (Brown-Sequard) syndrome. Patients commonly report that the feeling of pinprick is increased or feels like a mild electric shock or that the stimulus spreads in a ripple fashion from the point at which it is applied. The sensory useless hand (the numb clumsy hand syndrome) is a characteristic but uncommon feature, consisting of an impairment of function secondary to a pronounced alteration of proprioception, without loss of power, A lesion of the relevant root cutty zones or posterior columns in the spinal cord is postulated in such cases.

Impairment of Motor Pathways

Corticospinal tract dysfunction is common in MS. Paraparesis, or paraplegia, is a much more common occurrence rhan is significant weakness in the upper extremities. With severe spasticity, extensor or flexor spasms of the legs and sometimes the trunk may be provoked by active or passive attempts to rise from a bed or wheelchair. The physical findings include spasticity, usually more marked in the legs than in the arms. The deep tendon reflexes are exaggerated, sustained clonus may be elicited, and extensor plantar responses are observed. All of these in....tcsiaiions are coin monk asymmetrical. Occasionally, deep tendon reflexes may be decreased because of lesions interrupting the reflex arc at a segmental level, and one may observe an inverted reflex wherein one reflex, such as the triceps, is lost, and the efferent component is represented by a contraction of a muscle below the lesion, such as the triceps muscle. The Achilles reflex can be absent in lesions of the sacral segments of the spinal cord with or without concomitant sphincter and sexual problems. Occasionally, reduced reflexes reflect hypotonia resulting from cerebellar pathway lesions. Amyotrophy, when observed, most frequently affects the small muscles of the hand; lesions of the motor root exit /.ones may produce muscle denervation caused by axon loss. Secondary entrapment neuropathies are also a cause of muscle atrophy in patients with MS.

A common pattern of disease evolution seen in the spinal fotm of MS is an ascending pattern of weakness that begins with involvement of the lower extremities and spreads to involve first one upper extremity and then the other, beginning in rhe intrinsic hand muscles. Often there is an

associated weakness of the trunk muscles with abnormal posture and involvement of respiratory muscles.

Impairment of Cerebellar Pathways

Cerebellar pathway impairment results in gait imbalance, difficulty in performing coordinated actions with the arms, and slurred speech. Examination reveals the usual features of cerebellar dysfunction, such as dysmetria, decomposition of complex movements, and hypotonia, most often observed in the upper extremities. An intention tremor TI 1;y he noted m the limbs and head. Walking is impaired by truncal ataxia. Ocular findings of nystagmus, ocular dysmetria, and frequent refixation saccades suggest cerebellar or cerebellovestibular connection dysfunction. Speech can be scanning or explosive in character. In severe cases there is complete astasia (inability to stand), inability to use the arms because of a violent intention tremor, and virtually incomprehensible speech. Cerebellar signs are usually mixed with pyramidal (corticospinal) tract signs.

Impairment of Bladder, Bowel, and Sexual Functions

The extent of sphincter and sexual dysfunction often parallels rhe degree of motor impairment in the lower extremities. The most common complaint related to urinary bladder dysfunction is urgency, usually the result of uninhibited detrusor contraction, reflecting a suprasegmental lesion. As the disease progresses, urinary incontinence becomes more frequent. With involvement of sacral segments of the spinal cord, symptoms of bladder hypoactivity may evolve, such as decreased urinary flow, interrupted micturition, and incomplete bladder emptying. An atonic dilatatcd bladder that empties by overflow results from loss of perception of bladder fullness and is usually associated with urethral as well as anal and genital hypoesthesia, and sensory deficits in the sacral dermatomes. A dyssynergie voluntary sphincter, interrupting bladder emptying, will lead to frequent small-volume urinations, combined with a large postvoiding residual. When evaluating bladder incontinence or urgency in patients with MS, one must exclude other causes, particularly in multiparous women. Urinary tract infections are common in MS, especially in women. These infections may not cause fever and back pain, but may increase the extent of bladder and other neurological dysfunction.

Constipation is more common than fecal incontinence and is mainly due to decreased general mobility. Almost all patients with paraplegia require special measures to maintain regular bowel movements.

Sexual dysfunction, although frequently overlooked, is a common occurrence in MS. Approximately 50% of patients become completely sexually inactive secondary to their disease, and an additional 20% become sexually less active. Men experience various degrees of erectile dysfunction, often with rapid loss of erection at attempted intercourse, whereas loss of ejacuLition is less common. Most women preserve their orgasmic capabilities, sometimes even in the presence of complete loss of bladder and bowel function. Sexual dysfunction can be the result of multiple problems, including the direct effects of lesions of the motor and sensory pathways within the spinal cord in addition to psychological factors involved with self-image, self-esteem, and fear of rejection from the sexual partner. Mechanical problems created by spasticity, paraparesis, and incontinence further aggravate the problem.

Clinical Features Distinctive of Multiple Sclerosis

Although there are no clinical phenomena that are unique to MS, some are highly characteristic of the disease (Table 60.3). Bilateral internuclear ophthalmoplegia has been mentioned previously. Lhermitte's phenomenon is a transient sensory symptom described as an electric shock radiating down the spine or into the limbs on flexion of the neck. It may be infrequent or occur with the least movement of the head or neck. Although most frequently encountered in MS, this symptom can be seen with other lesions of the cervical cord, including tumors, cervical disc herniation, postradiation myelopathy, and following trauma.

Paroxysmal attacks of motor or sensory phenomena may arise as a manifestation of demyelinating lesions. Within the brainstem, lesions can cause paroxysmal diplopia,

Table 60,3; Common clinical features of multiple sclerosis

Clinical features suggestive of multiple sclerosis	*Clinical features not suggestive of multiple sclerosis*
Onset between ages 1 5 and 50	Onset before age 10 or after 60
Relapses and remissions	Steady progression
Optic neuritis	Early dementia
Lhermitte's sign	Rigidity, sustained dystonia
Internuclear ophthalmoplegia	Cortical deficits such as aphasia, apraxia, alexia, neglect
Fatigue	Deficit developing within minutes
Worsening with elevated body temperature	

facial paresthesia, trigeminal neuralgia, ataxia, and dysarthria. Motor system involvement results in painful tonic contractions of muscles of one or two (homolateral) limhs, trunk, and occasionally the face, but these only rarely occur in all four limhs or the trunk. These paroxysmal attacks usually respond to low doses of carbamazepine and frequently remit after several weeks to months, usually without recurrence.

Heat sensitivity is a well-known occurrence in MS (llhthoff's phenomenon; see discussion under Impairment of the Visual Pathways, earlier in this chapter); small increases in the body temperature can temporarily worsen current or pre-existing signs and symptoms. This phenomenon is encountered in other neurological diseases, but to a lesser extent, and is presumably the result of conduction block developing in nerves as the body temperature increases. Normally, the nerve conduction safety factor decreases with increasing temperature until a point is reached at which conduction block occurs; this point of conduction block is reached at a much lower temperature in demyelinated nerves.

Fatigue is a characteristic finding in MS, usually described as physical exhaustion that is unrelated to the amount of activity performed. Many patients complain of feeling exhausted on waking, even if they have slept soundly. Fatigue can appear also during the day but may be partially or completely relieved by rest. There is a poor correlation between fatigue and the overall severity of disease or with the presence of any particular symptom or sign. Unlike cognitive deficit, no MRI findings correlate with fatigue or with depression. Fatigue is often seen in association with an acute attack and may precede the focal neurological features of the attack and persist long after the attack has subsided.

DIAGNOSTIC CRITERIA

The cornerstone of the diagnosis of MS remains the neurological history and physical examination. To improve the homogeneity of MS patient groups being studied, the Schumacher Committee on Diagnostic Criteria for MS elaborated six items required to diagnose clinically definite MS: (1) objective CNS dysfunction, (2) involvement of white matter structures, (3) two or more sites of CNS involvement, (4) relapsing-remitting or chronic (more than 6 months) progressive course, (5) age 10-50 years at onset, and (6) no better explanation of symptoms as assessed by a competent neurologist. These criteria made no use of laboratory studies. Such stringent criteria would exclude some patients with MS; for example, they were fulfilled in only 95% of a group of patients who came to autopsy study. The criteria were modified for diagnosis in 1983 by Poser et al., expanding the age at onset to 59 years and using data derived from laboratory studies, including analysis of **the** CSF, evoked potentials (FT[1]), and neuroimaging These criteria were developed to ensure that only patients with MS were included in research studies. Recently, McDonald et al. have proposed new diagnostic criteria that include stringent guidelines for MRI and timing intervals to determine possible or definite MS (Fable 60.4). The outcome of a diagnostic evaluation is either MS, possible MS, or not MS.

There remains the clinical problem, distinct from research criteria, of the patient early in the course who does not meet diagnostic criteria. In the setting of a monophasic neurological illness that is clinically consistent with MS and in the presence of multifocal white matter lesions on MRI consistent with demyelinating plaques, the diagnosis of MS is almost certain. In the long-term

Table 60.4: McDonald et al. (2001) diagnostic criteria for multi] le sclerosis

Clinical pre$e?itatior!	*Additional data needed for MS diagnosis*
Two or more attacks; objective clinical evidence of 2 or more lesions	Num.
Two or more attacks; objective clinical evidence of 1 lesion	Dissemination in space, demonstrated by MR] OR two or more MRI-detected lesions consistent with MS Plus positive CSF OR await further clinical attack implicating a different site
One attack; objective clinical evidence of 2 or more lesions	Dissemination in time, demonstrated by MRI OR second clinical attack
One attack; objective clinical evidence of 1 lesion (monosymptomatic presentation; clinically isolated syndrome)	Dissemination in space, demonstrated by MRI OR second clinical attack OR two or more MRI-detected lesions consistent with MS Plus positive CIS!-" AND dissemination in time. demonsttated by MRI
Insidious neurological progression suggestive of MS	Positive CSF AND dissemination in space, demonstrated by (1) nine or more T2 lesions in brain or (2) 2 or more lesions in spinal cord or (3) 4-8 brain lesions plus one spinal cord lesion OR abnormal VF.P associated with 4-8 brain lesions, or with fewer than 4 brain lesions plus 1 spinal cord lesion demonstrated by MRI AND dissemination in rime, demonstrated by MRI OR continued progression for 1 year

Positive CSF-oligoclonal bands (detected preferably by isoelectric f lsing) of raised IgG index. MRI parameters as listed in Table 60.4.1 and Table 60.4.2.

Three or four of the following:
1. One gadolinium-enhancing lesion OR nine T2-hyperintense lesions if there is no gadolinium enhancing lesion
2. At least one infratentorial lesion
3. At least one juxtacortical lesion
4. At least three periventricular lesions

(Adapted from Barkhof et al. [1997] and Tintore et al. (20001.)

study of Brex ct al. (2002), which followed patients with initial demyelinating episodes for up to 14 years, in practical terms no diagnoses were encountered other than MS or suspected MS. Rarely, cases of postinfectious encephalomyelitis, ADFM. or vasculitis may present in a similar fashion. In addition, follow-up studies have shown that a significant percentage of patients with MRI lesions detected at onset do not progress to clinically symptomatic MS, even after many years of follow-up. The issue of the monophasic demyelinating disease is discussed in the next section. Such patients may be classed as suspected MS; they may, in fact, represent particularly benign forms of the disease.

Differential Diagnosis

The differential diagnosis of MS (Table 60.5) is quite limited in the setting of a young adult with two or more clinically distinct episodes of CNS dysfunction with at least partial resolution. 1' rob I ems arise with atypical presentations, monophasic episodes, or progressive illness. The unusual nature of some sensory symptoms and the difficulty patients experience in describing such symptoms may result in a misdiagnosis of hysteria. The retrospective nature of inquiries also blurs details of prior events, making clear ascertainment of prior attacks difficult in some cases, A monophasic illness with symptoms attributable to one site of the CNS creates a large differential diagnosis that includes neoplasms, vascular events, or infections.

Table 60.5: Differential diagnosis in multiple sclerosis

Inflammatory diseases

Lymphomatoid granulomatosis
Diseases of myelin
Metachromatic leukodystrophy (juvenile and adult)*
Adrenomyeloleukodystrophy*
Miscellaneous
Spinocerebellar disorders"[1]
Arnold-Chiari malformation
Vitamin B|2 deficiency*

"Indicates disorders that are predominantly important to differentiate in the setting of progressive disease.

Appropriate imaging studies may help clarify the situation, depending on the site of involvement and clinical progression. The most trouble arises with progressive CNS dysfunction, in which great care must be taken to exclude treatable etiologies (e.g., vitamin B_{12} deficiency, compressive spinal cord lesions, arteriovenous malformations, cavernous angiomas, Arnold-Chiari malformation), infectious causes (syphilis, HTLV-1, human immunodeficiency virus), or hereditary disorders (adult metachromatic leukodystrophy, adrenomyeloleukodystrophy, spinocerebellar disorders).

Table 60.4.2: MRI demonstration of time dissemination for McDonald et al. (2001) diagnostic criteria for multiple sclerosis

If a first scan occurs 3 months or more after the onset of the clinical event, the presence of a gadolinium-enhancing lesion is sufficient to demonstrate dissemination in time, provided that it is not at the site implicated in the original clinical event. If there is no enhancing lesion at this time, a follow-up scan is required. The timing of this scan is not crucial, but 3 months is recommended. A new T2 or gadolinium-enhancing lesion at this rime then fulfills the criteria for dissemination in time.

If the first scan is performed less than 3 months after the onset of the clinical event, a second scan done 3 months or more after the clinical event showing a new gadolinium-enhancing lesion provides sufficient evidence for dissemination in time. However, if no enhancing lesion is seen ar this second scan, a further scan not less than 3 months after the first scan that shows a new T2 lesion or an enhancing lesion will suffice,

The new criteria have advantages. The former categories of possible, probable, and definite MS have become obsolete. The MRI criteria are based on extensive data of Barkof et al. (1997) and Tintore ct al. (2000) and are designed ro retain sensitivity while enhancing specificity. They will have liulc usefulness in patients with clear-cut demyelinating syndromes such as optic neuritis or a brainstem syndrome: in such cases many clinicians will be satisfied with less stringent MRI criteria. In patients with obscure symptoms the criteria will help avoid premature or erroneous diagnosis and treatment. In addition, criteria for primary progressive MS are proposed.

Revisions to the McDonald criteria have been proposed. For example, the role of spinal cord lesions needs to be evaluated and expanded, It may take some time before the final crircrm are decided on and accepted as the standard for diagnosis.

A common error is to overinterpret multiple hypei intense lesions on MR1 as equivalent to MS. Clinical symptoms must be consistent with MS. A few white matter lesions in T2-weighted MRI scans are not infrequent, particularly in the elderly, and do not indicate a diagnosis of MS. CNS vasculitidcs such as systemic lupus erythematosus (SLE), Sjogren's disease, polyarteritis nodosa, syphilis, retroviral diseases, and Behcet's disease may all produce multifocal lesions with or without a relapsing-remitting course. SLE can present as a recurrent neurological syndrome before the systemic manifestations of this disease declare themselves. Behcet's syndrome is characterized by bucco-genital ulcerations in addition to the multifocal neurological findings, CNS sarcoidosis can be mistaken for MS with multifocal neurological and MRI lesions. Although rare, ADEM must be considered in the. differential diagnosis (sec Acute Disseminated Fivephalomyelitis, later in this chapter). An MS-like phenotype associated with mitochondrial gene defects has been described; it is of note that when there arc multiple MS cases in *a* family, maternal transmission is more frequent than paternal transmission.

More important than features characteristic for MS are features that should prompt the clinician to reconsider the diagnosis oi MS-red flags indicating that another diagnosis is more likely. Many physicians fail to pursue further diagnostic steps when a patient is labeled as having .MS. Features that should alert the clinician to the possibility of other diseases include (1) family history of neurological disease, (2) a well-demarcated spinal level in the absence of disease above the foramen magnum, (3) prominent back pain that persists, (4) symptoms and signs that can be attributed to one anatomical site, (5) patients who are over 60 years of age or less than 15 years at onset, and (6) progressive disease (see Table 60,3). None of these features excludes the diagnosis of MS, but in these situations one should seek other etiologies before accepting the diagnosis of MS.

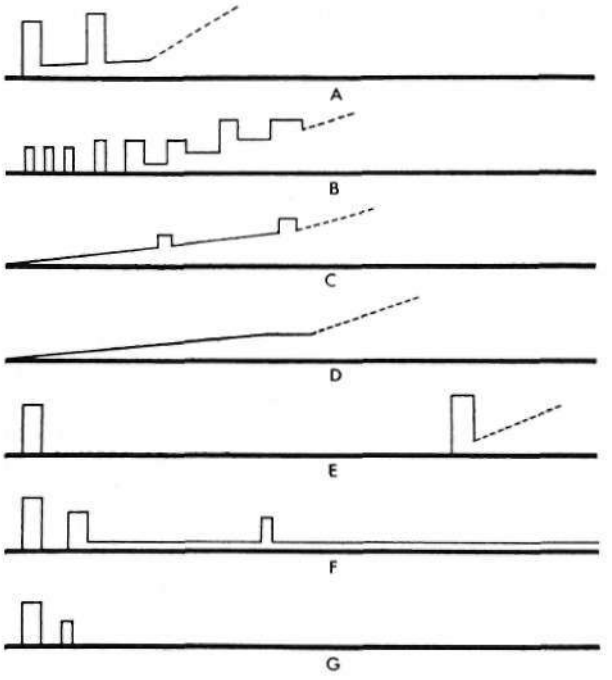

FIGURE 60.8 The course of multiple sclerosis. (A) Severe relapses, increasing disability, and early death. (B) Many short attacks, tending to increase in duration and severity. (C) Slow progression from onset, superimposed relapses, and increasing disability. (D) Slow progression from onset without relapses. (E) Abrupt onset with good remission followed by long latent phase. (F) Relapses ot diminishing frequency and severity, slight residual disability only. (G) Abrupt onset, few if any relapses after first year, no residual disability. (Reprinted with permission from McAlpine, D., Compston, A., Fbers, G., et at. 1VVK, AIIVW/JW'S *Multiple Sclerosis*, 3rd ed, Churchill Livingstone, London, p. 32.)

Course

The most characteristic clinical course of MS is the occurrence of relapses (Figure 60.8), which can be defined as the acute or subacute onset of clinical dysfunction that usually reaches its peak from days to several weeks followed by a remission during which the symptoms and signs resolve partially or completely. The minimum duration for a relapse has been arbitrarily established at 24 hours. Clinical symptoms of shorter duration arc less likely to represent what is considered as a true relapse (i.e., new lesion formation or extension of previous lesion size). Worsening of previous clinical dysfunction can occur concurrently with fever, infection, physical activity, or metabolic upset and last for hours to a day or more. Such worsening is thought to reflect conduction block in previously demyelinated axons. Relapses of MS vary markedly with regard to the CNS site involved; the frequency of attacks (the free interval between relapses ranges from weeks to years); the mode of onset (from quite sudden to subacute); and the duration, severity, and quality of remission. The frequency of relapses is highly variable and depends on the population studied and the closeness of observation and recording by patients and physicians. Summaries of many studies provide an average figure of 0.4-0.6 relapses per year. Patients followed closely in clinical trials have higher relapse rates, probably reflecting self-selection and closer reporting and examinations in such studies. The attack rate in the placebo group in clinical studies ranges from 0.8-1.2 attacks per year. In general, relapses arc more frequent during the first years of the disease and tend to wane in later years. A course marked by relapses, interspersed by periods during which the disease seems relatively dormant, is termed relapsing-remitting.

Approximately 15% of patients never experience a second relapse. The exact frequency of such benign MS is unknown, however, because many such individuals never come to medical attention. Autopsy studies found a significant numbers of cases with CNS pathology consistent with MS and yet no documented clinical evidence of

such disease. Similarly, MRI studies have shown MS-like plaques in T2- weigh ted scans in patients who have never-had a neurological episode. Asymptomatic relatives of patients with MS have MRI lesions consistent with dcmyelination in up to 15% of these relatives (Sadovnick et al. 1993). The use of MRI may expand the specttum of MS by detecting milder cases that previously were not included in prognosis studies.

A standardization of terms has been agreed on to determine the pattern and course of the illness (Lublin and Reingold 1996). Four categories of disease are described:

1. Relapsing-remitting MS: Clearly defined relapses with full recovery or with sequelae and residual deficit on recovery. The periods between disease relapses are characterized by a lack of disease progression.
2. Primary-progressive MS: Disease progression from onset with occasional plateaus and temporary minor improvements allowed.
3. Secondary-progressive MS: Initial relapsing-remitting diseast course followed hy progression with or without occasional relapses, minor remissions, and plateaus.
4. Progressive-relapsing MS: Progressive disease from onset, with clear acute relapses, with or without full recovery. The periods between relapses are characterized by continuing progression.

Two severity outcomes are also described: (1) Benign MS is disease in which the patient remains fully functional in all neurological systems 15 years after the disease onset; and (2) malignant MS is disease with a rapid progressive course, leading to significant disability in multiple neurological systems or death in a relatively short time after disease onset.

Data from a clinic-based study of 1100 patients who represented the population of the region found that 66% of patients at onset had relapsing and remitting disease, 15% had relapsing-progressive, and 19% had progressive disease from the onset. Patients evolved from a relapsing-remitting course to a progressive course; 85% of patients began with a relapsing course, but the proportion continuing as relapsing disease decreased steadily, so that by 9 years from onset, only one half were still relapsing. Likewise, the probability of reaching 6 on the Kurtzke disability score was 50% 16-17 years after onset. The course of MS with onset after the age of 40 was progressive in over 60% of patients.

The rate of clinical progression of MS is variable. The commonly used index of clinical disability, the Kurtzke disability status score (DSS), or the expanded version called the expanded disability status score (EDSS), uses numbers ranging from 0 for normal examination and function, to 10 for death caused by MS. This scale is nonlinear, with great emphasis on ambulation capabilities with scores above 4. Most MS populations have bimodal distributions of EDSS scores, with peaks at values of 1 and 6 (ambulation with unilateral assistance). The time spent by a patient at a given level of disability varies with the score. Thus, for patients with DSS scores of 4 or 5, median time spent at these levels was 1.2 years, whereas for those at DSS 1, median time to stay at that level was 4 years, and at DSS 6, it was 3 years. These results have powerful implications for the conduct of clinical studies with respect to patient selection, stratification, and duration of follow-up: If many patients of DSS 1 or *6* are included, little movement is seen in a group followed for a year or two. The rate of progression with chronic progressive disease in the placebo groups of three clinical trials ranged from 0.5-0.7 points per year on the DSS scale.

In a cohort of patients followed for *25* years, the following data emerged (Runmakcr and Andersen 1993): 80% of the patients had reached the progressive phase by 25 years, 15% of the patients had died, *65%* of the patients had reached EDSS 6 (requiring aids for walking), and 50% of the patients reached EDSS 6 within 16 years of onset.

The HDSS, although universally used m clinical trials, has a number of serious limitations. Even with special training and examiner blinding, interrater and intrarater variations in scoring are common. EDSS scores of 4 and higher depend almost entirely on the ability to walk, and developing dementia, vision loss, or weakness of hands may pass undetected by the scoring. An obvious implication of these facts is that other outcome measures should be used as well and that minor changes in EDSS alone should not be ovcrinterpreted.

The Multiple Sclerosis Functional Composite Scale (MSEC) is a clinical tool designed to avoid the problems encountered with the EDSS. The MSFC consists of three parts: (1) Paced Auditory Serial Addition Test (PASAT) (2) 9-Hole Peg Test (9HPT) and (3) Timed 25-Foot Walk (T25FW), These three measures take into account cognition, upper extremity, and lower extremity functions, A z-score is obtained for each measure and a combined z-score is then derived. The MSFC has been validated in several clinical trials. The tests can be performed by a nonphysician and are highly reproducible and predictable.

Effect of Exogenous Factors on the Course

The role of a variety of exogenous factors cither influencing the development of MS or inducing disease exacerbations has been examined using epidemiological techniques. A disproportionately high number of relapses occur in patients with MS who have suffered recently from viral infections, and a high number of infections are followed by acute attacks. Increased interferon-)' and TNF-a produced by cells of the immune system during viral infections may play a role in this increased relapse rate by increasing expression of ma]or histocompatibility complex class II antigens and adhesion molecules on cells of the immune

system and CNS, with a resultant increase in the number of activated T cells being attracted to the CNS.

Controversy exists about a link between occurrence of stressful events and exacerbation of MS. Trauma appears not to be implicated in disease induction or relapse, although in the experimental animal model EAE, lesions are most prominent at sites of pre-existent traumatic lesions. Performance of neurological diagnostic procedures such as myelography and lumbar puncture has not been linked with aggravation of the MS disease coutse, nor has administration of local or general anesthetics. Recent data do not establish a link between vaccination and disease exacerbations, and few clinicians withhold immunization programs, for example, for influenza or hepatitis.

Effect of Pregnancy on the Course

MS is a disease that predominantly affects women and has a maximum incidence during child bearing years. The influence of pregnancy on MS has been repeatedly examined, with evidence that relapses are reduced late in pregnancy and are more frequent than expected in the 3-monrh postpartum period. However, this is not the finding in all studies. There is general agreement that the overall prognosis is no different in women who have been pregnant, compared with those who have not. Studies of women with MS reveal no increase in stillbirths, ectopic pregnancies, or spontaneous abortions. These data would suggest that pregnancy has no ill effect on MS and that MS has no negative effect on the fetus or the course of pregnancy. In a study of postmenopausal women, there was no difference in disease severity in multiparous or nulliparous women. An important issue in the pregnant woman with MS is to avoid exposing the fetus to toxic drugs (Table 60.6).

Tabic 60.6: Safety in pregnancy of drugs used in the treatment of multiple sclerosis

Category B: Animal data showing no harm to the fetus; no human data available
Glatiramer acetate [Copaxone)
Pemoline
Oxybutymn
Fluoxetine (and other selective serotonin reuptake inhibitors)
Desmopressin
Category C; Animal data shows harm to the fetus; no human data available

PROGNOSIS

Although great individual variability exists with regard to disease prognosis, a variety of factors have been identified as possible prognostic indicators.

Sex: MS appears to follow a more benign course in wumui il'i.ii: in men.

Age at onset: The average age at onset of MS is 29 years. Onset at an eatly age is seemingly a favorable factor, whereas onset at a later age carries a less favorable prognosis. As previously stated, the pattern of disease varies in different age groups, with the re lapsing-remitting form being more common in younger patients and the progressive form being more common in the older age group. Data arc lacking as to whether prognosis differs as a function of age in patients with similar patterns of disease.

Initial disease course: The relapsing form of the disease is associated with a better prognosis than progressive disease. A high rate of relapses early in the course of illness may correlate with shorter time to reach EDSS 6, as docs a short first interval between attacks.

Initial complaints: Among initial symptoms, impairment of sensory pathways or cranial nerve dysfunction, particularly ON, is found in several studies to be ;• favorable prognostic feature, whereas pyramidal and particularly brainstem and cerebellar symptoms carry a poor prognosis.

Both benign and fulminant forms of MS arc recognized. There is no agreement among workers in the field as to the meaning of these terms, ft is the general experience that a patient whose disease has had a benign course for 15 years only rarely develops a more severe course. Patients with mild disease (KDSS score O-.i) 5 years after diagnosis only uncommonly progress to severe disease (EDSS score 6) by 10 years (7.5% of patients) and 15 years (11.5% of patients). The term *malignant MS* is variably used by different workers; some use it to imply a rapid course, others a clinical course in which there are frequent severe relapses with little tecovery. Clues to etiology, susceptibility, and resistance factors must be present in such extremes of the clinical spectrum but they remain elusive at present. Entities such as Devic's disease, Balo's concentric sclerosis, and particularly Marburg disease are more fulminant variants of MS with early disability and even death (Tabic 60.7).

Table 60.7: Risk of multiple sclerosis after monosymptomark episodes

		15	4-10	87%	53%	38%
		17	>10	88%	80%	73%

Conversion rate to clinically definire MS (CDMS) indicates that the patient had second clinical episode,

Optic Neuritis

The incidence of MRI abnormalities in children with ON is less than that in adults, and this factor, coupled with clinical experience, siii'.i'.i^f. tiui ihe r.iu- ;>' |ir(«-;vssuin i<> MS in children with isolated ON may well be less than that in adults. Five-year data from the original Optic Neuritis Treatment Trial revealed that the 5-year cumulative probability of developing clinically definite MS was 30% and did not differ by treatment group (oral prednisone, intravenous methylprednisolonc, placebo). However, MRI was a strong predictor; the 5-ycar risk of developing clinically definite MS was 16% in patients with no brain MRI lesions and 51% in patients with three or more lesions.

Myelopathic Syndromes

Acute Myelopathy

Patients presenting with acute complete transverse myelitis have a cited risk of MS of only 5-10%. However, partial or incomplete myelitis is a much more common clinical entity and bears more relevance to MS. Studies examining the issue of acute partial myelitis as an initial presentation of MS found that 57-72% of such patients had cranial MRI abnormalities consistent with MS. Follow-up from *i-5* years found that 60-90% of these patients developed MS, whereas 10-30% of those with normal MRI developed MS (Morrissey et al. 1993). CSF studies suggest that patients with monosymptom a tic disease with positive oligoclonal bands (OCBs) have a higher risk of evolution ro MS than those without OCBs, although CSF results do not help further in prognosis when compared with MRI alone. CSF analysis would be most useful in a situation in which MRI is not available.

Chronic Myelopathy

In patients with chronic progressive myelopathy, 60-70% have cranial MRI abnormalities consistent with MS in the absence of clinical evidence of disease above the level of the spinal cord. What remains unclear is whether the remaining 30% have a disease other than MS or whether MS can manifest as a purely spinal disorder. Probably both situations apply; improved spinal neuroimaging should help resolve this issue.

Diagnostic Studies

Although the diagnosis of MS remains clinical, a number of ancillary laboratory tests can aid in the diagnosis of MS. The tests used most often are neuroimaging, particularly MRI, analysis of CSF, and to a lesser extent, EP studies.

Neuroimaging

Magnetic Resonance imaging

MRI has changed significantly the approach to MS and is now the modality of choice as an aid to the diagnosis. MS pi a (.pies are typically found in the periventricular region, corpus callosum, centrum semiovale, and to a lesser extent, deep white matter structures and basal ganglia. Features typical of MS plaques have an ovoid appearance; lesions are arranged at right angles to the corpus callosum as if radiating from it ("Dawson's fingers"). The plaques appear hyperintense on proton density and T2-weightcd studies (Figure 60.9), whereas the plaques appear (if visible at all) hypointense on Tl-wcighted images. Such hypointense lesions on Tl-weighted scans ("black holes") are associated with evidence of axonal loss in addition to demyelination.

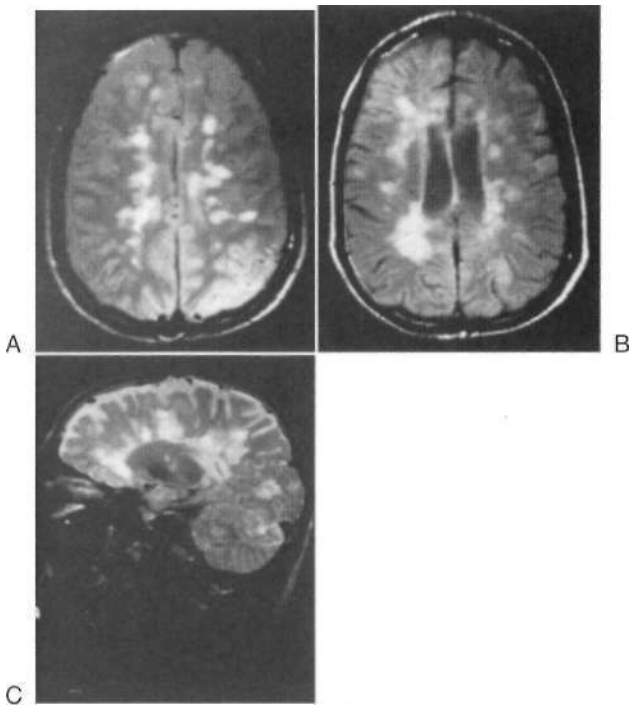

FIGURE 60.9 Magnetic resonance imaging studies in a 29-year-old man. (A) Multifocal lesions in the centrum semiovale (proton density image). (B) Multiple, at times confluent, white matter lesiims abutting the lateral ventricles (proton density image). (C) Lesions distributed in a radiating fashion from the corpus callosum ("Dawson's fingers"). Significant cerebral atrophy with vcntriculomcgaly and cortical atrophy is also noted (T2-wcightcd image).

The earliest studies of cranial MRI in MS rapidly established that MRI detected many more lesions than did computed tomographic (CT) scanning. Furthermore, plaques were readily detected in regions that were rarely abnormal on CT, such as the brainstem, cerebellum, and spinal cord. Most lesions seen on MRI correlate with lesions seen on pathology. However, some lesions that arc quite extensive on MRI show only small plaques on pathological examination, suggesting that much of the abnormal MRI signal may be a result of increased water content of the brain around such plaques caused by presumed BBB disruption. This would be consistent with the finding of reduction of size of plaques in serial studies of MS using MRI.

The major effect of MRI technology has been on diagnosis. Patients with clinically definite MS have white matter lesions typical of MS in over 90% of cases. One mnsl keep ::i mind lh.it other t. !NS diseases (e.g., ischemia, SLE, Behcet's disease, other vasculitides, HTLV-1, sarcoidosis) may have lesions on MRI that appear similar to MS. This is particularly true for ischemic lesions, which make MRI criteria much less reliable for the diagnosis of MS in patients over the age of 50 (Offenbacher et al. 1993). Several sets of criteria have been proposed for determining whether lesions seen on MRI arc caused by MS. The criteria take into account the typical sites of MS plaques and also consider the relatively frequent finding of scattered hyperintense signals on T2-weightcd images seen in the more elderly population and thought to he caused by vascular disease. Patients with at least three lesions, lesions abutting the ventricles, lesions in the posterior fossa, and lesions of greater than 5 mm are likely to have MS. If at least two of these thtee criteria were met in an initial group of patients with MS and elderly controls, these ctiteria had a sensitivity of 88% and specificity of 100%. Testing of a target, more diverse patient population indicated that these criteria had a sensitivity of 81% and a specificity of 96% (Offenbacher et al. 1993).

MRI scanning is both mote sensitive and more specific for predicting evolution to clinically definite MS than other paraelmieal investigations such as CT **scans,** CSF, or EP. Two-year follow-up of 200 patients tefetred for suspected MS showed that 30% {50% of those under age 50) bad developed clinically definite MS, of whom 84% had initial MRI scans thai were strongly suggestive <:. MS. Subsequent studies have shown even higher rates of progression to MS (Morrisscy et al. 1993) and that total MRI lesion number and load correlated with subsequent development of MS, degree of disability, and lesion load at follow-up (FUippi et al. 1994).

Efforts continue to delineate differences in the **MRI** appearance of acute or active lesions and chronic lesions. Acute lesions tend to be larger, with somewhat ill-defined margins when acute and become smaller with sharper margins as resolution occurs. This presumably reflects resolution of edema and inflammation present at the time of acute plaque formation, leaving only residual areas of demyelination, gliosis, and enlarged extracellular space with lesion evolution. The MRI appearance of primary progressive MS shows a smaller total disease burden, a greater preponderance of small lesions, fewer gadolinium-enhancing new lesions, and acquisition of fewer lesions per unit time than the secondary progressive form of MS.

Gadolinium-diethylcnetriaminepentaacetic acid, a para-magnetic contrast agent that can cross only disrupted BBB, has been used to assess plaque activity. Gadolinium increases signal intensity on T1-weighted images. The accumulation of gadolinium in plaques is associated with new or newly active plaques and has been associated with pathologically confirmed acute inflammation in MS. Gadolinium enhancement usually persists for less than 4 weeks but may persist up to 8 weeks in acute plaques, Gadolinium enhancement diminishes or disappears after treatment with corticosteroids, a therapy thought to restore the integrity of BBB permeability.

Allied to the concept of using MRI data as outcome measures of MS therapeutic studies is the notion of following disease burden, which is the total volume of brain affected by plaques as detected on MRI scans. This can be done by measuring the surface area of all plaques and multiplying by the slice thickness. This is most

reliable for thin-slice techniques and preferably with three-dimensional acquisition. A number of studies have examined the ability to detect lesion burden changes over time and have found that it is possible to detect changes that may not be clinically apparent (Figure 60.10).

The extent of cranial MRI abnormalities (and even pathology) does not necessarily correlate with the degree of clinical disability. Patients with small numbers of lesions may be quite disabled, whereas others may function well despite a large burden of disease as detected by MRI. Several possible explanations exist for this. Lesions may occur in areas that are clinically silent; small lesions in the spinal **cord** can cause major disability. MRI may miss lesions that are clinically relevant such as those in cortex, basal ganglia, and brainstem; and large plaques detected by MRI may not have functional correlates but reflect increased tissue water without impairment of neural function.

Several studies have shown that the amount of ongoing MR] activity (new or enlarging lesions, gadolinium-enhancing lesions, or both) exceeds the observed clinical activity by a factor of 2-10. This may reflect not only the factors discussed previously, but also may partly reflect under-re porting of minor symptoms and under-rccogninon of minor signs in patients with MS. It docs, however, suggest that MS is a much more dynamic and active disease, both in progressive and relapsing MS, than is clinically apparent and that MRI is essential to studies of therapy in MS.

The utility of cranial MRI in relation to spinal myelopathies was addressed previously in the section on monosymptomatic disease. Spinal MRI is an evolving technology that can detect lesions consistent with demycliuation in some but not all patients. In part, this may be caused by technical limitations of spinal MRI, but also may reflect involvement of small tracts in a relatively small anatomical structure. Many of the pathological lesions extend vertically in the affected tract, and such lesions may be best detected by transverse imaging. Newer technology detects lesions in 75% of patients with definite MS (Kidd et al. 1993). The frequency of abnormal signals in normal individuals is only 3%, as the non-MS hyperintense T2-weightcd signal seen m older patients mi cranial MRI appears not to occur in the spinal cord.

Conventional MRI technology provides excellent images, but makes it difficult to distinguish edema of an acute plaque from gliosis and demyelination of a chronic plaque. Using phosphorus MR specttoscopy, information on phospholipid metabolism can be obtained, whereas proton MR spectroscopy can generate information about other metabolic components, such as N-acetylaspartate (NAA), an exclusively neuronal marker, creatine phosphate

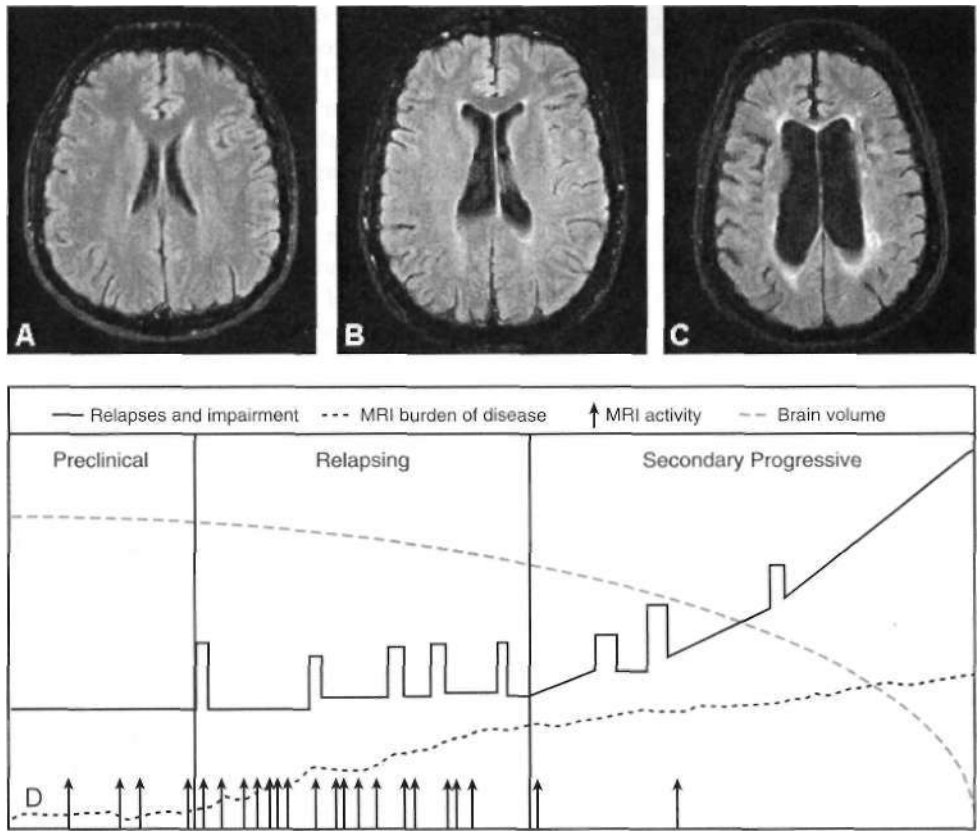

FIGURE 60.10 Changes in MRI scans with duration of disease. The first panels compare three scans from patients with different disease duration, indicating the appearance of atrophy and ventricular dilatation with time. The second panel indicates that as brain atrophy appears it is common to observe that the number of gadolinium-enhancing lesions declines.

(Cr) (energy marker), choline (membrane component), and lactic acid. Brains of patients with chronic MS have a reduced amount of NAA in comparison with choline and Cr; a reduced NAA to Cr ratio is the common means of expressing such a reduction. This reduced ratio implies loss of neurons or axons, which is consistent with pathological studies and appears to parallel disability in MS {Arnold et a I. 1994) (Figure 60.11). In acute MS lesions studied by MR spectroscopic imaging, the NAA to Cr ratio may be transiently reduced, whereas the levels of choline and lactic iicid i:i;i> lv He" ;iicd, pL.rli;'.ps retaied to myelin membrane disruption and tissue acidosis associated with acute plaque fotmation. Some investigators have found abnormal lipid peaks on MR spectroscopy, suggesting acute demyelination (Davie et al. 1994). The use of these metabolic parameters may both lead to a better understanding of the evolution of plaques in vivo and be useful as further adjunct measures of disease progression that antedates clinical disability. A number of new technological advances appear likely to enhance yet further the ability to understand the pathogenesis of the disease process.

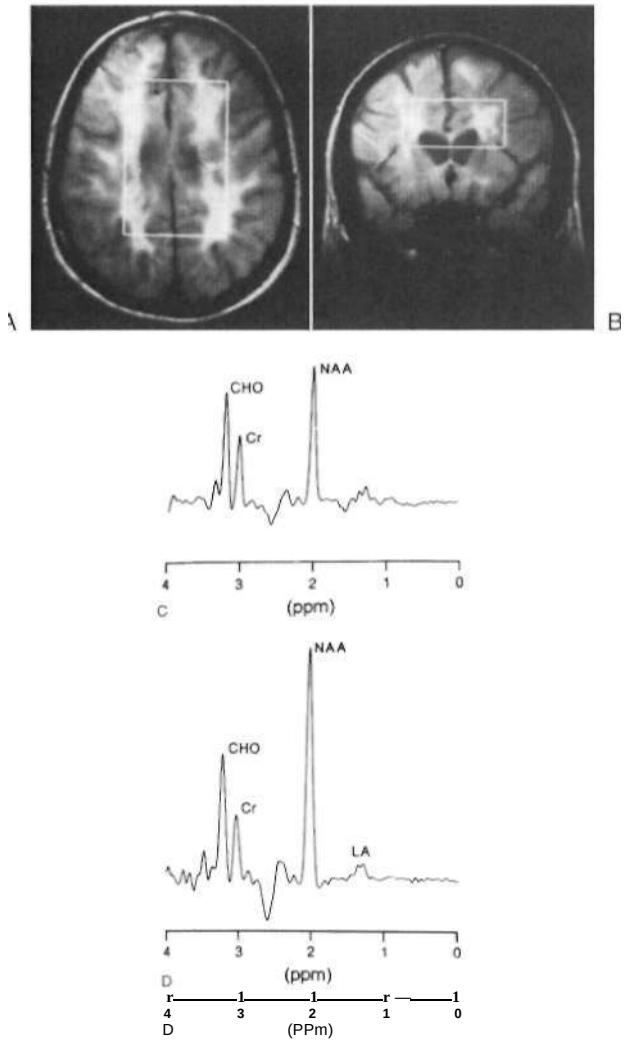

FIGURE 60.11 (A, B) Areas of confluent demyelination in a severely affected progressive multiple sclerosis patient. Outlines show volume of interest selected for spectroscopy study. (C) Spectra obtained with proton spectroscopy in this patient (I)) Spectra of normal brain. Note the reduced height of the N-acety I aspartate (NAA} peak with resultant reduction in the ratio of NAA to creatine (Cr). (CHO = choline; LA = lactic acid.)

Computed Tomography

The current utility of CT scans in the evaluation of patients with MS is largely to exclude other treatable or ominous etiologies as the cause of symptoms. Findings on CT of patients with MS include nonspecific atrophy, hypodense lesions often in a periventricular distribution, and contrast-enhancing lesions presumed to be active plaques with disruption of the BBB (see Figure 60.10).

Cerebrospinal Fluid

CSF findings alone cannot make or exclude the diagnosis of MS, but they can be useful adjuncts to clinical criteria. The CSF is grossly normal in MS, being clear, colorless, and under normal pressure. Total leukocyte count is normal in two thirds of patients, exceeding 15 cclls/uL in less than 5% of patients and only rarely exceeding 50 cells/uL (a finding that should raise suspicion of another etiology). The predominant cell type is the lymphocyte, the vast majority of which are T cells.

CSF protein (or albumin) level is normal in the majority of patients with MS. Albumin determinations are preferable because albumin is not synthesized in the CNS and thus gives a better indication of BBR disruption than does total protein, some of which may be synthesized within the CNS (i.e., immunoglobulin). Albumin levels are elevated in 20-30% of patients, although less than 1% of patients have a level twice that of normal (Table 60,8). A common finding in MS is an elevation of CSF immunoglobulin level relative to other protein components, implying intrathecal synthesis. The immunoglobulin increase is predominantly IgC, but the synthesis of IgM and IgA is increased also. The IgG shows an excess of IgGl and • light chains. The IgG level may be expressed as a percentage of total protein (normal <11%), as a percentage of albumin (normal <27%), by use of the IgG index (normal value <0.66), or by use of a formula for intra-BBB synthesis of IgG. An abnormality of CSF IgG production as measured by the IgG index or IgG synthesis rate is found in more than 90% of patients with clinically definite MS, and different formulas appear to have differing sensitivity and specificity. The sensitivity of IgG as a percentage of protein or albumin is slightly lower (see Table 60.8).

Linked to the elevation of IgG is the finding of OCRs in the cathodal region of an electrophoretic analysis of CSF. When normal CSF is electrophoresed, the cathodal region shows only a homogeneous blur of immunoglobulin. In MS and

Tabic 60.8: Cerebrospinal fluid abnormalities in multiple sclerosis

'"Other neurological diseases.

other conditions usually associated with inflammation or an immune response, electrophoretic analysis reveals a number of disctete bands distinct from the background; these bands represent excess antibody produced by one or more clones of plasma cells. In subacute sclerosing panencephalitis, the majority of these OCBs represent antibody directed against the causative agent, measles virus. However, in MS, there is no disease-specific antigen yet identified against which the majority of bands are directed. The pattern of banding remains relatively consistent in individual patients during the disease course, although bands may be added over time. Occasionally, patients with definite autopsy-proved MS do not have OCBs.

A common method for electrophoresis uses agarose gels, but a more sensitive assay is the use of isoelectric focusing on polyacrylamide gels. OCBs are found in 85-95% of patients with clinically definite MS (Table 60.9). Up to 8% of CSF samples from non-MS patients show OCBs; most are from cases of chronic CNS infections, viral syndromes, and autoimmune neuropathies. The presence of OCBs in monosymptomatic patients predicts a significantly higher rate of progression to MS than the absence of bands: 25% versus 9% at 3 years' follow-up. However, one must not assume that the presence of OCBs is equivalent to a diagnosis of MS, given the number of false-positive results that can occur and the variability in technique and interpretation in different laboratories.

The presence of myelin components and antimyelin antibodies in CSI' and other body fluids has been used to a limited extent as a measure of CNS myelin destruction and presumed demyelinating activity in the CNS (Whitaker et al. 1993).

Evoked Potentials

EPs arc the CNS electrical events generated by peripheral stimulation of a sensory organ (see Chapter 37A). The utility of EPs is the detection of a CNS abnormality of function that may be clinically undetectable. In the case of MS, detection of a subclinical lesion in a site remote from the region of clinical dysfunction supports a diagnosis of multifocal disease. The EPs also may help define the anatomical site of the lesion in tracts not easily visualized In imaging inpiu nerves, dorsal columns). The i h w niosi frequently used EPs are somatosensory (SSEP), visual (VER), and brainstem auditory-evoked responses. MRI technology has largely eliminated the utility of EPs, given the much greater anatomical information obtained and the much higher sensitivity of MRI in the diagnosis of MS (see Table 60.9).

SSEPs have abnormal results in 65-80% of patients with MS, including approximately one half of patients with MS who do not have sensory signs or symptoms. Some patients with clinical evidence of posterior column dysfunction may have normal SSEPs. Using pattern shift VERs, abnormalities are detected in over 90% of patients with a history of ON, even when visual acuity has returned to normal. Patients with clinically definite MS have abnormal VERs with a t're(|Lu-;icy <>• S.S'.',,. 11K- V ! K ıs parlieularh useful in those patients lacking clear clinical evidence of dysfunction above the level of the foramen magnum, such as those with a chronic progressive myelopathy. Ocular or retinal disorders must he excluded before attributing abnormal VERs to demyelination in the optic pathways. Brainstem auditory evoked response abnormalities are less frequent in MS than are VER or SSEP abnormalities, being present in 50-65% of patients with MS.

VARIANTS OF MULTIPLE SCLEROSIS

MS is a condition with many variable forms, but in most cases the common signs and symptoms described previously are readily apparent, and with proper laboratory confirmation the diagnosis is not difficult. However, there are several inflammatory demyelinating disotders that bear an unknown relationship to MS. They are listed here as

Tabic 60,9: Comparison of sensitivity of laboratory testing in multiple sclerosis

	VER	*BAER*	.....	*OCB*	*MRI*
Clinically definite multiple sclerosis	80-85%*	50-65%	65-80%	85-95%	90-97%

'Numbers show the percentage of patients with abnormal study results.

variants of MS, rather than as separate illnesses, because it is often found, after long follow-up, that the disease has reverted to a more standard variety of MS.

Recurrent Optic Neuropathy

There arc patients whose entire clinical illness is confined to the optic nerves. They may have sequential affection of one nerve, then the other, or they may have simultaneous bilateral vision loss, a state that is quite uncommon in classic MS. In some iriM.nuvs VI Is I <t IIK- head shows (in addition to lesions of the optic nerves) scattered intracerebral lesions, or a CSF examination shows OCBs, attesting to some degree of dissemination of the lesions. Children and prcadolescent patients are more likely than adults to have recurrent or simultaneous optic neuropathy. Rarely there is slowly progressive optic neuropathy, similar to that seen with optic nerve sheath tumors, such as meningioma. The distinction from an MS variant can be quite challenging. In bilateral ON, sarcoidosis is commonly a diagnostic consideration.

Devic's Disease (Neuromyelitis Optica)

A combination of bilateral optic neuropathy and cervical myelopathy make up this condition, which most authorities now classify as a variant of MS. Reported cases indicate that the myelopathy tends to be more severe, with less likelihood of recovery, and that the neuropathological features at autopsy are those of a much more severe necrotic lesion of the cord rather than incomplete dcmyelination. In some patients the optic neuropathy and the myelopathy occur at (In same time, in others on. or the other component is delayed. The longer the interval, the more like typical MS is the pathology. Because the optic nerve and the cervical spinal cord are two of the locations in the nervous system in which the lesions of MS are typically found, many patients could be classified as having Devic's disease, or syndrome. Little is to be gained by this nomenclature, because Devic's syndrome can be a manifestation of ADEM (see Acute Disseminated Encephalomyelitis, later in this chapter), or rarely of other autoimmune disease, such as SLE. This seems to be especially true of patients with relapsing Devic's syndrome, making up approximately one half the patients. In a few patients the distinction between an MS variant and SLE (so-called lupoid sclerosis) is essentially impossible to make, and some of these are patients with neuromyelitis optica.

Slowly Progressive Myelopathy

A syndrome of slowly progressive spinal cord dysfunction can present a major diagnostic challenge. If there are no sensory signs or symptoms, the entity known as primary lateral sclerosis, one ot the group of motor neuron diseases, may be the cause. HTLV-1 infection, vitamin B_{12} deficiency, and human immunodeficiency virus infection all can be excluded by appropriate tesring. Spinal dural arteriovenous fistula can cause a steadily or stepwise progressive myelopathy, usually in the lower spinal segments. Adrenomyeloneuropathy should be considered.

A number of patients remain do not fit into these categories, and their spinal MRI results arc repeatedly negative. VERs, CSF OCBs, and MRI of the head show no sign of demyelination elsewhere. No firm diagnosis is possible. Minor clues that MS is present may be furnished by a Lhermitte's sign that has come and gone or by undue sensitivity to elevated temperature. The degree of compression of the cervical cord by intervertebral disc disease is often an issue in the middle-aged patient, because a majority of persons have some degtee of disc disease, and following trauma there may be a T2 bright signal within the cord due to contusion. There is little doubt that some laminectomies have been carried out for cervical spondylosis where MS was the final correct diagnosis.

Progressive myelopathy caused by MS is part of the primary progressive MS group and carries the poor prognosis typical of that group. The choice of therapy is difficult. Some patients do better for a time with monthly intravenous corticosteroid therapy.

Acute Tumor-like Multiple Sclerosis (Marburg Variant)

Some patients with demyelinating disease present with a large acute lesion of one hemisphere (Figure 60.12) or rarely other locations, such as the spinal cord. Mass effect may occur, with compression of the lateral ventricle and shift across the midline. The clinical abnormalities in such patients are variable: They may be slight even in a patient with a massive lesion, whereas confusion, hemiparesis, or neglect syndrome may be seen in another patient with a lesion that appears no different. Much of the T2 bright lesion volume is often caused by edema and may be rapidly responsive to corticosteroids. {This change with corticosteroids also may occur with glioma or CNS lymphoma and is therefore not a useful diagnostic criterion.) Biopsy is often required.

In one series of 31 patients, the prognosis was good, most patients recovered well clinically, and their lesion volume rapidly cleared. In 24 of the patients the demyelinating lesion was solitary, whereas in the others one or more satellite nodules existed. Six of the patients were older than 57. In follow-up, 28 of the patients did not develop additional evidence of demyelinating activity during a period of 9 months to 12 years. Other authorities have reported a higher rate of recurrent disease, in particular a conversion to more ordinary types of MS, both clinically and by MRI scan criteria.

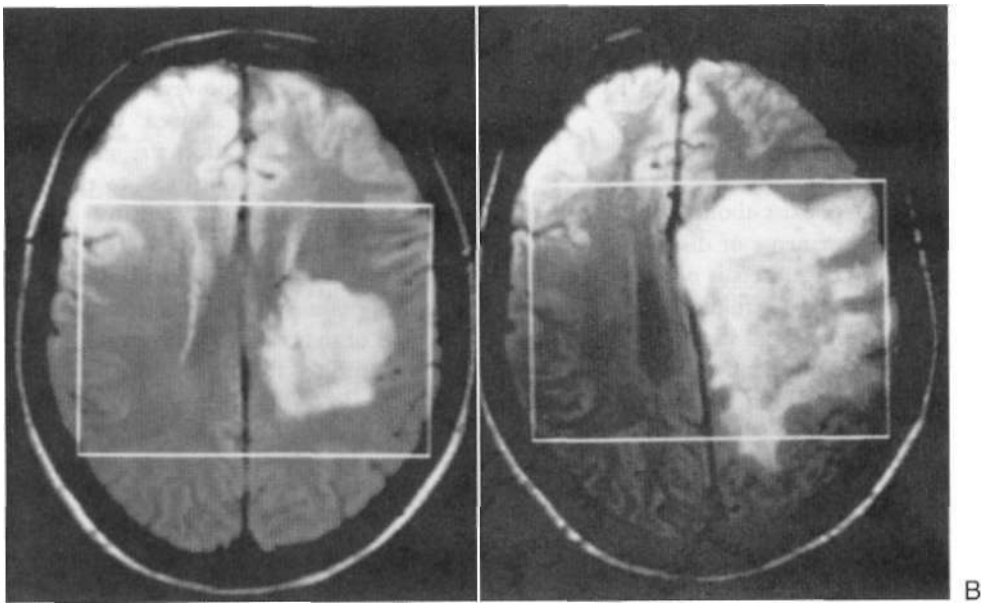

FIGURE 60.12 (A) Magnetic resonance sain showing a large white matter lesion initially without mass effect in a young woman with right hemiplegia developing over 5 days. (B) Marked increase in size of lesion with associated edema and mass effect 1 month later while on corticosteroids and at a time when clinical deficits wen- improving. Biopsy showed evidence of demyelination.

TREATMENT AND MANAGEMENT

In prior decades, treatment of this often progressive disease of young adults was judged to be ineffective, and many clinicians and patients adopted a nihilistic and pessimistic attitude. The advent of more effective symptomatic therapy, and the widely publicized U.S. Food and Drug Administration (FDA) approval of five agents capable of modifying the disease course have drastically changed that view. There remain many problems, particulatly the treatment of progressive MS, yet there arc clearly reasons for hope.

Treatment of MS should be directed toward these basic goals:

1. Relief or modification of symptoms
2. Shortening the duration or limiting the residual effects of an acute relapse
3. Preventing progression or slowing its pace
4. Supporting family and patient, alleviating social and economic effects, and advocating fot the disabled ot handicapped

Monitoring Disease Activity

Magnetic Resonance Imaging

A surrogate marker fot disease activity in MS is badly-needed. It is now clear from several of the completed interferon therapy trials that there is far more activity in MRI scans of patients than is apparent clinically. Some authors estimate a ratio of new MRI lesions to clinical events as 10 to 1 in patients with active telapsing-remitting MS. New MR! lesions may be measured by change in total T2 visible lesion load, by new or enlarging lesions, or by gadolinium enhancement. All three criteria have been used with success in one trial or another.

Several therapies are known to reduce the accumulation of MRI lesions in clinical trials; these include intetfeton-^i_a, interferon-/fit,, and mitoxantrone. Unpublished data suggest that cyclophosphamide blocks the appearance of new gadolinium-positive lesions. The MRI data have been strong indicators of clinical effectiveness in clinical trials and are clearly now a cornerstone of therapeutic investigations in MS. Nevertheless, problems exist. In the care of patients who ate not enrolled in large-scale trials, **MRI** plays only a doubtful role in monitoring the progress of treatment. Data from the National Institutes ot Health ttials of relapsing MS demonstrate that frequent scanning of an individual patient is required to obtain reliable information, possibly as often as once a month. Infrequent scans can miss lesions that have come and gone. In patients with progressive MS, the lesion load in the head MRI scans can remain unchanged while the patient steadily worsens. Often this state of affaits is caused by ptogressive spinal disease, which cannot be imaged well. A minority of patients with MS, possibly as many as 5%, have no MRI lesion characteristic of MS at all.

Advantages exist in some instances for single or relatively infrequent scans. In the eatly stages of illness, aftet a monosymptomatic relapse, many patients wish to know their risk of developing MS, which can often be defined hy MRI (see previous sections). In patients under rreatment in

whom disease activity develops and a change of therapy-is contemplated, additional evidence, for or against the change, can sometimes be derived from an MRI scan.

Immunological Data

Thus far, little relevant data exist about levels of cytokines or T-ccll subsets as measurements of disease activity. The expression of different T-cell subsets is not relevant. Levels in blood of the inflammatory cytokine 11,-12 appear to correlate \\ ith activin of relapsing MS and ma] functioE as a surrogate marker. Interferon-)', a cytokine that can itself provoke relapses in patients with MS, may decrease in blood levels when MS is treated successfully. Many investigators are in the process of measuring IL-2, TNF-D, IL-10, and other cytokines (see Chapter 46 for more details).

Clinical Examination

The eventual gold standard of success in MS treatments is the clinical condition of the patient. Every clinical trial includes these data as a primary or secondary outcome. Yet the difficulties of clinical measurement are exemplified by the number of scales and indices that are used. The problems of the EDSS were noted previously. A one-point increase or decrease in the EDSS is often taken as an endpoint; this may require special training of observers, and even rhen variability of observations occurs. The Air.bufuiun liiiKx, :i direct a^essrneiu ol walk MIL;„ is useful in most patients. MRI is increasingly considered as the primary endpoint.

Relief or Modification of Symptoms

Spasticity

Spasticity slows voluntary movement, impairs balance and gait, and may cause painful flexor or extensor spasms. Partial control is often possible, although recovery of motor power is rare.

Baclofen is a *y*- amino butyric acid agonist that can effectively relieve spasms and has modest effects in improving performance. Daily divided doses of 20-120 mg and occasionally more are used. Too large a dose may produce drowsiness or sufficient hypotonicity as to increase the degree of weakness. Intrathecal baclofen via an implanted pump can be effective against spasticity in suitable patients. The pump can be electronically regulated to deliver small doses of baclofen in pulses or a varied dose at different times over 24 hours to increase efficacy and decrease side effects. Its effectiveness has been demonstrated in several controlled trials, and the side effects are few.

Tizanidinc (Zanaflcx), a centrally active ^-noradrenergic agonist, may be used alone or in combination with baclofen because the mechanism of action is different. The medication, available in 4-mg tablets, must be gradually increased starting with 2 mg at bedtime. The side effects are similar to baclofen; however, a blind prospective trial in patients with MS showed that although it relieved spasticity, it did not affect strength.

Benzodiazepines contribute to the control of spasticity, although sedation and possible drug dependency are limiting factors.

Dantrolene sodium (Dantrium), an agent that acts within muscles on excitation-contraction coupling, is rarely used because of the risk of liver damage. If used, the medication must be titrated from 25 mg daily up to 100 mg three times a day.

4-Aminopyridinc and 3,4-diaminopyridine (3,4-DAP) are compounds that block potassium channels in the axolemma, and a double-blind trial showed improvement in motor strength. The risk of seizure and hepatitis has limited the use of these compounds.

Botulinum toxin type A (Botox) also has been shown to be effective in selective cases.

Tremor

One of the most disabling and hard to treat symptoms in MS is tremor. Appendicular tremors are usually seen in action or intention and may limit activities of daily living.

Weighted wrist bracelets and specially adapted utensils are a nonpharmaccutical option.

lsoniazid, 800-1200 mg per day, with pyridoxine, 100 mg per day, may have marginal success.

Anticonvulsants also have been reported to be helpful with tremor. Primidone (Mysoline), 125-250 mg two to three times per day, is recommended. Dizziness, somnolence, and nausea are the primary side effects. Carbamazepinc (Tegretol) in divided doses up to 800 nig per day has been used also. Gabapentin (Neurontin) in daily divided doses up to 3600 mg has shown some benefit.

Clonazepam (Klonopin), 0.5-2.0 mg one to four times daily, is effective. However the side effects, including ataxia, behavioral changes, confusion, and respiratory depression, must be kept in mind when treating patients.

Propranolol (Inderal), 20-40 mg two to three times daily, is another option. Caution must be taken in patients with concomitant cardiac, circulatory, or respiratory disorders.

Ondansetron (Zofran), 4-8 mg once or twice daily, has been reported effective in case studies of patients with MS. Side effects include diarrhea, headache, and elevated liver enzymes.

Surgical thalamotomy or deep brain stimulation may be used in patients with refractory disease.

Fatigue

Fatigue is seen in as many as 78% of patients and interferes with daily activities. Fatigue must be separated from

depression, medication side effects, or physical exhaustion from gait alterations.

Amantadine (Symmetrel), 100 mg twice a day, has relatively few side effects and is well tolerated by most patients. Caution must be taken in patients with renal insufficiency or seizure disorders. Studies have found an efficacy rate of 40%.

Modafinil (Provigil) is a wake fulness-promoting agent that is chemically and pharmacologically distinct from CNS stimulants, although the precise mechanism of action is unknown. Modafinil was recently approved for use in narcolepsy. There are open-labeled studies showing that Modafinil is effective for fatigue in MS patients. Oral dosage srarts at 200 mg in the morning and can be increased to 400 mg.

Pemoline (Cylcrt) is an alternative medication if no response to amantadine is seen. The starting dose is 18.75 mg twice daily and can be increased to a maximum of six tablets per day. The risk of hepatic failure is an obstacle to using this drug as first-line therapy. Some patients also may respond to methylphenidate (Ritalin), 10-60 mg per day in two to three divided doses.

Selective serotonin reuptake inhibitors, in addition to treating the depressive symptoms associared with MS, have been used to treat fatigue. Fluoxetine (Prozac), 10-20 mg once or twice daily, has a side effect profile including nausea, headache, extrapyramidal effects, hypotension, and mania. There is now a once weekly oral dosage of fluoxetine available.

Bladder Dysfunction

Symptomatic bladder dysfunction can be identified at some time during the course of MS in 50-80% of patients. The severity of bladder symptoms is unrelated to the duration of the disease but parallels the severity of othet neurological symptoms. Differentiating between bladder spasticity and hypotonia is important before initiating therapy because different medications are employed for each condition. Common disorders such as urinary tract infections, prostate and bladder cancer, and benign prostatic hypertrophy may mimic symptoms of neurological dysfunction and should be excluded.

Initial steps in managing bladder dysfunction include fluid management, timed voiding, and bedside commode.

Oxybutynin (Ditropan) is a first-line medication for l:vpi.T ivlli'\ii bladder without outlet obstruction. Dosage ranges from 2.5-5.0 mg one to three times daily. An extended release formulation is now available. General precautions and side-effect profiles of the anticholinergics must be observed.

Propantheline (Pro-Banthine), 15 mg three to four times per day, is another anticholinergic option for bypcr-reflcxic bladders without outlet obstruction.

Imipramine (Tofranil), a tricyclic antidepressant, 50-300 mg in divided daily doses, is also helpful, especially with enuresis. Side effects are similar to the anticholinergics. This medication has the dual effect of treating concomitant depression.

Desmopressin is also effective with hyper-re flex ic bladder without outlet obstruction. Doses of 20-40 ug daily are suggested. Adverse effects include nausea, flushing, and headache.

Toltcrodine (Detrol) is a muscarinic receptor antagonist with fewer side effects than anticholinergic medications. This medicine, given at 2 mg twice daily, was shown to reduce bladder frequency and urgency as well as urge incontinence. A long-acting formulation is now available.

Detrusor hypcr-reflexia with outlet obstruction may respond to Crede's maneuvers, antispasticity medications, or anticholinergics in combination with alpha-sympathetic blocking agents such as terazosin hydrochloride (Hytrin). The maintenance dose is 2-10 mg daily. Adverse effects include tachycardia, dizziness, syncope, headache, and asthenia.

Detrusor areflexia may respond to Crede's maneuvers, alpha-sympathetic blocking agents, or bethanecbo! chloride (Urecholine). The usual dose is 10-50 mg three to four times a day with a side-effect profile including diarrhea, excessive lacrimation, and flushing of the skin. This medication is also contra indicated in many common medical conditions.

Catheterization may be employed if the previously mentioned measures are ineffective; however, the long-term effects of catheterization must be considered. Squamous metaplasia of the bladder was significantly greater in patients who had been catheterized for more than 10 years (80%) in comparison with those catheterized for less than 10 years (42%) and those without catheters (20%).

Surgical correction, such as augmentation of bladder capacity with an exteriorized loop of bowel, for appropriate **patients** is **another** alternative.

Depression

Prevalence rates for depression in patients with MS range from 14-57% as compared with 1.3-3.7% in the general population. The lite time prevalence of depression in a group of patients with chronic medical disorders was 12.9%. The nature of a chronic debilitating neurological disorder contributes to depressive symptoms and coping problems. Patients taking multiple medications arc prone to depression, and the side-effect profile of the interferon-/) medications includes depression.

Selective serotonin reuptake inhibitors are the medication of choice for depressive symptoms in patients with MS. In addition to the previously mentioned fluoxetine, any of the other medications in this class may be used.

Amitriptyline (Elavil), 25-100 mg daily (or other tricyclic antidepressants in equivalent dosage), is a second-line

choice because of anticholinergic side effects. However, anticholinergic properties may be helpful to patients with symptoms of bladder spasticity or chronic pain, thus avoiding polypharmacy.

Sexual Dysfunction

Studies suggest that 45-74% of women with MS experience sexual dysfunction. These symptoms have been associated with depression, bowel dysfunction, fatigue, spasticity, and pelvic floor weakness. There was no association between duration of disease, type of disease, recent exacerbations, or disability scores. Erectile dysfunction in men is common, especially in patients with spinal cord involvement. Symptoms also may be caused by medications or psvchnio;;ie;i] issues.

Sildenafil (Viagra) has supplanted traditional approaches to erectile dysfunction in men, which used to include intracavernous papaverine, prostaglandin E, phentolamine, vacuum devices, and penile prostheses. Doses of 25-100 mg 1 hour before sexual intercourse arc used with minimal side effects, which include headache, flushing, dyspepsia, and musculoskeletal pain. Reports suggest caution in patients with cardiovascular disease. Sildenafil is probably also effective in women.

Cognitive Impairment

Problems with cognition are increasingly being recognized as an important deficit affecting patients with MS. Studies have found a correlation between dementia and lesion burden on MR1 as well as atrophy of the corpus callosum. In a study of patients with chronic progressive MS who underwent MRI scans and a neuropsychological screening battery, those who were impaired according to the neuropsychological screening battery had significantly more cerebral lesions than those who were judged unimpaired. Treatment of cognitive deficits consists of support, improvement of coping strategies, and treatment of depression.

Paroxysmal Symptoms

A variety of paroxysmal symptoms consist of brief, almost stereotypical, events occurring frequently and often triggered by movement or sensory stimuli. They are likely caused by ephaptic transmission of nerve impulses at sites ot previous dise.ise activity. These symptoms include, but are not limited to, trigeminal neuralgia, pain, paresthesia, weakness, tonic seizures, dysarthria and ataxia, pruritus, diplopia, akinesia, and hemifacial spasm and dystonia.

Anticonvulsants, especially carbamazepine and valproate (Depakote], have been used in their usual doses with some benefit. Newer anticonvulsants, such as gabapentin, have been used in small case studies.

Benzodiazepines also have been effective in some patients.

Baclofen, acetazolamide (Diamox), ibuprofen, and bromocriptine are cited as potentially beneficial with these paroxysmal symptoms.

Treatment Strategies

For some patients MS is a disease with one or two acute neurological episodes with no further evidence of disease activity. In others it is a chronic, relapsing, or progressive-disease with an unpredictable clinical course that generally spans 10-20 years, during which time neurological disability accumulates. Treatment of MS, as with diseases in other branches of medicine, has come to rely on prospective clinical trials. Most such trials have been designed to establish efficacy but do not last longer than 2 or 3 years and give only hints about long-term results of treatment. Patients may differ markedly from those who have been treated in clinical trials, yet therapeutic decisions must be made. Table 60.10 outlines the treatment paradigm used at our institutions.

Class I—Prospective, randomized, controlled clinical trial with masked outcome assessment and requires the following:
Primary outcomes are clearly defined.
Inclusion/exclusion criteria are clearly defined.
Adequate accounting of dropouts and crossovers wirh numbers sufficiently low to have minimal potential for bias.
Relevant baseline characteristics are presented and substantially equivalent between groups or there is appropriate statistical adjustment.
Class II—Prospective matched group cohort study with masked outcome assessment that meets a-d or a randomized controlled trial that lacks one criteria a-d.
Class III—A11 other controlled trials where outcome assessment is independent of patient treatment.
Class IV—Evidence from uncontrolled studies, case series, case reports, or expert opinion.

Treatment of Acute Attacks

Acute attacks are typically treated with corticosteroids. Indications for treatment of a relapse include functionally disabling symptoms with objective evidence of neurological impairment such as loss of vision and motor, cerebellar, or both kinds of symptoms. Thus mild sensory attacks arc typically not treated. In the past, adrenocorticotropic hormone and oral prednisone were primarily used. More recently, treatment with short courses of intravenous methylprednisolone, 500-1000 mg daily for 3-7 days, with or without a shorr prednisone taper is commonly used. ON may occur anytime during the course of MS or be one of

Tabic 60.10: Multiple sclerosis treatment strategies

Disease course/stage	*Treatment options*	*Evidence*
Monosymptomatic (e.g., optic neuritis)—Acute attack	IV methylprednisoione, 1000 mg for .5 days, without oral taper	Class I evidence
Rciapsing-remitting, no disease activity for so , T.I I VIM:-,. a ml/or no activitj on MR]	IV corticosteroids if acute attack occurs	Class I evidence
Relapsing-remitting, current disease at tl\ llv :llki (PI .Kill llv •••• \1U!	IV corticosteroids for acute attacks, plus for prevention (1) interferon iS-lb (Avonex), 30 pg 1M weekly; or (2) interferon *p-lb* (Betaseron), 1 ml SC qod; or (3) interferon /?-1a (Rebif), 22 or 44 micrograms SC three times/week; or (4) glatiramer acetate (Copaxone), 20 ug SC daily	Class I evidence for Avonex, Betaseron Rebif and Copaxone, All four are FDA approved
Relapsing-remitting, disease activity while on interferon or Copaxone	Add monthly bolus of IV methylprednisoione OR oral immunosuppressants	Class I and 11 evidence
Relapsing-remitting, accumulating disability (interferoii/Copaxoric/corticostcroid nonresponders)	IV monthly cyclophosphamide and pulse therapy OR IV mitoxantrone (Novantrone)	Class I evidence for Novantrone, which is FDA approved
Rapidly progressing disability	IV cyclophosphamide and corticosteroid 8-day induction, followed by pulse maintenance	Class III evidence
Very rapidly progressing disabiliry	Plasma exchange	Empiric
Secondary progressive	IV corticosteroid monthly pulses	Empiric
	IV cyclophosphamide/corticosteroid monthly pulses	Class 111 e\ ideuce
	Methotrexate, oral or SC, 7.5-20 mg/wk, with or without monthly corticosteroid pulses	Class I evidence
Primary progressive	IV corticosteroid monthly pulses	I'.nipiric
	Methotrexate, oral or SC, 7.520 mg/wk, with or without monthly corticosteroid pulses	]:.m pi vie
	Clcidribine, IV or SC	F.mpiric
	Consider mitoxantrone	Empiric

the initial symptoms. A randomized therapeutic trial in ON demonstrated that patients treated with oral prednisone alone were more likely to suffer recurrent episodes of ON as compared with those treated with intravenous methylprednisoione followed by oral prednisone (Beck et at. 1993). Furthermore, definite MS developed in 7.5% of the intravenous methylprednisoione group, 14.7% of the oral prednisone group, and 16.7% of the placebo group over a 2-year period (Beck et al. 1993). Five-year data from the same study showed that CDMS developed in 16% of patients with no MRI lesions at baseline and 51% in patients with 3 or more MRI lesions at baseline. Development of disability, even when the diagnosis of MS had been made, was very rare, reemphasizing the need for follow-up periods of decades and the benign nature of MS presenting with ON. These data support the use of high-dose intravenous methylprednisoione for acute MS attacks. High-dose intravenous methylprednisoione appears to be accompanied by relatively few side effects in most patients, although mental changes, unmasking of infections, gastric disturbance'., and an increased incidence of fractures have been reported. Baseline and yearly bone density scans are recommended for patients undergoing repeated courses of corticosteroid therapy. Anaphylactoid reactions and arrhythmias are rare, but may also occur. The immunological mechanisms of high-dose corticosteroids include reduction ot CI)4" cells, decrease in cytokine release from lymphocytes and cytokines including TNF, inter feron-y, and decreased class II expression (Kupersmith 1994). Corticosteroids have been shown to decrease IgG synthesis in the CNS and reduce CSF antibodies to MBP and OCBs. Intravenous methylprednisoione may decrease the entry of cells into the brain and may affect cytokine patterns also.

Two other trials have focused on oral corticosteroid use. A double-blind, ptacebo-controlled trial of oral methylprednisoione use in acute attacks involving 51 patients followed over *8* weeks showed a statistically significant beneficial effect of oral corticosteroids. Patients received a total of 3676 mg of oral methylprednisoione over 15 days with no serious adverse events. A second randomized trial of 80 patients evaluated oral versus intravenous methylprednisoione in acute relapses. The results showed no statistical difference between the treatment groups.

Disease-Modifying Treatments

The first meditation approved by the FDA for use in MS was recombinant interferon /t-lb (Betaseron), which has been shown in a double blind, placebo-controlled trial of 372 patients to decrease the frequency of relapses by 34% after 2 years in relapsing-remitting patients receiving 8 mlU every other day (IFNB MS Study Group 1993). In treated patients, the MRI T2 lesion burden went up only 3.6% over 5 years, compared with 30.2% in the placebo group (Paty ct al. 1993). No significant change in disease progression was seen over 5 years. Bclasm>n is administered every other day under the skin by self-injection. Side effects include influenza-like symptoms, depression, and reaaions at the injection site, but these tend to diminish with time. Elevated liver enzymes, leukopenia, and anemia were seen, and blood monitoring is suggested every 3 months. Also 34% of patients developed neutralizing antibodies that may reduce the clinical efficacy of the drug. The mechanism of action of interferon ,8-1 b is currently unknown.

A second double-blind, placebo-controlled study in 301 patients with relapsing-remitting disease investigated the efficacy of weekly intramuscular injections of 6 million U (30 ug) of interferon /J-la (Avonex), a glycosylated recombinant interferon-/* (Jacobs et al. 1996). Over 2 years the annual exacerbation rate decreased 29%. After 2 years the MRI data revealed a lesion volume of 122.4 (mean) in the placebo group compared with 74.1 (mean) in the Avonex group. The number of enhancing lesions on MRI over 2 years was 1.65 (mean) in the placebo group and 0.80 (mean) in the Avonex group. The proportion of patients progressing by the end of 104 weeks of the trial was 34.9% in the placebo group and 21.9% in the Avonex group representing a 37% reduction. Adverse events included mild influenza-like symptoms and mild anemia. No skin reactions occurred. Laboratory monitoring is suggested, but not mandatory because no serious liver toxicities occurred. Also, 22% of patients on treatment developed neutralizing antibodies.

Glatiramer acetatc/copolymer 1 (Copaxone) is a daily subcutaneous injectable synthetic polymer. In a large double-blind trial in relapsing-remitting MS involving 251 randomized patients (Johnson et al. 1998), the patients receiving Copaxone bad a 29% reduction in the relapse rate over 2 years. Extension data shows that over 140 weeks 41% of patients receiving placebos experienced worsening of their disability by greater than or equal to 1.5 HDSS steps, whereas only 21.6% of Copaxone-treated patients had worsening (Johnson et al. 1998). Side effects included local injection site reactions and transient systemic postinjection reactions including chest pain, flushing, dyspnea, palpitations, and anxiety. No laboratory monitoring is necessary. No neutralizing antibodies were detected in the study. The mechanism by which copolymer 1 may work in humans is unknown.

A randomized, double-blind, placebo-controlled study of interferon *fi-&* in higher doses was conducted in Europe (European Study Group 1998). This involved 560 patients with relapsing-remitting disease given subcutaneous interferon *fi-a* (Rebif). Patients were randomized to placebo, 22 pg, or 44 ug of Rebif three times a week for 2 years. There was a 27% reduction in the relapse rate in the group receiving 66 ug per week and a 33% reduction in the group receiving 132 ug per week. The MRI lesion burden showed a decrease of 1.2% in the group receiving 66 pg per week, a decrease of 3.8% in the group receiving 132 ug per week, and an increase of 10.9% in the group receiving a placebo. The side-effect profile was similar to the other interferons. Of note, 23.8% of the group receiving 66 pg per week and 12.5% of the group receiving 132 pg per week were positive for neutralizing antibodies. Rased on this data and a recent comparison trial of Avonex versus Rebif (EVIDENCE), Rebif was approved by rhe FDA in March 2002.

Both the EVIDENCE trial and a trial in Europe comparing high- and low-dose interferon (INCOMIN) were short-term trials and do not address the important question of which of these agents, if any, truly suppress the development of long-term disability. It docs appear that there is a detectable dose-response in the use of beta interferons.

Another factor to consider is that all four medications (Betaseron, Avonex, Copaxone, Rebif) are contraindicated in pregnancy. With al! three agents, when pregnancy occurs, treatment should be discontinued, and if relapses occur during pregnancy they are treated with intravenous corticosteroids. In addition, the safety of symptomatic medications for pregnancy must be kept in mind when managing these patients (see Table 60.6).

Much controversy has arisen since the introduction of the four approved medications for RR-MS. Analysis and comparison of these trials has been difficult because each trial used slightly different statistical, clinical, laboratory, and MRI measures. No direct comparison can be made because in each of the pivotal trials the drug was tested only against placebo. The neutralizing antibody issue is another point of contention. Current consensus does not recommend the routine testing of neutralizing antibody and does not recommend switching between interferons if neutralizing antibodies are in the high titer range.

As a general rule, all patients with relapsing forms of MS should be receiving one ol the immunonujJulamry agents indefinitely.

Treatment of Progressive Disease

Treatment directed at the progressive phase is the most difficult because the disease may be harder to affect once the progressive stage has been initiated. Immunosuppressive agents such as total lymphoid radiation, cyclosporinc, methotrexate, 2-chlorodeoxyadenosinc, cyclophosphamide

(Cytoxan), mitoxantrone, and azathioprine have shown some positive clinical effects in progressive disease. All of these nonspecific immunosuppressive agents suffer from the same basic defect: They may temporarily halt a rapidly progressive downhill course, but it is difficult, or dangerous, to employ them for more than a few months. MS is an illness of decades, not months. Therefore nonspecific immunosuppression often is a temporary solution, even if effective.

Total lymphoid irradiation has potent immunosuppressive effects, and a double-blind study of lymphoid irradiation reported benefit in patients with progressive MS. The ahsolute lymphocyte count appeared to be an indicator of therapeutic efficacy, with greater efficacy in patients with lower counts. Many patients began progressing again after initial therapy, and a major limitation of the use of total lymphoid radiation is that it may preclude the use of other treatments that affect the immune system at a subsequent time.

Large multicenter trials of cyclosporine indicate that cyclosporine has a beneficial, albeit modest, effect in ameliorating clinical disease progression, but it has not found clinical use because of the narrow benefit-to-risk ratio.

Weekly low-dose oral methotrexate (7.5 mg) was studied in a randomized, double-blind, placebo-controlled trial in 60 patients with chronic progressive disease and has been reported to positively affect measures of upper extremity function in progressive MS. Lower extremity function was not affected (Goodkin et al. *1995).*

Cyclophosphamide (Cytoxan) has been in use for treatment of patients with MS, despite conflicting data, since the early 1980s. When used, the drug is now given in monthly bolus injections and maintained over a year or more, usually with intravenous cotticostcroids. Effects often can be observed in patients younger than age 40 and especially in those who have been in the progressive phase for less than a year. The drug appears to be ineffective for primary progressive MS. Duration of treatment is limited by the risk of bladder cancer, which appears to increase with time and may depend on total accumulated drug dose.

A trial of mitoxantrone in 42 patients with active MS was published (Edan et al. 1997), in which patients were treated monthly with cither intravenous mcthytprednisolone plus intravenous mitoxantrone or intravenous methylprcdnisolone alone over 6 months. Although the numbers were small, a statistically significant reduction occurred in the number of relapses and an increase in the number of patients tree of attack. Also, 90% of the group receiving intravenous methyl prednisolone/intra venous mitoxantrone showed no new enhancing lesions on MRI versus only 31% in the group receiving intravenous methylprcduisolone. The risk of cardiotoxicity prevents prolonged usage.

Azathioprine has been studied in both relapsing-remitting and chronic progressive MS since 1971. A metaanalysis of the results of five double-blind and two single-blind, randomized, controlled trials of azathioprine use in MS showed only a small difference in favor of azathioprine after 2 years.

Interferon *fl-b* was studied in patients with secondary progressive MS in 32 centers in Europe. In this study 358 patients received placebo and 360 patients received interferon *fi-b* every other day subcutaneously for up to 3 years (European Study Group 1998). In the group receiving interferon *fi-b* a relative reduction of 21.7% occurred in the proportion of patients with progression. The rime to becoming wheelchair-bound was also significantly delayed, equivalent to 12 months *(p* < 0.01). The mean relapse rate was reduced overall by approximately 30% in the treatment group. In terms of MRI lesion volume, the group receiving placebo showed a mean increase of 8% compared with the group receiving interferon *fi-b,* which showed a mean decrease ot 5%. This study has major implications for the treatment of the largest single category of MS, and the effects on the cost of medical care and the search for other treatments arc obvious.

Monthly bolus intravenous corticosteroids, typically 1000 mg of methylprednisolone, arc used at many institutions for treatment of primary or secondary progressive MS. This use remains empiric because no relevant studies have been reported.

Immune globulin may help a number of autoimmune diseases and has been tried in MS. A randomized, placebo-controlled trial of monthly intravenous immunoglobulin in relapsing-remitting MS involved 150 patients over 2 years (Fazekas et al. 1997). In the group receiving placebo there were 11 6 relapses compared with 62 in the group receiving intravenous immunoglobulin, and 36% of the group receiving placebo were relapse-free compared with 53% of the group receiving intravenous immunoglobulin, with a significant *p* value of 0.03.

Other therapeutic strategies that are in [he process of trial are antibodies against inregrin, which block entry of immune cells into the CNS, antibodies against 11-2 receptor, T-cell vaccination, and other interferons. Accepting the limitations of monothetapy with the interferons or glatiramet, many investigators are attempting combinations with other agents, such as corticosteroids or chemotherapeutic drugs.

ACUTE DISSEMINATED ENCEPHALOMYELITIS (ADEM)

History

ADEM is a monophasic demyelinating syndrome that occurs in association with an immunization or vaccination (postvaccination encephalomyelitis) or systemic viral infection (parainfectious encephalomyelitis). It is characterized pathologically by perivascular inflammation, edema, and demyelination within the CNS and clinically by rapid development of focal or multifocal neurological

Table 60.11: Acute disseminated encephalomyelitis and related disui di'i's

Post vaccination: rabies, influenza?
Postinfectious: measles

dysfunction. The most precise clinical and pathological observations regarding ADEM are derived from case studies in which there has been a close link between the specific virus infection or vaccine and the syndrome. The syndromes arising after acute measles infection or rabies vaccine administration can be considered the prototypes of the illness. When cases with the clinical features of the syndrome occur with viral infections or vaccine administration linked by weak epidemiological data, problems arise (Table 60.11).

Postvaccination Acute Disseminated Encephalomyelitis

The occurrence of neuroparalytic accidents as a consequence of the Pasteur rabies vaccine prepared from spinal cords of rabbits inoculated with fixed rabies virus was recorded soon after introduction of the treatment. Similar neurological complications were observed as a consequence of the Jenner vaccine used for the prevention of smallpox.

The concern regarding the presence of neural tissue in vaccines as the majot factor in predisposing to neuroparalytic accidents has led to attempts to develop vaccines devoid of CNS tissue in the case of rabies and to the discontinuation of routine smallpox vaccination because the natural disease has been eradicated. The incidence of encephalomyelitis associated with the original Pasteur rabies vaccine prepared in rabbit brain has been estimated at 1 per 3000-35,000 vaccinations. An incidence rate of 1 per 25,000 vaccinations occurred with duck embryo rabies vaccine, a preparation containing minimal amounts of neural tissue; many of the complications with this vaccine involved the PNS. Introduction of the non-neural, human diploid cell vaccine has virtually eliminated neuroparalytic complications of rabies vaccinations.

Reports have associated ADEM with other vaccines, including pertussis, rubella, diphtheria, and measles. The association of influenza vaccination, particularly the swine influenza vaccine, with ADEM has been the subject of medicolegal conti nvei s\ . In i..i, (, Al 'I'M is not known in In-associated with any vaccine currently used in the United States, and the administration of influenza vaccine to people with MS does not induce relapse. ADEM developing after drug administration has been reported with sulfonamides and para-aminosalicylic acid/streptomycin. The aforementioned associations can only be substantiated by strong epidemiological evidence or by the development of a pathognomonic laboratory finding for ADEM, neither of which yet exists.

Measles-induced Acute Disseminated Encephalomyelitis

Descriptions of cerebral and cerebellar abnormalities after measles appeared in the mid- to late nineteenth century. By 1928, Ford summarized more than 100 cases and delineated subgroups of cases including those with diffuse cerebral features, focal ot multifocal cerebral findings, cerebellar dysfunction, and spinal cord abnormalities. The overall experience suggests that neurological sequelae complicate 1 in 400 to 1 in 1000 cases of measles infection, and that patients do not develop peripheral nerve damage, nor do relapses occur. The introduction of measles vaccination has greatly reduced the incidence of measles and its neurological complications, but the disease continues to occur in large epidemics in specific geographic areas with at-risk populations.

Idiopathic Acute Disseminated Encephalomyelitis

Cases of acute encephalomyelitis occurring in the setting of nonspecific viral illness arc difficult to diagnose with certainty and to distinguish from episodes of MS. Cases occurring in children at an age too young to overlap with MS are perhaps the most readily delineated. Features deemed characteristic of ADEM include simultaneous bilateral ON, loss of consciousness, meningismus, loss of deep tendon reflexes and retained abdominal reflexes in the presence of Babinski's reflexes, central body temperature of greater than 100"F, and severe shooting limb pains, Recovery from ADEM is more rapid compared with MS (days versus weeks) and usually more complete. Tentative associations with ADEM have been made with a wide array of viral and bacterial infections: rubella, mumps, herpes zoster, herpes simplex, influenza, Epstein-Barr virus, coxsackievirus, *Borrelia burgdorferi. Mycoplasma,* and *Leptospira.*

IAtvpl III children, an ia'i.il .ruck •I MS is ruin hundreds of times nunc common than is ADEM.

The hallmark clinical feature of the disorder is the development of a focal or multifocal neurological disorder following exposure to virus or receipt of vaccine. In some, but not all, cases, a prodromal phase of several days of fever, malaise, and myalgias occurs. The onset of the CNS disorder is usually rapid (abrupt or up to several hours), with peak dysfunction within several days. Initial features include encephalopathy ranging from lethargy to coma, seizures, and focal and multifocal signs reflecting cerebral (hemiparesis), brainstem (cranial nerve palsies), and spinal cord (paraparesis) involvement. Other reported findings include movement disorders and ataxia. Each of these findings may occur as an isolated feature or in various combinations.

Recovery can begin within days, with complete resolution noted on occasion within a few days, but more often over the course of weeks or months. The mortality varies between 10% and 30%, with complete recovery in 50%. Poor prognosis is correlated with severity and abruptness of onset of the clinical syndrome. In the postrabies vaccine case series, a mortality of 18% was recorded. At a mean follow up of 17 months, 68% "1 survivors were complexly recovered, and 32% were partially recovered, most with minimal deficits. In three patients in the series, a relapse of neurological deficits occurred during the recovery period. No patients were recorded as having relapses after complete recovery had occurred.

Measles virus-associated ADEM may carry a worse prognosis than vaccine-associated disease. In earlier series, the occurrence of acute hemiplegia, which was intetprctcd as vascular occlusion and akin to the syndrome of acute hemiplegia of childhood, carried a particularly unfavorable prognosis with respect to recovery. Relapses are rare.

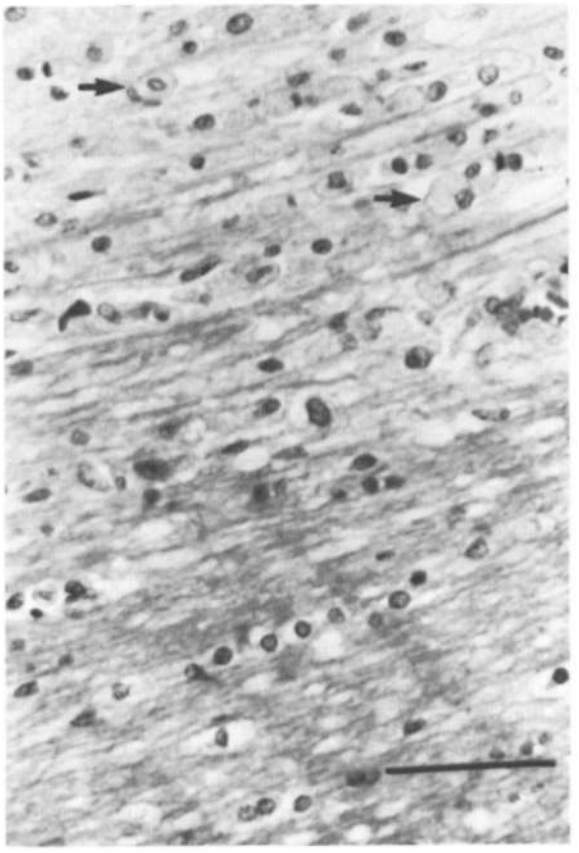

FIGURE 60.13 Lesion of acute disseminated encephalomyelitis showing dcmyelination and macrophage infiltration *{arrows)* (hematoxylin and eosin; bar = 50 |im). (Courtesy Dr. S. Carpenter.)

Laboratory Features

The hallmark lesions of ADEM are perivascular inflammation and surrounding demyclination within the CNS (Figures 60,13 and 60.14). Vessel necrosis is frequently observed. The demyclinating aspect may be minimal or widespread, with coalescence of the multiple lesions. Some meningeal reaction may be apparent also. Reports of MRI studies, largely from apparent sporadic cases of ADEM, describe multifocal CNS lesions initially indistinguishable from those observed in MS. In ADEM, after several weeks lesions show at least partial resolution without the appearance of new lesions; this is unlike MS. In some cases lesions ean [HTSIM, MKI in ADF.M. .is with MS, is more sensitive than CT scanning, which may in some cases show enhancing lesions. The usual CSF formula is normal pressure, little or no increase in cell count (<100 cells/uL) and a modest increase in protein. Well-documented cases exist with totally normal CSF. Cases with high cell counts, including some polymorphonuclear cells and high protein values, occur and seemingly reflect a more necrotizing disease process. The high counts usually return to normal within a few days. The CSF immunoglobulin content is not usually increased, and **OCB** patterns ate not usually observed. In many patients with postrabies vaccination and postmeasles ADEM, one can show some systemic blood lymphocyte sensitivity to MBP in vitro. Although technically difficult to assess, CSF lymphocyte sensitivity to MBP may be even more marked than is systemic lymphocyte sensitivity. The occurrence of cases without MBP sensitivity indicates that this assay is insufficiently sensitive to establish or exclude the diagnosis of ADEM.

The diagnosis ol ADEM can usually be made with confidence ;n tlu setting of .1 clear-cul antccedenl evcnl sttongly associated with the disorder, such as measles infection or vaccination. The occurrence of an acute focal or multifocal CNS syndrome subsequent to a more nonspecific viral illness or vaccination in which the epidemiological link with ADEM is weak does create a wider differential diagnosis, particularly depending on the age of the patient and the clinical manifestations of the disease. The following would be included in this differential diagnosis: (1) an initial episode of what will prove to be MS; the presence of increased levels of IgG in the CSF may favor the diagnosis of MS; follow-up MRI may be needed, because initial MR]

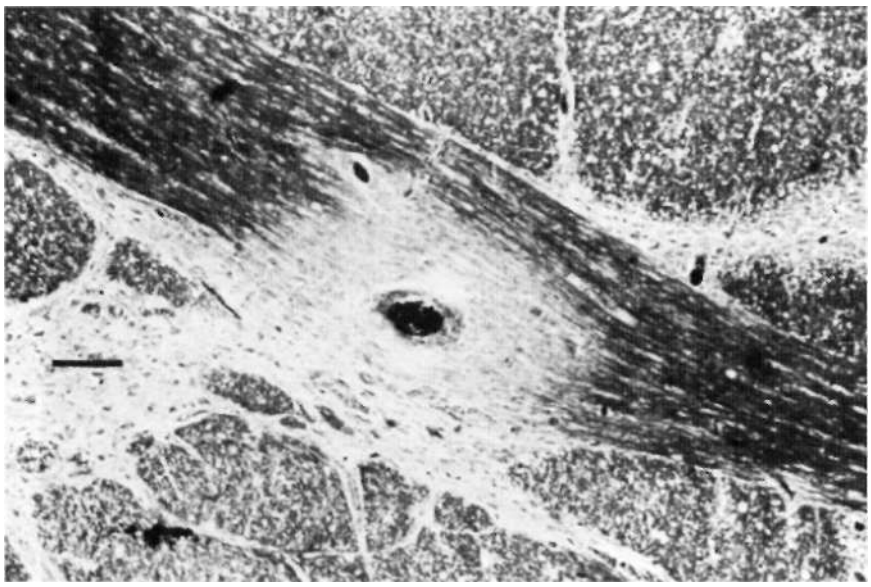

FIGURE 60.14 Penvenular zone of (linui'liii.iriou in brainstem of patient with acute disseminated encephalomyelitis (Heidcnhain Woclkc stain; bar — I 00 p i).

scans may appear similar in the two diseases; the occurrence of a nonspecific viral illness before the onset of the clinical neurological syndrome does noi di->ungmsh between MS and ADEM, because the incidence of exacerbations of MS is increased following such infections; (2) CNS vasculitis with or without systemic features {such as disseminated intravascular coagulation or serum sickness); (3) multiple cerebral infarcts, particularly embolic from infected cardiac valves; and (4) chronic meningitis or granulomatous disease (sarcoidosis). If the main clinical feature is unifocal, encephalitis, abscess, or rumor needs to be excluded.

Treatment

The current favored therapy for ADF.M is corticosteroids, based to some extent on their efficacy in EAE, although no clinical controlled studies have been conducted. Immunosuppressants such as cyclophosphamide have been used in refractory cases, as well as plasmapheresis. Data on the various other immunotherapies described in the section on MS are lacking.

OTHER INFLAMMATORY DEMYELINATING DISEASES OF THE CENTRAL NERVOUS SYSTEM

Acute Hemorrhagic Leukoencephalitis

Acute hemorrhagic leukoencephalitis is a rare entity that represents a hypetacute form of ADEM, in a parallel fashion to the hyperacute forms of EAE. The most frequent antecedent history is that of an upper respiratory infection. Given the nonspecific nature of the antecedent event and the lack of a specific diagnostic clinical laboratory rest, the exact incidence and lull clinical spectrum ot the disorder can only be estimated and are based largely on descriptions of autopsy-proved cases. The clinical manifestations mimic ADEM, but arc more abrupt in their development and more severe. They include focal or multifocal signs, seizures, and obtundation. Relapse following initial recovery has been described. Fever is common. The CSF usually demonstrates increased pressure, protein, and both white and red cells. The peripheral white blood cell count also is usually increased. CT scans in suspected clinical cases show an initially normal scan followed by low-density white matter lesions developing within 72 hours of the first symptoms. With improvement, the lesions on CT may largely resolve. MRI may yield additional information on lesion evolution.

The differential diagnosis of this syndrome includes entities that presenr as rapidly evolving focal cerebral disorders with fever and obtundation. These include brain abscess and encephalitis, particularly caused by herpes simplex, in addition to those syndromes considered in the section on ADEM.

Pathology

This disorder represents a more severe and destructive form of ADEM. The CNS white matter shows necrotizing vasculitis involving venules and capillaries. There are perivascular accumulations of polymorphonuclear cells and red blood cells. The perivascular dcinyehnatmg lesions frequently coalesce to form large lesions.

Treatment

Corticosteroids arc frequently used in suspected cases, with no firm data yet available regarding efficacy.

Chronic or Recurrent Forms of Postinfectious and l'o s t v acci n a tio n En ccp halo myelitis

As previously stated, the clinical hallmark of ADEM occurring after measles infection or rabies vaccination is its course. Relapses occurring during the recovery phase could well represent physiological conduction blocks rather than true reactivation of immune-mediated mechanisms. Recurrent encephalomyelitis cases are described, however, particularly in the pediatric age groups. Recurrent cases in adults, if they occur, would be difficult to distinguish from MS. The existence of chronic or recurrent encephalomyelitis cases might be considered as a parallel of the peripheral neuritis syndromes, of which acute nonrelapsing Guillain-Barre syndrome is the prototype, but in which chronic and recurrent cases are reported. The basis of these latter syndromes and their relation to classic Guillain-Barre syndrome remain unresolved. The animal models of encephalomyelitis (EAE) and peripheral neuritis (experimental allergic neuritis) can both be induced in relapsing form, if one selects animals of critical age and specific genetic background,

Combined Central and Peripheral Demyelinating Disease

The existence of combined central and peripheral demyelinating disease as a postinfectious disorder or as a complication following administration of vaccines not known to contain PNS, and CNS tissue remains highly questionable based on available epidemiological evidence. Cases of combined PNS and CNS involvement following swine influenza vaccination were reported, but some of these cases had subacute progressive courses. To date, no convincing in vitro immune sensitization to cither viral or neural antigens has been shown in such cases. Reports of combined centtal and peripheral demyelination syndromes do exist in which onion bulb formation in the PNS is demonstrated, indicating recurrent demyelination and remyelination. Some, although not ail, of these patients have clinical features consisrent with MS. Whether such combined demyelination represents a chance occurrence of two processes or a distinct disease is unresolved.

Site-Res trie ted Forms of Postinfectious Demyelinating Disorders

Acute and Subacute Transverse Myelitis

Acute and subacute transverse myelitis is defined as the development of isolated spinal cord dysfunction over hours or days in patients in whom no evidence exists of a compressive lesion. In the combined experience of several series reviewing complete transverse myelitis, 37% of patients reported a preceding febrile illness. The initial symptoms are paresthesias, back pain, or leg weakness; 37% of patients had the maximal deficit within I day, 45% in 1-10 days, and 18% in more than 10 days. Outcome was rated as good in 42%, fair in 38%, and poor in 20%. The prognosis may be worse in the rapid-onset group of patients. Only approximarely 7% of patients develop MS by clinical criteria. Whether these cases represent a homogeneous entity remains speculative and doubtful, particularly because the ages of reported cases range from 4-83 years. In addition, acute transverse myelitis is known to occur on a background of systemic vasculitis, such as SLE and that associated with heroin abuse. One must distinguish complete transverse myelitis from the partial or incomplete syndromes that more frequently predict evolution to MS in 50-90% of patients.

Optic Neuritis

The clinical features of ON are described in the previous section on MS. In ON associated with MS, the majority of clinical episodes are unilateral, although VERs also may indicate involvement of the contralateral eye. Simultaneous bilateral ON is rare in MS, although somewhat more frequent in Dcvic's disease. The estimated incidence of subsequent development of MS following an initial episode of ON varies widely among different series (from less than 20% to more than 70%). The issue remains whether some cases of isolated ON do represent formes frustes of ADEM. In this regard, cases of ON occurring after childhood exanthems would represent the best example of parainfectious ON, Cases are reported following measles, rubella, mumps, and varicella. Most patients had bilateral optic-nerve involvement; additional neurological abnormalities occurred in only a minority of patients. The young age of the patients further suggests that these events arc not the initial manifestations of MS. The prognosis for recovery of vision is good in most cases, perhaps less so in postvaricella cases.

Cerebetlilis

Acute, isolated ataxia has been observed after many different viral illnesses but most frequently in association with varicella infections. Cerebellar araxia accounts for 50% of the postvaricella neurological syndromes, which overall occur in 1 in 1000 cases of childhood varicella. The prognosis for recovery is excellent, although the duration of symptoms varies from a few days up to 3-4 weeks. The fact that most cases remit spontaneously and that the etiology (direct invasion versus autoimmune) is unresolved leaves the issue of corticosteroid therapy unsettled.

Chapter 61
Hypoxic/Anoxic and Ischemic Encephalopathies

Bruce D. Snyder and Robert B. Daroff

Hypoxic/anoxic and ischemic central nervous system (CNS) injuries may result from a number of conditions, such as cardiac arrest, carbon monoxide intoxication, or septic shock. Corrective action aimed at the underlying disorders must be instituted immediately to ensure survival and minimize residual CNS damage. Hypoxic states have been subdivided into four categories: (1) insufficient cerebral blood flow, (2) reduced oxygen availability, (3) reduced oxygen carriage by rhe blood, and (4) metabolic interference with the use of available oxygen. Clinically, these mechanisms often coexist, causing an anoxic-ischemic encephalopathy (AIE), and can result in a wide spectrum of CNS dysfunction (Table 61.1).

SYNCOPE AND CONFUSIONAL STATES

Syncopal attacks {see Chapter 2) are brief episodes of global cerebral ischemic anoxia. The brief loss of consciousness is followed by an almost immediate return of full awareness. If the drop in cardiac output is prolonged beyond a few seconds, a few clonic movements or an actual generalized tonic-clonic seizure may occur. Distinguishing a syncopal attack from a primary convulsive disorder can at times be difficult; a prodrome of tight-headcdness, the prompt cessation of ictal activity after circulation is restored, and the usually brief or absent postictal state after syncopal attacks are helpful.

More prolonged but still brief episodes of global hypoxia may be followed by minutes to hours of confusion (see Chapter 4) and potentially the appearance of an amnestic syndrome resembling Korsakoff's psychosis (see Chapter 63). The predominantly anterograde amnesia may persist for weeks and occasionally is permanent. The persistent anterograde amnesia, with otherwise preserved cognition, presumably reflects the selective vulnerability of hippocampal neurons to anoxic insult.

Certain agents, such as carbon monoxide and cyanide, or pharmaceuticals such as nitroprusside (Curry and Arnold-Capelt 1991) (see Chapter 64) can produce states of histotoxic hypoxia. These types of poisons disrupt cellular mechanisms for carrying and using oxygen. Nervous system damage is virtually identical to lesions resulting from ischemic or anoxic hypoxia.

Prolonged states of marginal cerebral perfusion or reduced oxygen availability (e.g., respiratory failure, high-altitude exposure, or profound hypotension) initially result in mild cognitive deficits that may ptogress to frank confusion. If such conditions are more severe and prolonged, a typical delirium is seen with fluctuating levels of alertness, hallucinations, and delusions. Sensitivity to given levels of arterial blood pressure, oxygen, and carbon dioxide varies significantly among patients. Delirium in the critically ill patient may, of course, be multifactorial, and hypoxia may be one of many factors to consider (see Chapter 4).

Acute mountain sickness (see Chapter 64E) is common among nonacclimatized persons who ascend higher than 6500 feet. Headache, malaise, anorexia, and nausea occur and are due to the development of mild cerebral edema. Factors that suppress ventilatory drive, such as sedation (e.g., ethanol ingestion), worsen the condition. Symptoms of headache with nausea, vomiting, and especially obtundation require immediate descent and treatment with acerazolamide, corticosteroids, and oxygen (Ikv,ruehka 1992). Stroke-prone individuals are at greater risk at high altitudes, and previously asymptomatic intracranial masses may declare themselves.

Tabic 61.1: Clinical syndromes of central nervous system hypoxia and ischemia

"Mild" sustained hypoxia
  Cognitive impairment
    Confusional states
    Delirium
Brief anoxic-ischemic events
    Syncope
    Abortive or actual generalized seizure activity
Sustained severe hypoxia
    Coma with residual neurological deficits
      Dementia
      Vegetative state
      Brain death
    Seizure activity
    "Watershed" infarction of cerebrum, cerebellum, spinal cord
    Infarction distal to a pre-existing arterial stenosis or occlusion
    Postanoxic demyelination

FOCAL CEREBRAL ISCHEMIA

Prolonged hypotensive episodes associated with delirium or impaired levels of consciousness may result in cerebral infarction. Focal neurological deficits may then coexist with diffuse dysfunction due to generalized neuronal injury. Several mechanisms of infarction (hemodynamic, embolic, and thrombotic) may be involved. Failure of perfusion pressure can result in areas of infarction in the arterial watershed zones, the end-arreriolar territories lying at the boundary of brain areas supplied by a single major intracranial artery, such as the middle cerebral artery. These border-zone areas are last in line for blood supply when cerebral perfusion pressure is reduced. Watershed zones extend high over the cortical convexity to involve the visual cortex, visual association areas, and superior parietal lobules. Further anteriorly, the upward extent of the primary motor and sensory cortices, including interhemispheric structures, may be damaged. Cortical areas surrounding the primary speech areas are within these vulnetable zones, as are sectors of cerebellar cortex, the basal ganglia, and the thoracic spinal cord.

infarction in watershed areas can cause characteristic clinical signs, including transcortical aphasias, cortical blindness (with varying degrees of anosognosia), bibrachial paresis with possibly some gait dysfunction (man-in-a-barrel syndrome), cerebellar dysmetria, and anterolateral spinal cord infarction (usually midthoracic}. Rarely, extensive and selective loss of central spina! cord gray matter can result in a diffuse amyotrophic picture. Although watershed infarctions are generally symmetrical, underlying pre-existing cervical atherosclerotic disease (e.g., unilateral carotid occlusion or high-grade stenosis) may lead to strictly unilateral or predominantly unilateral infarction. In these circumstances, the infarct is in the central area of perfusion of the stenotic vessel; hence, the distribution of the lesions is the inverse of watershed infarcts (see Chaptet 57A).

Cardiogenic embolization may complicate myocardial infarction, cardiac arrhythmias, valvular heart disease, or cardiopulmonary arrest. Resultant cerebral or brainstem infarctions may occur. Hypotensive crises due to sepsis or hypovolemia can be associated with cerebral venous thrombosis with parasagittal or mesodiencephalic infarction (see Chapter 57A). Parasagittal venous cortical infarctions are generally hemorrhagic and often heralded by prominent focal seizure activity. Thrombosis of the cerebral venous system can propagate ro the cerebral venous sinuses, resulting in impaired cerebrospinal fluid absorption and the development of hydrocephalus with gradually declining alertness. Thrombotic propagation to the straight sinus and vein of Galen can cause high midbrain infarction with an itreversible comatose state.

POSTANOXIC COMA

The specific duration of anoxia necessary to produce prolonged loss of consciousness and profound cerebral damage is unknown. Individual variation may be significant. Factors such as prcarrcst blood glucose levels, preischemic medications (e.g., aspirin or calcium-channel blockers), and associated hypothermia (as in cold-water drownings and avalanche victims) may be important. (Mullner et al. 1998). Young children are somewhat more resistant to anoxic damage. Generally, at least 4 or 5 minutes of circulatory arrest is considered sufficient to cause serious brain injury, but the duration of anoxia is rarely well defined in clinical settings.

After resuscitation, the severely anoxic patient is in deep coma, often transiently without even the most resilient brainstem response, the pupillary light reflex. Survivors regain brainstem functions over the first 1-3 hours but generally require supported ventilation. Initially flaccid, the patient subsequently manifests decerebrate or decorticate posturing. Seizure activity of various kinds appears in almost one of every three patients within the first few days (Snyder et al. 1980; Snyder et al. 1980). Axial myoclonus can be so violent that mechanical ventilation is disrupted. Asynchronous distal limb myoclonus also may be seen. Generalized tonic-clonic seizures occasionally occur, due to a variety of toxic or metabolic factors. The increased cardiovascular strain due to seizure activity may be dangerous to the patient; additionally, hyperthermia and increased cerebral metabolic demand due to seizures may reduce the chances of cerebral recovery.

Later, after some degree of cerebral recovery, parrial simple and partial complex seizures may develop. Partial complex status epilepticus can appear as simply a prolongation of the patient's postanoxic stupor or

confusional state. The clinician should consider the diagnosis of nonconvulsivc status epilepticus in patients who plateau in a stuporous state or secondarily decline in level of alertness. The only clinical sign may be gaze deviation with nystagmus.

Recovery rates vary among these patients. With time, initial flaccidity is replaced by reflex motor posturing. This, in turn, is succeeded by avoidance movements, reflex grasping, eye opening, and finally, arousal, as manifested by complex interaction with the environment. As patients emerge from postanoxic coma, several clinical patterns are seen. The patient arousing early (within 24 hours) is frequently agitated and confused for a period of hours to days but ultimately recovers most cognitive functions. The patient's combativeness may necessitate the use of neuroleptics and poses difficulties for nursing care and cardiopulmonary stability. Hainpcr.dnl, ri^peridnl, or similar, less sedating, nonanticholmergic dopaminergic blocking agents may provide good control without further clouding the sensorium. The use of sedatives, anticonvulsants, and the like will tend to delay arousal and make clinical assessment more difficult. The clinician must weigh this against the requirements of patient care and safety.

As awareness is regained, the clinician can begin to assess cognitive and sensorimotor deficits. The effects of focal or multifocal infarction become apparent. Patients with more diffuse cortical damage display affective shallowness and lability[7], inattention, impaired logical flow of thought, hallucinations, and delusions. These gradually clear at varying rates and to varying degrees. Involvement of the basal ganglia, either because of watershed infarction or diffuse neuronal loss (particularly after carbon monoxide intoxication), can result in prominent movement disorders that may be cboreoathetoid or even strikingly parkinsonian. Similarly, cerebellar signs, such as limb dysmetria or truncal ataxia, may appear. Most typically, in patients with residual motor dysfunction, combinations of these signs are seen.

Memory acquisition seems particularly sensitive to hypoxia. After a significant hypoxic episode, anterograde amnesia with deficits in acquiring and retaining new information may be permanent. Some patients whose coma persists beyond 4 or *5* days slowly become responsive to the environment, if only in a limited fashion. These patients remain cognitively impaired, although recovery proceeds to some extent for up to a year. Structured environments, neuroleptic medication, bladder and bowel programs, and rehabilitative therapy may help optimize functioning.

Persistent Vegetative State

Sniiir |io>M:ioxic voituimse patients develop a vegetative state. They begin to open their eyes within a few days but make no apparent contact with the environment. Motor responses continue to be decorticated or decerebrate posturing. Triple-flexion leg withdrawal may be seen, along with spontaneous clonus, flexor or extensor thrusting of the legs, or shivering, Brainstem reflexes recover quickly; sleep-wake cycles appear. With eye opening, other behaviors emerge such as yawning, bruxism, spontaneous smiling or crying, sneezing, and blinking to threat. Absolutely no consistent nonreflexive response to stimulation can be established with the patient. These patients do not consistently follow moving people or objects with their gaze. They meet the criteria for being called *vegetative.* If this condition persists for a month after resuscitation, it is considered a persistent vegetative state (PVS) (Ashwal et al. 1995). Pathologically, there is virtually complete forebrain necrosis with preservation of the brainstem. The electroencephalogram (EEG) is diffusely abnormal. Arousal changes may be seen in the EEG record with stimulation of the patient but normal reactive alpha activity is absent. Serial brain scans demonstrate diffuse and multifocal cerebral damage; severe cerebral atrophy develops during ensuing months of survival. These patients must be distinguished from those with central pontine infarctions, who are "locked in" or de-efferented but have normal cognition with preserved awareness. Other comalike states should be distinguished from TVS (American Neurological Association Committee on Ethical Affairs 1993) as well (see Chapter 5).

Cerebral Edema

The mechanisms for the development of cerebral edema in hypoxia are discussed in Chapter *65,* but the role of edema in A1E remains uncertain. Patients with AIE do not develop papilledema, although ischemic papillopathy may be observed rarely. Measurements of intracranial pressure (ICP) yield equivocal results. In small reported series, some—but not all—postresuscitation patients have had either elevated ICP or evidence of diffuse cerebral edema on imaging studies. Intracranial hypertension may be more likely to occur after cardiac arrest due to respiratory failure. The effects of prearrest hypercapnia and acidosis are unclear.

Autopsies of patients in coma due to AIE have revealed the presence of gross brain edema and cerebral liquefaction when there had been both a deep level of coma and prolonged survival (5 days or more). Patients who died within 24 hours of cardiopulmonary arrest (CPA) in deep coma do not show cerebral edema or liquefaction, suggesting that brain swelling is a postnecrotic phenomenon in these patients. In the setting of global anoxic ischemia, the presence of high ICP may portend a poor prognosis related to antecedent widesptead tissue death. There is no established indication for the use

of corticosteroids, osmotic diuretics, barbiturate-induced coma, hyperventilation, or ventriculostomy.

Delayed Postanoxic Deterioration

Occasionally, patients seem to arouse early and begin to recover well from anoxic coma, only to relapse with the appearance of apathy, confusion, gait disturbance, spasticity, incontinence, movement disorders, and dysarthria. Pathologically, there are varying degrees of demyclination in the centrum semiovale, bilateral pallidal necrosis, and patchy cortical necrosis, especially in the hippocampi. With supportive care, these patients may recover but are often left with residua] deficits. This unusual disorder is most often seen after carbon monoxide poisoning, in which the clinical picture is frequently that of parkinsonism. Indu ulimls older than 50 years are at greater risk !ur delayed deterioration. The overall frequency of delayed neurological degeneration in several series of cases of carbon monoxide intoxication approximates 2.75% (Gottfried ct al. 1997). An oligodendroglial injury resulting in delayed demyelination is a speculation.

Other Sequelae

Recovery of cognitive functions generally proceeds rapidly during the first several weeks after anoxic injury and seems to plateau by 3 months. Moderate to severe biparietal dysfunction (acalculia, apraxia) occurs in one of every three survivors. Almost one half of patients are left with moderate to severe memory impairment. Problems with planning and organizational skills, as well as depression, arc common. It remains unclear whether these patients may show some continued cognitive recovery in the first several years after their AIE.

Movement disorders frequently emerge during recovery from severe hypoxic events. Bilateral hemiparesis, pseudobulbar palsy, parkinsonism, tremor, choreoathetosis, and dystonia may appear as the patient awakens from coma or may develop weeks to months later (Govaerts et al. 1998). Features of different disorders may coexist in a given patient. Treatment is often unsatisfactory, and medications that seem to benefit one problem may well worsen others.

Epilepsy is uncommon in surviving postanoxic patients, although one syndrome deserves mention: delayed-onset action sensitive myoclonus (Lance-Adams syndrome) can be extremely disabling and may occur in patients who have made good cognitive recoveries from AIE, Intractable stimulus- and action-sensitive, asynchronous, distal limb myoclonus occasionally emerges days to weeks after recovery from anoxic coma. These patients often improve over the course of years after onset of myoclonus (Werhahn et al. 1997). Clonazepam and valproic acid may be therapeutically effective.

Prognosis of Anoxic Coma after Cardiopulmonary Arrest

("PA is associated with a high rate of morbidity and mortality and is rhe most common cause of severe anoxic injury. Of patients who survive until hospital admission, in-hospital mortality rates range from 54% to 88%. Of those surviving to hospital discharge, 20% die in 1 year, and 40% within 3 years; of the remaining patients, 75% have severe neurological impairment (Mullner et al. 1998), often with severe memory deficits (Mecklinger et al. 1998).

Statistics describing the outcome for patients in anoxic coma have varied somewhat in different clinical scries, largely because of patient selection criteria. Some investigators reported series of consecutively tcsuscitated patients, whereas others have selected those who remain in deep coma for some specified period. The clinician must be aware of the differences in selection criteria when attempting to apply a specific set of published statistics to a given patient. The use of sedatives, analgesics, muscle relaxants, or anticonvulsants may weaken the applicability of published statistics to a specific case.

Survival after CPA is closely correlated with the duration of coma. Individuals who are either arousablc or fully alert within 12 hours of resuscitation tend to do well neurologically, although they still experience a 25% mortality rate, related primarily to their underlying cardiac disease. In a series of consecutive patients with an overall 40% survival rate, the presence of initial postanoxic unarousability was a negative prognostic sign, with only 28% of that group surviving. The level of consciousness or motor responsiveness to stimulation may fluctuate after resuscitation; a decline within 48 hours is generally associated with a fatal outcome. A declining level of consciousness at any time during hospitalization also is associated with a reduced survival rate and poorer outcome. Prognosis in the first few hours of resuscitation remains uncertain. Patients making reflex responses to pain (decorticate or decerebrate posturing) within 1-3 hours of CPA still have a 20-30% possibility of survival with good outcome. Patients who achieve arousal within 72 hours of resuscitation may do well. Such arousal, however, does not guarantee either survival or independent functioning. The clinician should be cautiously optimistic while continuing vigorous life support in such situations. Occasional patients do not achieve full alertness for up to 10 days after CPA (Snyder et al. 1980; Snyder et al. 1980). The delay may relate to some superimposed or associated metabolic factor, in which case outcome may still be quite good.

A meta-analysis of published work rating prognosis after CPA led to the following conclusions: when evaluated 3 days after CPA, the absence of pupil light reflexes, the absence of any motor response to pain, and the absence of cortical evoked responses (SSEP) to median nerve stimulation were each 100% predictive of a poor outcome or death (Zandbergen et al. 1998).

* Absent pupillary light reflex, absent corneal responses, absent spontaneous conjugate roving gaze; each count as one abnormal finding.
Source: Adapted from Snyder, B. D., Gumnit, R. J., Leppik, I. E., et al. 1981, "Neurologic prognosis after cardiopulmonary arrest: IV. Brainstem reflexes," *Neurology,* vol. 31, pp. 1092-1097.

Cranial nerve (brainstem) reflexes correlate in a highly significant fashion with outcome (Table 61.2). When these reflexes are lost after having been initially present (e.g., the recurrent loss of pupillary reactions}, survival is extremely unlikely. Whereas the absence of brainstem reflexes is highly predictive of poor outcome and death, the presence of intact reflexes is not a clear indicator of good outcome (Snyder ct.nl. 1981).

Persistent early onset myoclonus (myoclonic status epilepticus) is a negative prognostic finding (Krumholz and Berg 2002). Guidelines for predicting very good and very poor prognosis appear in Table 61.3.

This sort of prognostic information is used to guide the clinician and family in decisions related to life support and the aggressiveness of clinical management. A discussion of the complex ethical issues behind these decisions is beyond the scope of this chapter. Medicolegal considerations are evolving and vary from state to state and country to country. In the United States, the sanctioned termination of life support is restricted to situations of brain death and medical futility, including PVS. Prognosis for life and function in postanoxic PVS patients is virtually nil; there are very rare reported cases of recovery of awareness after 1 to 2 years of survival but with ptofound sensorimotor disability.

We will not review clinical data for the prediction of outcome from anoxic injury in infants and children (see Kriel et al. 1994), but the combination of magnetic resonance imaging and spectroscopy may provide the best prognostic information (Dubowitz et al. 1998), Outcome assessments in children must be based on more prolonged follow-up, with recognition of the difficulty of judging intellectual capabilities in the developing child. Young mammals seem to be more resistant to anoxic injury than their ciders, which suggests that data collected in adult clinical series are not directly applicable to children. Further discussion of the assessment of the critically ill child is presented in Chapter 7.

BRAIN DEATH

Guidelines for determining death in the adult are well established (see Chapter 5). The rwo principal categories are irreversible cessation of cardiopulmonary function and irreversible cessation of CNS function. In the former group, clinical examination is all that is necessary to determine death. In the CNS group, a patient with ongoing circulatory function who is being artificially ventilated presents a more difficult issue. The diagnosis of brain death is based on

Tabic 61.3: Guidelines that identify patients wirh poor or good prognosis after cardiopulmonary arrest

Time after cardiac arrest clinical sign	*Patients with virtually no chance of regaining independence*	*Patients with best chance of regaining independence*
Initial examination	No pupillary light reflex"	Pupillary light reflexes present; motor response decorticate posturing or decerebrate posturing; spontaneous eye movements conjugately roving or orienting
1 day	1-day motor response no better than decorticate posturing; spontaneous eye movements neither orienting nor conjugate; roving	1-day motor response withdrawal or better; I-day eye opening to noise or spontaneously
i days	3-day motor response no better than decorticate posturing	Motor response withdrawal or better; spontaneous eye movements normal

"In the absence of some other cause.
Source: Adapted from Levy, D. E., Caronna, J. J., Singer, B. H., et al. 1985, "Predicting outcome from hypoxic-ischemic *corns." JAMA,* vol. 253, pp. 1420-1426.

absence of all cerebral and brainstem functions persisting over a period of observation sufficient to exclude any possibility of recovery. Once a patient has met brain-death criteria, a repeat evaluation 6 hours later is advised Wijdicks [L·9v.. Twenty four hours ol observation is recommended in states of postanoxic damage. Periods of observation may be reduced if suitable techniques, such as a nuclear medicine cerebral blood flow study, establish beyond a doubt that no blood flow exists to the brain. Electrocerebral silence on EEG is considered a desirable but not necessary confirmatory feature; in any event, EEG recordings to establish cerebral death require a high level of technical and interpretive expertise.

Complicating conditions, such as hypothermia, neuromuscular blockade, severe peripheral neuropathies, lower motor neuron disorders, and comalike states (e.g., loekcdin syndrome, the presence of sedative or analgesic drugs, or reversible metabolic abnormalities), must all be considered and ruled out before making a diagnosis of brain death.

Guidelines for determining brain death in children must deal specifically with the age group from full-term newborn to the 5-year-old. Features unique to the childhood criteria are primarily the changing periods of recommended observation relative to the patient's age. For children of age 7 days to 2 months, two examinations and two EEGs 48 hours apart are required. For those of age 2 months to I year, a 24-hour interval is adequate. After 1 year of age, laboratory testing need not be performed, and a 12-hour interval is adequate for most cases.

ELECTRODI AGNOSTIC STUDIES

Electroencephalography

Cardiac arrest results in a stereotyped sequence of EEG changes (see Chapter 36A). In the first 6-9 seconds after a CPA, there is no change in ongoing EEG activities. At 7-9 seconds, thctc is a transition from normal frequencies to generalized, frontal-dominant 100- to 200-uV delta activity. By 14-18 seconds aftet CPA, there is generalized voltage attenuation with no recognizable EEG activity. If the cardiac arrest is brief, EEG activities recover in 5-12 seconds after a reverse sequence.

Normothermic individuals incurring a hypoxic-ischemic insult develop varying degrees of cerebral damage. A wide variety of abnormal EEG patterns appear, some of which have prognostic significance for neurological outcome. Burst-suppression activity and other periodic generalized phenomena denote severe cerebral dysfunction (Young ct al. 1994).

The term *alpha coma* refers to an F,FG pattern comprising widespread alpha-frequency activity that is not reactive to eye opening or other stimulation, recorded from a patient in coma. It occurs in patients after anoxic-ischemic insults and drug intoxication. Because continuous fT< i recording b.is nn: been widi\\ UM\I in monitoring comatose individuals, the actual frequency and significance of alpha coma is unclear, but its persistence is usually associated with a fatal outcome.

The absence of detectable EEG activity in individuals studied after CPA is ominous, although one must consider how long after CPA the tracing was taken. Proper interpretation of EEGs demonstrating no detectable cortical activity requires ascertaining conditions capable of causing temporary reversible loss ol [K(, activity (e.g., anesthesia, hypothermia). Occasional patients with no detectable EEG activity for up to 8 hours after resuscitation have subsequently regained consciousness.

There are several detailed systems of grading the conventional EEG in adults to aid in determining prognosis after CPA (Yamashila el al. 19951. ITGs showing normal or near-normal frequency, activity, topography, and reactivity arc assigned low grades; those with delta activity, intermittent voltage attenuation, electrocerebral silence, or the patterns mentioned in the preceding paragraphs are assigned higher grades. Patients with grade 1 EEGs (normal or near normal) have a good prognosis for neurological recovery. Patients with grade 4 or 5 EEGs (e.g., alpha-coma, intermittent voltage attention, or electrocerebral silence) die, usually without regaining consciousness. Patients with grade 2 or 3 FF.Gs (mild or moderate abnormalities) experience variable outcomes not accurately predicted by a single post-CPA EEG. In these patients, sequential EEGs may be of some prognostic assistance.

Evoked Potential Studies

The absence of the early cortical complex (N20-P27) of somatosensory-evoked potentials (SSEPs) (see Chapter 36A) in comatose patients (excluding those with brain disease, drug intoxication, major medical abnormalities other than acidosis, or coma of unknown origin) makes it unlikely that the patient will ever regain consciousness. Combining the results of the clinical examination, EEG, and SSFPs improves the sensitivity for predicting prognosis (Chen et al. 1996).

A practical clinical approach to the electrophysiological study of individuals {Figure 61.1) with AIE may begin with a conventional bedside EEG and SSEP recorded S-24 hours after resuscitation. If clinically required, repeat recordings, made on days 3 and 7 after resuscitation allow detection of specific EEG and SSFP patterns that denote a poor neurological prognosis. In addition, the rate and direction of changes in electrocortical activity can be established, with attendant short-term and long-term prognostic implications.

fin. proper **use** ni (ke-.e electrophysiological **techniques** requires technical and interpretive experience and expertise, Minimal technical standards and guidelines are available to assist the clinician (American Electroencephalographic

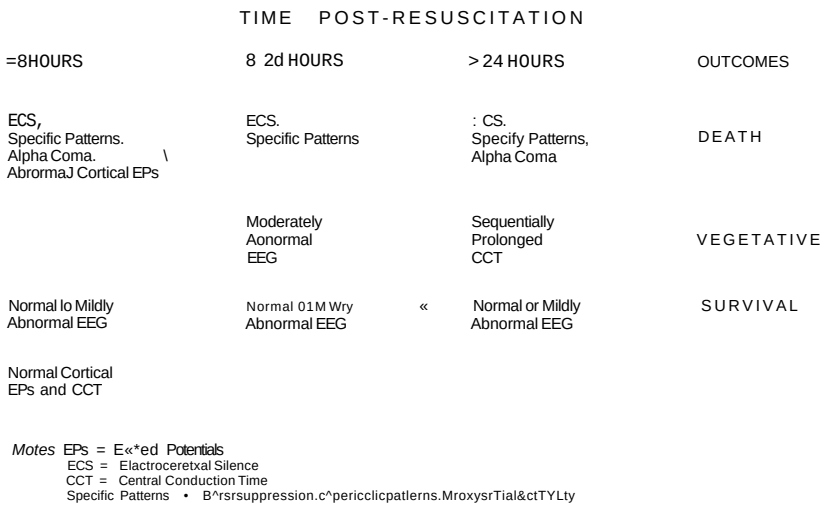

FIGURE 61.1 Time course and neurological implications of eiecrro-eneeplialograpfiie (KEG) and evoked potentials in hypoxic-ischemic coma.

Society 1994). Most of these patients are studied in the intensive care unit, where sources of artifact are legion and often difficult to eliminate. Recognizing artifact is essential.

Other Laboratory Aids in Assessing Prognosis

In addition to the electrophysiological techniques reviewed here, investigators have explored other laboratory techniques for predicting outcome after CPA. Neuroimaging and radionuclide studies have been useful in establishing cerebral nonperfusion and brain death. The concentrations of potassium and lactate in the CSF correlate with the severity of CNS insults in clinical series of patients with a variety of disorders. There are no established correlations, however, for patients with AIE alone. Large elevations of CSL creatine kinase-BB levels are closely correlated with poor outcome but are no more accurate than EEGs and SSEPs in outcome prognostication. Levels of S-100 protein are increased in patients with poor prognosis (Rosen et al. 1998). Magnetic resonance spectroscopy in vivo is also prognostically useful (Berek et al. 1997).

MANAGEMENT **OF COMA** DUE **TO** ANOXIC-ISCHEMIC ENCEPHALOPATHY

The patient who is confused, delirious, or comatose during or after an anoxic injury presents difficult diagnostic and treatment issues.

AIE after CPA is a metabolic coma with static or improving course that is often complicated by seizure activity. Diagnostic difficulty is increased because new factors, such as sepsis and drug effects, may intervene during the p.mer.v's prolonged ilhirv,. Primary intracranial disease can resemble anoxic states and may coexist with them, and care must he taken to rule out other relevant factors. Patients presenting with cardiac arrhythmias may have sustained a primary intracranial insult, such as a subarachnoid or intracerebral hemorrhage. The optic fundi should be inspected for papilledema, peripapillary nerve fiber layer hemorrhages, or subhyaloid hemorrhages. findings such as these or unilateral third cranial nerve-palsies should lead to a search for other intracranial pathology.

Continued monitoring of the neurological status serves to warn of deteriorating medical status, to establish the neurological prognosis (as outlined earlier), and to identify neurological complications, such as status epilepticus. Cerebral imaging studies, lumbar puncture, and EEG techniques may assist in ruling out other diagnoses.

Complications of anoxic coma may involve virtually every organ system. Blood pressure and pulmonary function usually require support. Fluid and electrolyte management may he complex. Hyperglycemic hyperosmolar crises may result from combinations of endogenous and exogenous catecholamines, corticosteroids, osmotic diuretics, and glucose infusions, particularly in the diabetic patient.

Two recent studies (Bernard et al. 2002; Hypothermia after Cardiac Arrest Study Group 2002) suggest that patients may benefit from the induction of mild hypothermia for 12 to 24 hours postarrest. The investigators began externa! cooling within 100 minutes after resuscitation from out-of-hospital cardiac arrest and suppressed shivering with deep sedation and neuromuscular blockade. Cooling seemed quite safe with no documented complications. Cooled patients were 16-23% more likely to achieve fair to good outcomes than controls.

Anticonvulsant therapy is indicated if seizure activity-does not respond promptly to the correction of metabolic factors. Axial myoclonus can be very difficult to control. Benzodiazepines (clonazepam, lorazepam) or valproic acid may be effective, but neuromuscular blockade or deep sedation with midazolam will more likely be required to prevent distuption of ventilation and interference with nursing care.

As noted previously, current evidence suggests that post-CPA brain swelling is a postnecrotic event. There is no indication for the active treatment of brain edema in this setting. Glucocorticoids and calcium-channel blockers are of no value in treating All[1]..

The patient with emerging focal neurological deficits may have sustained one or more cerebral infarctions. Diagnostic studies can rule out other intracranial structural lesions. Anticoagulation may be indicated in patients at high risk for recurrent infarction (e.g., those with atrial fibrillation, intracardiac thrombus), but routine anticoagulation after CPA is not indicated.

Chapter 62
Toxic and Metabolic Encephalopathies

Alan H. Lockwood

Toxic and metabolic encephalopathies are a group of neurological disorders characterized by an altered mental status. Typically, they are caused by the failure of organs other than the nervous system or the presence of an endogenous or exogenous toxin or drug. Although the brain is isolated from the rest of the body by the blood-brain barrier (BBB), the nervous system often is affected severely by organ failure that may lead to the buildup of toxic substances normally removed from the body. This is encountered in patients with hepatic and renal failure, Damage to homeostatic mechanisms affecting the internal milieu of the brain, such as the abnotmalities of electrolyte and water metabolism associated with renal failure or the syndrome of inappropriate antidiuretic hormone (SIADH) secretion, also affect brain function. In some cases, deficiency of a critical substrate after the catastrophic failure of an organ, such as hypoglycemia caused by fulminating hepatic failure, is the precipitating factor. Frequently, the history and physical examination provide information that defines the affected organ system. In other cases, the cause is evident only after laboratory data are examined.

CLINICAL MANIFESTATIONS

Encephalopathy that develops insidiously may be difficult to detect. The slowness with which abnormalities evolve and replace normal cerebral functions makes it difficult for patients and families to recognize deficits. When examining patients with diseases of organs that are commonly associated with encephalopathy, neurologists should include encephalopathy in the differential diagnosis.

Mental status abnormalities are always present and may range from subtle abnormalities, detected by neuropsychological testing, to deep coma. The level and content of consciousness reflect involvement of the reticular activating system and the cerebral cortex. Deficits in the spheres of selective attention and the ability to process information appear to underlie many metabolic encephalopathies and affect performance on many tasks. These deficits are manifested as disorders of orientation, cognition, memory, affect, perception, judgment, and the ability to concentrate on a specific task. Evidence ftom studio of patients with cirrhosis (sec Hepatic Encephalopathy, later in this chapter) suggests that metabolic encephalopathies are the result of a multifocal cortical disorder rather than uniform involvement of all brain regions. Among patients with coma of unknown cause, nearly two thirds ultimately are found to have a metabolic causal agent. A complete discussion of coma is found in Chapter 5.

The ueuro-ophthalmological examination is extremely important in the differentiation of patients with metabolic disorders from those with structural lesions. The pupillary light reflex and vestibular responses are almost always present, even in patients with deep coma. However, it is common for these reflexes to be blunted. Exceptions include severe hypoxia; ingestion of large amounts of atropine or scopolamine; and deep barbiturate coma, which is usually associated with circulatory collapse and an isoelectric electroencephalogram (EEG). The pupils arc usually slightly smaller than normal and may be somewhat irregular. The eyes may be aligned normally in patients with mild encephalopathy. With more severe encephalopathy, dysconjugate roving movements may occur. Other cranial nerve abnormalities may be present, but are less useful in formulating a differential diagnosis.

Motor system abnormalities, particularly slight increases in tone, are common. Other signs and symptoms of metabolic disorders may include spasticity with extensor plantar signs (in patients with liver disease}, multifocal myoclonus (in patients with uremia), cramps (in patients with electrolyte disorders), Trousseau's sign (in patients with hypocalcemia), tremors, and weakness.

Asterixis, a sudden loss of postural tone, is common. To elicit this sign, the patient should extend the arms and

elbows while dorsiflexing the wrists and spreading the fingers. Small lateral movements of the fingers may be the earliest manifestation. More characteristically, there is a sudden flexion of the wrist with rapid resumption of the extended position, the so-called flapping tremor. Asterixis also may be evident during forced extrusion of the tongue, forced eye closure, or at the knee in prone patients asked to sustain flexion of the knee. Electrophysiological studies have shown the sudden onset of complete electrical silence of muscles that coincides with the lapse of posture. This sign, once thought to be pathognomonic of hepatic encephalopathy (HE), occurs in a variety of conditions, including uremia, other metabolic encephalopathies, and drug intoxication. Asterixis may be present in patients with structural brain lesions.

Generalized seizures occur in patients with water intoxication, hypoxia, uremia, and hypoglycemia, but only rarely as a manifestation of liver failure. Focal seizures, including epilepsia partialis continua, may be seen in patients with hyperglycemia. Multifocal myoclonic seizures may occur in patients with uremia, after hypoxic brain injury, and in other disorders (see Chapters 24 and 77).

TOXIC ENCEPHALOPATHIES

Hepatic Encephalopathy

Disorders of the liver are a common cause of death resulting from disease. Among the poor, the incidence of cirrhosis may be as much as 10 times higher than the national average, and accounts for almost 20% of their excess mortality. As patients with chronic liver disease enter the terminal phases of their illness, encephalopathy becomes an increasingly important cause of morbidity and mortality. However, it is important to stress that mild encephalopathy is common in patients with cirrhosis. This treatahle problem is commonly overlooked. The unfortunate term *subclinical encephalopathy* has been used by some to describe a mild form of encephalopathy.

A clinical concensus statement seeks to minimize the substantial confusion in the literature and in clinical practice concerning the diagnosis of HE (Eerenci et al. 2002). A multi-axial system was proposed. The initial categorization addresses the presence of hepatocellular disease and portacaval shunting. Patients with acute liver disease or fulminating hepatk failure, a disorder occurring in patients with previously normal livers who exhibit neurological signs within 8 weeks of developing liver disease, form the first group. A second group consists of a small number of patients who are free of hepatocellular disease, but who have portacaval shunting of blood. The largest number of patients have hepatocellular disease with shunts. Further subdivisions address temporal aspects—whether HE is episodic, persistent, or minimal. Causal considerations are then applied to separate patients with precipitated HE from those with recurrent and ideopathic encephalopathy, and to identify the severity of the syndrome.

The features that differentiate patients with fulminant hepatic failure from those with the much more common portal systemic encephalopathy are shown in Table 62.1. The clinical criteria that are useful in defining the severity of HE are shown in Table 62.2.

An episode of HE may be precipitated by one or more factors, some of which are iatrogenic. In one series, the use of sedatives accounted for almost 25% of all cases. A gastrointestinal (GI) hemorrhage was the next most common event (18%), followed by drug-induced azotemia and other causes of azotemia (15% each). Excessive dietary

Table 62.1: Features distinguishing fulminating hepatic failure from chronic hepatic encephalopathy or portal systemic encephalopathy

Feature	*Fulminating hepatic failure*	*Portal systemic encephalopathy*
History		
Onset	! Ml.lib ;u ..If	Varies; may be insidious or subacute
Mental state	Mania may evolve to deep coma	Blunted consciousness progresses to coma
Precipitating factor	Viral infection or hepatotoxin	Gastrointestinal hemorrhage, exogenous protein, drugs, uremia
History of liver disease	No	Usually yes
Symptoms		
Nausea, vomiting	Common	i iiusual
AkInrniiiiil --•:iin	Common	Unusual
Signs		
Liver	Small, soft, tender	Usually large, firm, no pain

Collateral circulation	Absent	Present
Ascites	ı ····..··ıı	May be present
Laboratory Tests		
Transaminases	Very high	Normal or slightly high
Coagulopathy	['[•L'HL'lll	Often present

Table 62.2: Neuropsychiatry abnormalities associated with cirrhosis severity of encephalopathy*

	Grade 1 (mild)	*Grade 2 (moderate)*	*Grade 3 (severe)*
Consciousness	Alert, trivial Lick of awareness, short attention span	Slight blunting	Lethargic, somnolent
Behavior	Personalis change, fatigue, abnormal sleep pattern	Slight lethargy, disinhibition	Bizarre, paranoia
Affect	Irritable, depressed	Anxious, angry	Blunted
Cognition	Selective visuospatial abnormalities	Impaired	Too impaired to test reliably
Neurological examination	Tremor, asterixis, hypetactive reflexes, Babinski's reflex	Blunted consciousness, slurred speech	Dilation of pupils, nystagmus

*Grade 0: Overtly normal in all spheres. Grade 4: Coma, intact oculocephalic and pupillary light reflexes, no appropriate response to noxious stimuli,

protein accounted for 10% of episodes; hypokalemia, constipation, infections, and other causes accounted for the remaining cases. As liver disease progresses, patients appear to become more susceptible to the effects of precipitants. Ilir, phcilnmenim lias been iTlenvd i<> as M\iii h\ petsensi tivity. Other data that show older patients are more likely to develop HE after the transpigular intrahepatic portosystemic shunts suggest that age-related changes in the brain affect the susceptibility to the agents that cause HE.

The diagnosis of HE is based on the signs and symptoms of cerebral dysfunction in a setting of hepatic failure. Usually, standard laboratory test results, including serum bilirubin and hepatic enzymes, are abnormal. Products of normal hepatic function, including serum albumin and clotting factors, often are low, leading to prolongation of the prothrombin time. Measurements of the arterial ammonia level may be helpful in diagnosing HE. When obtaining blood samples for an ammonia determination, care must be taken to be certain that the sample is of arterial origin (venous ammonia levels may be artificially high, especially after the outpouring of ammonia by muscle made ischemic by applying a tourniquet). The sample should be placed on ice and carried by hand to the laboratory for immediate analysis. Delays can result in ammonia production in the specimen, producing a spuriously elevated result. Normal or minimally elevated blood ammonia values in a comatose patient with long-standing disease should be interpreted with some caution because of the possibility of an altered dose-response relationship between the arterial ammonia concentration and blood flow and oxygen metabolism, discussed elsewhete in this section.

The EEG may be the most useful of the commonly used laboratory diagnostic tests. Bursts of mode rate-to-high-amplitude (100-500 pV), low-frequency (1.5- to 2.5-Hz) waves are the most characteristic abnormality. There are three stages in the EEGs evolution: a theta stage with diffuse 4- to 7-Hz waves; a triphasic phase with surface-positive maximum deflections; and a delta stage, characterized by random, arrhythmic slowing with little bilateral synchrony. Computerized analysis of the EEG, designed to identify abnormalities in the spectra, may become a valuable means to identify patients with minimal encephalopathy.

Neuropsychological tests are an underused and valuable means to diagnose encephalopathy and monitor the response to therapy. Sixty percent or more of all patients with cirrhosis with no overt evidence of encephalopathy exhibit significant abnormalities when given a battery of neuropsychological tests. Tests of attention, concentration, and visuospatial perception arc the most likely to be abnormal. Specific tests that are useful include Trailmaking A and B, the digit symbol and the block design subtests of the Wechsler Adult Intelligence Scale (Revised), and the Purdue Pegboard, These abnormalities appear regardless of the cause of the cirrhosis. Patients with alcoholic cirrhosis typically have more difficulty with memory deficits than patients with nonalcoholic cirrhosis. Even though these patients appear to be normal, the degree of impairment, particularly in the visual-spatial sphere, may be severe enough to interfere with the safe operation of an automobile or other dangerous equipment, especially if visual-spatial performance is required. Language functions are usually normal. Treatment with lactulose lessens the severity of the test score abnormalities in many cases. These data, combined with other studies showing that the quality of life is affected by these abnormalities, suggest that neuropsychological tests should be used more extensively for the routine evaluation of all patients with cirrhosis, particularly those without overt evidence of HE.

Abnormal event-related potentials, characterized by prolonged latencies and altered waveforms characterize visual event-related potentials may be abnormal in patients with minimal encephalopathy. Although there has been less experience with auditory P300 potential recordings, in which the subject is asked to discriminate between a rare and common tone, differences in latencies and waveforms also have been associated with encephalopathy. A combination of visual-evoked potentials, auditory P300s, and selected neuropsychological tests (such as Trailmaking A and B) may be useful in detecting minimal encephalopathy in cirrhotic subjects. It is uncettain whether this less complex approach to detecting minimal encephalopathy

will prove to be more reliable and cost-effective than a focused neuropsychological test battery.

Neuroimaging

Although the diagnosis of HK is typically made on the basis of clinical ctiteria, neuroimaging techniques are commonly employed to exclude structural lesions. Magnetic resonance imaging (MRI) and spectroscopic^ studies have revealed new insights into the pathophysiology of HE (Lockwood ct al. 1997). On Tl-weighted images, it is common to find abnormally high signals arising in the pallidum. These arc seen as whiter than normal areas in this portion of the brain, as shown in Figure 62.1. In addition to these more obvious abnormalities, a systematic analysis of MRI images shows that the Tl signal abnormality is quite widespread and is found in the limbic and extrapyramidal systems, and generally throughout the white matter. A generalized shortening of the T2 signal occurs also. This abnotmality is less evident on visual inspection of the images because of the generally short duration of T2 signals. These abnormalities have been linked to an increase in the cerebral manganese content. The abnormalities become more prominent with time and regress after successful liver transplantation. The unexpected finding of high Tl signals in the pallidum should suggest the possibility of liver disease.

Proton magnetic tesonance (MR) spectroscopical techniques also have been applied to the study of patients with citrhosis. In the absence of absolute measures that are referable to concentrations, the signal of specific compounds is usually teferenced to creatine and expressed as a compound-to-creatinc ratio. There is genera! agreement among studies that an inctease in the intensity of the signal occurs at approximately 2.5 ppm that is attributed to glutamine plus glutamatc. With high-field-strength magnets, this peak can he resolved into its components. Results show that the increase is attributable to glutamine, as expected on the basis of animal investigations. Correlations between the glutamine concenttation, generally considered to be a reflection of exposure of the brain to ammonia, and the severity of the encephalopathy, have led some to propose that MR spectroscopy may be useful in the diagnosis of HE.

Myoinositol and choline signals decrease, whereas N-acety (aspartate rL-.on.mci-, ;.i nciircm:il scirkcr are am sistently normal. MR spectroscopic studies are difficult and expensive to perform. Because they show no clear advantage over less costly and readily accessible psychometric tests, they are not likely to he used clinically. Neuroimaging studies are not generally required in patients with HE. They may be useful in the diagnosis of coexisting structural lesions of the brain, such as subdural hematomas or other evidence of cerebral trauma, or complications of alcohol abuse and thiamine deficiency, such as midline cerebellar atropin, third ventricular dilatation and mamillary body atrophy.

Pathophysiology

The pathophysiological basis for the development of HF is still not completely known. However, treatment strategies for the disorder are all founded on theoretical pathophysiological mechanisms. A number of hypotheses have* been advanced to explain the development of the disorder, Suspected factors include hyperammonemia; altered amino acids and neurotransmitters, especially those related to the y-aminobutyric acid (GAIiAl-beii/odiazepinL- complex; mcrcaptans; and short-chain fatty acids. Although none of the current hypotheses is completely capable of explaining the development of HE, it is likely that ammonia plays a central role. Because of the complexity of the metabolic derangements that attend liver disease, other factors may contribute synergistically to the development of this complex disotder.

Cerebral Blood Flow and Glucose Metabolism. Whole-brain measurements of cerebral blood flow (CBE) and metabolism are norma! in patients with grade 0-1 HE, but reductions occur in more severely affected patients. The positron-emission tomography (PET) data show clearly that minimal forms of HE are caused by the selective impairment of specific neural systems rather than global cerebral dysfunction. This is a novel concept, because more traditional thinking suggests that brain regions are affected more uniformly by the action of toxins. Sophisticated statistical techniques designed to analyze images have made it possible to identify specific brain regions in which glucose metabolism is abnotmal in patients with low-grade encephalopathy and abnormal neuropsychological test scores (Lockwood ct al. 2002). Reductions occur in the cmgulare gvrus, an important element m the attentional system of the brain and in frontal and parietal association cortices. These PF7T data are in accord with cottical localizations based on the results of neuropsychological tests. Figure 62.2 shows the results of correlation analyses between scores on selected neuropsychological tests and sites of reduced cerebral glucose metabolism.

Role of Ammonia. HE is linked to hyperammonemia. Patients with encephalopathy have elevated blood ammonia levels that correlate to a degree with the severity of the encephalopathy. Metabolic products formed from ammonia—most notably glutamine and its transamination product, ketoglutaramic acid—also are present in excess cerebrospinal fluid (CSF) in patients with liver disease. Treatment strategies that lower blood ammonia levels are the cornerstone of thctapy.

Tracer studies performed with ' N-ammonia have helped clarify the role of this toxin in the pathophysiology of HE. Ammonia and other toxins arc formed in the GI tract and carried to the liver by the hepatic portal vein, whetc toxification reactions take place. Portal systemic shunts cause ammonia to bypass the liver and enter the system

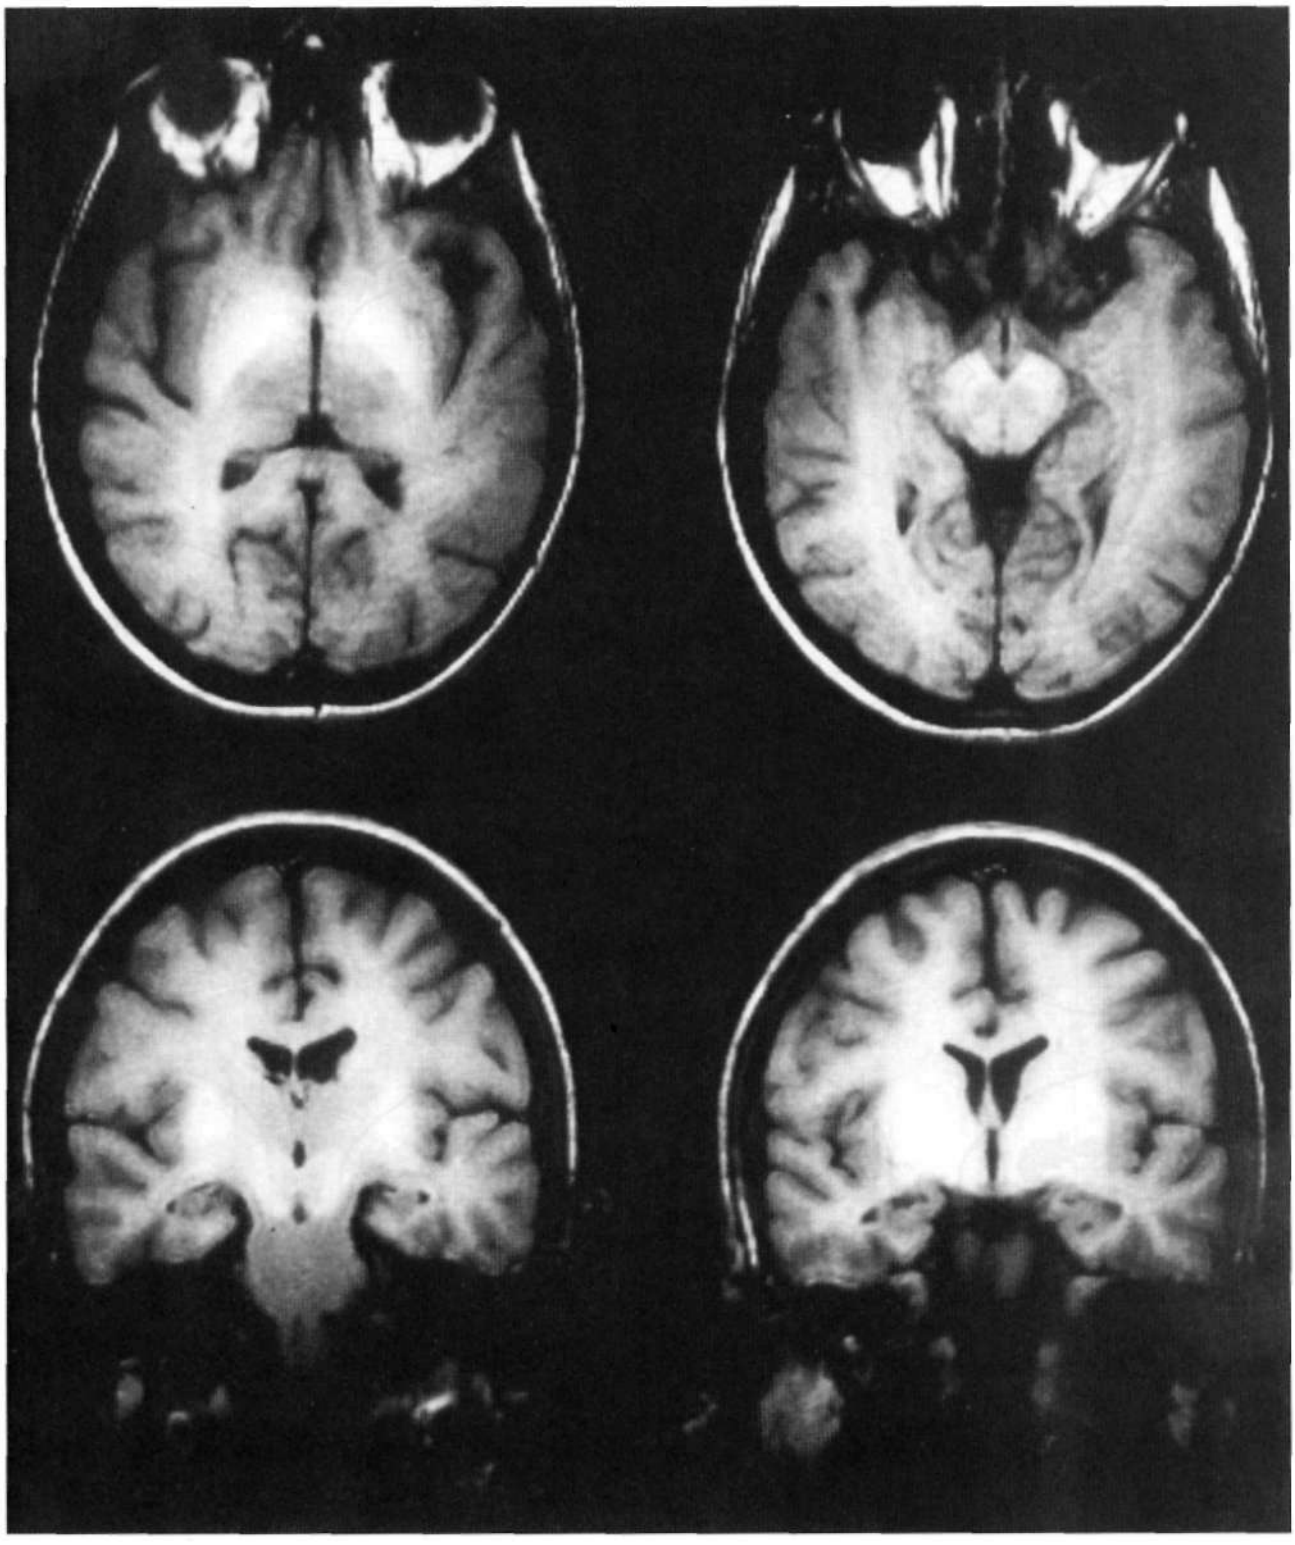

FIGURE 62.1 Tl-weighted magnetic resonance images from a patient with cirrhosis of the liver. Note high signal in basal ganglia, cerebral peduncles, and substantia nigra.

circulation, where it is transported to the various organs as determined by their blood flow. The liver is the most importaiil uri;;ni for ;hc delii\ii'v.uii>[i of ./nnmonia. However, in patients with portacaval shunting of blood, because of the formation of varices, transcutaneous intrahepatic portacaval shunts or surgically created shunts, skeletal muscle becomes more nupnn.iiir as [lie fraction of blood bypassing the liver increases. Under the

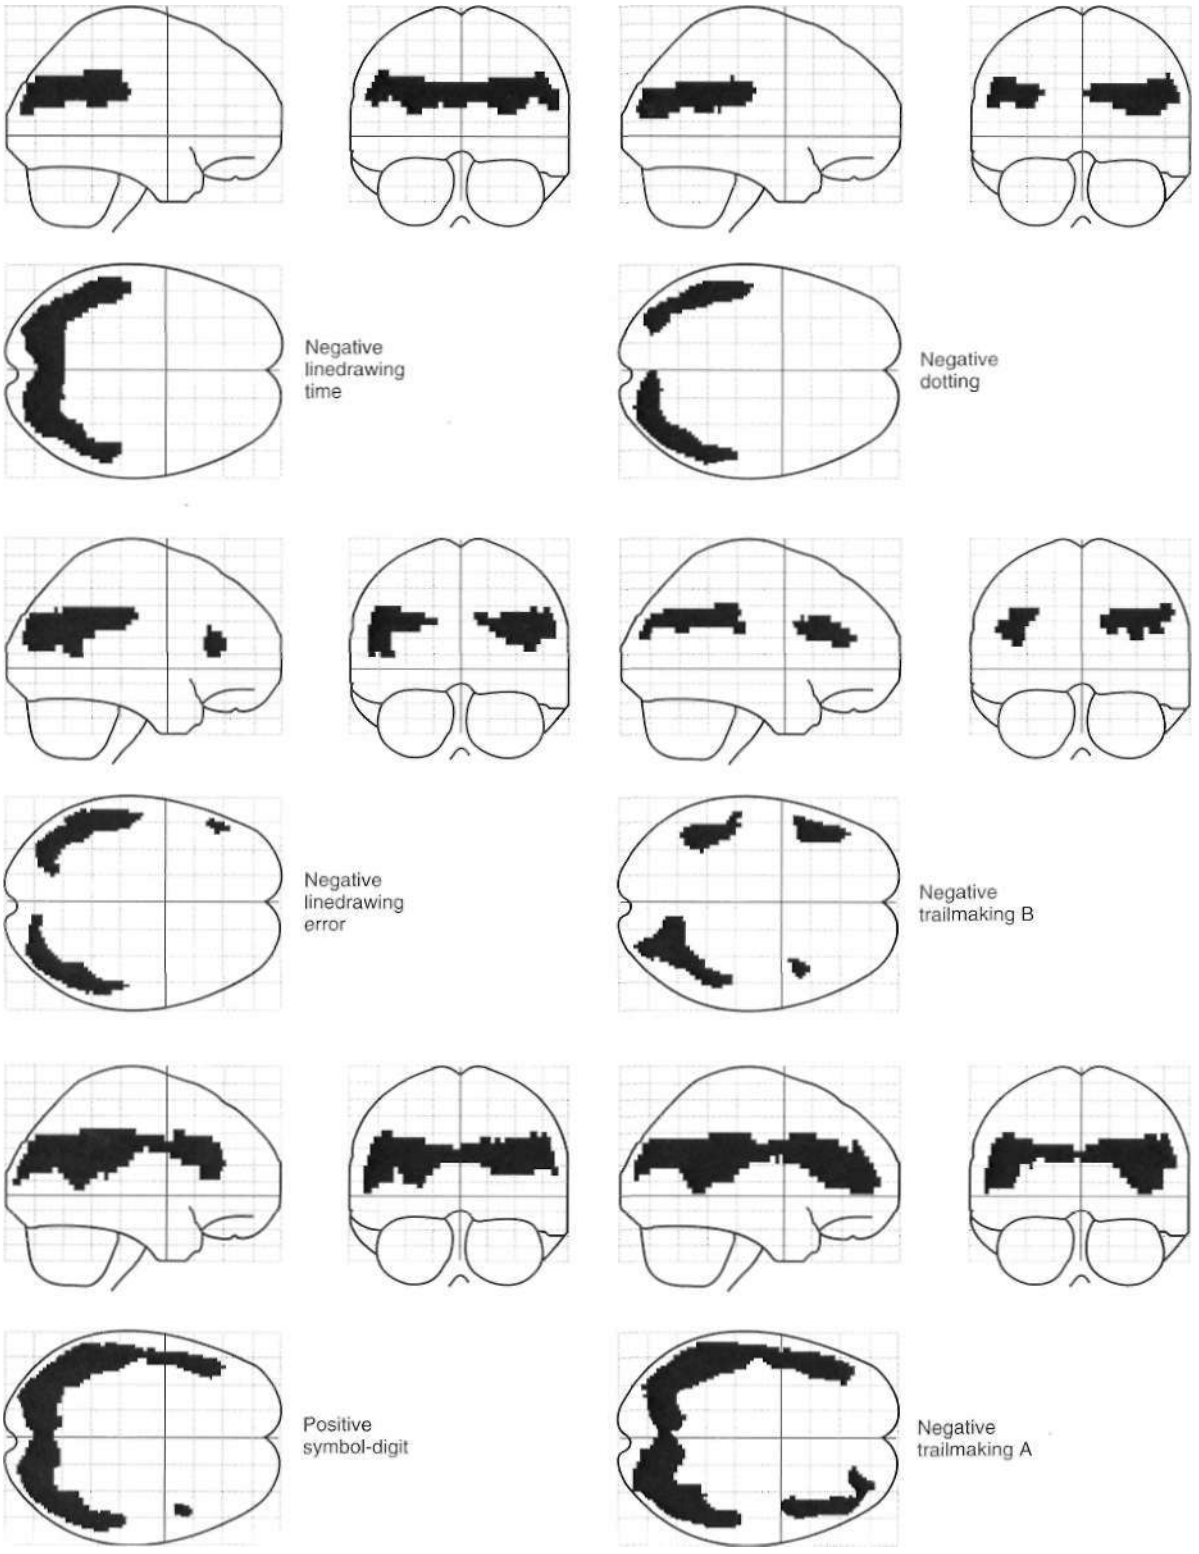

FIGURE 62.2 Correlations between performance, as measured by age-corrected *z* scores, **and metabolism for** various subtests in the composite battery. Only those subjects able to complete the test arc included in the analyses. The SPM Z image projections arc as in other figures. They all show significant correlations with bilateral parietal associative cortcxt with increasing correlations with frontal regions. The disparity of these results, particularly with regard to the correlations with frontal lobe metabolism, like the factor loading scores, suggests that the different tests appear to make different demands on cerebral resources. [Used with permission from I.ockwood, A. **H., Weissenborn, K.,** Bokeineyer, M., Tietge, et al. 2002, "Correlations between cerebral glucose metabolism and neuropsychological test performance in nonalcoholic cirrhotics," *Metabo Brain Dis,* vol. 17, pp. 29-40.)

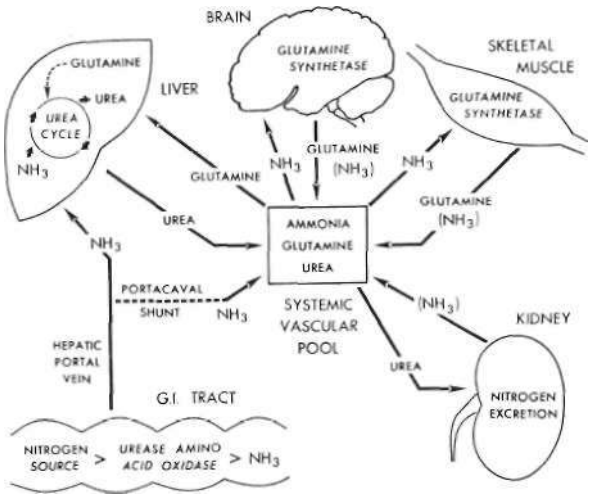

FIGURE 62..1 Human ammonia metabolism. The brain becomes more sensitive to ammonia as time progresses. Although the reasons for this are largely unknown, studies of cerebral ammonia metabolism have shown that the blood-brain barrier is more permeable to ammonia in patients with liver disease than in controls. Thus at a given arterial ammonia concentration, more ammonia enters the brain of a patient with cirrhosis than a patient without cirrhosis. This observation may explain the presence of encephalopathy in patients with near-normal arterial ammonia levels. In addition, ammonia may cause anorexia by stimulating hypothalamic centers, leading to reductions in muscle mass and an impaired ability of muscle to detoxify ammonia. CI —gastrointestinal. (Adapted from Lock wood, A. H., McDonald, J. M., Reiman, R. E., et al. 1979, "The dynamics of ammonia metabolism in man: Effects of liver disease and hyperammonemia,"/ *Clin Invest*, vol. 6"5, pp. 449-460.

most extreme conditions, muscle becomes the most important organ for ammonia detoxification. It is partly for this reason that nutritional therapy for patients should be designed to prevent development of a catabolic state.

Ammonia is always extracted by the brain as arterial blood passes through the cerebral capillaries. When ammonia enters the brain, metabolic trapping reactions convert free ammonia into metabolites (Kgure 62.3). The adenosine triphosphate (ATP(-catalyzed glutaminc synthetase reaction is the most important of these reactions. The BBB is approximately 200 times more permeable to uncharged ammonia gas (NH3) than it is to the ammonium ion (NH4+); however, because the ionic form is much more abundant than the gas at physiological pH values, substantial amounts of both species appear to cross the BBB in humans. Because of this permeability difference and because ammonia is a weak base, relatively small changes in the pH of blood relative to the brain have a significant effect on brain ammonia extraction. As blood becomes more alkalotic, more ammonia is present as the gas and cerebral ammonia extraction increases; however, the role this has in the production of HE is not known.

Other Pathophysiological Mechanisms

Abnormalities of Neurotransmission. Since the early 1970s, a variety of hypotheses have suggested that HE is caused by disordered neurotransmission. Although early hypotheses related to putative false neurotransmitters were disproved, there is still a substantial effort in this direction.

As a result of the false neurotransmitter hypothesis, it was shown that the ratio of plasma amino acids (valine + leucine + isoleucine) to (phenylalanine + tyrosine) was abnormal in encephalopathy patients, leading to the development of amino acid solutions designed to normalize this ratio, which arc now commercially available. Although infusion of the solutions normalizes the ratio and patients improve, the results of several controlled clinical trials arc inconclusive; it is not clear whether the amino acids or the associated supportive care measures caused the improvement noted.

Substantial effort has been focused on potential abnormalities of the GABA-benzodiazepine complex. Initial attention was directed at GAB A itself. Early reports that GABA concentrations were elevated in patients with encephalopathy have been disproved, and attention has shifted toward the presence of benzodiazepines or benzodiazepine-like compounds. A number of anecdotal reports have described dramatic improvements in patients who were refractory to more conventional therapy after they were given flumazenil. Some of the patients in the reports had been given benzodiazepines during the course of their care; however, whether a patient has been given benzodiazepines is not always clearly the case, and very low concentrations of benzodiazepines and their metabolites may be found in blood and CSF of patients with encephalopathy. Typically, these concentrations are substantially lower than concentrations that relieve anxiety, and appeal to be too low In produce coma. In controlled studies, patients given flumazenil are more likely to improve than those given placebo, but it is not clear that benzodiazepine displacement is the mechanism, because these patients do not have benzodiazepines in their systems. This raises the possibility that any of flumazenii's beneficial actions may be related to some other action of the drug. More recent theories have linked the presence of a increased expression of peripheral types of benzodiazepine receptors to HE. These receptors are found on mitochondrial membranes and are implicated in intermediary metabolism and neurosteroid synthesis. Hyperammonemia causes an increase in peripheral types of benzodiazepine receptors and creates a potential for an increase ill inhibitory tone in the brain, hi add in 011, there arc significant alterations in cerebral serotonin and dopamine metabolism, and a reduction in postsynaptic glutamate receptors of the N-methyl-D-aspartate type. Thus there is a substantial interest in the potential role of neurotransmitters in the pathogenesis of HE. As of yet, there is no unifying hypothesis and no rational thetapcutic approach based on altering neurotransmission.

Fatty Acids. Short-chain fatty acids affect a variety of metabolic processes, including uncoupling oxidative phosphorylation, alteting the mitochondrial respiratory state and state control mechanisms, and inhibiting the urea cycle that may, in turn, lead to hyperammonemia. They work synergistically with ammonia to produce coma in experimental animals.

Medium-chain fatty acid dehydrogenase activity deficiency may lead to the development of a clinical syndrome similar (o Rcy.'-, syndrome (see Chapter f.SR}. Indeed, many early cases of Reye's syndrome may have been caused by this metabolic deficiency.

Mercaptans. Mercaptans are thio-alcohols. In this class of compounds, the -Ol 1 group is replaced by an -SH group. Methanethiol is the principal mercaptan in humans, is formed by the cataholism of methionine, and occurs in measurable amounts in blood and exhaled air. Injecting or inhaling mercaptans produces coma in animals, and there were early teports of correlations between the concentration of mercaptans in the blood and the severity of encephalopathy in individual patients. An improved methodology for measuring mercaptans has confirmed their presence in elevated amounts in encephalopathy patients, but the correlation between the concentration and the neurological status is poor. Because mercaptans work synergistically with short-chain fatty acids, ammonia, or both to produce coma, synergistic effects may be of importance in humans.

Neuropathology

The Alzheimer's type II astrocyte is the neuropathological hallmark of hepatic coma. An account of the original descriptions of this change was provided in translation by Adams and Foley in 1953. In this report, they presented their own findings of this astrocyte change in the cerebral cortex and the lenticular, lateral thalamic, dentate, and red nuclei, offering the tentative proposal that the severity of these changes might be correlated with the length of coma, The cause of the astrocyte change was established by studies that reproduced the clinical and pathological characteristics of HE in primates by continuous infusions of ammonia. In studies of rats with portacaval shunts, astrocyte changes become evident after the fifth week, Before coma develops, there is an increase in astrocytic protoplasm and a proliferation of endoplasmic reticulum and mitochondria, suggesting that these are metabolieally activated cells. After the production of coma, the more typical signs of the Alzheimer's type II change became evident as mitochondrial and nuclear degeneration appeared. Norenbcrg (1998) suggested that HE is an astrocytic disease, although oligodendroglial cells arc affected as well,

The neuroparhological-neurochemical link between astrocytes and the production of hyperammonemic coma is strengthened by immunohistochemical studies that localized glutamine synthetase to astrocytes and their end-feet. Similar findings for glutamate dehydrogenase have been described. Long-standing or recurrent HE may lead to the degenerative changes in the brain characteristic of i ion - Wilson i a n hepatocerebral degeneration. Brains of these patients have polymicrocavitary degenerative changes in layers five and six of the cortex, underlying white matter, basal ganglia, and cerebellum. Intranuclear inclusions that are test positive by periodic acid-Schiff also are seen, as are abnormalities in tracts of the spinal cord.

Treatment

Ideally, the management of patients with cirrhosis should involve a cooperative effort be I ween he pa tologists. surgeons, neurologists, and psychologists with additional input from nurses and dieticians. Practice guidelines published by the American College of Gastroenterology identify four goals: (1) Provide supportive care, (2) identify and treat precipitating factors, (3) reduce the nitrogenous load from the gut, and (4) assess need for long-term therapy (Rlci and Cordoba 2001; Ferenci et al. 2002).

Initial diagnostic and therapeutic efforts should be directed at the identification and mitigation of precipitating factors and reducing the nitrogenous load arising from the GI tract. This is accomplished by a brief withdraw! of protein from the diet and the administration of cleansing enemas, followed by the use of lactulose. Antibiotics maybe used as an alternative to lactulose. After the acute phase of HE, patients should receive the maximum amount of protein that is tolerated. Prolonged periods of protein restriction should be avoided. Protein is required for the regeneration of hepatocytcs and prevention of a catabolic state and muscle wasting.

In patients who have cirrhosis without overt encephalopathy, diagnostic efforts should be directed toward identifying patients with minimal encephalopathy and monitoring the effects of treatment. The inappropriate terms *subclinical* or *latent HE* have been too commonly applied to patients with minimal encephalopathy. Patients with minimal encephalopathy have a diminished quality of life and benefit from therapy, typically lactulose. Although rigorous criteria have not been developed to establish this diagnosis, deficits on neuropsychological test scores are usually used as the criterion. Some have advocated the use of computerized EEG analysis for this purpose with a focus on abnormal slowing seen on an analysis of the spectrum, Follow-up testing is needed to monitor treatment.

Lactulose. Lactulose is a mainstay for the treatment of both acute and chronic forms of HE. It is a synthetic disaccharide metabolized by colonic bacteria to produce acid and causes an osmotic diarrhea.

A widely held but incorrect theory concerning the mechanism of action of lactulose centers on its ability to acidify the colon. Acidification presumably trapped ammonia as the charged and nonabsorbable ammonium

ion, thereby preventing ammonia absorption. This theory has been questioned because lactulose treatment does not increase the fecal ammonia concentration or the total amount of ammonia excreted. The effect of lactulose is attributable to its role as a substrate in bacterial metabolism, leading to an assimilation of ammonia by bacteria or reducing deamination of nitrogenous compounds. It is probably the single most important agent in the treatment of acute and chronic encephalopathy. The usual dose of lactulose is 20-30 g three or four times a day, or an amount sufficient to produce two or three stools per day. Lactulose also can be given as an enema. Lactitol, another synthetic disaccharide, is also effective. Although it is nt>i yet available in the United States, it may have some advantages over lactulose because it can be prepared in a crystalline form that may make it more acceptable to patients who' may object to the taste of lactulose preparations.

Amino Acids. The hypothesis that altered plasma amino acid ratios (discussed earlier), especially the (valine + leucine + isoleucine) to (phenylalanine + tyrosine) ratio, affect brain neurotransmitter pools has led to attempts to treat encephalopathy by normalizing the blood-amino acid profile with branched-chain amino acids. After preliminary open trials suggested a possible therapeutic benefit, a number of controlled trials were undertaken. Although they failed to show a clear beneficial effect, amino acid solutions (oral and parenteral) are still used.

Complications and Prognosis

The incidence of HE is probably underestimated, mainly because n on-neurologists are usually the primary physicians of these patients and may miss early, subtle signs of cerebral dysfunction. It is important to establish the diagnosis of Lib promptly and proceed with vigorous treatment. Although HE is potentially completely reversible, prolonged or repeated episodes risk transforming this reversible condition into non-Wilsonian hepatocerebral degeneration, a severe disease with fixed or progressive neurological deficits, including dementia, dysatthria, gait ataxia with intention tremor, and chorcoathetosis. Other patients may develop evidence of spinal cord damage, usually manifested by a spastic paraplegia. This complication may be a part of the spectrum of hepatocerebral degeneration. Differentiating correctly between early myelopathy or hepatocerebral degeneration and the motor abnormalities that characterize reversible encephalopathy may not always be possible. Because of the high sensitivity of MRI, M -.]io-.-.iNr i i.ii rhi-n recln:<)1o;Ly will aid in this difficult task. Patients with HE may develop toxin hypersensitivity, wherein previously, innocuous levels of toxins caused symptoms. This concept implies that there may be a steadily increasing risk for developing permanent neurological damage as toxin hypersensitivity evolves.

Severe hepatic coma carries a substantial risk of death. Fulminant hepatic failure is usually the result of massive necrosis of hepatocytcs and is defined as a syndrome in which the signs of encephalopathy develop within 8 weeks of the onset of the symptoms of liver disease in a patient with a previously normal liver. This condition has been desctibed as "metabolic chaos," because of coexisting acid-base, renal, electrolyte, cardiac, and hematological abnotmalities, usually culminating in GI bleeding, ascites, sepsis, and death frequently caused by cerebral edema. In spite of intensive treatment, patients who become comatose have an 80-85% mortality. Improvements in liver transplantation have led to better treatment and improved survival for these patients. Transplantation is associated with its own spectrum of neurological problems (see Chapter 55A).

Uremic Encephalopathy

Neurological disorders in patients with renal failure may present more problems for the neurologist than are found in patients with failure of other organ systems. This is primarily because of the complexity of the clinical status of many of these patients. Many of the disorders that lead to the development of renal failure, such as hypertension, systemic lupus erythematosus, diabetes melhtus, and others, are frequently associated with disorders of the nervous system. Thus it may be difficult to determine whether new neurological problems are caused by the primary disease or by secondary effects of uremia. Similarly, it is frequently difficult to determine whether neurological problems are the consequence of the progression of renal disease and progressive azotemia, the treatment of renal failure by measures such as dialysis and its associated disequilibrium and dementia syndromes, or a complication of transplantation and immunosuppression. With increasing numbers of renal transplants and improved treatment designed to prevent rejection, it is likely that the complexity of these issues will continue to increase. For these reasons, good cooperation and communication between neurologists and the nephrologists and transplant teams who care for these patients arc important,

Patbophysio logy

Clinically, patients with uremic encephalopathy exhibit many of the signs and symptoms described earlier in this chapter. Perhaps the most notable difference between these patients and those with otbet forms of metabolic encephalopathy is the frequent coexistence of signs of obtundation (suggesting nervous system depression) and twitching, myoclonus, agitation, and occasionally seizures (suggesting neural excitation). Little is known of the pathophysiology of uremic encephalopathy. As in HE, the complexity of the normal kidney's functions makes it likely that failure of the

organ leads to a variety of abnormalities that exert -.ynr !;i.-,lu JL'lekTi<ni\ **:.'kvls 0:1 ibr hi LI in.**

As in other metabolic encephalopathies and other conditions associated with a depression of consciousness, CEF and metabolism are reduced.

Water, Electrolyte, and Acid-Base Balance. Although derangements in electrolyte, water, and acid-base balance are common in patients with renal failure, they usually do nol ntaki a substantial com nbutu >n In t:ic dcvL-liipruciil of uremic encephalopathy. Disordered water balance is, however, a major factor in the syndrome of dialysis disequilibrium (see Syndromes Related to Dialysis, later in this chapter). Many patients complain of headache, fatigue, and other relatively nonspecific symptoms at the time of dialysis that are attributable to the removal of free water and solutes from the vascular compartment and a lag in re-establishing a new steady-state osmotic equilibrium with the brain. More severe forms of dialysis disequilibrium arc now rare. Before the current level of sophistication in equipment, membranes, and schedules for dialysis was developed, severe abnormalities of the EEG, epileptic seizures, coma, and even death occurred as the result of this syndrome.

Calcium and Parathyroid Hormone. Abnormal calcium metabolism and abnormal control of the parathyroid glands are common in uremic patients, including those receiving dialysis. Experimental studies have shown a doubling of the brain calcium content and serum parathyroid hormone levels within days of the onset of acute renal failure. EEG slowing correlates with elevations in the plasma content of the N-terminal fragment of parathormone. Treatment with 1,25 dihydroxyvitamin D leads to improvements in the KEG and reductions in N-reniniial fragment parathyroid hormone concentrations. Brain calcium concentrations may be related to the activity of an ATP-dependent sodium-calcium transporter protein.

Neurotransmitters, Disorders of plasma amino acids, most notably glutaminc, glycine, aromatic and branched-chain amino acids, and potential relationships to GABA, dopamine, and serotonin, have led to speculations that neurotransmitter function may be abnormal in patients with uremic encephalopathy. Others have suggested that brain calcium abnormalities may exert an effect on neurotransmitter release. These hypotheses remain unproven.

Treatment and Its Complications

Dialysis is the primary treatment for uremic encephalopathy. This may be preceeded by a period of peritoneal dialysis, which can be administered ro ambulatory patients. Many patients ultimately require transplantation.

Epileptic seizures occur in up to one third of all uremic patients. In evaluating patients with seizures, it is essential to determine whether the seizure is the result of uremia or the consequence of some other coexisting or causative illness, such as malignant hypertension with encephalopathy, intercurrent infection, dialysis disequilibrium syndrome, or cerebral infarction. Usually, the seizures caused by uncomplicated uremia arc generalized, but focal motor seizures and epilepsia partialis continua occur.

Treatment of uremic seizures is complicated by abnormalities of anticonvulsant metabolism and plasma binding encountered in patients with renal failure; phenytoin, a mainstay in seizure treatment, is affected particularly. Regardless of the route of phenytoin administration, uremic patients have lower drug levels than do normal controls, and plasma levels ot the metabolite 5-phenyl-5-para-hydroxylphenylhydantoin are higher. The half-life of phenytoin is shortened in uremia and unrelated to the binding of phenytoin to plasma proteins or to the volume of distribution. Plasma protein binding studies of phenytoin in normal and uremic patients show that normal people have approximately 8% unbound, or free, whereas uremic patients have between 8% and 25% in the unbound state. The unbound fraction correlates well with both the blood urea nitrogen and the creatinine concentration in Moo J, will[1] Ix'lui cnnylaiion with ovar.niiic :h.in blond urea nitrogen. In regulating phenytoin doses in uremic patients, it is critical to use the free drug level rather than the more commonly used total drug level. As a general rule, the free level should be kept between 1 and 2 ug/ml,, roughly 10% of the therapeutic level for total phenytoin. Phenytoin toxicity is difficult to manage in uremic patients because the drug is not removed by dialysis.

Phcnobarbital is also a useful drug for treating seizures in uremic patients in spite of the fact that it is excreted by the kidneys. Plasma phcnobarbital levels are unaffected by uremia and may be used to monitor therapy.

Orher abnormalities detected on examination of uremic patients include asterixis, tremor (which may appear before asterixis), and myoclonus. These signs do not require specific therapy and usually clear as the mental status responds to dialysis or transplantation. Tetany and spontaneous carpopedat spasms also may occur.

Treating renal failure by dialysis and transplantation has given rise to a number of neurological syndromes. Because of the large number of patients being treated by these modalities, especially dialysis, it is important to recognize currently described complications and to be alert to the possibility that new syndromes will emerge as treatment modalities evolve.

Although dialysis is clearly an important life-sustaining treatment modality for patients with renal failure, two important neurological syndromes related to this modality are recognized: dialysis disequilibrium syndrome and dialysis dementia syndrome. The former is an acute syndrome that may be seen during or after a single dialysis treatment; the latter is a chronic condition that emerges subacutely or chronically after prolonged treatment by

dialysis. The treatment and prophylaxis of these syndromes have become much more successful as our understanding of their pathophysiology has improved.

Dialysis disequilibrium syndrome occurs during or immediately after treatment by either hemodialysis or peritoneal dialysis. Symptoms range from subtle signs to death, and include seizures (usually grand mal, although focal seizure's may occur), coma, and death. Other symptoms that may be encountered include disorientation, headache (often associated with nausea, restlessness, or fatigue), muscle cramps, and tremulousness. During the acute syndrome, disorganization and KEG slowing may be seen, and CSF pressure is elevated. EEGs recorded during chronic maintenance hemodialysis show that there is usually some abnormality during the treatment of stable patients, with the most significant abnormalities seen in patients reporting symptoms such as fatigue.

The symptoms of dialysis disequilibrium are probably caused by the development of cerebral edema. Uremic patients have increased serum and brain osmolality because of the accumulation of urea and idiogenic osmoles. When rapid hemodialysis is compared with slow hemodialysis, the water and osmole content of brains of the animals treated by rapid dialysis is found to be greater than in those treated by slow dialysis. Urea concentration in the CSF and the brain exceeds the plasma urea concentration in both treatments. Rapid hemodialysis also is associated with the development of CSF acidosis and a significant osmotic gradient between blood and brain not explained by sodium, potassium, chloride, or urea concentration. These conditions result in the obligatory water retention by the brain relative to blood, which causes the brain to swell. Idiogenic osmoles are probably of critical importance in the development of this syndrome. Presumably under conditions of slower dialysis, the brain has an opportunity to rid itself of idiogenic osmoles and is less susceptible to the development of edema during dialysis. The presence of acidosis in the central nervous system also may be important. Recognizing these mechanisms has led ro a rcducuoii in the severity and incidence of this potentially fatal disorder.

Dialysis dementia syndrome is now rare and is a more serious syndrome. It is a subacute syndrome of impaired memory with personality changes, apractic dysarthric speech, myoclonus, seizures {usually multifocal), and an abnormal EEG characterized by slowing with multifocal bursts of more profound slowing and spikes. Aluminum levels in the brains of patients with the syndrome are higher than the levels in controls, in uremic patients not receiving dialysis, and in uremic patients on dialysis but without the syndrome. Epidemiological studies of the relationship of the syndrome to the aluminum content of dialysate fluid have established the latter as the probable source of rhe aluminum and the most likely cause of the syndrome. In general, all areas with large numbers of cases of the dialysis dementia syndrome had high aluminum concentrations in dialysis fluid (100-500 pg/liter). Cases occurred most frequently in areas with a high aluminum content in the municipal water supply; removal of aluminum from dialysis baths, preferably by deioni/ation, has markedly reduced the incidence of the syndrome. Although it seems clear that the majority of cases of dialysis dementia can be related to aluminum in the dialysate, there are unexplained sporadic cases occurring in centers with low aluminum levels. In these patients, blood aluminum levels appear to be high, suggesting that CI aluminum absorption may be of occasional importance in the pathogenesis of the disorder,

Treatment of the syndrome has been difficult, and link-success has been reported.

METABOLIC DISTURBANCES

Disorders of Glucose Metabolism

Under normal conditions, glucose is the exclusive fuel for the brain. The brain, unlike other organs such as rhe liver and skeletal muscle, is able to store only trivial quantities of glucose as glycogen. Because brain glucose concentrations are normally low, approximately 25% of the plasma concentration, and the cerebral metabolic rate for glucose is high, [he brain is highly vulnerable in interruptions in the supply of glucose. Hyperglycemia is tolerated by the brain better than hypoglycemia, but it, too, produces neurological symptoms, largely because of osmotic effects.

Physiology

Glucose Homeostasis. After ingesting food, blood glucose levels begin to climb, wbich, in concert with a number of complex factors, leads to the release of insulin from the pancreas. Insulin has the combined effects of suppressing hepatic glucose production and fostering the storage of glucose, particularly as glycogen in the liver. After carbohydrate absorption is complete, homeostasis is maintained by hepatic glveogeunlysis. Normally, the liver contains sufficient glycogen stores to maintain the blood glucose concentration at 80-90 mg/dE for 24-36 hours. After this time, glue oncogene sis becomes the principal mechanism for maintaining adequate plasma glucose levels. Alanine and glutamine are the amino acids that, along with lactate and pyruvate, are the most important glucose precursors. Initially, most glue oncogenes is takes place in the liver, but with extended starvation, the kidney begins to produce glucose, accounting for roughly one half of the glucose produced. Approximately one half of the glucose produced in the postabsorptive state is metabolized by the brain. Because the metabolic processes of glucose homeostasis, including insulin release, glycogen break down, and gluconeogenesis, arc complex and involve the pancreas, liver, and other organs, it is not surprising that an extensive list of conditions may present as hypoglycemia.

Cerebral Glucose Metabolism. Under normal conditions with a mean CBF of 50 mL/100 g of brain per minute and a glucose concentration of approximately 5 mmol/liter, large amounts of glucose are presented to the brain at all times. Approximately 10% of this total is transported across the BBB by a glucose transporter enzyme that exhibits Michaelis-Mentcn kinetics. Once in the brain, the majority of the glucose is metabolized by the glycolytic pathway and then by the tricarboxylic acid cycle to generate the ATP needed to maintain brain function. Normally, approximately 85% of the glucose that enters the brain is metabolized in this fashion. The remaining glucose is metabolized by the hexose monophosphate shunt and converted to glycogen. After the administration of uniformly labeled glucose, label appears in carbon dioxide in the venous blood in less than 1 minute and eventually appears in a variety of amino acids, proteins, and other compounds.

Measuring cerebral glucose metabolism was revolutionized by the development of PET using an 18F-labcled glucose analogue, fluorodeoxyglucose (FDG). FDG PET scans of the brain are an important aspect in the preoperative investigations of patients with intractable seizure disorders.

Clinical Aspects of Hypoglycemia

Diagnosing hypoglycemia on the basis of clinical symptoms is ftaught with hazards. Although the majority of symptoms are attributable to nervous system dysfunction, they are extremely varied, nonspecific, and not always present, even when blood glucose levels are very low. Because of the close link between the symptoms of hypoglycemia and the brain, some authors use the term neuroglycopenia to refer to symptomatic hypoglycemia. There arc three syndromes: acute, subacute, and chronic.

The acute syndrome most commonly develops as the result of the action of short-acting insulin preparations or oral and hyperglycemics and begins with vague symptoms of malaise, feeling detached from the environment, restlessness associated with hunger, nervousness that may lead to panic, sweating, and ataxia. Patients may recogni/.e these symptoms. The symptoms respond quickly to oral or parenteral glucose. An EEG during this period may reveal nonspecific abnormalities. Attacks may end spontaneously or proceed rapidly to generalized seizures and coma, with the attendant risk of permanent brain injury. These patients may arrive in the emergency department m coma with no history.

The subacute syndrome is the most common form and occurs in the fasting state. Most of the symptoms listed for the acute syndrome are absent. In their place is a slowing of thought processes and a gradual blunting of consciousness with a retention of awareness, although amnesia for the episode is common. The diagnosis may be difficult to establish until the possibility of hypoglycemia is considctcd or routine testing uncovers the abnormality. Hypothermia is encountered frequently in this form of the disorder, and unexplained low body temperatures always should be followed by a blood glucose measurement.

Chronic hypoglycemia is rare and, if confirmed, suggests a probable insulin-secreting tumor or obsessively good control by a diabetic. Plasma hemoglobin A_{1t}. levels arc helpful in making this differential diagnosis. This syndrome is characterized by insidious changes in personality, memory, and behavior that may be misconstrued as dementia. Unlike those of the acute and subacute forms of hypoglycemia, these symptoms are not relieved by administering glucose, suggesting the presence of neuronal injury. Clinical improvement after removal of the source of the exogenous insulin is gradual, extending over periods as long as a year.

The symptoms of sweating, tremor, and the sensation of warmth may be attributed to activity of the autonomic nervous system. The inability to concentrate, weakness, and drowsiness arc attributable to neuroglycopenia. Hunger, blurred vision, and other symptoms are of uncertain cause.

Diabetics may develop hypoglycemia without being aware of the usual warning symptoms, a condition known as *hypoglycemia unawareness,* which may occur in a complete or partial form in up to 17% of all episodes in patients with type 1 diabetes (MacLeod et al. 1993). The underlying mechanisms appear to be related to the occurrence of prior episodes of hypoglycemia, altered neuroendocrine responses that regulate blood glucose levels, and central nervous system dysfunction that may interfere with symptom detection and analysis (Lingenfclser et al, 1993).

There are special problems associated with detecting hypoglycemia in neonates and children that center on the various nonspecific symptoms {e.g., pallor, irritability, and feeding difficulties) and on the variable sensitivities of individual children to a given plasma glucose concentration. As with adults, the diagnosis is most likely to be made when the physician consciously keeps his or her index of suspicion high and when glucose measurement is done routinely when there is any doubt about a diagnosis. The risk of missing the diagnosis and having irreversible neuronal injury develop in the patient justifies liberal use of screening measures and, in some cases, presumptive treatment with parenteral glucose.

Because of the complexity of glucose homeostasis, the causes of hypoglycemia arc many and varied, and a detailed discussion is beyond the scope of this chapter. In general, most authors present a physiological classification as shown in Table 62.3.

Drugs are frequently cited as an important cause of hypoglycemia. In some cases the effect of a drug may be pnk'ruiak'i.: by .i lvsnvtinn of food intake. Ai;i'-v;iyving causes have been found and should aid in the diagnosis of the disorder. In the newborn period, administration of sulfonylureas to the mother dominated as a cause of

Table 62.3: Causes of hypoglycemia

Postprandial hypoglycemia (reactive)
Postoperative rapid gastric emptying (alimentary hyperinsulinism)
Fructose in tolerance
Galactosemia
I rlkIli:- intolerance
Idiopathic
Fasting hypoglycemia
Overuse of glucose
Elevated insulin levels
Exogenous insulin (therapeutic, factitious)
Oral hypoglycemic (therapeutic, factitious)
Islet cell disorders (adenoma, nesidioblastosis, cancer)
Excessive islet cell function (prediabetes, obesity)
Antibodies to endogenous insulin
Normal to low insulin levels
Kctotic hypoglycemia
Hypermetabolie state (sepsis)
Rare extra pancreatic tumors
Carnitine deficiency
Antibodies to endogenous insulin
Underproduction of glucose
Hormone deficiencies (growth hormone, glucagon, hypoad renal ism)
Enzyme disorders
Glycogen metabolism (glycogen phosphorylase, glycogen synthetase)
Hexosc metabolism (glucose-6-phosphatase, fructose-1,6-bi phosphatase)
Glycolysis, Krebs cycle (phosphoenolpyruvate carboxykinase, pyruvate carboxylase, malate dehydrogenase)
Alcohol and probably other drugs
Liver disease (cirrhosis, fulminant hepatic failure)
Severe malnutrition

hypoglycemia. From 0-2 years, salicylate ingestion dominates. Surprisingly, alcohol predominated as a cause in the 2- to 7-year age group. Alcohol-containing cough syrups **and** alcoholic beverages were responsible. Sulfonylureas again dominate in the 11- to 30-ycat and 50 and older age groups. Alcohol predominated between the ages of 30 and 50 years. Significant numbets of patients in most age groups were encountered in whom beta blockade with propranolol was a factor in masking the symptoms of developing hypoglycemia. The use of beta blockers in patients receiving insulin or oral hypoglycemic agents therefore should be avoided. A number of risk factors have been recognized that predispose to the development of hypoglycemia. These include (in addition to diabetes) decreased caloric intake (usually related to severity of some illness or disruption of dietary routines), uremia, livet disease, infection, shock, pregnancy, neoplasia, and burns.

Hypoglycemia is associated with a substantial morbidity. A study of 600 patients with diabetes showed that the frequency of severe hypoglycemia was 1.60 episodes pet patient per year and that it occurred twice as often in patients with the type 1 form of the disorder (MacLeod et al. 1993). Among patients with severe episodes of hypoglycemia, injuries and convulsions occurred at rates of 0.04 and 0.02 episodes per patient per year. Five patients had automobile accidents caused by hypoglycemia. Patients with episodes of severe hypoglycemia were more likely to have had priot sevete episodes, were on insulin longer, and had lower hemoglobin $A]_c$ concentrations. A southern California medical examiner found 123 deaths caused by hypoglycemia in a series of 54.S.50 autopsies. The risk of death is highest in patients with the most sevete hypoglycemia and the largest number of risk factors. Among hospitalized patients, whites have the lowest mortality (approximately 6%), whereas black and Hispanic patients have mortalities of 30% and 46%, respectively.

Hypoglycemia is a medical emergency, and all patients suspected of being hypoglycemic, including all patients with coma of unknown cause, should be treated with parentetal glucose after adequate blood samples ate obtained fot laboratory testing. It is prudent to dtaw extra blood so that insulin and hemoglobin $A|_e$ levels can be measured if indicated by the patient's subsequent coutse. These measures are particularly important in patients with obscure histories and in whom factitious hypoglycemia may be present. The total amount of glucose administeied may be of little consequence if the patient is found to have a notmal or elevated plasma glucose concenttation. Exogenous glucose is harmful to the brain during hypoxia or ischemia, and caution must be exercised in administering glucose to this group of patients.

Clinical Aspects of Hyperglycemia

Although thetc ate many causes of hyperglycemia, diabetic ketoacidosis (DKA), nonketotic hyperosmolar coma, and iatrogenic factors, such as parenteral hyperalimentation, are the most important. DKA is a relatively common disorder affecting patients with type 1 diabetes. It is frequently precipitated by an infectious process in a patient who has been otherwise stable, develops ovet sevetal days, and is heralded by polyuria and polydipsia caused by the osmotic diuresis produced by glucosuria. These symptoms ate followed by anorexia, nausea, disorientation, and coma. On physical examination, sustained hyperventilation is common, especially in patients with severe acidosis. The diagnosis is frequently suspected on the basis ot clinical findings, but labotatory data, including the plasma glucose, arterial blood gases, electrolytes, and an appropriate test for ketone bodies, ate essential fot confirming the diagnosis and management.

Nonketotic hyperosmolar coma, by contrast, is a feature of type 2 diabetes and is thus encountered in older patients, commonly as the first manifestation of the disease. This syndiome evolves more slowly than DKA, and the period of polyuria is more prolonged, leading to much mote severe dehydration. Because glucose is a less effective dipsogen than other solutes, watet-sceking behavior is not as strong in this group of patients as it is in patients with

hypematremic hyperosmolality, thus promoting the development of dehydration. Suppressed water-seeking behavior, combined with the inhibitory effect of hypertonicity on insulin release, can lead to severe dehydration and hyperglycemia that can be in excess of 2000 mg/dL. The disorder's signs and symptoms are those of hyperosmolality, hypovolemia, and cerebral dysfunction, with epileptic si'i/LLivs inYiirnns! in MUHC individuals. Precipitating factors include infection, gastroenteritis, pancreatitis, and, occasionally, treatment with glucocorticoids or phenytoin. Because many total parenteral nutrition protocols use solutions with high glucose contents, hyperglycemia is a potential complication of their use.

DKA is an insulin-deficient state, and insulin is the cornerstone of therapy. In the absence of insulin, peripheral glucose uptake and glycogen formation are reduced, and glycogenosis and lipblysis are accelerated, leading to the formation of acidic ketone bodies and hyperglycemia. When plasma glucose levels exceed the renal threshold (usually approximately 180 mg/dL), glucosuria and a forced osmotic diuresis ensue. The treatment of DKA is designed to reverse these pathophysiological abnormalities and consists of administering insulin to enhance glucose uptake, enhance glycogen formation by nonccrchral tissues, and reduce the rate of ketone body formation that occurs during low-insulin, high-glucagon states that promotes the entry of fatty acids into mitochondria, where they are converted to ketones. Replacing fluid and electrolytes also is required, as is treatment of precipitating factors. It is important to remember that overly vigorous treatment with rapid restoration of plasma osmolality to normal levels can lead to the development of cerebral edema (see Complications of Treatment, later in this chapter).

Neurologists may become involved in the diagnosis and management of patients with nonketotic hyperosmolar coma when a patient has no prior history of diabetes and is brought to the emergency department with unexplained coma or seizures. Because hyperosmolality and the associated hypovolemia are usually much more severe in this condition than in DKA, maintaining an adequate blood pressure and cardiac output are the first priorities in treatment. One or two liters of normal saline should be given rapidly to restore blood volume and to begin to reduce plasma osmolality. Additional fluid and insulin therapy then can be initiated as indicated by laboratory and clinical data. These patients may require intensive monitoring with arterial and Swan-Ganz catheters to monitor the circulatory system status and avoid inducing a volume overload; at the same time, adequate amounts of fluid should be given to restore osmolality to normal levels. The exact mechanisms leading to the development of the syndrome, particularly the absence of ketosis, are not fully explained.

ComplicationsofTreatment. AlthoughtreatmentofDKA has improved, the mortality rate is still appreciable. The majority of patients who succumb do so because of cardiovascular collapse or from complications of the precipitating factor. A small number of patients die unexpectedly when laboratory and clinical indicators all show initial improvement,

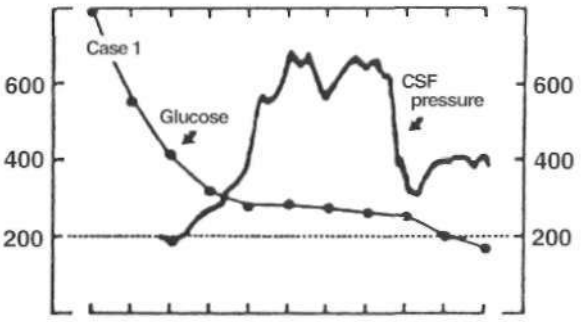

FIGURE 62.4 Blood glucose and intracranial pressure during treatment of diabetic ketoacidosis. The untreated hyperosmolar state leads to the intracerebral accumulation of idiogenic osmoles. As blood glucose and osmolality levels decrease during treatment, free water niters the brain more rapidly than idiogenic osmoles arc shed, leading to an increase in intracranial pressure from the swollen brain. This mechanism presumably operates in all cases in which hyperosmolality is corrected rapidly. CSF = cerebrospinal fluid. (Reprinted with permission from Clements, R. S. Jr, Blumenthal, S. A., Morrison, A. D., et al. 1971, "Increased cerebrospinal fluid pressure during treatment of diabetic kcroses," *Lancet,* vol. 2, pp. 671-675.)

Clinically, patients with DKA who die experience rapid neurological then cardiovascular deterioration. Postmortem examinations of the brains show lesions similar to those seen in acute asphyxia, including capillary dilation with perivascular and pericellular edema. Death is heralded by a rapid evolution of signs and symptoms indicating an increase in intracranial pressure. Approximately one half of patients die during the initial episode of DKA. The rate and degree to which the plasma glucose level is lowered is not a major risk factor for death.

Some degree of cerebral edema attends the treatment of most patients with DKA, occasionally to the high level of 600 mm CSF pressure, as shown in Figure 62.4.

The data suggest that at least mild, clinically silent cerebral swelling may be much more common than is realized in cases of DKA. Rare, unknown factors appear to trigger a malignant increase in intracranial pressure in a small number of patients, producing a syndrome characterized by rapid neurological deterioration and death caused by neurological and circulatory collapse. Published experience suggests that if this diagnosis is made, prompt, aggressive treatment of cerebral edema is indicated, preferably using intracranial pressure monitoring as a guide to therapy. Nevertheless, there is still a high mortality.

Glucose and Cardiopulmonary Resuscitation. A number of studies suggest that hyperglycemia is associated with an

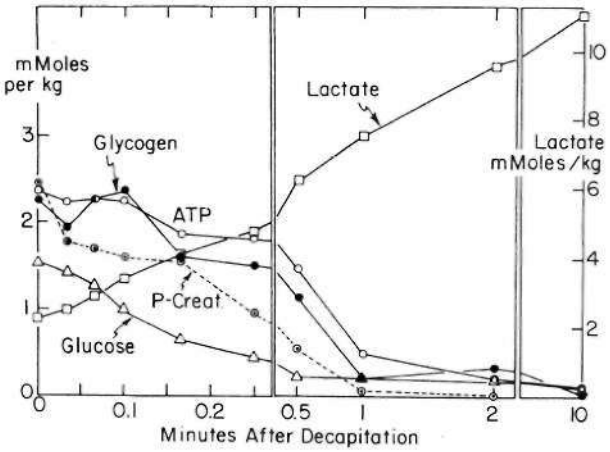

FIGURE 62.S Neurochemical consequences of decapitation. Experimental animals were decapitated and then frozen at various times thereafter. Brains were assayed for metabolites, as shown in the figure. As can lie seen, high-energy phosphates are depleted rapidly. Glucose and glycogen also are consumed, generating lactate, as metabolism changes from the normal aerobic condition to an anaerobic state. The changes shown in this figure are analogous to those following acute hypoxia or cerebral infarction. ATP = adenosine triphosphate; P-Crcat = phosphocreatine. (Reprinted with permission from Lowry, O. H. & Pasonneau, J, V. 1964, "The relationships between substrates and enzymes of glycolysis in brain," / *Biol Chem*, vol. 239, pp. 31-42.)

increase in the severity of complications of cerebral ischemia and hypoxia. The presumption is that blood, and hence brain, glucose levels are higher in hyperglycemic individuals and that this glucose produces more lactate during the hypoxic-ischemic insult. This sequence is shown in Figure 62.5, in which the metabolic consequences of decapitation in animals are shown. Glucose is metabolized anaerobically to lactate, which, with the hydrolysis of ATP, causes acidosis. A large number of experimental studies suggest that cerebral acidosis is an important determinant of brain injury, including acidosis associated with lactate production during ischemia. The results of these studies have been extended to humans, in whom a less favorable outcome was suggested for stroke patients with diabetes and hyperglycemia compared with euglycemic diabetic stroke patients.

A number of animal studies have shown that the risk of neurological injury during resuscitation from cardiopulmonary arrest increases if exogenous glucose is administered. This issue has been investigated in humans by Longstretch et al. (1993), who randomly administered 5% dextrose in water or half-normal saline while treating out-of-hospital cardiopulmonary arrest. These treatments did not produce significant differences among three measures of outcome: awakening, survival to admission to the hospital, or discharge from the hospital. However, because patients with ventricular fibrillation or asystole with high blood glucose levels at the time of admission to the hospital were less likely to awaken than patients with lower blood glucose levels, they concluded that it is appropriate to restrict the amount of glucose administered during cardiopulmonary resuscitation.

Disorders of Water and Electrolyte Metabolism

Patients with abnormalities of water and electrolyte metabolism frequently exhibit signs and symptoms of cerebral dysfunction. Typically, these patients have altered states of consciousness or epileptic seizures that herald the onset of the abnormality. The vulnerability of the nervous system to abnormalities of water and electrolyte balance arises from changes in brain volume, especially the brain swelling that may be associated with water intoxication; the abnormalities are symptomatic almost immediately because the brain is enclosed by the rigid skull. The role played by electrolytes is also important in maintaining transmembrane potentials, neurotransmission, and a variety of metabolic reactions, such as those involving the role of calcium and calmodulin. Although most clinicians are aware of the importance of water and electrolyte disturbances as a cause of brain dysfunction, the importance of the brain in the control of water and electrolytes is less well appreciated.

Disordered Osmolality

Osmotic Homeostasis. The serum, and hence whole-body osmolality, are regulated by complex neuroendocrine and renal interactions that control thirst and water and electrolyte balance. When serum osmolality increases, the brain loses volume; when osmolality falls, the brain swells, Events related to water loss are illustrated in Figure 62.6. The brain has little protection in terms of volume changes when an osmotic stress is acute. Examples of acme osmotic stress may be found in patients with heat stroke, inadvertent solute ingestion (particularly in infants), massive ingestion of water (which may be psychogenic), hemodialysis, and diabetics with nonketotic coma. When osmotic stress is applied more slowly over a longer period, the predicted volume changes arc smaller than would be expected. The mechanisms that underlie these protective adaptations are not known completely but involve the gain of amino acids in the case of the hyperosmolar state and the loss of potassium in the hypo-osmolar state. Experimental studies have failed to identify all of the osmotically active particles that must exist in the brain after a given osmotic stress is applied. These unidentified molecules are called *idiogenic osmoies.*

Hypo-osmolality and Hyponatremia. Hypo-osmolality almost always is associated with hyponatremia. The diagnosis usually is made by laboratory testing. Conditions associated with hyponatremia are shown in

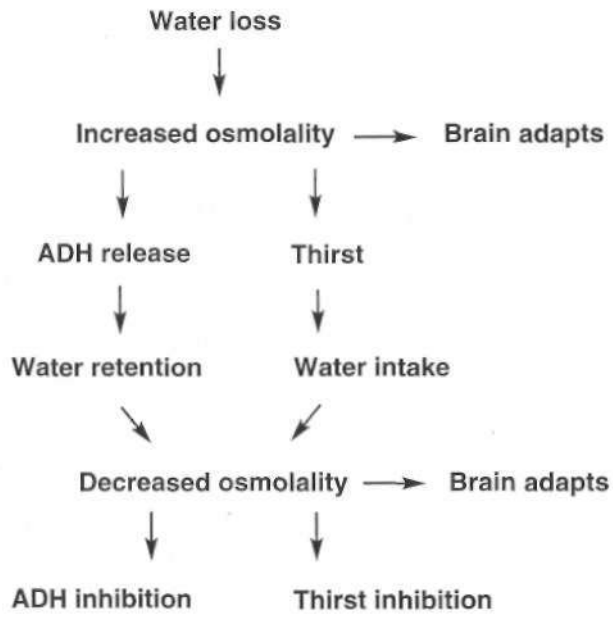

FIGURE 62.6 Water balance and tlie brain. A reduction in water (or an increase in water loss or solute gain) stimulates tbirst and vasopressin release, leading to increased water conservation and intake, which in turn reduces vasopressin levels and ends thirst. Excessive water intake or excessive water loss leads to hypo-osmolality or hyperosmolality and the loss or gain of osmotically active particles in the brain, respectively. Excessively rapid treatment of these conditions may lead to the development of neurological symptoms. ADH = antidiuretic hormone,

Table 62.4. When hyponatremia is encountered, a measurement of serum osmolality should be performed to differentiate true from pscudo hypo-osmolaliry, which may be encountered in patients with lipemic serum or in neurological patients treated with mannitol.

A large and diverse group of neurological conditions is associated with hyponatremia as a result of SIADH,

Postoperative state
Idiopathic

as shown in Table 62.5. SIADH is characterized by hyponatremia in the face of normal or increased blood volume, normal renal function, and the absence of factors that normally operate to produce antidiuretic hormone

release. The syndrome may be relatively asymptomatic, in which case water restriction is the treatment of choice. In more severe cases, hypertonic saline combined with a diuretic may be required. Overly zealous treatment may produce central pontine myclinolysis (sec Therapy, later in this chapter). Chronic syndromes have been treated successfully with a variety of drugs, including the tetracycline dcmeclocycliue, which interferes with the action of antidiuretic hormone on the renal tubules.

Great care must be taken when considering the diagnosis of SIADH in patients with subarachnoid hemorrhage. Patients with subarachnoid hemorrhage, hyponatremia, and reduced blood volume may not have true SIADH. In these patients fluid restriction may lead to further volume reduction and cerebral infarcts during the period of the highcsi risk for vasospasm, The mechanisms underlying this phenomenon are not clear, but may be related to the complexity of the peptidergic neurotransmitter systems in the vicinity of the third ventricle and to the possibility that they are damaged by the ruptured aneurysm. Damage is especially likely with an aneurysm on the anterior communicating artery. Hyponatremia occurs in approximately 1 % of patients with recent surgical procedures. Because the symptoms are frequently mild or attributed to the surgery itself, this diagnosis may be missed. Typically, these patients seem to do well in the immediate postoperative period and then develop symptoms and signs of encephalopathy. Men and postmenopausal women are less likely to develop postoperative hyponatremia than women who are still menstruating. Complications, such as respiratory arrest, are particularly likely to occur in menstruating women and occur at higher serum sodium concentrations than in men or menopausal women. Thus it is important to be particularly vigilant when evaluating younger women with postoperative encephalopathy.

Therapy. The treatment of hyponatremia always has been controversial and has become more so since the link between hyponatremia and the subsequent development of central pontine myclinolysis was recognized and experimental replication of the syndrome achieved. Harris et al. *(1993)* reviewed this problem. They were not able to identify rite rue a I which sera m sodium was con,.., led, the absolute magnitude of the correction, or the type of solution infused as a factor that predisposed to the development of central pontine myelinolysis. They noted that there are undoubtedly thousands of patients with symptomatic hyponatremia who have been treated successfully using a large number of protocols but who have not been reported. This makes it impossible to estimate the risk of central pontine myclinolysis associated with any given treatment regimen. However, because they were unable ro identify any cases of central pontine myelinolysis among the 185 published examples of symptomatic hyponatremia (published since 1954) in which patients were allowed to "self-correct" during a period of water restriction (as opposed to the infusion of saline solutions of varied concentrations), they suggested that the preferred therapy of hyponatremia might be water restriction and discontinuing diuretics. Fraser and Arieff (1997) recommend the use of hypertonic sodium chloride for the treatment of symptomatic hyponatremia. Infusions should be adjusted to increase the plasma sodium concentration at a rate of 1 mmol/liter per hour. Complicating factors such as evidence for cerebral edema or seizures require more rapid correction of the deficit. A rate of 4-5 mmol/liter per hour was suggested. Hypertonic saline therapy may he discontinued when patients become asymptomatic, when the serum sodium reaches 120-125 mmol/liter, or when the plasma sodium has increased by a total of 20 mmol/liter. Protection of the airway and ventilatory support may he required. Diuretics acting at the loop of Henle, such as furosemide, may be required. It is important to monitor electrolytes at frequent intervals (every 2 hours) and to avoid the administration of excessive amounts of sodium and the production of hypemarremia.

Hyperosinoiality. Hyperosmolality is less common than hypo-osmolality but may present with similar symptoms or evidence of intracranial bleeding caused by the tearing of veins that bridge the space between the brain and dural sinuses. Usually, hyperosmolality is diagnosed by laboratory findings of an elevated scrum sodium or, perhaps more commonly, hyperglycemia in diabetics. The syndrome frequently is caused by dehydration, especially in hot climates; by uncontrolled diabetes with or without ketosis; and, less frequently, by central lesions that reset the osmotically sensitive regions of the brain. As with hypo-osmolality, cautious correction of the defect is important. Replacement should be given orally, if possible. The first half of the deficit can be given rapidly, but the second half must be given with much more caution to avoid producing iatrogenic brain swelling as the whole-body osmotic pressure decreases.

Chronic hyperosmolality is associated with relative brain volume preservation as a result of the production of idiogenic osmoles, as described earlier. Administering free water at a rate that exceeds the rate at which the brain is able to rid itself of idiogenic osmoles is associated with the development of paradoxical brain edema that occurs at a time when serum glucose and electrolyte concentrations are normalized. This is illustrated by the data in Figure 62.4, in which the CSF pressure was measured continuously as hyperglycemia caused by diabetes mellitus was corrected. The increase in intracranial pressure is undoubtedly caused by adapted brain cells imbibing free water as serum osmolality decreases in response to therapy. If patients undergoing treatment for hyperosmolar states develop new neurological signs, including altered consciousness and seizures, rhe diagnosis of brain swelling should be considered, Mannitof treatment to restore osmolality to the

prior elevated level may be required to prevent death caused by brain swelling.

Disorders of Calcium

Hypercalcemia and hypocalcemia both have diverse causes associated with disordered parathyroid gland function and a variety of oilier conditions. Under normal circumstances, approximately one half of the total serum calcium is bound to proteins, mainly albumin, and one half is in the ionized form, the only form in which it is active. When there is doubt about the ionized calcium concentration, as in patients with hypoalbuminemia, direct measurement of ionized calcium with ion-sensitive electrodes may be required.

Hypercalcemia is associated with hyperparathyroidism; granulomatous diseases, especially sarcoidosis; treatment with drugs including thiazide diuretics; vitamin D; calcium itself; tumors that have metastasized to bone; and thyroid disease. Many cases are idiopathic. The symptoms and signs of hypercalcemia may be protean. Severe hypercalcemia affects the brain directly, causing coma in extreme cases. In this group of patients, metastatic tumors are common, especially multiple myeloma and tumors of the breast and lung. Cancer patients seem to be particularly vulnerable to developing hypcrcaleemia after a change in therapy. Less severe hypercalcemia may cause altered consciousness with a pseudodementia syndrome and weakness. GI, renal, and cardiovascular abnormalities also may be present.

Severe hypercalcemia is life threatening. Initial treatment consists of a forced diuresis using saline and diuretics. Because the volumes ol saline thai are required ma\ he large, a central venous or Swan-Ganz catheter may be needed lo monitor thcrap-.. OIKC the initial phase ol treatment is accomplished, further management is determined by the cause of the hypcrcaleemia.

f lypocalcemia usualh is associated with hypoparathyroidism. The neurological symptoms are caused by the enhanced excitability of the nervous system. Symptoms include paresthesias around the mouth and fingers, cramps caused by tetanic muscle contraction, and, in more extteme cases, epileptic seizures. In more chronic hypocalcemia, headache caused by increased intracranial pressure may occur, and extrapyramidal signs and symptoms such as chorea or parkinsonism may be encountered. These patients may have calcification of the basal ganglia, evident on computed tomographic scans of the brain. The physical examination should include attempts to elicit Chvostek's and Trousseau's signs. Cataracts and papilledema may be seen.

Severe hypocalcemia should be treated with infusions of calcium to treat or prevent epileptic seizures or laryngeal spasms, both of which are life-threatening but unusual complications. Chronic therapy usually involves the administration of calcium and vitamin D. Care must be taken to avoid hypercalcemia and hypercalciuria. Consultation with an endocrinologist is prudent, but continued neurological care may be necessary, especially in patients with extrapyramidal syndromes, who may require specific treatment.

Disorders of Magnesium

Hypermagnesemia is an unusual condition because ol unease with which normal kidneys act to preserve magnesium homeostasis. The most frequent cause of hypermagnesemia is infusions given to treat symptoms of eclampsia, in which its effect to lower blood pressure and inhibit the nervous system is desirable. Care must be observed in administering magnesium to patients with renal failure. This group of patients is the most vulnerable and the most likely to develop hypermagnesemia because the kidneys' homeostatic function is impaired. Hypocalcemia potentiates the effects of excess magnesium. Severe hypermagnesemia is life threatening, and concentrations in excess of 10 mEq/liter must be treated. Discontinuation of magnesium preparations usually suffices. When cardiac arrhythmias are present or circulatory collapse is possible, calcium must be infused, especially when hypocalcemia is present.

Isolated Hypomagnesemia is unusual. Magnesium deficiency usually occurs in patients with deficiencies of other electrolytes. Hypomagnesemia may result from a diet deficient in magnesium, including prolonged parenteral alimentation with insufficient or no magnesium replacement, malabsorption, and alcoholism. Excess magnesium loss from the GI tract or the kidneys also can lead to calcium deficiency. Magnesium deficiency is usually part of a complex electrolyte imbalance, and accurate diagnosis and management of all aspects of the state are necessary to ensure recovery.

Pure magnesium deficiency has been produced experimentally and is expressed primarily through secondary reductions in serum calcium levels in spite of adequate dietary calcium intake. Ultimately, anorexia, nausea, a positive Trousseau's sign, weakness, lethargy, and tremor develop but are rapidly abolished by magnesium repletion. Balance studies indicate that magnesium deficiency causes a positive sodium and calcium balance and a negative potassium balance. Magnesium is necessary for proper mobilization and homeostasis of calcium and the intracellular retention of potassium. Some of the effects of magnesium depletion are secondary to abnormalities of potassium and calcium metabolism.

Disorders of Manganese

Manganese poisoning occurs primarily in manganese ore miners and causes parkinsonism. As presented in the section on HE, there is increasing evidence rhat accumulation of this metal in the brain causes the Tl MR! hyperintensities and may be associated with disorders of dopaminergic neurotransmission.

DRUG OVERDOSE AND TOXIC EXPOSURES

The tentative diagnosis of intentional or accidental drug overdose must be considered during the course of the evaluation of almost all emergency department patients with altered behavior (see Chapter 64B). Most overdoses are attributable to drugs in one of six groups that account for more than 80% of all positive laboratory results. They are, in order of decreasing frequency, ethanol, benzodiazepines, salicylates, acetaminophen, barbiturates, and tricyclic antidepressants. Table 62.6 classifies dtugs into four groups based on the usefulness of toxicotogieal information and the relationships between drug levels and symptomatology. Regional poison control centers usually are staffed by well-informed, helpful personnel and should be consulted when further information is needed or there is uncertainty about the contents of specific products. Reported patterns of drug overdoses vary among communities and with time. Illicit drug availability varies substantially by region and evolves constantly. So-called designer drugs arc unpredictable. As benzodiazepine use has increased and replaced barbiturates used as sleeping pills, barbiturate intoxications have declined. The prevalence of overdose varies as a function of the numbet of prescriptions written.

Miscellaneous Disorders

Neurologists may be asked to evaluate patients with vague complaints such as headache, poor concentration and memory, and other symptoms to determine whether toxin exposure is a contributing factor. These requests may occur during the coutsc of ordinary patient care, litigation, or more systematic population-based investigations, hi some instances, the doctor-patient relationship is clouded by political or legal ramifications of the questions asked and the possible answers. Concerns about Gulf War syndrome typify this dilemma. Many veterans of the Persian Gulf conflict contend that a variety of problems ranging from the complaints outlined previously to more definitive problems, such as amyotrophic lateral sclerosis, a variety of cancers, birth defects among their children, and others, are the consequence of exposure to chemicals, including insecticides, pytidostigmine bromide, and nerve agents. This anxiety was heightened by the revelation in the summer of 1997 that the destruction of a munitions depot in Khamisiyah, Iraq, in March 1991 released a cloud of sarin that exposed almost 100,000 troops to this nerve agent. Kven though there were no documented acute effects of sarin on the exposed combatants, suspicion and distrust of the federal authorities charged with evaluating the Gulf War veterans were heightened by the chatges of cover-up that were inevitable because of the delay in acknowledging the exposure. In spite of investigations that have failed to show excess mortality in Gulf War veterans, increases in birth defects in their children, or more frequent hospitalizations, this issue is far from settled. The findings of a Presidential Advisory Council and an independently chartered commirtce appointed by the National Academy of Sciences Institute of Medicine also have failed to satisfy those who believe that Gulf War syndrome is a real entity.

Tahlc 62.6: Characteristics of drug overdose

1. Toxicity predicted by drug level—specific therapy determined by toxicology
   Acetaminophen, digoxin, ethylene glycol (not detected by most systems), lithium, salicylates, theophylline
2. Toxicity parallels drug level—supportive care required
   Barbiturates, ethanol, phenytoin
3. Toxicology confirms only clinical impression—clinical decisions determined by direct patient evaluation
   Cyanide, narcotics, organophosphates, tricyclic antidepressants
4. Toxicity correlates poorly with drug level—clinical decisions determined by direct patient evaluation
   Amphetamines, benzodiazepines, cocaine, hallucinogens, neuroleptics, phencyclidine, phenylpropanolamine

Source: Based on Mahoney, J. D., Gross, P. L., Stern, T. A., et al. 1930, "Quantitative scrum toxic screening in the management of suspected drug overdose," *Am} Emer Med,* vol. 8, pp. 16-22.

A similar and parallel situation has arisen among some who complain that pesticide exposure has affected their health. Because many pesticides are organophospbate cholinesterase inhibitors (OPCIs; differing from nerve agents in potency), links between exposure and a variety of complaints have been claimed or sought. "Worldwide, OPCIs are a common cause of death in agricultural workers, particularly in underdeveloped nations. In Western countries, death is less common, but accidental or intentional exposure may occur (ingestion by children, overdose among adults and agricultural workers). OPCIs may cause peripheral neuropathy, as described in Chapter 64B, and a subacute condition characterized by proximal weakness and respiratory failure known as intermediate syndrome. Comparisons among control populations and OPCI-exposed subjects have shown differences in performance on certain neuropsychological tests, buttressing claims of disability and distress among exposed individuals. Epidemiological, case control, and animal model studies all suggest that pesticide exposure may be related to the subsequent development of Parkinson's disease (Lockwood 2000). Efforts to redefine pesticide tolerances, the maximal permissible concentration of pesticides in food, arc complicated by predictable disagreements between pesticide manufacturers and public lie,l till groups. Recently [he pesticide industry has sponsored experiments that appear to be designed to raise tolerances. In these studies, pesticides have been administered to volunteers who are monitored for adverse effects. Ethical challenges to these studies arc unresolved.

The clinical neuroscience community faces a major challenge in aiding regulatory bodies as they develop

rules that govern exposure to potential toxins that respect the boundaries of science while providing adequate protection for the public and social accountability.

Chapter 63
Deficiency Diseases of the Nervous System

Yuen T. So and Roger P. Simon

Undernutrition causes a wide spectrum of neurological disorders. Although deficiency of almost any nutrient can lead to some kind of neurological symptoms, the B vitamins (thiamine, pyridoxine, nicotinic acid, and vitamin B12), vitamin E, and perhaps folic acid are the most important to the nervous system. Despite great advances since the turn of the twentieth century, nutritional deficiency is still a serious worldwide problem. Kwashiorkor and marasmus arc endemic in many underdeveloped countries. The problem in Western countries is usually the result of dietary insufficiency from chronic alcoholism or malabsorption states from gastrointestinal (GI) diseases. Drugs such as isoniazid and hydralazine also interfere by altering vitamin metabolism.

Most causes of nutritional deficiency, whether dietary or malabsorptive, do not selectively deplete a single vitamin. This is especially true among the malnourished populations in underdeveloped countries, in which the diet may lack more than one vitamin, and overlapping neurological syndromes are the result. One exception is pernicious anemia, in which malabsorption is restricted to vitamin Bu-

Individual vitamin requirements are influenced by many factors. The daily need of thiamine and nicotinic acid, important compounds in energy metabolism, increases proportionally with increasing caloric intake and energy need. For example, symptoms of thiamine deficiency often occur in at-risk patients during periods of vigorous exercise and high carbohydrate intake. Other factors, such as growth, infection, and pregnancy, may worsen deficiency states, although the relationship is not precisely known. Vitamin requirement is genetically determined in some cases, as in some infants dependent on unusually large doses of pyridoxine to prevent seizures. Low scrum levels of vitamins in many individuals do not necessarily correlate with the occurrence of symptoms, and laboratory data should always be interpreted in light of clinical findings.

The most frequent neurological deficits fall into several categories (Table 63.1). Peripheral neuropathy, the most common, occurs with the deficiency of many vitamins. Cerebral dysfunction, ranging from mental dullness to acute encephalopathy, may occur with deficiency of vitamin $B]_2$ or in Wernicke-Korsakoff syndtome. Myelopathy usually suggests a deficiency of vitamin ii_{l2}, although vitamin E

Tabic 63.1: Neurological manifestations in deficiency diseases

Neurological manifestations	*Associated nutritional deficiencies*
Peripheral neuropathy	Thiamine, vitamin $B_{1;}$, vitamin E, pyridoxine, folate
Dementia, encephalopathy	Vitamin B|>, nicotinic acid, thiamine, folate
Seizures	Pyridoxine
Myelopathy	Vitamin B_{12}, vitamin E, folate
Myopathy	Vitamin D, vitamin E
Optic neuropathy	Vitamin B12, thiamine, folate, and probably others
Spinocerebellar degeneration	Vitamin ¥.

and folate have been implicated in rare instances. A spinocerebellar degeneration may occur with severe vitamin E deficiency.

VITAMIN B_{12} DEFICIENCY

The terms *vitamin B\2* and *cobalamin* are used interchangeably in the literature. Cobalamins are abundant in meat, fish, and most animal by-products. Although vegetables are generally devoid of the vitamin, strict vegcranu:^ alnu.M ik'\cr develop a clinical deficiency, because only 1 ug of vitamin $B|_2$ is needed per day, and an adequate amount is available in legumes. Intestinal absorption of vitamin R_{12} requires the presence of intrinsic factor, a binding protein secreted by gastric parietal cells; inadequate availability[7] of intrinsic factor is probably the most common cause of vitamin Bi_2 malabsorption. The transport protein transcobalamin II binds Bj_2 and is important in transporting it to the liver. Deficiencies may also occur with derangement of this transport process.

Clinical Features

The onset of symptoms is insidious, with paresthesias in the hands or feet in the majority of patients. Weakness **and** unsteadiness of gait are the next most frequent complaints. Lhermitte's sign may be present, and a myelopathy may develop. Cerebral symptoms, such as mental slowing, depression, confusion, delusions, and hallucinations, are quite common, and occasionally patients present with only cognitive or psychiatric symptoms. Many patients also complain of dyspepsia, flatulence, altered bowel habits, or other GI symptoms.

On examination, most patients show signs of both peripheral nerve and spinal cord involvement, although either can be affected first in the early stage of the disorder. Loss of vibration or joinr position sense in the legs is the most consistent abnormality. If impaired position sense is severe, Romberg's sign may be present. Tendon reflexes **often** are decreased or absent in the legs, although the effect on reflexes is quite variable. Motor impairment, if present, results from pyramidal tract dysfunction and is most sevete in the legs, ranging from mild clumsiness and byper-reflexia to spastic paraplegia and extensor plantar responses. Visual impairment occasionally is encountered and may antedate other manifestations of vitamin deficiency; ophthalmological examination reveals bilateral visual loss, optic atrophy, and centrocecal scotomata. Brainstem or cerebellar signs, or even reversible coma, may occur.

Laboratory Studies

As most patients present with clinical features suggesting a myelopathy or encephalopathy, imaging studies are necessary to exclude structural causes. Magnetic resonance imaging (MRI) abnormalities may be seen in tin- lateral or posterior columns in patients with subacute combined degeneration (Figure **63.1).** Both treatment-reversible T2

FIGURE 63.1 Vitamin $B|_2$ deficiency myelopathy. Gadolinium enhanced, Tl-weighted cervical and upper thoracic MRI image •Jiriv-.Ty. iin:ki'd ailiancc-mc-nt ol pnstcrioi i><;,: o! .:. ill yen nld African-American woman wheelchair bound due to an 18-month history of progressive myelopathy; B12 level: 60 pg/mL. (Courtesy R. Laurcno.)

enhancement and spinal cord swelling have been described (Locatelli et al. *1999).* Based on case reports (reviewed by Locatelli), symptoms or signs may precede MRl changes by at least 2 weeks, are most prominent at 3-5 months, and can normalize over as few as 10 weeks with treatment. Residual imaging abnormalities may persist after treatment, and MRl resolution may be greater than clinical normalization. Radiographically, myelopathy and encephalopathy seem distinct. The encephalopathy may be accompanied by multiple deep white matter lesions seen on T2-wcighted images, which become confluent with disease progression. Radiographical improvement is seen within a few months, and clinical normalization occurs over a few years of treatment (Stojsavljevic et al. 1997),

Nonspecific electroencephalographic abnormalities may be present, and follow-up electroencephalography in selected cases can provide one of the earliest physiological responses to vitamin B12 therapy. Visual and somatosensory responses are frequently abnormal; nerve conduction studies show abnormally small or absent sural nerve sensory potentials in approximately 80% of patients, providing evidence for an axonal polyneuropathy.

Serum assay of cobalamin provides a direct assessment of its bioavailability, although it is important to recognize certain limitations. Most of the cobalamins present in serum are bound to several transport proteins, trauscobalamin (TC) II and haptocorrins (formerly TC I and III). The cobalamin bound to TC TI is the most important physiological fraction, but it accounts for only 10-30% of the serum level measured by standard laboratory methods. Serum levels are influenced by conditions that affect rranscobalamin concentrations. Myeloproliferative and hepatic disorders may raise the concentration of haptocorrins and cause a falsely normal serum level. A misleadingly high serum level also may result from the presence of an abnormal cobalamin-binding protein. In contrast, pregnancy and contraceptives may give falsely low measurements in the absence of deficiency. Folate deficiency also causes falsely low cobalamin serum level that corrects after folate replacement.

The classic hematological manifestation of pernicious anemia is a macrocytic anemia. Erythrocyte or bone marrow macrocytosis or hypersegmentation of polymorphonuclear cells may be present without anemia. Hematological abnormalities may be absent at the time of neurological presentation and are thus insufficiently sensitive for use in diagnosis, particularly true if the patient is taking folate supplements.

Homocysteine and methylmalonic acid are precursors of vitamin Bji-dependent pathways. Because norma! hematological studies and serum cobalamin level do not exclude a deficiency state (Savage et al. 1994), assay of serum levels of these metabolites is important in any patient with suspected deficiency. This is especially true in those with scrum vitamin B,i levels in the range of 200-350 pg/mL, even though these levels may be above the "lower limit of normal" reported by many reference laboratories. Testing of metabolites is also necessary in those with neurological deficits secondary to nitrous oxide abuse and some inherited metabolic disorders (see Pathogenesis and Etiology, later in this chapter). Homocysteine level should be measured either at fasting or aftct an oral methionine load. The blood sample should be refrigerated immediately after collection because levels increase if whole blood is left at room temperature for several hours. The concentration of either lioiiu icvstc:i.- or rutl". in;ilocic .ice is c'cviiled in over 90% of patients with cobalamin deficiency. The specificity of the finding is less clear because there are many other causes of increase of these metabolite levels (Table 63.2).

Abnormally low serum vitamin R,j or elevated metabolite levels provides confirmatory evidence of deficiency in the presence of an appropriate neurological picture. A dietary history is helpful occasionally, though inadequate dietary intake is seldom a sole cause of cobalamin deficiency. Schilling's test should be considered to further document the underlying cause of malabsorption. Further evaluation should include measurement of antibodies against parietal cell and against intrinsic factor (IF), either of which may be elevated in 60-90% of patients with autoimmune gastritis and intrinsic factor deficiency. Antiparietal cell antibodies are nonspecific and arc present in autoimmune endocrinopathies as well as occasional normal individuals. In comparison to antiparietal cell antibodies, anti-IF antibodies are less sensitive and more specific.

In cases of uncertain diagnosis, it is useful to institute a therapeutic trial of parenteral cobalamin while monitoring serum levels of homocysteine and methylmalonic acid both before and after treatment. In cobalamin-deficient patients, homocysteine and methylmalonic acid levels typically normalize within 7 to 10 days after treatment.

Physiology

Dietaty vitamin B_{12} binds readily to intrinsic factor, and the complex is transported to the terminal ileum, where

it is absorbed into the circulation via specific receptors on ileal mucosal cells. Once absorbed, vitamin $B]_2$ binds to transcobalamin II for transport to tissues. As much as 90% of total body vitamin Bi_2 (1-10 mg) is stored in the liver. Even when vitamin absorption is severely impaired, many years arc needed to deplete the body store. A clinical relapse in pernicious anemia after interrupting vitamin $B_{!2}$ therapy takes an average of 5 years to be recognized.

Biochemistry

Two biochemical reactions depend on vitamin B_{12}. One involves methylmalonic acid as precursor in the conversion of mcthylmalonyl coenzyme A (CoA) to succinyl CoA. The importance of this to the nervous system is unclear. The other is a folate-depcndent reaction in which the methyl group of methyltctrahydrofolate is transferred to homocysteine to yield methionine and tetrahydrofolate. The reaction depends on the enzyme methionine synthase that uses cobalamin as a cofactor. Methionine is converted to S-adenosylmethionine (SAM), which is used for methylation reactions in the nervous system, including DNA symbols in dividing cells (Snow 1999).

Pathology

The term *subacute combined degeneration of the spinal cord* describes the pathological process seen in vitamin B_{12} deficiency. Microscopically, spongiform changes and foci of myelin and axon destruction are seen in the white matter of the spinal cord. The most severely affected regions are the posterior columns at the cervical and upper thoracic levels (Figure 63.2); pathological changes also are seen commonly in the lateral columns, whereas the anterior columns are involved in only a small number of the advanced cases. The pathological findings of the peripheral nervous system are those of axonal degeneration, but in some cases there is evidence of demyelination. Involvement of the optic nerve and cerebral white matter also occur.

Pathogenesis and Etiology

Pernicious anemia caused by defective intrinsic factor production by parietal cells accounts for many cases of vitamin h_{J2} deficiency. These patients may have demonstrable circulating antibodies to parietal cells or lymphocytic infiltrations of the gastric mucosa, suggesting an underlying autoimmune disorder. Another cause of intrinsic factor deficiency is gastrectomy, although it rarely leads to symptomatic deficiency in isolation. Other cases of malabsorption are surgical resection of the terminal ileum and the blind loop syndrome. Prolonged use of drugs such as colchicine, neomycin, and omeprazole may cause vitamin deficiency by their interference with intestinal absorption. Dietary insufficiency in strict vegetarians occurs only rarely. Low serum level of vitamin $[i,_{\pm}$ also occurs in patients with acquited immunodeficiency syndrome (AIDS), though the significance is unknown; serum homocysteine and methylmalonic acid levels are within the normal range in most of these patients, and cobalamin supplement often fails to induce clinical improvement. The vacuolar myelopathy seen in AIDS patients resembles subacute combined degeneration both clinically and

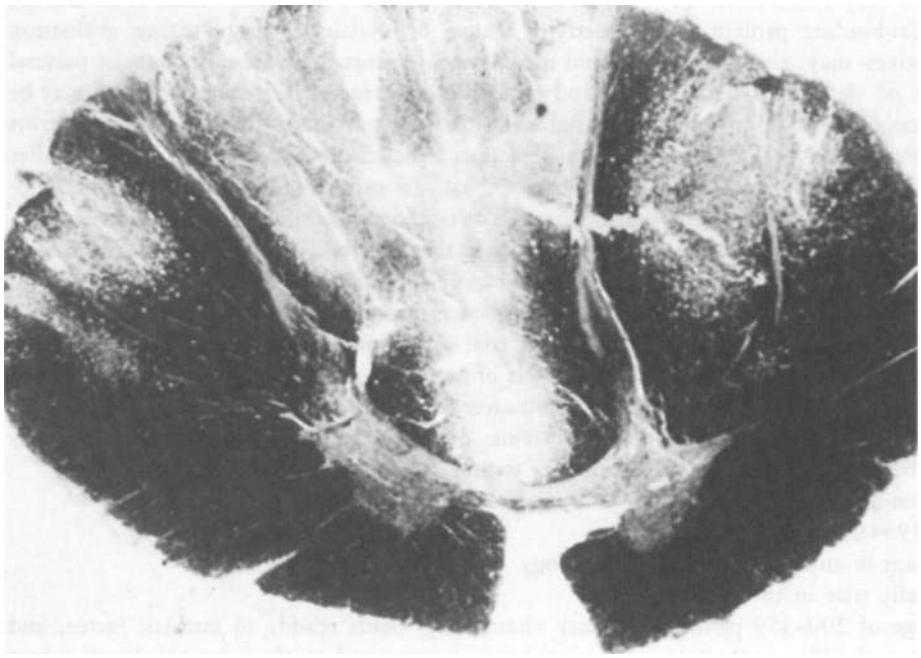

FIGURE 63.2 Subacute combined degeneration of the spinal cord in vitamin B_{tl} deficiency. Demyelination and loss of axons are more widespread in posterior than in lateral columns (Weigert's stain). (Courtesy Dr. Michael F. Gonzales.)

pathologically. It is hypothesized that immune mediated mechanisms may limit the availability of S-adenosylmethionine (Di Rocco et al. 2002).

After heavy abuse of nitrous oxide, subjects may develop a clinical syndrome of myeloneuropathy indistinguishable from that of vitamin B_{12} deficiency. Symptoms include numbness, paresthesia, Lhermitte's sign, gait ataxia, and leg weakness. Subjects improve slowly when nitrous oxide is stopped, but the myelopathy may not recover completely. Serum vitamin B_{12} level and Schilling's test result are normal, and hematological derangements arc usually inconspicuous. The mechanism appears to be an interference with the vitamin B_{12}-dependent conversion of homocysteine to methionine. The other pathway, conversion of methylmalonyl coenzyme A to succinyl coenzyme A, is unaffected by . nitrous oxide. Prolonged exposure to nitrous oxide is necessary to produce neurological symptoms in normal individuals. By contrast, patients who are already vitamin B_{12} deficient may experience neurological deficits after brief exposures to nitrous oxide during general anesthesia. Symptoms typically appear 2-6 weeks after surgery and resolve quickly with vitamin B_{12} treatment (Marie et al. 2000).

Course and Prognosis

With proper treatment, at least partial improvement can be expected. Most of the symptomatic improvement occurs during the first 6 months of therapy, although it may not be complete for a year or more. The need for early diagnosis and treatment is underscored by the observation that remission correlates inversely with the time lapse between onset of symptoms and initiation of therapy. The myelopathy is least likely to make a complete recovery.

Treatment and Management

Any patient with clinically overt vitamin B_{12} deficiency should be treated with parenteral vitamin therapy aimed at replenishing the total body pool. The usual regimen uses intramuscular injections of 100 ug daily or 1000 ug twice weekly for 2 weeks. This is followed by weekly injections of 1000 ug for another 2-3 months. If Schilling's test demonstrates malabsorption of vitamin Bi_2, the patient should be placed on lifelong maintenance therapy, usually in the form of monthly 1000 ug injections. The parenteral dose of vitamin B_{12} recommended here provides quantities considerably higher than the body's requirement. Although there is no evidence that overdosing can speed neurological recovery, adverse reactions to these doses of vitamin B_{12} are unknown.

Oral preparations of intrinsic factor are available but are not reliable for clinical use. Antibodies to intrinsic factor may nullify its effectiveness in the intestinal lumen, and many patients eventually become refractory to intrinsic factor therapy.

FOLATE DEFICIENCY AND HOMOCYSTEINE

Theoretically, folate deficiency should produce the same neurological deficits as those seen in vitamin B_{12} deficiency because of its importance in the production of methionine, S-adcnosy I methionine, and tetra hydro folate (see Biochemistry under vitamin B_{12} Deficiency). However, overt neurological manifestations like those seen in vitamin Bi_2 deficiency are rare in folate deficiency. This is probably due to alternative cellular mechanisms that are available to preserve S-adenosylmcthionine levels in times of folate scarcity. In contrast, accumulating evidence in recent years suggests that chronic folate deficiency is likely to manifest in a subtle manner. Folate deficiency may result in mild cognitive impairment or increased stroke risk in adults and increased frequency of neural tube defects in babies bom to folate-deficient mothers (Diaz-Arrastia 2000). Since 1998, the U.S. Food and Drug Administration has mandated fortification of grain products with folate. The level of supplement on the average increases the dietary folate intake of adults by 100 ug per day. The impact of this policy remains to be seen.

Clinical Features

Folate deficiency may rarely produce a syndrome indistinguishable from subacute combined degeneration of vitamin Bi_2 deficiency. The majority of patients with laboratory evidence of folate deficiency do not have overt neurological findings or have mild cognitive impairment.

Serum homocysteine is an important surrogate marker for folate metabolism (sec Laboratory Studies under vitamin B_{12} Deficiency). Though deficiency of vitamin B_{12} or B_{fi} as well as several other factors can raise scrum homocysteine, most cases of elevated homocysteine level are due to folate deficiency. Numerous studies over the past 30 years have identified hyperhomocystinemia as an independent risk factor for cerebrovascular disease, coronary artery disease, peripheral vascular disease, and venous thrombosis. For cerebrovascular disease, the association is strongest for multi-infarct dementia and white matter microangiopathy, but there is little or no association with cardioembolie or large artery disease. Even a modest increase in scrum level, in the range of 15 to 20 umol/I., engenders a recognizable increase in risk.

Although a low folate level is present in many elderly asymptomatic people, the prevalence is much higher in the psychiatric and Al/.hcimer's disease populations (Reynolds 2002). Moreover, a low folate level appears ro correlate with depression and cognitive impairment. Even in healthy older adults, a low folate level is associated with subtle but

significant deficits in neuropsychological test performance. The relationship is stronger when serum homocysteine is used as a surrogate marker. This connection cannot he explained simply by an increased risk of multi-infarct dementia or other cerebrovascular diseases.

Clinical observations in two inborn errors of metabolism reinforce our understanding of the role of homocysteine in neurological diseases. Hereditary deficiency of cystathionine ^-synthase leads to hypcrhomocystinemia and hyperhomocysteinuria. The homozygous form presents with markedly elevated homocysteine levels, mental retardation, premature atherosclerosis, and seizures. The heterozygous individuals have milder elevations of homocysteine and also have increased risk of vascular disease. A much more common condition is a C-to-T substitution at codon 677 in the gene coding for N^5,N^{11}-methylenetetrahydrofolatc reductase (MTHFR). Homozygotes for this C677T mutation comprise about 5-10% of the white population. These individuals have mildly elevated homocysteine levels and increased risk of vascular disease.

Laboratory Studies

Plasma and erythrocyte folate levels may be measured directly. Erythrocyte level is generally more reliable than plasma level because it is less affected by short-term fluctuation in intake. Serum homocysteine measurement is discussed in Laboratory Studies under Vitamin Bi_2 Deficiency.

Pathogenesis and Etiology

Absorption of folate occurs in the jejunum and, to a lesser extent, the ileum. Chronic alcoholism is an important cause of folate deficiency. Folate deficiency also may complicate small bowel disease (e.g., sprue, Crohn's disease, and ulcerative colitis). Other populations at risk are pregnant women and patients receiving anticonvulsant drugs that interfere with folate metabolism. Sulfasalazine, methotrexate, triamterene, and oral contraceptives also may cause folate deficiency, although the mechanism is often unclear. Intrathecal methotrexate, in particular, causes a leukoencephalopathy associated with marked elevation of homocysteine levels in the cerebrospinal fluid.

Treatment and Management

Prospective studies on the use of folate in the prevention of vascular disease are under way. Results from these trials will greatly enhance our knowledge of the role of folate in human diseases. In women of childbearing potential with epilepsy, daily folate supplement of 0.4 mg or more is recommended as prophylaxis against neural tube defect. In patients with documented folate deficiency, the initial dose is usually 1 mg of folate three times per day, followed by a maintenance dost- of 1 mg per day. For acutely ill patients, parenteral doses of 1-5 mg may be given. Even with oral doses as high as 15 mg per day, there is no substantiated report of toxicity. It is important to keep in mind that large doses of folate can cotrcct the megaloblastic anemia of vitamin Bi_2 deficiency without altering the neurological abnormalities. A hematological response to folate, therefore, does not preclude the diagnosis of pernicious anemia.

VITAMIN E DEFICIENCY

Vitamin E is a free radical scavenger and an antioxidant and has attracted considerable attention for its potential use in the prevention and treatment of vascular diseases and neurodegenerative diseases such as Alzheimer's disease and amyotrophic lateral sclerosis. The pharmacological use of vitamin E in these conditions has yet to be unproven. We will limit the following discussion to the neurological manifestations of vitamin E deficiency.

Clinical I'eaiiircs

Vitamin E is a fat-soluble vitamin that is normally stored to a massive degree in the body. Clinical symptoms typically do not begin until many years of malabsorption deplete the vitamin reserves. This takes 15-20 years in adults, but clinical onset as early as 2-3 years of age may occur in children, presumably because of their small vitamin reserves.

The usual presenting symptoms are weakness or gait unsteadiness. Neurological examination reveals a syndrome of spinocerebellar degeneration, often accompanied by a varying degree of peripheral nerve involvement. Some patients are diagnosed erroneously with Friedreich's ataxia. The most consistent abnormalities arc limb ataxia, areflexia, and severe loss of vibration and position sense. Cutaneous sensation usually is spared or affected to a lesser degree. Approximately one half of the patients have nystagmus, ptosis, or partial external ophthalmoplegia. Mild to moderate proximal weakness is common, although weakness can be diffuse or predominantly distal. Babinski's sign may be present.

Laboratory Studies

The diagnosis is not difficult when the appropriate neurological syndrome and a low serum vitamin E level are both present. Serum level should be interpreted in light of the clinical findings. Some patients with low levels do not have demonstrable neurological deficits. Moreover, plasma vitamin K is largely incorporated into chylomicrons and is

highly dependent on the concentrations of total plasma lipids, cholesterol, and very low density lipoproteins,

Other laboratory abnormalities, despite their nonspecific nature, help to clarify the diagnosis. Stool fat is increased in many patients with malabsorption syndromes causing hypovitaminosis E, and serum carotene concentration is often abnormally low, both reflecting a generalized state of fat malabsorption. Cerebrospinal fluid should be normal, Nerve conduction studies usually reveal a mild axonal neuropathy, with small or absent sural nerve action potentials and normal or slightly slow motor nerve conduction. Somatosensory and visual evoked responses are frequently abnormal. High signal lesions in the posterior columns on T2-weighted MRI images have been reported (Vorgerd etal. 1996).

Physiology and Biochemistry

By reacting with free radicals and perhaps with other oxidative intermediates, vitamin E functions as an antioxidant capable of Stabilizing polyunsaturated membrane lipids. It is potentially important in maintaining the integrity of cellular membranes. Whether this action bears any relationship to the development of neurological deficits in the deficiency state is uncertain.

Pathology

Few cases of proven vitamin E deficiency have come to autopsy. Degeneration of large myelinated fibers may be present in the peripheral nerves, posterior columns, and sensory roots. Accumulations of lipopigments are seen in both neurons and endothelial cells, especially prominent in tile spinal cord and the cerebellum.

Pathogenesis and Etiology

Like other fat-soluble compounds, vitamin K depends on the presence of pancreatic esterases and bile salts for its solubilization and absorption in the intestinal lumen. Neurological symptoms of deficiency occur most commonly in patients with significant fat malabsorption (Table 63.3). A reduced bile salt pool may be caused either by reduced hepatic excretion, as in congenital cholestasis, or by interruption of the enterohepatic rcabsorption of bile, as in patients with extensive small bowel resection. Other settings for malabsorption include cystic fibrosis, adult celiac disease, and abnormalities of specific vitamin E receptors, such as in abetalipoproteinemia.

A rare familial form of fat malabsorption is abetalipoproteinemia (Bassen-Kornzweig syndrome), a disorder in which impaired chylomicron and lipoprotein synthesis is partly responsible for the impaired fat absorption

(Kayden 1993). In addition to a neurological syndrome similar to that seen in other vitamin E-deficient states, spiky red blood cells (acanthocytes) and retinal pigment changes are characteristic. Another hereditary cause of vitamin E deficiency may be due to a genetic defect in the assembly or secretion of chylomicrons, leading to a chylomicron retention disease that is demonstrable in the intestinal mucosa (Aguglia et al. 2000).

A syndrome of ataxia with isolated vitamin E deficiency (AVED) occurs in patients without gastrointestinal disease or generalized fat malabsorption. Mutations in the a-tocopherol transfer protein gene on chromosome 8ql3 are responsible (Cavalier et al. 1998). This condition is inherited in an autosomal recessive manner. The defect appears to be impaired incorporation of the vitamin into hepatic lipoproteins that are necessary for delivery to tissues.

Treatment and Management

The recommended daily requirement of vitamin E in normal adults is 10 mg (equivalent to 10 IU) of d,l-alpha-tocopherol acetate, a commonly available form of the vitamin. In the deficiency state, a wide range of doses has been used, ranging from 200 mg per day to 100 mg per kg per day. Although there is little consensus on the optimal therapeutic dosage, there is also no evidence of toxicity from overdose. A reasonable approach is to begin therapy with a preparation of water-miscible tocopherol at a dose of 200-600 mg per day. The clinical picture and serum level should be followed; if no improvement occurs, higher oral dosages or even parenteral administration should be tried. Supplementation of bile salts may be ol value in Mime patients.

PELLAGRA (NICOTINIC ACID DEFICIENCY)

Nicotinic acid *(niacin,* another term for nicotinic acid, was introduced to avoid confusion with the alkaloid nicotine) is converted in the body to two important coenzymes in

carbohydrate metabolism; nicotinamide adenine dinucleotide and nicotinamide adenine dinucleoridc phosphate. Dietary deficiency of nicotinic acid produces *pellagra* (from the Italian *pelle agra,* meaning *rough skin).* Pellagra classically occurs in populations who consume primarily corn as their carbohydrate staple. Corn lacks nicotinic acid as well as tryptophan, a precursor that can be converted in the body to nicotinic acid. In underdeveloped countries, pellagra is still a common health problem. Even in the United States, pellagra was endemic until approximately 1940 in the South and in alcoholic populations, it has now largely disappeared, credited to the widespread consumption of bread enriched with niacin.

Clinical Features

Pellagra affects three organ systems in the body: the gastrointestinal tract, skin, and nervous system (hence the mnemonic of the three Ds; diarrhea, dermatitis, and dementia). The chief gastrointestinal symptoms are anorexia, diarrhea, stomatitis, and abdominal discomfort. Skin changes range from erythema to a reddish-brown hypcrkeratotic rash distributed ovet much of the body, with the face, chest, and dorsal surfaces of the hands and feet being most involved.

The neurological syndrome of pellagra is not well defined. Reported cases, especially of patients with alcoholic pellagra, frequently are confounded by other coexisting central nervous system disorders. The primary early symptoms are neuropsychiatric (e.g., irritability, apathy, depressed mood, inattentiveness, memory loss) and may progress to stupor or coma. In addition to the confusional state, spasticity, Babinski's sign, gegenhalten, and startle myoclonus may be prominent on neurological examination.

Nonendemic pellagra occurs rarely in patients with alcoholism or malabsorption secondary to gastrointestinal disease. The diagnosis of nonendemic pellagra can be made only on clinical grounds because there is no available blood niacin level determination, and diagnosis is frequently difficult because diarrhea and dermatological changes may be absent. Unexplained ptogressivc encephalopathy in alcoholic patients not responsive to thiamine therapy (see Wernicke-Korsakoff Syndrome, later in this chapter) should raise the possibility of pellagra.

Treatment and Management

The recommended daily allowance for nicotinic acid is *6.6* mg/1000 kcal dietary intake. Oral nicorinic acid in doses of 50 mg three times a day is usually sufficient to treat symptomatic patients. Alternatively, parenteral doses of 25 mg can be given two to three times a day. Nicotinamide has a similar therapeutic efficacy in pellagra, but it does not have the vasodilatory and cholesterol-lowering activities of niacin.

VITAMIN B_t, (PYRIDOXINS) DEFICIENCY

Although the term *pyridoxine* often is used synonymously with vitamin Bg, two other naturally occurring compounds—pyridoxal and pyridoxamine—possess biological activities similar to pyridoxine. All three compounds are readily converted to pyridoxal phosphate, the coenzyme form important for the metabolism of many amino acids.

History

The original recognition of one of the complications of pyridoxine deficiency provides a useful lesson in nutrition. (a the early 1950s, physicians in the United States riKoimk'ivd cases nt an LIIIIIIMI.II sri/uiv ilisordci in inunls at the age of several weeks to a few months. These seizures were difficult to control with the usual anticonvulsants. In contrast, the response was often dramatic when vitamin B_f, was given. As more patients were identified, it became clear that the symptomatic infants had been fed a commercially prepared formula that contained only 60 mg/liter of vitamin $B_{(„}$ or approximately one third the amount found in other infant formulas. The underlying cause eventually was traced to a manufacturing process that apparently reduced the formula's pyridoxine content.

Clinical Features

Even with better awareness of the problem, sporadic cases of infantile seizures from dietary vitamin B_f, deficiency still occur, most commonly as a result of breastfeeding by malnourished mothers from poor socioeconomic backgrounds or in underdeveloped countries. The typical patients have a normal birth history and are entirely healthy until the development of hyperirritability and an exaggerated auditory stattle. Recurrent convulsions often occur abruptly, as may status epilepticus. Once the dietary insufficiency is corrected, patients become free of seizures and develop normally.

Another form of pyridoxine-responsive seizure occurs in infants with a congenital dependency on pyridoxine. They develop symptoms despite a normal dietary supply of pyridoxine. In contrast to infants with dietary deficiency, most of these children manifest seizures earlier in life (within days of birth) and require much larger doses of pyridoxine (5-100 mg) to control their convulsions. Long-term administration of large amounts of pyridoxine is needed, generally in the range of 10 mg per day. Even after several years of successful treatment, seizures often reappear within days of pyridoxine withdrawal.

Pyridoxine dependency should be considered in infants with undiagnosed seizures, especially in those with a poor response to anticonvulsants.

Adults are much more tolerant of vitamin B_A deficiency. Not only are most adult diets adequate in pyridoxine and related compounds, but also symptoms are rare even when there is demonstrable low vitamin level, Isoniazid and a few other drugs, such as hydralazine and penicillamine, are responsible for many adult cases. This is especially a problem in slow inactivators of isoniazid, among whom as many as 50% may develop peripheral neuropathy when treated with the drug. Sensory symptoms generally appear first, consisting of numbness, tingling, and occasionally burning pain in the distal portions of the feet. If the drug is continued, symptoms may spread prox.im.ally to the knees and hands, burning pain is disabling in some instances. On examination, there is distal weakness, depressed tendon reflexes, and impaired distal sensation,

Use of high doses of pyridoxine (1000 mg per day or more) for several months causes a distal sensory length-dcpciulrilt .'VHi.i'i r.i'Uiopatln 1:1 .1 tinsc dependem mar.:KT. Reported patients ingesting such a high dose for a prolonged period had a syndrome of sensory ataxia, with impaired cutaneous and deep sensation, areflexia, and Romberg's sign, Many years of taking doses as low as 200 mg per day may also cause a mild, predominantly sensory polyneuropathy. Hence, in therapeutic use of pyridoxine, it seems prudent to limit the dosage to 100 mg per day or less.

Treatment and Management

Treatment of pyridoxine-relatcd seizures in infants was discussed earlier. The neurotoxicity of isoniazid and hydralazine is dose dependent. Even with high doses of isoniazid, pyridoxine supplements of 50 mg per day can prevent the development of neuropathy in nearly all patients,

BERIBERI (THIAMINE DEFICIENCY POLYNEUROPATHY)

Beriberi literally means extreme weakness. It affects the heart and peripheral nerves, producing congestive cardiomyopathy, sensorimotor polyneuropathy, or both. The classical wet and dry forms refer to **the** presence or absence of edema.

Clinical Features

The neuropathy generally progresses over several weeks or months. Affected patients characteristically complain of paresthesias or pain of the feet. Walking becomes difficult. Distal muscle weakness with foot drop appears as the neuropathy worsens. Muscle tenderness and cramps, especially of the calves, are prominent in some patients, When cardiac dysfunction is present, patients also experience tachycardia, palpitations, dyspnea, fatigue, and ankle-edema.

The most common finding is a stocking-glove distribution of cutaneous sensory loss and distal weakness. Deep tendon reflexes of the ankles are losr in the majority of patients. Cranial nerve deficits are unusual, although there may be laryngeal nerve paralysis producing hoarseness and voice weakness. A subacute optic neuropathy may occur rarely in thiamine-deficient patients secondary to a ketogenic diet used to control epilepsy.

Laboratory Studies

Diagnosis of beriberi is based on recognizing the appropriate clinical features in a background of nutritional deficiency. Thiamine levels in scrum and urine may be decreased, though the levels do not reliably reflect tissue concentrations. Erythrocyte transketolase activity level is dependent on thiamine and provides an assay of functional status. Pyruvate accumulates during thiamine deficiency, and elevated serum level provides additional confirmation. A blood sample should be drawn before initiation of treatment because these laboratory abnormalities normalize quickly.

Dectrodiagnostic studies show an axonal neuropathy with reduced amplitude of sensory and motor responses, normal or mildly reduced conduction velocity, and neurogenic changes on electromyography. Lumbar puncture sometimes shows a mildly elevated opening pressure, a finding probably related to the presence of congestive heart failure. Cerebrospinal fluid examination is otherwise unremarkable. If cardiac impairment is present, electrocardiographic abnormalities or cardiac enlargement on chest roentgenography may occur.

Physiology and Biochemistry

Thiamine is the precursor for the coenzyme thiamine pyrophosphate, which catalyzes the oxidative decarboxylation of pyruvate and alpha-ketoglutarate, with the eventual production of coenzyme A. Thiamine pyrophosphate also serves as a cofactor for the transketolase reaction in the hexose monophosphate shunt, A corollary of the biochemistry is the dependence of the thiamine requirement on the body's metabolic rate, with the requirement being greatest during periods of high metabolic demand or high glucose intake. This explains the clinical observation that symptoms of thiamine deficiency frequently occur during periods of refceding or intravenous administration of glucose.

Pathology

Ultrastructural and morphomctric analysis of sural nerve biopsy reveals axonal loss of wallenan type. Segmental demyelination is infrequent and is probably secondary to axonal degeneration.

Epidemiology

Beriberi is rare in most industrialized nations. Even in Japan, where beriberi once accounted for over 20,000 deaths a year, the disease has ail but disappeared. An exceptional outbreak occurred in the 1970s in young people with a history of an unbalanced diet high in instant food, unfortified rice, and other carbohydrates and deficient in protein and vegetables. The symptoms typically appeared acutely or subacutely after a period of strenuous athletic training or heavy work. Exercise precipitated the condition by raising the metabolic requirement for thiamine. Other causes of increased metabolic demands such as pregnancy, malignancy, and systemic infection may rarely precipitate symptoms, especially in people with marginal nutritional status. In developed countries, many cases are probably related to alcoholism, but ir is difficult to distinguish beriberi from alcoholic neuropathy.

Course and Prognosis

Cradual return of sensory and motor function can be expected after thiamine replenishment. Mildly affected patients experience considerable improvement after a few weeks of treatment; in severe cases, improvement may take many months and may be incomplete.

Treatment and Management

The major goal is to initiate a balanced diet with supplements of thiamine and other vitamins. Thiamine is water soluble and usually supplied as thiamine hydrochloride, either in crystalline form or as a 100-mg/mL solution. The minimum daily requirement is 0.3 mg/1000 kcal dietary intake in normal subjects, but the requirement is higher during pregnancy and old age. For therapeutic purposes, 50-100 mg per day is used. The parenteral form of thiamine should be considered whenever there is doubt about adequate gastrointestinal absorption.

Infantile Beriberi

\n ,ui;li' \> iuln>i:n- "I i':i: • mi:u- drl k::.no in miauls iii i .its in the rice-eating populations of Asia, most frequently in breastfed infants less than I year of age; thiamine is often deficient in breast milk from mothers who eat primarily polished rice. Although the disorder is called *infantile beriberi,* it bears little resemblance to the adult form, Acute cardiac symptoms arc common, often preceded by a prodrome of anorexia, vomiting, deficient weight gain, and restlessness. Dyspnea, cyanosis, and signs of heart failure follow and can lead rapidly to death. Arytenoid edema and recurrent laryngeal neuropathy give rise to hoarseness, dysphonia, and eventually aphonia. Early warning signs of coughing and choking may be mistaken for respiratory tract infections. Central nervous system manifestations include drowsiness, ophthalmoplegia, and convulsions. These symptoms often begin abruptly and carry a grave prognosis. Parenteral administration of 5—20 mg of thiamine can be hfesaving and should never be delayed.

WERNICKE-KORSAKOFF SYNDROME

Wernicke's Encephalopathy

History

Although there were earlier descriptions of patients with probably the same form of encephalopathy, Carl Wernicke is credited with recognizing the disease in 1881. He described an acute syndrome of mental confusion, ophthalmoplegia, and gait ataxia in three patients, two of whom were alcoholics. At autopsy, multiple small hemorrhages were seen in the periventricular gray matter, primarily around the aqueduct and the third and fourth ventricles.

C,li>m\il Vvdtttrcs

Although the most common clinical setting for Wernicke's encephalopathy is chronic alcoholism, a large number of cases occurs in other conditions, with the only prerequisite being a poor nutritional state, either from inadequate intake, malabsorption, or increased metabolic requirement (Table 63.4). Wernicke's encephalopathy may be

Table 63.4: Associated conditions in nonalcoholic patients with Wernicke's encephalopathy

Hemodialysis or peritoneal dialysis
Prolonged intravenous feeding
Rcfccding after prolonged fasting or starvation
Anorexia nervosa
Dieting and gastric plication
Acquired immunodeficiency syndrome

precipitated acutely in at-risk patients by intravenous glucose administration or carbohydrate loading,

Wernicke's original description of the clinical triad of confusion, ophthalmoplegia, and ataxia is still valid. The confusion.il state develops over days or weeks and is characterized by inattention, apathy, disorientation, and memory loss. Stupor or coma is rare. Ophthalmoplegia, when present, commonly involves both lateral recti, either in isolation or together with palsies of other extraocular muscles. Patients may have horizontal nystagmus on lateral gaze, and many also have vertical nystagmus on upgaze. Sluggish reaction to light, light-near dissociation, or other pupillary abnormalities are sometimes seen. Truncal ataxia is common, but limb ataxia is not, findings similar to those seen in alcoholic cerebellar degeneration.

Other frequent, findings include hypothermia and postural hypotension, reflecting involvement of hypothalamic and brainstem autonomic pathways. Signs of nutritional deficiency and complications of alcoholism are common. These include peripheral neuropathy, tongue redness, skin changes, and liver abnormalities.

Laboratory Studies

Wernicke's encephalopathy is a clinical diagnosis, though brain MRI can be very helpful. MRI may show signal abnormalities on T2-wcighted, fluid-attenuated inversion recovery (FLAIR), and diffusion-weighted images in the periaqueductal regions, medial thalami, and bilateral mamillary bodies (Doherty et al. 2002). The lesions sometimes show contrast enhancement. The signal abnormalities typically resolve completely with prompt treatment, but shrunken mamillary bodies may be seen as a late residual finding. The cerebrospinal fluid is either normal or shows a mild elevation in protein. Serum thiamine level and erythrocyte transketolase activity may be depressed, and there also may be an elevation of serum pyruvate. Treatment should not be withheld while the clinician waits for laboratory results because a delay may lessen the likelihood of recovery.

Physiology

The clinical findings reflect the localization of pathological abnormalities in this disease, namely, the prominent involvement of periventricular structures at the level of the third and fourth ventricles. Lesions of the nuclei of the III, VI, and vestibular nerves are responsible for the eye findings. The truncal ataxia is probably caused by the vestibular dysfunction and involvement of the superior cerebellar vermis.

Biochemistry

Biochemistry is discussed in the section on beriberi.

Pathology

The pathological process depends on the age of the lesions. Macroscopically, varying degrees of congestion, petechial hemorrhages, shrinkage, and discoloration may be present (Figure 63.3). Chronic lesions are characterized by foci of glial proliferation and myelin pallor primarily affecting the aforementioned locations. In acute lesions, dilatation and hyperplasia of small blood vessels occur, with punctate hemorrhages in the subependymal gray matter.

Epidemiology

The frequency of "Wernicke's encephalopathy as estimated from various autopsy studies is approximately 0.8-2.8%, a figure far greater than that expected from clinical studies. Only 20% of the cases in one scries were diagnosed during life. This is disturbing because Wernicke's encephalopathy is readily preventable and treatable. One reason for undcr-recognition is that some patients do not have the classic triad of ataxia, ophthalmoparesis. and encephalopathy. Misdiagnosis also may result from an overemphasis on alcoholism as a cause (see Table 63.4). Wernicke's encephalopathy

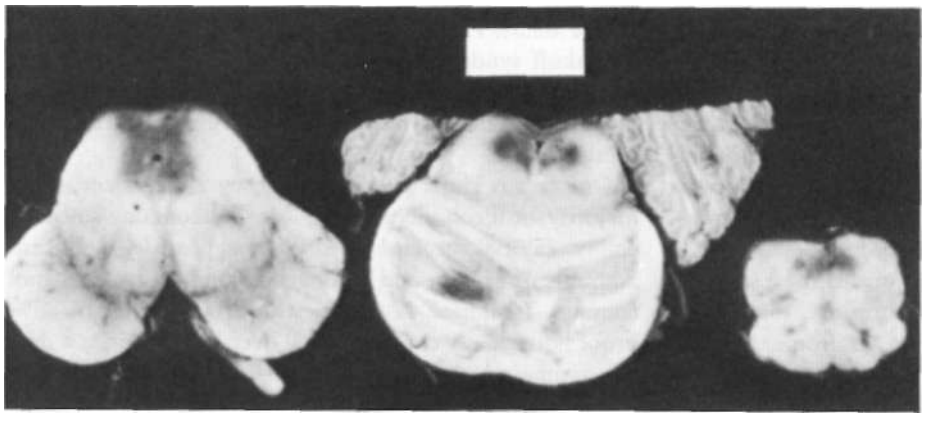

FIGURE 63.3 Acute Wernicke's disease. Hemorrhagic areas are seen adjacent to the fourth ventricle and aqueduct in the *{from right to left)* medulla, pons, and midbrain. (Courtesy Dr. Michael F. Gonzales.}

occurring under other settings may be mistaken for encephalopathy of uremia, dialysis, sepsis, or other systemic diseases.

Course and Prognosis

If left untreated, Wernicke's encephalopathy is progressive. The mortality, even with thiamine treatment, is 10-20%. With treatment, the majority- of ocular signs resolves within hours, although a fine horizontal nystagmus persists in approximately 60% of patients. Apathy and lethargy improve over days or weeks. The gait disturbance resolves much more slowly, and in one third or more of cases, gait may be abnormal even months after treatment. As the global confusional state recedes, some patients are left with a Korsakoff's syndrome—a disorder of impaired memory and learning.

Treatment and Management

Patients suspected of Wernicke's encephalopathy should receive thiamine before administration of glucose to avoid precipitation of acute symptom worsening. Thiamine is the only treatment known to alter the outcome. Thiamine of 50-100 mg should be given parenterally in the acute stage because intestinal absorption is unreliable in debilitated and alcoholic patients. Thiamine can then be continued daily through the acute period.

Korsakoff's Syndrome

Like Wernicke's encephalopathy, Korsakoff's syndrome is historically defined in chronic alcoholism. Shortly after Wernicke's original treatise, Korsakoff, a Russian psychiatrist, described this amnesia syndrome in 20 alcoholic men. At the time, however, neither Wernicke nor Korsakoff recognized the relationship between the encephalopathy and impaired memory. The clinical connection and the pathological similarity between the two conditions were not appreciated until 10 years later by other investigators.

Korsakoff's syndrome and Wernicke's encephalopathy do not represent separate diseases but arc different stages of one disease process (Wernicke-Korsakoff syndrome). Korsakoff's syndrome typically follows Wernicke's encephalopathy, emerging as ocular symptoms and encephalopathy subside. In *Korsakoff's syndrome,* memory is impaired out of proportion to other cognitive functions. This is due to the selective localization of the lesions in the diencephalon and temporal lobes. Injury to these regions, regardless :?t cause (e.g., infarction, trauma, tumors, or herpes encephalitis), can produce a syndrome indistinguishable from the amnesia syndrome seen in alcoholic patients.

Clinical Features

The memory impairment is characterized by the presence of both anterograde and retrograde amnesia. Affected patients have severe difficulty establishing a new memory, always coupled with a limited ability to recall events that antedate the onset of illness by several years. Most patients are disoriented as to place and time. Alertness, attention, social behavior, and most other aspects of cognitive functions are relatively preserved. Confabulation can be a prominent feature, especially in the early stages, although it may be absent m some patients.

Pathology

The histopathoJogieal changes in patients with Korsakoff's syndrome are similar to those in patients with predominantly Wernicke's encephalopathy. Patients with Korsakoff's syndrome have, in addition, involvement of the dorsal medial nucleus of the thalamus.

Course and Prognosis

Despite treatment with thiamine, improvement in memory function is slow and usually incomplete, and those who improve usually do so after a 1-month delay or longer. Occasionally, patients may not achieve maximal improvement for more than a year.

Treatment and Management

Except for the initial thiamine administration, treatment usually is limited to social support. Many patients **require** at least some form of supervision, either at home or in a chronic care facility.

OTHER NUTRITIONAL DISEASES ASSOCIATED WITH ALCOHOLISM

The neurological consequences of alcohol abuse have been recognized for centuries, but little is known about their pathogenesis. A nutritional cause is often invoked (Table *63.5).* However, with the exception of Wernicke-Korsakoff syndrome and rare cases of pellagra, no single nutritional factor has been defined conclusively. Many investigators instead have proposed a direct neurotoxicity of alcohol.

One fact is clear: Dietary deficiency is prevalent in the majority of alcoholic patients. Alcohol contains so-called empty calories because it docs not provide significant amounts of protein and vitamins. A gram of pure ethanol contains 7 calories. A person who drinks a pint of 86% proof liquor daily consumes well over 1000 calories a day, approximately one half of the daily caloric requirement. The alcohol consumption inevitably results in reduced

Table <i3,,S: Neurological complications associated with alcohol abuse

Nutritional deficiency

  Alcoholic myopathy
  Amblyopia
  Cerebellar degeneration
  Marchiafava-Bignnmi disease

intake of other foods. The problem is compounded further by malabsorption and abnormal metabolism of vitamins, both of which are common in alcoholics.

Alcoholic Neuropathy

Neuropathy is the most frequent neurological complication of alcoholism. Depending on the method of ascertainment, it may be diagnosed in 10-75% of alcoholic patients. Most affected patients are between 40 and 60 years of age, and in essentially all cases, there is a history of chronic and heavy alcohol intake.

Clinical Features

Alcoholic neuropathy is a mixed sensory and motor disorder. The onset of symptoms is usually insidious, beginning in the feet and progressing proximally and symmetrically. Paresthesia is the most common presenting complaint. Many patients also complain of pain, either an aching discomfort in the calves or a burning sensation over the soles. Dysesthesias at times become so severe that a light touch or gentle rubbing over the skin is interpreted as intensely unpleasant (Koike et al. 2001). Interestingly, pain is more often a problem in those with milder neuropathy.

On examination, signs of a distal symmetrical polyneuropathy are invariably present. Both deep and superficial sensations are affected. Ankle tendon reflexes and sometimes knee reflexes arc absent. Weakness and wasting are limited to the distal feet in mild cases but can 11)volvi' the distal upper extremities in more severe cases. Rarely, there may be vagus-recurrent laryngeal nerve involvement, with prominent hoarseness and weakness of voice.

Other manifestations of chronic alcoholism are often evident. Liver cirrhosis, hepatic encephalopathy, Wernicke-Korsakoff syndrome, alcoholic cerebellar degeneration, and alcohol withdrawal symptoms all occur frequently at the time of evaluation. Trophic skin changes in the form of hypcrpigmentation, edema, ulcers, and cellulitis in the distal part of the feet may also occut. There may be radiological suggestions of a distal neuropathic arthropathy (Charcot's forefeet, acrodysrrophic neuropathy), with phalangeal atrophy, bony resorption, and subluxation of small joints in the feet. Repeated ttauma and infections to insensitive parts of the feet are probably responsible; this syndrome is prevalent in the south of France and Spain, where the term *TbcvenanVs syndrome* is applied.

Laboratory Studies and Pathology

The pathology of alcoholic neuropathy is predominantly axonal loss. Nerve conduction studies show reduced amplitude of sensory nerve responses with normal or mildly reduced conduction velocities. Electromyography may reveal signs of denervation and reinnervation in distal muscles of the lower extremities. Axonal degeneration of both myelinated and unmyelinated fibers is present on sural nerve biopsy. In approximately one fourth of patients, autonomic dysfunction may be demonstrated by abnormalities in heart rate variation to deep breathing, Valsalva maneuver, and postural change (Mouforte et al. 1995).

l'<.itboi>cnesis

Both alcohol neurotoxicity and thiamine deficiency may play major roles in the pathogenesis of alcoholic neuropathy. Many patients with alcoholic neuropathy have no evidence of nutritional deficiency but there are also reports that a balanced diet and supplemental vitamins occasionally produce improvement in neuropathy in those patients who continued to drink heavily.

Treatment and Management

It seems prudent to treat most affected patients with supplemental multivitamins and a balanced diet. Most patients probably do not respond to vitamin supplements alone, and abstinence from alcohol is paramount for treatment success. Even under ideal conditions, recovery is slow and incomplete.

Tobacco-Alcohol or Nutritional Amblyopia

Tobacco-alcohol amblyopia is a syndrome of vision loss caused by a selective lesion of the optic nerves. In Western countries, most affected patients ate chronic and severe alcoholics, often with a history of poor dietary intake or marked weight loss. Vision loss occurs insidiously and

painlessly, progressing in both eyes over a period of several weeks. The mosi common deficit* arc unpaired visual acuity and the presence of central or centrocecal scotomata. Even in severely affected subjects, the optic discs may show only mild pallor.

Although it is commonly called tobacco-alcohol amblyopia, neither agent has been proved to be directly responsible for the vision loss. The underlying cause is probably a nutritional deficiency. The disease is essentially identical to the amblyopia seen in prisoners of war and malnourished individuals who have no access to either alcohol or tobacco. Moreover, treatment with a combination of an adequate diet and B vitamins, despite the continuation of drinking and smoking, results in visual recovery. Dietary deficiencies of vitamin B_{12}, thiamine, folate, and riboflavin, all of which have been linked to optic neuropathy, may individually or together be responsible.

Marchiafava-ISignami Disease

In 1903, Marchiafava and bignami, two Italian pathologists, described a curious syndrome of selective demyelination of the corpus callosum in alcoholic Italians who indulged in large quantities of red wine. The disease seems to affect severe and chronic alcoholics in their middle or late adult life, with a peak frequency between 40 and 60 years of age. It is not restricted to any one ethnic group and consumption of red wine is not an invariable feature. Because of the background history of alcohol abuse, a nutritional cause has been invoked, but no nutritional factor has been identified. A toxic cause, such as direct toxicity of ethanol or other constituents, seems equally plausible.

A clinical diagnosis is often difficult, because neurological presentations vary considerably. Mental and motor slowing, other personality and behavior changes, incontinence, dysarthria, seizures, and hemiparesis occur to a varying extent. Occasional patients present with *a* coma. The most common picture on neurological evaluation is that of a frontal lobe or dementing syndrome. Sucking, grasping, and ;;e;;erih.iin.'ii may be prominent. 'I hese symptoms have a tendency to remit, and many patients survive and later die of an unrelated cause.

Pathologically, selective involvement of the central portion of the corpus callosum occurs; the anterior and posterior portions are spared or affected to a much lesser degree. There also may be symmetrical involvement of other white matter tracts. Magnetic resonance imaging is valuable for premortem visualization of these white matter lesions.

Treatment should be directed at nutritional support and rehabilitation from alcoholism. In those patients who recovered, it is not clear whether improvement was a result of vitamin supplementation or merely a tcflection of the disease's natural history.

Alcoholic-Nutritional Cerebellar Degeneration

Although the prevalence of this disorder is not known, alcoholic cerebellar degeneration is likely the most common of the acquired degenerations of the cerebellum. Men arc affected more frequently than women, and the incidence peaks in the middle decades of life. Alcohol abuse is long-standing in all patients, and alcoholic polyneuropathy occurs in most patients. The clinical syndrome is usually quite stereotyped. The presentation is a progressive unsteadiness in walking that evolves over weeks or months. Less commonly, a mild gait difficulty may be present for some time, only to worsen acutely during binge drinking or an intercurrent illness. On examination, the most obvious finding is a truncal ataxia, readily demonstrated by a wide-based gait and difficulty with tandem walking. Limb ataxia, if present, is much milder than the truncal ataxia and more severe in the legs than in the arms. In contrast to Wernicke's encephalopathy, nystagmus and ocular dysmetria arc uncommon. Dysarthria, tremor, and hypotonia are rare findings. With abstinence I. . . .; alcohol JI:J niiirilional supplement.'), improvement in cerebellar symptoms occurs slowly but may be incomplete.

The pathological changes consist of selective atrophy of the anterior and superior parts of the cerebellar vermis, with the cerebellar hemispheres involved to a lesser extent, lirain imaging is useful in demonstrating the atrophy during life. Histologically, cell loss involves all neuronal types in the cerebellum, although Purkinje's cells are the most severely affected. A mild secondary loss of neurons is common in the deep cerebellar nuclei and the inferior olivary nuclei. In some patients, concomitant pathological changes of Wernicke's encephalopathy may be present.

MISCELLANEOUS DEFICIENCY DISEASES

Strachan's Syndrome and Related Disorders

In 1887, Strachan, a medical officer in the West Indies, described a syndrome of severe painful polyneuropathy, sensory ataxia, vision loss, and mucocutaneous excoriations. Although it was originally known as *jdimncan neuritis,* hundreds of cases were quickly recognized around the world. More recent cases are seen primarily in underdeveloped countries and in prisoners of war. Nutritional deficiency plays a leading role in the pathogenesis of this disorder, but specific vitamins have not been identified. The majority of patients likely had deficiencies of multiple vitamins, especially that of thiamine.

The clinical picture varies from patient to patient. The essential features are (1) a polyneuropathy that is often sufficiently severe to produce sensory ataxia; (2) amblyopia with optic atrophy; (3) tinnitus, hearing

loss, and sometimes vertigo; and (4) a varying combination of stomatoglossitis, genital soreness and excoriation, and corneal degeneration. Gait ataxia and loss of sensation to vibration and joint position are prominent findings.

In the absence of a distinctive cause, there seems to be little value in distinguishing Strachan's syndrome from nutritional amblyopia and polyneuropathy. As in other deficiency diseases, treatment is directed toward establishing adequate diet and replenishing vitamins. Some degree of improvement can be expected, especially in the polyneuropathy.

An outbreak of optic and peripheral neuropathy in Cuba provides further insight into the etiology of this nutritional condition (Roman 1994). The Cuban outbreak occurred in 1992-1993, coinciding with a period of food shortage and rationing. Clinical manifestations included a varying combination of retrobulbar optic neuropathy, peripheral neuropathy, sensorineural deafness, spasticity, position and vibration sense loss, dysphonia, and dysphagia. Increased risk was associated with poor dietary intake, smoking, heavy alcohol drinking, weight loss, and excessive sugar consumption. No toxic etiological agent was identified. Supplementation of multivitamins to the entire Cuban population coincided with abatement of the epidemic. A dependence on cane sugar and a relative deficiency of meat and vegetables (and hence the B vitamins) seemed responsible for the outbreak.

Vitamin A

Dietary deficiency of vitamin A is uncommon in Europe and the United States. Deficiency may occur rarely in fat malabsorption syndromes, such as sprue, biliary atresia, and cystic fibrosis. A few cases occurred in infants put on nondairy formula free of vitamin A.

The earliest sign of deficiency is reduced ability to see in dim light (night blindness). Rctinol, an aldehyde form of vitamin A, binds with the protein opsin to form rhodopsin, which is responsible for vision at low light levels. Xerosis, or keratinization, of the conjunctiva and cornea often accompanies the night blindness. Some patients have the characteristic Bitot's spots, which are white, foamlike spots appearing at the side of the cornea. These eye findings are caused by metaplasia of epithelial cells and, if severe, can lead to permanent blindness. Rarely, infants may manifest a syndrome of raised intracranial pressure, bulging fontanelles, and lethargy.

Patients with signs of vitamin A toxicity or overdose are also likely to see a neurologist. The classic syndrome of toxicity is that of pseudotumor cerebri with headache and papilledema. The skin is often dry and pruritic, and patients may complain of generalized joint or bone pain. Especially in children, joint swelling and hyperostoses are often evident on roentgenography. Chronic daily consumption of more than 25,000 IU may produce toxicity, although most reported patients consumed much higher doses over a shorter period of time. Unusual foods, such as polar bear liver and halibut liver, contain high concentrations of vitamin A and have caused acute toxicity. Serum retinol level is useful in the diagnosis. The generally accepted lower limit of normal is 20 mg/dL, whereas concentrations in excess of 100 mg/dL are suggestive of toxicity.

Vitamin D

Derangement in vitamin D and calcium metabolism is responsible for a syndrome of proximal weakness that often occurs in the setting of vitamin D deficiency and osteomalacia. Although the pathogenesis of the disorder is not fully elucidated, patients recover partially or completely with vitamin D treatment. The disorder may be caused by a diversity of systemic conditions, including hyperparathyroidism, hypophosphatemia, chronic renal failure, anticonvulsant use, malabsorption, dietary deficiency, and inadequate exposure to sunlight.

A waddling gait and proximal weakness of the pelvic girdle is the most prominent finding on examination. Neck muscles also may be weak, but bulbar and ocular weakness is not present. Tendon reflexes and sensation are normal. Aside from the manifestations of myopathy, accompanying clinical features include a long history of multiple bone fractures, vertebral collapse, and disabling bone pain. Bone pain mainly affects the pelvic girdle, and the muscles are usually not painful. The pain may make the actual weakness difficult to assess. When vitamin D therapy is instituted, the pain disappears quickly, and true muscular weakness is unmasked.

Serum creatine kinase level is usually normal or mildly elevated. Nonspecific type II muscle fiber atrophy is seen on biopsy. Electromyography typically shows short-duration, low-amplitude, and polyphasic motor unit potentials without spontaneous activities, features similar to those of other metabolic myopathies. Other laboratory abnormalities of deranged bone metabolism are present. Osteomalacia is evident by roentgenography. Serum alkaline phosphatase almost always is abnormally high, and serum calcium and phosphorus may be normal or mildly decreased. These laboratory studies return to normal after a short period of vitamin D therapy. Muscle weakness, however, recovers much more slowly over a period of several months.

Vitamin D deficiency and compensatory increase of parathyroid hormone are common in hospitalized or immobilized patients (Thomas et al. 1998). Some of the contributing factors include insufficient exposure to sunlight, anticonvulsant drug therapy, renal dialysis, and Parkinson's disease. The deficiency poses a risk for bone loss and fracture. Its effect on neuromuscular function in this population is uncertain.

Protein-Calorie Malnutrition

Millions of infants and children in underdeveloped countries suffet ftom varying degrees of protein and calotie deficiencies and manifest two interrelated syndromes, marasmus and kwashiorkor. Marasmus is primarily a result of caloric insufficiency and is characterized by extreme emaciation and growth failure in early infancy. These infants usually have never been breast fed or were weaned before the age of 1 year. Kwashiorkor is seen most commonly in children weaned between 2 and 3 years of age, and its primary underlying cause is protein deficiency. The signs of kwashiorkor are edema, ascites, hepatomegaly, sparse hair, and skin depigmentation.

The earliest and most consistent neurological signs in these children are apathy to the environment and extreme irritability. In addition, weakness, generalized muscle wasting, hypotonia, and hvporeflexia occur frequently. Cognitive deficits may be permanent despite improvement in nutrition. It is difficult to separate the effects of malnutrition from those of socioeconomic deprivation, but comparison studies in siblings show persistent impairment of intelligence attributable to malnutrition. Autopsy and imaging studies show the brain to be slightly atrophic and neutonal development less mature in these patients.

A mild encephalopathy, usually no more than transient dtowsiness, sometimes occurs during the first week of dietary treatment. Occasionally, children develop asterixis or coma or even die as a result of their treatment. Other children manifest a transient syndrome of rigidity, coarse tremors, myoclonus, and exaggerated tendon reflexes during the first few weeks of recovery from malnutrition.

Chapter 64
Effects of Toxins and Physical Agents on the Nervous System

A. EFFECTS OF OCCUPATIONAL TOXINS ON THE NERVOUS SYSTEM

Michael J. Aminoff

Neurotoxic disorders, especially those with an iatrogenic basis, arc well described. Hence any neurological condition, such as a peripheral neuropathy, may be thought to be caused by a neurotoxin and may be the subject of potential litigation. Nevertheless, neurotoxic disorders are occurring increasingly as a result of occupational or environmental exposure to chemical agents and often go unrecognized.

RECOGNITION OF NEUROTOXIC DISORDERS

Exposure to neurotoxins may lead to dysfunction of any part of the central, peripheral, or autonomic nervous system and the neuromuscular apparatus. Neurotoxic diMirJirs .:,i..- nvotuii/id iv.ulily il n Jusr temporal relationship exists between the clinical onset and prior exposure to a chemical agent, especially one known to be neurotoxic. Known neurotoxins produce stereotyped or characteristic neurological disturbances that generally cease to progress soon after exposure is discontinued and ultimately improve to a variable extent. Recognition of a neurotoxic disorder is more difficult when exposure is chronic or symptoms are nonspecific. Diagnosis may be clouded by concerns about possible litigation, and the problem is compounded when the exposure history is unclear. Patients often attribute symptoms of an idiopathic disorder to chemical exposure when no other cause can be found. Such patients have often been exposed to several chemical agents or are known to abuse alcohol or other dtugs, thereby further confounding the issue.

Single case reports that an agent is neurotoxic arc unreliable, especially when the neurological symptoms are frequent in the general population. Epidemiological studies may be helpful in establishing a neurotoxic basis for symptoms. However, many of the published studies are inadequate because of methodologic problems such as the selection of appropriate control subjects. Recognition of a neurotoxic basis for neurobchavioral disorders, for example, requires matching of exposed subjects and unexposed controls, not only for age, gender, and race but also for premorbid cognitive ability; educational, social, and cultural background; and alcohol, recreational drug, and medication use. Laboratory test results are often unhelpful in confirming that the neurological syndrome is caused by a specific agent, either because the putative neurotoxin

cannot be measured in body tissues or because the interval since exposure makes such measurements meaningless.

The part of the central, peripheral, or autonomic nervous system and of the neuromuscular apparatus that is damaged by exposure to neurotoxins depends on the responsible agent. The pathophysiological basis of neurotoxicity is often unknown. In considering the possibility of a neurotoxic disorder, it is important to obtain a detailed account of all chemicals to which exposure has occurred, including derails of the duration and severity of exposure, any protective measures taken, and the context in which exposure occurred. Then it must be determined whether any of these chemicals are known to be neurotoxic and whether symptoms are compatible with the known toxicity of the suspected compound. Many neurotoxins can produce clinical disorders thai resemble well-known metabolic, nutritional, or degenerative neurological disorders, and it is therefore important to consider these and any other relevant disease processes in the differential diagnosis. Neurotoxins cause diffuse rather than focal or lateralized neurological dysfunction. In recognizing new neurotoxic disorders, a clustering of cases is often important, but this may not be evident until patients are referred for specialist evaluation.

The neurological disorder is typically monophasic. Although progression may occur for several weeks after exposure has been discontinued (coasting), it is eventually arrested and improvement may then follow, depending on the severity of the original disorder. Prolonged or progressive deterioration long after exposure has been discontinued, or the development of neurological symptoms months to years after exposure, suggests that a neurotoxic disorder is not responsible.

This section reviews the neurotoxicity of some occupational and environmental agents, in alphabetical order.

ORGANIC: CHEMICALS

Acrylamide

Acrylamide polymers are used as flocculators and are constituents of certain adhesives and products such as cardboard or molded parts. They also are used as grouting agents for mines and tunnels, a solution of the monomer being pumped into the ground where polymerization is allowed to occur. The monomer is neurotoxic, and exposure may occur during irs manufacture or in the polymerization process. Most cases of acrylamide toxicity occur by inhalation or cutaneous absorption. The acrylamide is distributed widely throughout the body and is excreted primarily through the kidneys. The mechanism responsible for its neurotoxicity is unknown. Studies in animals have shown early abnormalities in axonal transport, and this ma\ accomn tor ihe lusloparhological changes discussed here.

Clinical manifestations of acrylamide toxicity depend on the severity of exposure. Acute high-dose exposure results in confusion, hallucinations, reduced attention span, drowsiness, and other encephalopathy changes. A peripheral neuropathy of variable severity may occur after acute high-dose or prolonged low-level exposure. The neuropathy is a length-dependent axonopathy involving both sensory and motor fibers; some studies suggest that terminal degeneration precedes axonopathy and is the primary site of involvement (LoPachin, Ross, and Lehning 2002), Hyperhidrosis and dermatitis may develop before the neuropathy is evident clinically in those with repeated skin exposure. Ataxia from cerebellar dysfunction also occurs and relates to degeneration of afferent and efferent cerebellar fibers and Purkinje cells. Neurological examination reveals disral sensorimotor deficits and early loss of all tendon reflexes rather than simply the Achilles reflex, which is usually affected first in most length-dependent neuropathies. Autonomic abnormalities other than hyperhidrosis are uncommon. Gait and limb ataxia are usually greater than can be accounted for by the sensory loss. With discontinuation of exposure, the neuropathy coasts, arrests, and may then slowly reverse, but residual neurological deficirs are common. These consist particularly of spasticity and cerebellar ataxia; the peripheral neuropathy usually remits because regeneration occurs in the peripheral nervous system. No specific treatment exists.

Klectrodiagnostic studies provide evidence of an axonal sensorimotor polyneuropathy. Workers exposed to acrylamide may be monitored electrophysiological!)' by recording sensory nerve action potentials, which arc attenuated early in the course of the disorder, or by measuring the vibration threshold. Histopathological studies show accumulation of neurofilaments in axons, especially distally, and distal degeneration of peripheral and central axons. The role of neurofilament accumulation in the generation of axonal degeneration has been questioned (Stone ct a!. 2001). The large myelinated axons are involved first. The affected central pathways include the ascending sensory fibers in the posterior columns, the spinocerebellar tracts, and the descending corticospinal pathways. Involvement of postganglionic sympathetic efferent nerve fibers accounts for the sudomotor dysfunction. Measurement of hemoglobin-acrylamidc adducts may be useful in predicting the development of peripheral neuropathy.

Allyl Chloride

Ally I chloride is used for manufacturing cpoxy resins, certain insecticides, and polyacrylonitrile. Exposure leads to a mixed sensorimotor distal axonopathy. Cessation of exposure is followed by recovery of variable degree. Intra-axonal accumulation of neurofilaments occurs multifocally before axonal degeneration in animals exposed to this

compound. Similar changes may occur also in the postero-lateral columns of the spinal cord.

Carbon Disulfide

Carbon disulfide is used as a solvent or soil fumigant, in perfume production, in certain varnishes and insecticides, in the cold vulcanization of rubber, and in manutacniring viscose rayon and cellophane films. Toxicity occurs primarily from inhalation or ingestion but also may occur transdermally. The pathogenetic mechanism is uncertain but may involve a chelating effect of carbon disulfide metabolites, direct inhibition of certain en/ymes, or the release of free radicals following cleavage of the carbon-sulfur bond. Most reported cases have been from Europe and Japan.

Acute inhalation of concentrations exceeding 300-400 ppm leads to an encephalopathy, with symptoms that vary from mild behavioral disturbances to drowsiness and, ultimately, to respiratory failure. Behavioral disturbances may include explosive behavior, mood swings, mania or depression, confusion, and other psychiatric disturbances. Long-term exposure to concentrations between 40 and 50 ppm may produce similar disturbances. Minor affective or cognitive disturbances may be revealed only by neuro-psychological testing.

Long-term exposure to carbon disulfide may lead also to extrapyramidal or pyramidal deficits, impaired vision (Gobba 2000), absent pupillary and corneal reflexes, optic neuropathy, and a characteristic retinopathy, A small-vessel vaseulopathy may be responsible (Huang et al. 2001). A clinical or subclinical polyneuropathy develops after exposure to levels of 100-150 ppm for several months or to lesser levels for longer periods and is characterized histologically by focal axonal swellings and ncurofilamen-tary accumulations.

No specific treatment exists other than the avoidance of further exposure. Recovery from the peripheral neuropathy generally follows the discontinuation of exposure, but some central deficits may persist.

Carbon Monoxide

Occupational exposure to carbon monoxide occurs mainly in miners, gas workers, and garage employees. Other modes of exposure include poorly ventilated home-heating stoves and suicide attempts. The neurotoxic effects of carbon monoxide relate to intracellular hypoxia. Carbon monoxide binds to hemoglobin with high affinity to form carboxyhcmoglobin; it also limits the dissociation of (i\ylieinoL;lobir ami binds ro various enzymes. Acute toxicity leads to headache (Hampson and Hampson 2002), disturbances of consciousness, and a variety of other behavioral changes. Motor abnormalities include the development of pyramidal and extrapyramidal deficits. Seizures may occur, and focal cortical deficits sometimes develop. Treatment involves prevention of further exposure to carbon monoxide and administration of pure or hyperbaric oxygen (Hawkins, Harrosin, and Charters 2000). Neurological deterioration may occur sevetal weeks after partial or apparently full recovery from the acute effects of carbon monoxide exposure, with recurrence of motor and behavioral abnormalities. The degree of recovery from this delayed deterioration is limited, and some patients lapse into a persistent vegetative state.

Pathological examination shows hypoxic and ischemic damage in the cerebral cortex as well as in the hippocam-pus, cerebellar cortex, and basal ganglia. Lesions are also present diffusely in the cerebral white matter. The delayed deterioration has been related to a diffuse subcortical leukoencephalopathy, but its pathogenesis is uncertain.

Ethylene Oxide

Ethylene oxide is used to sterilize heat-sensitive medical equipment and as an alkylating agent in industrial chemical synthesis. A by-product, ethylene chlorohydrin, is highly toxic. Operators of sterilization equipment should wear protective ventilatoty apparatus to prevent occupational exposure. Acute exposure to high levels produces headache, nausea, and a severe, reversible encephalopathy. Long-term exposure to ethylene oxide or ethylene chlorohydrin may lead to a petipheral sensorimotor axonopathy and mild cognitive changes, for example, in operating-room nurses and sterilizer workers. Recovery generally follows cessation of exposure. Neuropathy may be produced in rats by exposure to ethylene oxide, and the residual ethylene oxide in sterilised dialysis tubing may contribute to the poly-neuropathy occurring in patients undergoing chronic hemodial; sis.

Hex a carbon Solvents

The hexacarbon solvents w-hexane and methyl «-butyl ketone ate both metabolized to 2,5-hexanedione, which targets proteins required for the maintenance of neuronal integrity (Spencer, Kim, and Sabri 2002) and is responsible in large part for their neurotoxicity. This neurotoxicity is potentiated by methyl ethyl ketone, which is used in paints, lacquers, printer's ink, and certain glues. «-Hexane is used as a solvent in paints, lacquers, and printing inks and is used especially in the rubber industry and in certain glues. Workers involved in the manufacturing of footwear, laminating processes, and cabinetry, especially in confined, unventilated spaces, may be exposed to excessive concen-trations. Methyl H-butyl ketone is used in the manufacture of vinyl and acrylic coatings and adhesives and in the printing industry. Exposure to either of these chemicals by

inhalation or skin contact leads to a progressive distal sensorimotor axonal polyneuropathy. Optic neuropathy or maculopathy and facial numbness also have followed w-hexane exposure. The neuropathy is related to a disturbance of axonal transport, and histopathological studies reveal giant multifocal axonal swelling and accumulation of axonal neurofilaments, with distal degeneration in peripheral and central axons. Myelin retraction and focal demyelination are found at the giant axonal swellings.

Acute inhalation exposure may produce feelings of euphoria associated with hallucinations, headache, unsteadiness, and mild narcosis. This has led to the inhalation of certain glues for recreational purposes, which causes pleasurable feelings of euphoria in the short tetm but may lead to a progressive, predominantly motor neuropathy and symptoms of dysautonomia after high-dose exposure and a more insidious sensorimotor polyneuropathy following chronic use.

Electrophysiological findings include increased distal motor latency and marked slowing of maximal motor conduction velocity as well as small or absent sensory nerve action potential[1], and electromyographic signs of denervation in affected muscles. The conduction slowing relates to demyelinative changes and is unusual in other toxic neuropathies. A reduction in the it/e or sensory nerve action potentials may occur in the absence of clinical or other electrophysiological evidence of nerve involvement. Central involvement may result in abnormalities of sensory evoked potentials. The cerebrospinal fluid is usually normal, but a mildly elevated protein concentration is sometimes found. Despite cessation of exposure, progression of the neutological deficit may continue for several weeks or months (coasting) before the downhill course is arrested and tecovery begins. Severe involvement is followed by incomplete recovery of the peripheral neuropathy. When the polyneuropathy does resolve, previously masked signs of central dysfunction, such as spasticity, may become evident.

Methyl Bromide

Methyl bromide has been used as a refrigerant, insecticide, fumigant, and fire extinguisher. Its high volatility may lead to work-area concentrations sufficient to cause neurotoxicity[7] from inhalation. Following acute high-level exposure, an interval of several hours or more may elapse before the onset of symptoms. Because methyl bromide is odorless and colorless, subjects may not even be aware that exposure has occurred. Hence chloropicrin, a conjunctival and mucosal NTH nit, > aimmonl) added to warn ot mhalatinn exposure. Acute methyl bromide intoxication leads to an encephalopathy with convulsions, delirium, hyperpyrexia, coma, pulmonary edema, and death. Acute exposure to lower concentrations may result in conspicuous mental changes including confusion, psychosis, or affective distutbances; headache; nausea; dysarthria; tremulousness; myoclonus; ataxia; visual disturbances; and seizures.

Long-term low-level exposure may lead to a polyneuropathy in the absence of systemic symptoms. Distal paresthesias are followed by sensory and motor deficits, loss of tendon reflexes, and an ataxic gait. Visual disturbances, optic atrophy, and upper motor neuron deficirs may occur also. Calf tenderness is sometimes conspicuous. The cerebrospinal fluid is unremarkable, although clectrodiagnostic study results reveal both sensory and motor involvement. Gradual improvement occurs with cessation of exposure.

Treatment is symptomatic and supportive. Hemodialysis may also be helpful in removing bromide from the blood (Yamano et al. 2001). Chelating agents have been used in the past but are of uncertain utility.

Org an o chlorine Pesticides

The organochlorinc pesticides include aldrin, dieldrin, and lindane as well as the once popular insecticide dichlorodiphenyltrichloroethylene, commonly called *DD'i.* Tremor and convulsions may follow acute high-level exposure, but the effects of chronic low-level exposure are uncertain. Chlordecone, which belongs to this group, may produce a neurological disorder characterized by "nervousness," tremor, clumsiness of the hands, gait ataxia, and opsoclonus. Minor cognitive changes and benign intracranial hypertension may occur. The pathophysiology of the disorder has not been established.

Organophosphates

Organophosphates are used mainly as pesticides and herbicides bur are also used as petroleum additives, lubricants, antioxidants, flame retardants, and plastic modifiers. Most cases of organophosphate toxicity result from exposure in an agricultural setting, not only among those mixing or spraying the pesticide or herbicide but also among workers returning prematurely to sprayed fields. Absorption may occur through the skin, by inhalation, or through the gastrointestinal tract. Organophosphates inhibit acetylcholinesterase by phosphorylation, with resultant acute cholinergic toxicity. This has both central and neuromuscular manifestations. Symptoms include nausea, salivation, lacrimation, headache, weakness, and bronchospasm in mild instances and bradycardia, tremor, chest pain, diarrhea, pulmonary edema, cyanosis, convulsions, and even coma in more severe cases. Death may result from respiratory or heart failure. Treatment involves intravenous administration of pralidoxime (1 g) together with atropine (1 mg) subcutaneously every 30 minutes until sweating and salivation are controlled. I'ralidoxime accelerates reactivation of the inhibited acetylcholinesterase, and atropine is

effective in counteracting muscarinic effects, although it has no effect on the nicotinic effects such as weakness or respiratory depression. It is important to ensure adequate ventilatory support before atropine is given. The dose of pralidoximc can be repeated if no obvious benefit occurs, but in refractory cases it may need to be given by intravenous infusion, the dose being titrated against clinical response. Functional recovery may take approximately 1 week, although acetylcholinesterase levels take longer to reach normal levels.

Carbamate insecticides also inhibit cholines re rases but have a shorter duration of action than organophosphate compounds. The symptoms of toxicity are similar to those described for organophosphates but are generally milder. Treatment with atropine is usually sufficient.

Certain orga no phosphates cause a delayed polyneuropathy that occurs approximately 2-3 weeks after acute exposure. In the past, contamination of illicit alcohol with triorthocresyl phosphate ("Jake") led to large numbers of such cases. There is no evidence that peripheral nerve dysfunction follows prolonged low-level exposure to organophosphates (Lotti 2002). Paresthesias in the feet and cramps in the calf muscles are followed by progressive weakness that typically begins distally in the limbs and then spreads to involve more proximal muscles. The maximal deficit usually develops within 2 weeks. Quadriplegia occurs in severe cases. Although sensory complaints are typically inconspicuous, clinical examination shows sensory deficits. The Achilles reflex is typically lost, and other tendon reflexes may be depressed also; however, in some instances evidence of central involvement is manifest by brisk tendon reflexes. Cranial nerve function is spared typically. With time, there may be improvement in the peripheral neuropathy, but upper motor neuron involvement then becomes unmasked and often determines the prognosis for functional recovery. There is no specific treatment to arrest progression or hasten recovery. Electro diagnostic studies reveal an axonopathy with partial denervation of affected muscles and small compound muscle action potentials but normal or only minimally reduced maximal motor conduction velocity.

The delayed syndrome follows exposure only to certain organophosphates such as triorthocresyl phosphate, leptophos, trichlorfon, and mi pa fox. The neurological disturbance relates m some way to phosphorylation and inhibition of the enzyme neuropathy target esterase (NIT"), which is present in essentially all neurons and has an uncertain role in the nervous system (Glynn ct al. 1998). In addition, *aging* of the inhibited NTF (loss of a group attached to the phosphorus, leaving a negatively charged phosphoryl group attached to the protein) must occur for the neuropathy to develop. The precise cause of the neuropathy is uncertain, however. No specific treatment exists to ptevent occurrence of the neuropathy following exposure, but measurement of lymphocyte NTE has been used to monitor occupational exposure and predict the occurrence of neuropathy. Moreover, the ability of any particular organophosphate to inhibit NTE in hens may predict its neurotoxicity in humans.

Three other syndromes related to organophosphates require brief comment. The intermediate syndrome occurs in the interval between the acute cholinergic crisis and the development of delayed neuropathy, typically becoming manifest within 4 days of exposure and resolving in 2-3 weeks (Guadarrama-Naveda, de Cabrere, and Matos-Bastidas 2001). It reflects excessive cholinergic stimulation of nicotinic receptors and is characterized clinically by respiratory, bulbar, and proximal limb weakness. It relates to the severity of poisoning and to prolonged inhibition of acetylcholinesterase activity but not to the development of delayed neuropathy. The syndrome of clipper's flu refers to the development of transient symptoms such as headache, rhinitis, pharyngitis, myalgia, and other flulike symptoms in farmers exposed to organophosphate sheep dips. Vague sensory complaints (but no objective abnormalities on sensory threshold tests) may also occur (Pilkington et al. 2001). Whether these complaints relate to mild organophosphate toxicity is uncertain. Similarly uncertain is whether chronic effects (persisting behavioral and neurological dysfunction) may follow acute exposure to organophosphates. The occutrencc of chronic symptoms in the absence of any episode of acute toxicity is unlikely. Evaluation of reports is hampered by incomplete documentation and the variety of agents to which exposure has often occurred. Carefully controlled studies may clarify this issue in the future.

Pyrethroids

Pyrethroids are synrhetic insecticides. Occupational exposure has led to paresthesias that have been attributed to repetitive activity in sensory fibers as a result of abnormal prolongation of the sodium current during membrane excitation. Treatment is purely supportive.

Solvent Mixtures

In the 1970s a number of reports from Scandinavia suggested that house paintets, in particular, developed a disturbance of cognitive function that related to exposure to mixtures of organic solvents. However, further studies (including cases previously diagnosed with the disorder) have failed to validate the earlier reports, which in many instances were methodologically flawed. Furthermore, workers performing the same basic tasks in different companies have highly variable levels of solvent exposure, complicating the interpretation of published studies (Horstman et al. 2001). Because of these factors, the existence of so-called "painter's encephalopathy" in those

exposed to low levels of organic solvents for a prolonged period remains uncertain.

Styrene

Styrene is used for manufacturing reinforced plastic and certain resins. Occupational exposure occurs by the dermal or inhalation routes and is typically associated with exposure to a variety of other chemicals, thereby making it difficult to define the syndrome that occurs from styrene exposure itself. Acute exposure to high concentrations of styrene has led to cognitive, behavioral, and attentional disturbances. Less clear are the consequences of exposure to chronic low levels of styrene. Abnormalities in psychomotor performance have been reported, but there is little compelling evidence of persisting neurological sequelae in this circumstance. Visual abnormalities (impaired color vision and reduced contrast sensitivity) have also been described (Castillo et al. 2001).

Toluene

Toluene is used in a variety of occupational settings. It is a solvent for paints and glues and is used to synthesize benzene, nitrotoluene, and other compounds. Exposure occurs among workers laying linoleum, spraying paint, and working in the printing industry, particularly in poorly ventilated locations. Chronic high exposure may lead to cognitive disturbances and to central neurological deficits with upper motor neuron, cerebellar, brainstem, and cranial nerve findings and tremor. An optic neuropathy may occur, as may ocular dysmetria and opsoclonus. Disturbances of memory and attention characterize the cognitive abnormalities, and subjects may exhibit a flattened affect. M,I::IH'IK K-MJIUIKV ::ii;i;;i:u:. :MRI) shows cerebral atrophy and diffuse abnormalities of the cerebral white matter; symmetrical lesions may be present in the basal ganglia and thalamus and the cingulate gyri. Thalamotomy may ameliorate the tremor (Miyagi et al. 1999). Lower levels of exposure lead to minor neurobeksvior.il disUirhina-..

Tricliloro ethylene

Trichloroethylene is an industrial solvent and degrcaser that is used in dry cleaning and the manufacture of rubber. It also has anesthetic properties. Recreational abuse has occurred because it may induce feelings of euphoria. Acute low-level exposure may lead to headache and nausea, but claims that an encephalopathy follows chronic low-level exposure are unsubstantiated. Higher levels of exposure lead to dysfunction of the trigeminal nerve, with progressive impairment of sensation that starts in the snout area and then spreads outward. This has been particularly associated with rebreathing anesthetic circuits where the trichlorcthylcnc is heated by the carbon dioxide absorbent. With increasing exposure, facial and buccal numbness is followed by weakness of the muscles of mastication and facial expression. Ptosis, extraocular palsies, vocal cord paralysis, and dysphagia may occur also, as may an encephalopathy, but occurrence of a peripheral neuropathy is uncertain. The clinical deficit relates to neuronal loss in the cranial nerve nuclei and degeneration in related tracts. With discontinuation of exposure, the clinical deficit generally resolves, sometimes over 1-2 years, bur occasional patients are left with residual facial numbness or dysphagia.

Vacor

Vacor, *a* rodenticide, has led to severe autonomic dysfunction accompanied by a usually milder sensorimotor axonopathy following its ingestion. The mechanism by which this develops is unclear, but it may relate to an impairment of fast anterograde axonal transport. Acute diabetes mellitus also resulrs from necrosis of the beta islet cells of the pancreas.

METALS

Aluminum

Aluminum exposure is responsible for dialysis encephalopathy, which is characterized by speech disturbances, cognitive decline, seizures, and myoclonus.

Arsenic

Arsenic poisoning can result from ingestion of the trivalent arsenite in murder or suicide attempts. Large numbers of persons in areas of India, Pakistan, and certain other countries are chronically poisoned from naturally occurring arsenic in ground water (Hall 2002). Traditional Chinese medicinal herbal preparations may contain arsenic sulfide and mercury and arc a source of chronic poisoning. Uncommon sources of accidental exposure include burning preservative-impregnated wood and storing food in antique copper kettles. Exposure to inorganic arsenic occurs in workers involved in smelting copper and lead ores.

With acute or subacute exposure, nausea, vomiting, abdominal pain, diarrhea, hypotension, tachycardia, and vasomotor collapse occur and may lead to death. Obtundation is common, and an acute confusion a 1 state may develop. Arsenic neuropathy takes the form of a distal axonopathy, although a demyelinating neuropathy is found soon after acute exposure. The neuropathy usually

develops within 2-3 weeks of acute or subacute exposure, although the latent period may be as long as 1-2 months. Symptoms may worsen over a few weeks despite lack of further exposure, but eventually stabilize. With low-dose chronic exposure, the latent period is more difficult to determine. In either circumstance, systemic symptoms arc also conspicuous. With chronic exposure, similar but less severe gastrointestinal disturbances develop, as may skin changes such as melanosis, keratoses, and malignancies. Mees' lines are white transverse striations of the nails (striate leukonychiae) that appear 3-6 weeks after exposure **(Figure** 64A.1). As a nonspecific manifestation of nail matrix injury, Mees' lines can be seen in a number of other conditions, including thallium poisoning, chemotherapy, and a variety of systemic disorders.

The neuropathy involves both large- and small-diameter fibers. Initial symptoms are typically of distal, painful dysesthesias and are followed by distal weakness. Proprioceptive loss may be severe, leading to marked ataxia. The severity of weakness depends on the extent of exposure. The respiratory muscles are sometimes affected, and the disorder may simulate Guillain-Barre syndrome both clinically and electrophysiologically. Elcctrodi a gnostic studies may initially suggest a demyelinating polyradiculo-neuropathy, but the changes of an axonal neuropathy subsequently develop. Arsenic levels in hair, nail clippings, or urine may be increased, especially in cases of chronic exposure.

Detection of arsenic in urine is diagnostically useful within 6 weeks of a single large-dose exposure or during ongoing low-level exposure. Inorganic arsenic values over 25 ug per 24 hours are abnormal. Methods are available in reference laboratories to distinguish between inorganic (toxic) and organic (sea food-derived) arsenic compounds. Arsenic bound to keratin can be detected in hair or nails months to years after exposure. Pubic hair is preferable to scalp hair for examination because it is less liable to environmental contamination. Levels exceeding 10 ug/g of tissue arc abnormal. Other abnormal laboratory features include aplastic anemia with pancytopenia and moderate cerebrospinal fluid protein elevation. Nerve conduction studies in chronic arsenic neuropathy reflect the changes of distal axonopatby with low-amplitude or unelicitable sensory and motor evoked responses and preserved conduction velocities. Electromyography typically shows denervation in distal extremity muscles. In the subacute stages, however. Mime clectropl'.\ siolnejcil v.mnv-., such .is partial motor conduction block, absent F responses, and slowing of motor conduction velocities are suggestive of demyelinating polyradiculoneuropathy. Progressive slowing of motor conduction velocities sufficient to invoke consideration of segmental demyelination has been reported in the first three months after massive exposure. Biopsies of peripheral nerves show axonal degeneration in chronic cases. Arsenite compounds react with protein sulfhydryl groups, interfere with formation of coenzyme A and several steps in glycolysis, and are potent uncouplers of oxidative phosphorylation. These biochemical reactions are responsible for the impaired neuronal energy metabolism, which in turn results in distal axonal degeneration.

Chelation therapy with either water-soluble derivatives of dimercaprol (DMSA or DMPS) or penicillamine is effective m controlling the systemic effects of acute arsenic poisoning and may prevent the development of neuropathy if it is started within hours of ingestion (Graeme and Pollack 1998). There is little evidence that chelation in the **later** stages of arsenic neuropathy promotes clinical recovery. The neuropathy itself often improves gradually over the course of many months, but depending on the

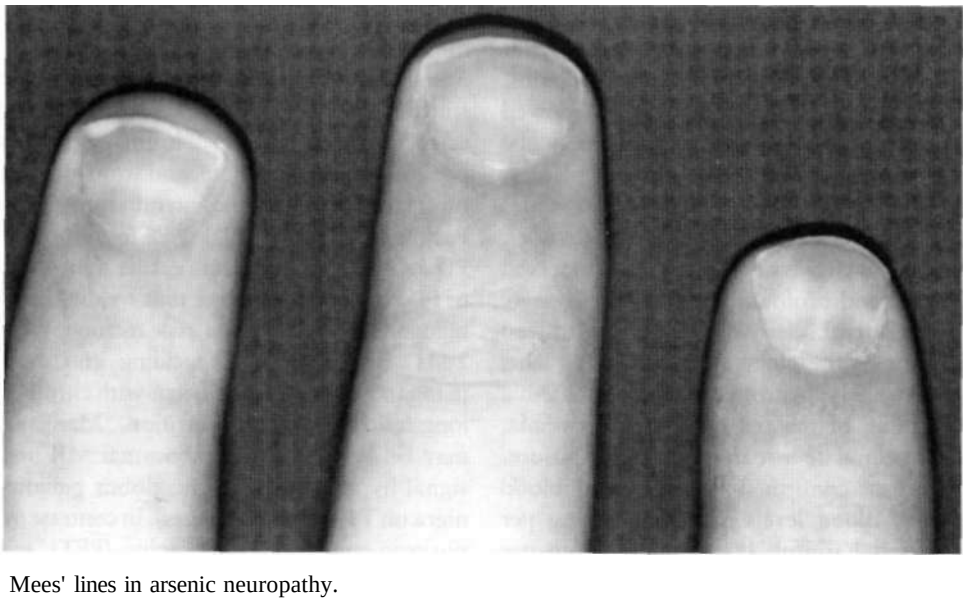

FIGURE 64A.1 Mees' lines in arsenic neuropathy.

severity of the deficit when exposure is discontinued, a substantial residual neurological deficit is common.

Lead

Occupational exposure to lead occurs in workers in smelting factories and metal foundries and those involved in demolition, ship breaking, manufacturing of batteries or paint pigments, and construction or repair of storage tanks. Occupational exposure also occurs in the manufacture of ammunition, bearings, pipes, solder, and cables. Non-industrial sources of lead poisoning are home-distilled whiskey, Asian folk remedies, earthenware pottery, indoor firing ranges, and retained bullets. Lead neuropathy reached epidemic proportions at the end of the nineteenth century because of unfcontrolled occupational exposure but now is rare because of strict industrial regulations. Exposure also may result from ingestion of old paint in children with pica and consumption of illicit spirits by adults. Absorption is commonly by ingestion or inhalation but occasionally occurs through the skin.

The toxic effects of inorganic lead salts on the nervous system commonly differ with age, producing acute encephalopathy in children and polyneuropathy in adults. Children typically develop an acure gastrointestinal illness followed by behavioral changes, ^HIIUMHM. drowsiness, reduced alertness, focal or generalized seizures, and {in severe cases) coma with intracranial hypertension. At autopsy, the brain is swollen, with vascular congestion, perivascular exudates, edema of the white matter, and scattered areas of neuronal loss and gliosis. In adults, an encephalopathy is less common, but behavioral and cognitive changes are sometimes noted. In adults, lead produces a predominantly motor neuropathy, sometimes accompanied by gastrointestinal disturbances and a microcytic, hypochromic anemia. The neuropathy is manifest primarily by a bilateral wrist drop sometimes accompanied by bilateral footdrop or by more generalized weakness that may be associated with distal atrophy and fascieulations. Sensory complaints are usually minor and overshadowed by the motor deficit. The tendon reflexes may be diminished or absent. Older reports describe a painless motor neuropathy with few or no sensory abnormalities and distinct patterns of weakness affecting wrist extensors, finger extensors, and intrinsic hand muscles. Preserved reflexes, fascieulations, and profound muscle atrophy may simulate amyotrophic lateral sclerosis. A rare sign of lead exposure is a blue line at the gingival margin in patients with poor oral hygiene. Hypochromic microcytic anemia with basophilic stippling of the red cells, hyperuricemia, and azotemia should stimulate a search for lead exposure.

Lead intoxication is confirmed by c lev a red blood and urine lead levels. Blood levels exceeding 70 j.iu, pet 100 mL are considered harmful, but even levels greater than 40 tig per 100 mL have been correlated with minor nerve-conduction abnormalities. Lead inhibits erythrocyte ^-aminolevulinic acid dehydratase and other enzymatic steps in the biosynthctic pathway of porphyrins. Consequently, increased red cell protoporphyrin levels emerge together with increased urinary excretion of 5-aminolevulinie acid and coproporphyria Excess body lead burden, confirming past exposure, can be documented by increased urinary lead excretion aftet a provocative chelation challenge with calcium ethylenediaminetetraaceric acid. Only a few electrophysiological studies have been reported in patients with overt lead neuropathy. These investigations indicate a distal axonopathy affecting both motor and sensory fibers. These observations corroborate changes of axonal degeneration seen in human nerve biopsies, Contrary to the findings in humans, lead produces segmental demye11nation in animals. Lead is known to cause early mitochondrial changes in cell-culture systems, but the biochemical mechanisms leading to neurotoxicity remain unknown.

Lead encephalopathy is managed supportively, but corticosteroids arc given to treat cerebral edema, and chelating agents (dimercaprol or 2,3-dimercaptopropane sulfonate) are prescribed also. No specific treatment exists for lead neuropathy other than prevention of further exposure to lead. Chelation therapy does not hasten recovery.

Manganese

Manganese miners may develop neurotoxicity following inhalation for prolonged periods (months or years) of dust containing manganese. Headache, behavioral changes, and cognitive disturbances ("manganese madness") are followed by the development of motot symptoms such as dystonia, parkinsonism, retropulsion, and a characteristic gait called "cock-walk" manifested by walking on the toes with elbows flexed and the spine erect. There is usually no tremor and the motor deficits rarely improve with l.-dopa therapy. Manganese intoxication has been reported in miners, smelters, welders, and workers involved in the manufacture of dry batteries; after chronic accidental ingestion of potassium permanganate, and from incorrect concenttation of manganese in parenteral nutrition. Welders with Parkinson's disease (PD) were found to have their onset of PD an average of 17 years earlier than a control population of PD patients, suggesting that welding, possibly by causing manganese toxicity, is a risk factor for PD (Racette et al. 2001). In addition to welding and manganese mining, manganese toxicity may occur with chronic liver disease and long-term parenteral nutrition. Manganese intoxication may be associated with abnormal MR imaging (abnormal signal hyperintensity in the globus pallidus and substantia nigra on'11-weighted images). In contrast to PD, fluorodopa positron-emission tomography (PET) scans arc usually normal in patients with manganese-induced parkinsonism,

and raclopride (D2 receptor) binding is only slightly reduced in the caudate and normal in the putamen. Neuronal loss occurs in the globus pallidus and substantia nigra pars reticularisj as well as in the subthalamic nucleus and striatum. There is little response to L-dopa of the extrapyramidal syndrome, which may progress over several years (Huang et al. 1998). Myoclonic jerking may occur, sometimes without extrapyramidal accompaniments (Ono, Komai, and Yamada 2002),

Mercury

The toxic effects of elemental mercury (mercury vapor), inorganic salts, and short-chain alkyl-mercury compounds predominantly involve the central nervous system and dorsal root ganglion sensory neurons. Inorganic mercury toxicity may result from inhalation during industrial exposure, as in thermometer and battery factories, mercury processing plants, and electronic applications factories. In the past, exposure occurred particularly in the hat-making industry. No evidence exists that the mercury contained in dental amalgam imposes any significant health hazard. Differences in health and cognitive function between dentists and control subjects cannot be attributed directly to mercury (Ritchie et al. 2002), Clinical consequences of exposure include cutaneous erythema, hyperhidrosis, anemia, proteinuria, glycosuria, personality changes, intention tremor ("hatter's shakes"), and muscle weakness. The personality changes ("mad as a hatter") consist of irritability; euphoria; anxiety; emotional lability; insomnia; and disturbances of attention, with dtowsiness, confusion, and, ultimately, stupor. A variety of other central neurological deficits may occur but are more conspicuous in patients with organic mercury poisoning,

The effects of methyl mercury (organic mercury) poisoning have come to be widely recognized since the outbreak that occurted in Minamata Bay (Japan) in the 1950s when industrial waste dischatged into the bay led to contamination of fish that were then consumed by humans. Outbreaks have occurred also following the use of methyl mercury as a fungicide, because intoxication occurs if treated seed, intended for planting, is eaten instead. Methyl and ethyl mercury compounds have been used as fungicides in agriculture and in the paper industry. Methyl mercury and elemental mercury are potent neurotoxins that cause neuronal degeneration in the cerebellar granular layer, calcarine cortex, and dorsal root ganglion neurons. The primary molecular target of methyl mercury is probably sulfhydryi ligands in enzyme complexes or critical membrane sites.

The characteristic features of chronic methyl mercury poisoning are sensory disturbances, constriction of visual fields, progressive ataxia, tremot, and cognitive impairment. Electrophysiological studies have shown that these symptoms relate to central dysfunction. Sensory disturbances result from dysfunction of sensory cortex or dorsal root ganglia rather than petipheral nerves, and rhe visual complaints also relate to cortical involvement. Pathological studies reveal neuronal loss in the cerebral cortex, including the parietal and occipital regions, as well as in the cerebellum. A few cases presenting with peripheral neuropathy or a predominantly motor neuronopathy resembling amyotrophic lateral sclerosis have been described in association with intense exposure to elemental mercury vapors.

The diagnosis of elemental or inorganic mercury intoxication usually can be confirmed by assaying mercury in urine. Monitoring blood levels is recommended for suspected organic mercury poisoning.

Chelating agents increase urinary excretion of mercury, but insufficient evidence exists to substantiate the claim that chelation increases the rate or extent of recovery.

Tellurium

Tellurium is used in the manufacture of various alloys; the coloring of glass, ceramics, and metalware; the production of rubber; and the manufacture of thermoelectric devices. Inhalation of volatile tellurium compounds may lead to headache, drowsiness, a metallic taste, hypohidrosis, skin rashes and discoloration, and a curious odor resembling garlic on the breath. Recovery generally occurs spontaneously.

Thallium

Thallium salts cause severe neuropathy and central nervous system degeneration that has led to their discontinued use as rodenticides and depilatories. Most intoxications result from accidental ingestion, attempted suicide, or homicide. After consumption of massive doses, vomiting, diarrhea, or both occur within hours. Neuropathic symptoms, heralded by limb pain and severe distal paresthesia, are followed by progressive limb weakness within seven days. Cranial nerves, including optic nerves, may be involved. Ptosis is common. In severe cases, ataxia, chorea, confusion, and coma as well as ventilatory and cardiac failure may ensue. Alopecia, which appears 2-4 weeks after exposure, provides only rerrospective evidence of acute intoxication. A chtonic progressive, mainly sensory neuropathy develops in patients with chronic low-level exposure. In this form, hair loss is a helpful clue.

Electrocardiographic findings of sums tachycardia, U waves, and T-wave changes of the type seen in potassium depletion are related to the interaction of thallium and potassium ions. Electrophysiological findings are characteristic of distal axonal degeneration. Autopsy study results confirm a distal axonopathy of peripheral and cranial nerves. Studies in animals show accumulation of swollen mitochondria in distal axons before wallcrian degeneration of nerve fibers. The diagnosis is confirmed by the

demonstration of thallium in urine or bodily tissues. High levels are found m central nervous system gray matter and myocardium. The toxic effects of thallium may be related to binding of sulfhydryl groups or displacement of potassium ions from biologic membrane systems.

With acute ingestion, gastric lavage and cathartics art-given to remove unabsorbed thallium from the gastro-intestinal tract. Oral potassium ferric ferrocyanide (Prussian blue), which blocks intestinal absorption, together with intravenous potassium chloride, forced diuresis, and hemodialysis, has been used successfully in acute thallium intoxication.

Tin

Although ingested inorganic tin usually produces little or no systemic and neurological complications, organic tin compounds used in various industrial processes have definite neurotoxicity. Intoxication with trimethyl tin leads to multifocal central dysfunction with conspicuous behavioral disturbances, emotional lability, confusion, disorientation, cognitive disturbances, sleep dysfunction, headaches, and visual disturbances. Triethyl tin may lead to severe cerebral edema with headache, papilledema, and behavioral abnormalities that generally resolve some weeks after discontinuation of exposure.

Chapter 64
Effects of Toxins and Physical Agents on the Nervous System

B. EFFECTS OF DRUG ABUSE ON THE NERVOUS SYSTEM

Yuen T. So

Drug abuse occurs in several different forms. The use of drugs such as heroin or cocaine may be termed abuse simply because they are illegalal or are obtained illegally. Legal prescription drugs, such as the opioid analgesics and benzodiazepines, also may be abused if taken in excessive amounts or used solely for recreational purposes. *Drug dependence* refers to either a psychological dependence or a physical dependence. In the former, drug-craving or drug-seeking behavior emerges when the drug is not available. Physical dependence, on the other hand, implies the appearance of physiological symptoms and signs during drug withdrawal. *Drug tolerance* is defined as a diminished response to the same dosage of a drug and reflects either increased metabolism of the drug or reduced physiological response to the drug at its normal cellular target.

Of the abused drugs that result in emergency room visits, cocaine is the most commonly encountered. This is followed in frequency by heroin, marijuana, and methamphctamine. The so-called *club drugs* have risen in popularity in recent years. They are frequently used in dance clubs and include GHB (gamma hydroxybutyrate), kern mine, MDMA (3,4-rnethyleiiedioxymcthamphcraminc or *ecstasy),* LSD (lysergic acid diethylamide), and methamphetamine. All these drugs have been implicated in causing deaths in one way or another. Aside from the biological effects to be discussed in this chapter, forensic data link these drugs to many vehicular accidents, blunt trauma, and gunshot and other penetrating injuries and deaths.

All the substances of abuse have potent acute and chronic .•tlirr- (in t'le nervous -.ystern. h i– helpt.k l‹> divide flic neurological consequences of drug abuse into three broad categories according to the mechanism of action (Table 64B.1). First, acute intoxication or overdose often leads to delirium, stupor, or coma, sometimes accompanied by myoclonus, seizures, or serious systemic consequences such as respiratory depression and cardiovascular collapse. Second, chronic use of most of these agents often leads to drug tolerance or dependence. With abrupt abstinence of a habitually used drug, a patient may present for emergency care with an acute withdrawal syndrome. Third, drug abuse may affect the nervous system indirectly via infectious and embolic consequences of intravenous drug use, hypersensitivity ot immunological mechanisms, or some other manner that is not yet understood.

Urine screening of drugs of abuse is widely used in the diagnostic evaluation of patients (Table 64B.2).

The detection times listed in Table 64B.2 are rough estimates at best, as detection is dependent on the time, dose, and route of administration, a subject's metabolism, and the characteristics of the screening assay. Negative test results are difficult to interpret, and detection is particularly problematic for the designer amphetamines (see MDMA, latet in this chapter). Positive results may be confirmed by an alternative method such as gas chromatography and mass spectroscopy. The urine test provides only qualitative information of recent drug use. Because urinary levels are dependent on time and clearance, they often do not correlate with toxic symptoms,

The first part of the following discussion reviews the pharmacological effects of commonly abused drugs, wirh emphasis on the acute effects and the withdrawal syndromes. The second part discusses the indirect effects of drug abuse on the nervous system.

Tabic 64B.1: Neurological complications of drug abuse

Acute intoxication and overdose
Drug withdrawal syndrome
Indirect complications of drug abuse
  Infectious endocarditis
    Cerebral or spinal cord abscess
    Meningitis or encephalitis
    Myelopathy
  Strokes
    Cerebral or spinal cord infarct
    Postanoxic encephalopathy
    Hemorrhage
Brachial plexitis
Nerve compression
Rhabdomyolysis

PHARMACOLOGICAL EFFECTS

Opioid Analgesics

The name *opium* came from the Greek word for *juice* because the drug was derived from the juice of the poppy. Its medicinal uses were discovered as early as the third century BC. Opium contains more than 20 alkaloids. Morphine was the first to be isolated, in 1806, and was named after Morpheus, the Greek god of dreams. Other alkaloids, such as codeine, were discovered soon afterward. By the middle of the nineteenth century, the use of these compounds was widespread in medicine.

Pharmacology

Opiates refer only to those drugs derived from opium and include the naturally occurring alkaloids as well as semi-synthetic derivatives. Kndorphins are endogenous opioid peptides and encompass the enkephalins, dynorphins, and jS-endorphins. The term *opioid* is more inclusive and is used for all agonists and antagonists with morphine-like activities as well as the naturally occurring and synthetic opioid peptides. These compounds act on the three opioid receptor subtypes, /*, *S,* and *K,* and have a wide spectrum of activities as analgesics, psychotomimetics, miotics, and suppressants of respiration, cough, and gastric motility.

Development of drug tolerance and dependence is an almost unavoidable physiological consequence of repeated use of opioids. For example, when used in prolonged treatment of pain, increasingly higher doses of opioids are often required to maintain the same degree of pain control. The pharmacological basis of this phenomenon is poorly understood, although the N-methyl-d-aspartatc (NMDA) receptor may play an important role. Neither tolerance nor dependence predicts drug abuse; thus the fear that tolerance may develop should not interfere with the appropriate use of opioids.

Table 64B.2: Common drugs of abuse: maximum time interval after last drug use when drugs and their metabolites are still detectable by enzyme immunoassay of urine

Drug	*Maximum detection time after last use*
Amphetamine	48 hrs
Cocaine	48 hrs
Benzodiazepines*	5 to 7 days
Barbiturates, long-acting	7 days
Barbiturates, short- or intermediate-acting	1 to 2 days
Heroin*	4 ro 5 days
Methadone	3 days
Morphine	48 hrs
Phencyclidine*	2 wks
Propoxyphene	48 hrs

'Maximum detection times given for chronic users. Single dose in nonhabitual users is cleared considerably more rapidly.

Drug Abuse

A prescription opioid analgesic may be abused. A typical patient may seek multiple physicians for prescription, present with exaggerated complaints, or engage in other drug-seeking behavior. A second group of abusers are the street addicts, typified by use of the illegal drug heroin. Heroin crosses the blood-brain barrier rapidly. Heroin's effect on the brain is identical to that of morphine. Three milligrams of heroin is roughly equivalent to 10 mg of morphine. Heroin may be snorted (sniffed up the nose), smoked, injected subcutaneously {"skin-popping"), or administered intravenously ("mainlining"). Heroin is sold in the streets in varying degrees of purity, and it is sometimes combined with cocaine ("spcedball").

Acute Effects

Aside from the analgesic effects, morphine and heroin acutely produce a sense of rush, accompanied by either euphoria or dysphoria. Hallucinations may occur also. Other effects include pruritus, dry mouth, nausea and vomiting, constipation, and urinary retention. Examination may show pupillary constriction so marked that it may be difficult to discern the light reflex. Overdose of heroin leads to coma and respiratory suppression. Hypotension and hypothermia also occur, but seizures are rare.

Acute treatment of opioid overdose should include close monitoring of vital signs and, if necessary, support of blood pressure and respiration. Naloxone is a safe and effective opioid antagonist and should be used immediately in any suspected opioid overdose. Naloxone is also useful for diagnosis, because it induces immediate reversal of coma and respiratory depression in a patient with opioid over-dose. For treatment of respiratory depression, 2 mg of naloxone is given parenterally, and the dose is repeated as needed up to a total of 10-20 mg. Because the half-life of

naloxone (1—4 hours) is shorter than most opioid agonists, it should be given in repeat boluses and the patient should be monitored closely through the at-risk period, With careful titration of the dose, respiratory depression can be reversed without precipitating acute opioid withdrawal.

Drug Dependence and Withdrawal

With development of drug dependence, symptoms and signs of withdrawal appear hours after the last opioid use. Drug craving appears first, followed by restlessness and irritability. Autonomic symptoms such as sweating, Inclination, and rhinorrhea then emerge. Still later, piloerection, aching, nausea, abdominal cramps, diarrhea, and coughing develop. Tin- time ol tile appearance of withdrawal symptoms depends on the duration of action of the drugs. With morphine and heroin, withdrawal symptoms appear within *6-9* hours of rhe last dose, peak at 24-72 hours, and last approximately 10 days. With methadone, symptoms appear within approximately 12-24 hours, peak at 6 days, and last approximately 3 weeks.

Opioid withdrawal in adults, although unpleasant, is usually not life threatening. In contrast, opioid withdrawal in neonates is sometimes accompanied by myoclonus, seizures, or even status epilepticus. This occurs typically in newborns of opioid-dependenr mothers. Naloxone used during the treatment of respiratory depression sometimes precipitates withdrawal reactions. Acute administration of paregoric or methadone is an effective treatment. Phcnobarbital may be used if there has been prenatal exposure to other drugs such as barbiturates and alcohol.

Oral methadone, a long-acting opiate, is used to relieve opioid withdrawal symptoms. A dose of 10 to 20 mg once or twice a day is sufficient in most patients. The dose is then gradually reduced, win the hope of eventually achieving detoxification. Clonidine, an a_2-adrenergic agonist, suppresses the autonomic disturbances of opioid withdrawal and is useful when combined with methadone. Methadone is becoming a primary drug of addiction.

Sedatives and Hypnotics

Sedatives and hypnotics as a group have calming effects and are capable of inducing sleep when taken in sufficient dti.vigev The group includes die bcn/.odia/.cpincs. barhitu rates, and various less commonly used agents. As with opioid analgesics, manifestations of abuse include excessive use of prescription drugs, recreational use, drug overdose, drug dependence, and withdrawal symptoms. The benzodiazepines are among the most frequently prescribed medications in Western countries and account for over one-half of the overdoses in the United States. Addicts often use benzodiazepines and barbiturates in conjunction with heroin. Alcoholics also sometimes use them to alleviate symptoms of alcohol withdrawal.

Benzodiazepin es

All the benzodiazepines share similar effects on the central nervous system, and the differences among individual drugs are largely those of dosage and duration of action. The benzodiazepines with rapid onset of action, such as diazepam, are among the most likely to be abused.

Acutely, the recipient experiences varying degrees of lassitude, drowsiness, confusion, amnesia, euphoria, and impairment of other psychomotor functions. Even in conventional dosages, these neurological effects are potentially dangerous, especially in elderly people. Falls, for example, may result from drowsiness and motor incoordination. Sufficiently severe overdose leads to coma, although benzodiazepines arc less likely than barbiturates and opioids to cause respiratory or cardiovascular depression. Thus benzodiazepine overdose is rarely fatal unless other drugs are used concurrently. Still, treatment of comatose patients should be directed to immediate assessment and management of cardiovascular and respiratory functions. Flumazenil is a specific antagonist for benzodiazepines. It reverses rapidly the stupor or coma of overdose, although its usefulness is limited by its short action of only 30-60 minutes. A dose of 0.2-5.0 mg given intravenously over 2-10 minutes is sufficient to reverse benzodiazepine overdose. A lack of response is strong evidence that another drug is involved.

Chronic use of benzodiazepines may lead to tolerance and physical dependence. Withdrawal symptoms typically occur within 24 hours of cessation of use of a short-acting benzodiazepine and approximately 3-7 days after stopping a long-acting agent. Withdrawal symptoms include irritability, increased sensitivity to light and sound, sweating, tremor, tachycardia, headache, and sleep disturbances. In more severe withdrawal states, delirium, hallucinations, and seizures may occur. Withdrawal symptoms may last several weeks. Reinstituting the benzodiazepine, followed by gradual tapering of the dosage, is usually sufficient to treat these withdrawal symptoms.

Barbiturates

The acute symptoms of barbiturate use are **similar to those** of alcohol and include euphoria, sedation, slurred speech, and gait ataxia. Severe intoxication leads to coma, hypotension, and hypothermia. Breathing may be slow or rapid and shallow. Cheyne-Stokes breathing, respiratory depression, and eventually apnea occur with sufficient intoxication. Treatment is primarily supportive. The lethal dose varies, but as a general rule, ingestion of more than 10 tunes the hypnotic dose is likely to be dangerous. Gastric lavage may be useful within 24 hours because barbiturates

may reduce gastric motility. Hemodialysis or hemoperfusion is rarely necessary.

Withdrawal symptoms are similar to those seen with alcohol withdrawal. Insomnia, irritability, tremor, tachycardia, nausea, and vomiting are common. With short-acting barbiturates, symptoms usually begin within 36 hours; the long-acting barbiturates are associated with a longci delay of several days. In sevcte cases, delirium tremens and seizures may occur. Treatment of withdrawal consists of reinstitution of the batbiturates, followed by gradual tapeting.

Other Sedatives and Hypnotics

Othet sedatives and hypnotics are abused much less frequently than barbiturates and benzodiazepines. Mctha-qualone was popular in the 1970s. Overdose is characterized b; delirium, myoclonus, and seizures, sometimes followed by coma and acute congestive heart failure. Glurcthimide overdose leads to coma, hypotension, and, less frequently, respiratory depression. Abuse of this agent is recognized by its anticholinergic effects, which produce dilated unteactive pupils. Other uncommonly abused drugs include paraldehyde, chloral hydrate, meprobamate, and ethchlorvynol. Ethchlorvynol overdose is characterized by its long duration of action, which may last many days. Treatment includes diuresis, perironeal dialysis or hemodialysis, or hemoperfusion with activated charcoal or resin.

Psychomotor Stimulants

Psychomotot stimulants all share sympathomimetic effects on the central nervous system. Cocaine is the most commonly abused. It may be administered intranasal!}' or parcntcrally or may be smoked (crack). Amphetamine, dextroamphetamine, methamphetamine, and methylphenidate also have significant abuse potential. Another drug in this group is MDMA or *ecstasy,* as ir has hallucinogenic effects in addition to its stimulant properties. Other agents such as fenflutamine, phentermine, ephedtinc, and phenylpropanolamine have less liability for abuse.

Acute Effects

In modetate doses, stimulants produce mood elevation, increased alertness, reduced fatigue, dectcased appetite, and enhanced performance in various tasks. There arc individual differences in the psychic effects of these stimulants. Some patients develop paranoia, delusions, hallucinations, agitation, and violence. Other patients may be depressed or lethargic. Systemic symptoms include palpitation, pupillary dilation, tachycatdia, and hypertension. For patients presenting to the emergency room, systemic complications such as hyperthermia, dehydration, and rhabdomyolysis are sometimes encountered. An increased risk of myocardial infarction is also especially well documented with cocaine use,

Of the neurological symptoms seen in the emergency room, headache is probably the most common and ftequcntly accompanies other more serious symptoms. Some patients may present with encephalopathy, myoclo'-nus, or seizures. Seizures are usually self-limiting, although status epilepticus is an uncommon but well-recognized complication of overdose.

Of the abused stimulants, cocaine is the most likely to cause seizures (Zagnoni and Albano 2002). Seizures are more likely when cocaine is smoked (crack) or given intravenously than with other modes of administration. The estimate of seizure frequency varies widely from 1^40%, depending on the study population. Typically, seizures occur within 1-2 hours of cocaine use. Other drugs, such as methamphctamine, amphetamine, MDMA (ecstasy), methylphenidate, ephedrine, and phenylpropanolamine also cause seizures. MDMA in particular has been linked to the development of hyponattcmia with resultant seizures and encephalopathy. The mechanism may involve inappropriate secretion of antidiuretic hormone (Hartung et al. 2002).

Both acute ischemic and hemorrhagic strokes have been reported in association with stimulant use. This is especially true for cocaine and amphetamine, although other stimulants may also be responsible. Stroke is discussed further later in this chapter (see Indirect Neurological Complications). Movement disorders are sometimes seen after stimulant use (Catdoso and jankovic *199i).* Hyperkinetic movement disorders may be exacerbated or may develop *de novo* in cocaine users. These include vocal and motot tics, chorea, dystonia, and acute dystonic reaction to neuroleptics. Rarely, dyskinesias may persist months after abstinence (Weiner et al. 2001). Otomandibular stereotypies such as teeth-grinding and tongue protrusion are common among amphetamine users.

Treatment of overdose should include supportive measures such as oxygen, cardiac monitoring, cooling for hyperthermia, antihypertensives, and blood pressure and ventilatory support as necessary, Sedarives may be used judiciously to treat agitation. Seizures arc managed with benzodiazepines and phenytoin. Forced diuresis and urine acidification promote drug excretion bur should be avoided if myoglobinuria is present.

Drug Dependence and Withdrawal

Aftet repeated use of cocaine or amphetamines, tolerance develops to the euphoric and anorexic effects of these agents. A wide range of psychiattic symptoms have been described in chronic active users. Functional imaging studies have shown altetations of dopamine and serotonin transporters in the brain, although the clinical significance of these findings is unknown. Acute abstinence aftet

chronic use manifests primarily as fatigue and depression. The withdrawal syndrome is seldom life-threatening, with the exception of those who develop suicidal ideations. Treatment with imipramine or other antidepressant drags may be helpful.

Other Substances of Abuse

MDMA (1,4-methylenedioxymethampketamine) or Ecstasy

MDMA merits a special mention as it has become a very popular club drug internationally, and there is a widely held misconception among users that it is safe. The drug is used commonly on college campuses and at all-night dance parties. As its name implies, MDMA is a derivative of methamphctamine, and it has properties of both a stimulant and a hallucinogen (Kalant 2001). The hallucinogenic effects result from its structural resemblance to mescaline.

Complications from MDMA's acute stimulant effects were discussed in the previous section (see Psychomotor Stimulants). Although the incidence of serious complications with MDMA use is low, the unpredictability of these serious and sometimes fatal complications is of great health concern. Adding to the unpredictability is the fact that the street name *ecstasy* has also been applied by vendors and users to other related compounds: 3,4-merhylenedioxyamphetamine (MDA), N-ethyl-3,4-methylcncdioxyamphetamine (MDF.A), and paramethoxyamphetamine (PMA). These compounds share the biological effects of MDMA and have also been linked to serious complications. These drugs are often referred to as "designer-drugs" or "designer-amphetamines," because they were created by illicit attempts to achieve a blend of amphetamine-like and mcscaline-like pharmacological properties.

MDMA has been linked to death from hyperthermia, hyponatremia, seizures, rhabdomyolysis, hepatic failure, coagulopathy, and cardiac arrhythmias. Recent studies also suggest long-term neurotoxicity with MDMA use. MDMA acutely causes massive central serotonergic discharge that is the physiological basis for its pleasurable psychic effects. By contrast, habitual users often report depression or lethargy during the time period between drug binges. Neuropsychological testing reveals impairment in verbal and visual memory in abstinent MDMA users compared to controls. Autopsy study in one patient demonstrated depletion of serotonin level in the striatum (Kish ct al. 2000). Functional imaging studies also suggest a long-lasting alteration of brain function.

Marijuana

Tetrahydrocannabinol is the primary active ingredient of marijuana and has effects on mood, memory, judgment, and sense of time. A sense of relaxation, subjective slowing of time, euphoria, and depersonalization can occur during its use. Variable degrees of anxiety, paranoia, sedation, and sleepiness may occur also. High doses of tetrahydrocannabinol produce hallucinations, paranoia, or a frank panic reaction. Treatment of such cases generally requires only calm reassurance. Tolerance develops with chronic use. Irritability, restlessness, and insomnia are typical after abrupt discontinuation.

Pbencyclidine and Ketamine

Phencyclidine and ketamine were developed as anesthetics. At progressively increasing dosages, analgesia, anesthesia, stupor, and coma develop. At moderate doses, phencyclidine and ketamine produce variable degrees of euphoria, dysphoria, relaxation, paranoia, and hallucinations. Psychosis, agitation, bizarre behavior, and catatonia arc common. These may be accompanied by physical signs of fever, hypertension, sweating, miosis, and horizontal as well as vertical nystagmus. Treatment is largely supportive. Violent behavior may require restraint. Rhabdomyolysis is common with overdose, and myoglobinuria should be looked for and treated if discovered.

Anticholinergics

The recreational use of anticholinergics includes abuse of prescription drugs as well as use of plants that contain the belladonna alkaloids atropine and scopolamine. These agents are abused for their pharmacological ability to induce delirium and hallucinations. The psychoactive effects are accompanied by mydriasis, dry and flushed skin, tachycardia, urinary retention, and fever. Severe overdose may lead to myoclonus, seizures, coma, and death. Acute treatment employs intramuscular or intravenous injection of 1 mg of physostigmine. This is followed by titrating doses of 0.5-2.0 mg of physostigmine every 30 minutes to 2 hours.

inhalants

1'his group ol compounds comprises a wide range ol volatile compounds, including various hydrocarbons, nitrites, and nitrous oxide. Many are present in common household and industrial products. Despite the diversity of chemicals, the acute effects are similar. At low to moderate doses, these chemicals induce a sense of euphoria, relaxation, incoordination, and slurred speech. These effects resemble alcohol intoxication for most practical purposes. Higher doses produce psychosis, hallucinations, and seizures. The duration of action is typically only 15-30 minutes, but the effects may be sustained by continual use. Various complications such as cardiac arrhythmia; suffocation from the use of plastic bags, vomiting, and aspirations; and, rarely, sudden death have been reported.

Aside from die acute neuropsychological effects, different systemic and neurological complications may result from chronic abuse of individual agents. Lead intoxication may result from sniffing leaded gasoline. A peripheral neuropathy with disabling weakness and slow nerve-conduction velocities may result from the chronic use of M-hcxane. Nitrous oxide abuse leads to a syndrome of subacute combined defeneration similar to that seen in vitamin]>L' deficiency. Cerebral and cerebellar dysfunctions are seen after chronic toluene abuse. Mild cognitive dysfunction has been associated with chronic exposures to many volatile hydrocarbons. Systemic complications include renal, hepatic, and bone marrow abnormalities after exposure to benzene and methemoglobinemia after use of alkyl nitrite,

Hallucinogens

The hallucinogens as a group cause alteration of mood, perception, and thought processes without significantly changing alertness, memory, and orientation. The synthetic ergot LSD is the best-known example and is still popular among drug abusers. In addition, a wide range of plants and mushrooms are known to be hallucinogenic. Acute ingestion leads to rapid onset of dizziness, blurred vision, nausea, and weakness followed by hallucinations that are often visual and complex. There may be depersonalization and a distortion of time. Sometimes the experience is terrifying (the so-called 'Lbad trips"), resulting in injuries to self or others. Physical signs include fever, tachycardia, hypertension, mydriasis, seizures, and coma.

INDIRECT NEUROLOGICAL COMPLICATIONS

Stroke

Drug abuse increases the risk of strokes. In retrospective studies of stroke patients between 15 and 44 years of age, drug abusers accounted for 12-31% (Sloan et al. 1998). Drug abuse was the most important risk factor for stroke in those younger than 35 years of age. The relative risk of stroke was 6.5 after controlling for other stroke risk factors. The possible mechanisms are diverse (Table 64B.3) and arc dependent on the route of drug administration and the agents involved. The risk increase does not take into consideration the abuse of alcohol and tobacco, both of which, though legal, also increase stroke risk.

The evaluation of patients with drug-related strokes should include a careful search for endocarditis or other source of embolization, a full cardiac evaluation, erythrocyte sedimentation rate, and antiphospholipid antibody assay. Cerebral angiography may be necessary, especially when vasculitis, aneurysms, or vascular malformations are suspected.

Table 64B.3: Probable mechanisms of strokes associated with drug abuse

Intravenous drug abuse
Endocardins, infectious or marantic
Embolization of foreign materials
Right-tO-left shunt in pulmonary vasculature
Mycotic aneurysm
Direct effects of drugs
Vascular injury: hypertensive changes, arterial dissection
Acute severe hypertension
Vasoconstriction or vasospasm
Impaired auto regulation
Indirect effects of drugs
Vasculitis
Pre-existing vascular malformation or aneurysm
Cardiomyopathy and arrhythmia
Antiphospholipid antibodies
Nephropathy and secondary hypertension
Hypotension or hypoxia from overdose
Acquired immunodeficiency syndrome or HIV iiiUvnon

Embolism

The sources of embolism include valvular disease secondary to infective or marantic endocarditis, mural thrombi of cardiomyopathy, right-to-left shunt, aortic or other arterial dissection, and foreign materials injected during intravenous drug abuse. Strokes occur in approximately 20% of cases of infective endocarditis; many of them are due to intravenous drug abuse. Early recognition is important because prompt antibiotic therapy can markedly reduce the risk of stroke. Mycotic aneurysm complicates 1-3% of cases of endocarditis and may cause intracerebral hemorrhage, Angiography should be considered when mycotic aneurysm is suspected, although the role and timing of surgery are controversial.

Kmboli of particulate materials often occur because of the poorly controlled sale and manufacture of these injected drugs. Some intravenous preparations of methyl ph en idate, meperidine, and pentazocine are made by crushing or dissolving drug tablets. Other intravenous preparations may contain insoluble fillers such as talc. Undissolved particles, if injected intravenously, become lodged in the lungs and may cause pulmonary hypertension and arteriovenous fistulae. This in turn provides a path for emboli materials to reach the cerebrovascular circulation.

Vasculitis and Other Vasculopathies

Vasospasm is associated with many drugs of abuse, most notably the psychostimulants such as cocaine, amphetamines, methylphenidatc, and phenylpropanolamine, for poorly understood reasons, some drugs of abuse also lead to the development of vasculitis. This has been best documented in some patients with amphetamine abuse and less convincingly in a few patients who abused

phenylpropanolamine, cocaine, or heroin. The diagnosis of vasculitis without histological verification is difficult, because the classic angiographic findings of segmental narrowing and beading of intracerebral arteries do not distinguish among vasculitis, vasospasm, arteriosclerosis, and other vasculopathics. Abstinence should be the first step in treatment of patients suspected to have vasculitis. The role of immunosuppressive therapy is undefined. It is not clear if the clinical course and response to treatment of drug-induced vasculitis are different from those of other vasculitis of the nervous system.

Hypotension and Anoxia

Anoxic brain injury often follows drug overdose, most notably overdose from heroin and other opiates. An autopsy series of heroin addicts observed that 2% had ischemic injury to the globus pa Hid us. Delayed postanoxic encephalopathy also rarely occurs. The clinical manifestations are similar to those described after prolonged cardiac arrest, respiratory failure, and carbon monoxide poisoning.

Cocaine

Cocaine is without question the most important cause of drug-related stroke and accounts for approximately 50% of all cases. Neurological symptoms typically develop within hours of cocaine use, although rarely symptoms may progress gradually for up to a week. Seizures sometimes accompany the strokes. There are reports of transient ischemic attacks or ischemic infarctions of almost any area of the brain or spinal cord. In most series, over half of the ischemic infarcts involve die middle cerebral artery territory. Asymptomatic subcortical white matter lesions are also more prevalent in cocaine users when compared to normal controls. The difference is especially apparent in older subjects, irrespective of the years of cocaine use (Bartzokis et al. 1999). Intraparenchymal or subarachnoid hemorrhage is another common mode of presentation (Aggarwal et al. 1996; Noltc, Brass, and Fletterick 1996).

There arc several porential pathophysiologic mechanisms of cocaine-induced stroke. Acute hypertension, vasospasm, and vasoconstriction probably play an important role (Kaufman et al. 1998). Under experimental conditions in cocaine users, modest intravenous doses of 40 mg or less can induce vasospasm of large arteries and reduce cerebral Hood flow by 25 oO'V I'hese doses .ire lower than those habitually consumed by many chronic cocaine users. Preexisting vascular pathology may be a key factor in some patients. Among those who present with intracranial hemorrhages, approximately one-half have underlying cerebral aneurysms or vascular malformations. Endocarditis, myocardial infarction, cardiac arrhythmias, aortic dissection, and anticardiolipin antibodies arc other observed associations.

Myelopathy

An acute myelopathy may develop rarely after drug abuse. The association is best documented in heroin abuse and rarely in cocaine use. For rhe most part, the syndrome resembles an anterior spinal artery syndrome. Paraparesis, urinary retention, and a segmental sensory level appear acutely. On examination, posterior column function is often relatively spared. Myelography, magnetic resonance imaging (MRI), and cerebrospinal fluid findings are usually normal, although mild elevation of cerebrospinal fluid protein may be present. There are several possible causes. Watershed infarct secondary to hypotension may be responsible. Embolic infarct from injected particulate material may account for other cases, as may hypersensitivity or vasculitis.

Rhabdomyolysis and Myopathy

It is unclear whether any of the commonly abused drugs are directly toxic to muscles. Evidence of muscle injury ranges from asymptomatic elevation of serum creatine kinase to frank myoglobinuria and renal failure. The observations are made most commonly in the abuse of heroin, cocaine, amphetamine, MDMA, and phencyclidinc. The patients were typically severely intoxicated. Possible mechanisms include trauma, crush :njur>, hypotension, hypertension, fever, seizures, and excessive muscular activities,

Repeated intramuscular injections of meperidine, pentazocine, or heroin sometimes lead to focal fibrosis and weakness of the injected muscles. Contractures develop slowly. The affected muscles have a woody and firm quality. Weakness is mild and is limited to the injected muscles. Flccrronv. ogniphic elimination ot affected areas demonstrates reduced insertional activity (suggesting extensive fihrotic replacement of the muscle), short duration, and small-amplitude motor-unit action potentials.

Ncuroparhy and Plexopathy

Compressive or stretch injuries ro peripheral nerves and plexuses result from drug abuse of any kind. Focal neuropathies may also develop as a result of compartment syndrome and secondary nerve ischemia. The most commonly affected sites are the brachial plexus, the radial nerve at the upper arm, the ulnar nerve at the elbow, the sciatic nerve in the gluteal region, and the peroneal nerve at the fibular head. Some cases of idiopathic brachial or lumbosacral plexitis have been attributed to heroin use. A potential though tin proven cause is a hypersensitivity reaction to heroin or the accompanying adulterant.

Many drug abusers have physical signs of a distal sensory or sensorimotor polyneuropathy, but a causal

relationship to the ahused drugs is difficult to establish because confounding factors such as alcohol abuse and systemic diseases are often present. An exceptional example is in the chronic use of hydrocarbon inhalants (Smith and Albers 1997), in which the neuropathy is similar to that observed during industrial outbreaks caused by exposure to ji-hexane or methyl w-butyl ketone. Distal paresthesias and numbness appear first, followed by development oi distal weakness. Weakness worsens with continuing abuse and may progress to involve proximal muscles of both upper and lower limbs.

Chapter 64
Effects of Toxins and Physical Agents on the Nervous System

C. NEUROTOXINS OF ANIMALS AND PLANTS

Neil E. Schwartz and Yuen T. So

Naturally occurring neurotoxins of animals, plants, and fungi are of great scientific interest in addition to their obvious clinical concern. Many of them serve as important tools used by investigators to probe the workings of the nervous system. One of the oldest and best-known examples is curare, a plant toxin used in Claude Bernard's classical experiments on neuromuscular transmission over 100 years ago, a-Bungarotoxin, from the venom of the banded krait, is a competitive blocker of the acetylcholine receptor that has proven to be invaluable for studies of the neuromuscular junction and myasthenia gravis. Our understanding of the mechanisms of neurotransmitter release has been enhanced by toxins such as a-latrotoxin, from the black widow spider. Likewise, the toxins from a multitude of plants and fungi have helped advance our knowledge of many aspects of cellular neurophysiology. This chapter highlights some of the more common and clinically relevant neurotoxins that might be encountered by the neurologist in the United States.

NEUROTOXINS OF ANIMALS

The neurotoxins of animals serve several essential functions in nature. Reptiles and arthropods use venoms to defend against predators and to immobilize prey. Some venom may contain enzymes that aid in the digestion of consumed food. Many of these agents are among the most potent neurotoxins known to humankind {Table 64C.1) (Markland 1997). Major components of snake and insect venoms are disulfide-rich small molecules that exhibit phospholipase A_2 activity (Schiavo, Matteoli, and Montecucco 2000). Despite their biological potency, mortality caused by these agents is uncommon. The rarity is in part a result of the healthy respect most people have for snakes, spiders, and scorpions. Moreover, most bites result in a relatively small amount of envenomation that is well below lethal dosage. Mortality tends to occur at the extremes of age.

Snakes

The overwhelming majority of venomous snakebites in the United States are inflicted by the pit vipers (subfamily *Crotalidac),* a group that includes rattlesnakes (genera *Crotalus* and *Sistrurus),* fer-dc-lances (genus *Bothrops),* and the bushmaster *(Lachesis muta).* Moccasins (genus *Agkistrodon),* including cottonmouths and copperheads, account for up to half of pit viper envenomations in the United Stares (Litovitz et al, 2002). Pit vipers are so named because of an identifiable heat-sensing foramen "pit" between each eye and nostril; they have a triangular head with elliptical pupils and retractable, canalized fangs (Gold, Dart, and Barish 2002). All but one species of rattlesnake has a characteristic rattle on the tip of its tail. Coral snakes (family *Eiapidae)* such as *Micrurus fulvius tenere* (Texas coral snake) and *Micrurus fulvius fulvius* (eastern coral snake) are the only native venomous snakes that are not pit vipers; they account for less than *5%* of envenomations in the United States. Important venomous snakes in other

Table 64C.1: Neurotoxins of snakes and arthropods

Source	*Toxins*	*Physiological site of action*
Snake (various species)	a-Bungaroroxin, cobrotoxin	Postsynaptic: competitive blockade of AChR
Snake (various species)	*0* Bungarotoxin, crotoxin, notexin, taiposin	Presynaptic: inhibition of ACh release
Black widow spider *(Latrodectus mactans)*	cr-Latrotoxin	Presynaptic: facilitation of ACh release, followed by (lerlerion •••• Ac h
Scorpion *(Tityus serrulatus)*	Tityustoxin	Presynaptic: facilitation of ACh release Postsynaptic: inhibition of Na^{+1} channel inactivation
Scorpion *(Centrtiroides* sp.)	At least two groups of toxins	Presynaptic: membrane depolarization

Ach = acetylcholine; AchR = acetylcholine receptor; Na^+ = sodium.

parts of the world include Elapidae such as cobras, mambas, kraits, coral snakes *(Maticora* sp.), and most Australian venomous snakes. Bites from these non-native species among zoo petsonncl and amateur snake keepers are not unusual. Viperidae (true vipers) include the puff adder, daboon viper, rhinoceros-horned viper, and Russell's viper, *Hydrophiidae* (pelagic sea snakes) are highly neurotoxic but rarely bite humans.

As many as 25% of pit viper bites and half of coral snake bites are "dry" and do not result in envenomation. Signs and symptoms of envenomation may vary. Morbidity and mortality depend on the venom composition of the local snakes and the availability and sophistication of emergency medical care. In the United States, approximately 6400 snake bites were reported in 2001 (about one-fifth of which were from rattlesnakes). Mortality, fortunately, is uncommon (averaging *5.5* deaths/year) and is due mostly to diamondback rattlesnake bites. By contrast, over 10,000 deaths are reported yearly from the Nigerian savannas and apptoximatcly 23,000 from West Africa. Up to 110,000 deaths per year worldwide have been reported, with many more individuals experiencing permanent morbidity. Young male adults are bitten most commonly, with about half of all bites in persons aged 18—28. In many cases of snakebite, the subject is intoxicated with alcohol.

Snake venoms are composed of a complex mixture of peptides, many of which have enzymatic activity. Low-molecular-weight polypeptides in the venom have neurological activities on both presynaptic and postsynaptic elements of the neuromuscular junction (see Table 64C.1). Diverse effects on platelets, endothelial cells, and the coagulation cascade, as well as almost every organ system, are responsible for much of the morbidity and mortality of envenomation. Some of the toxins may be directly myotonic; rhabdomyolysis and compartment syndrome are sometimes seen after envenomation. Considerable species and geographic variations occur in the spectrum of biological activities. For example, snakebites may cause primarily neuromuscular paralysis in one region, whereas bites by the same species in another region may result mainly in coagulopathy and hemorrhage. In general, when weakness is present, the pattern of involvement resembles myasthenia gravis, with predilection of the neck flexors and ocular, bulbar, and proximal limb muscles. Respiratory paralysis, if severe and untreated, may lead to death,

At the time of patient presentation, fear and panic are common symptoms; the accompanying autonomic reactions should not be mistaken for systemic symptoms of envenomation. The cardinal signs of pit viper envenomation are local pain, swelling, and erythema. Early signs of envenomation include tender regional lymph nodes; nausea; and a metallic, rubbery, or minty taste in the mouth. Systemic symptoms appear over the ensuing 12-24 hours and consist of a variable combination of perioral or limb paresthesias, muscle fasciculations, weakness, hypotension, and shock. Ptosis is common following envenomation by some Mojave rattlesnakes. In contrast to pit viper envenomation, little pain or swelling accompanies coral snake bites. After a delay of up to 24 hours, cranial nerve palsies, dysphagia, diffuse weakness, areflexia, and respiratory suppression may develop. Initial laboratory evaluation should include complete blood cell and platelet counts, coagulation panel, fibrinogen, fibrin split products, serum chemistries, creatine kinase, and urinalysis. In patients with significant weakness, nerve-conduction studies with repetitive stimulation testing may reveal a pattern of either presynaptic or postsynaptic blockade. The observed changes consist of reduced amplitude of the compound muscle action potentials, decremental response to low-frequency repetitive stimulation, and postexercise and post-tetanic facilitation. Treatment includes calming and supportive measures. Even in the absence of life-threatening symptoms, a patient should be monitored for at least 6 hours if bitten by a pit viper and 12 hours if bitten by a coral snake. Appropriate antivenin should be administered as soon as it is certain that significant envenomation has occurred.

Spiders

Of the commonly encountered spiders, few produce significant symptoms in humans. Venom is injected via fangs (chelicerae). The female widow spider *(Latrodectus* sp.)

is the most important worldwide in terms of morbidity and is the only one commonly found in the United States with significant neurological morbidity. Over 2600 widow spider bites were reported in the United States in 2001,16 of which had major health consequences; there were no fatalities if.mn it/. et .{.. 2l>iUj, In fact, no deaths have bt.rn reported to the Ametican Association of Poison Control Centers since 1983. *Vboneutria* (banana spiders) from South America and *Atrax* (funnel web spiders) from Australia also cause neurotoxic lesions. Black widow spider *[Latrodectus mactans mactans)* venom contains a-larroxin, a neurotoxin capable of inducing neurotransmitter release from presynaptic cholinergic, noradrenergic, and aminergic nerve endings. Re-uptake is hindered as well.

Although the toxin itself is fat mote potent than those found in snake venom, most spider bites do not cause many symptoms because only a small volume of venom is injected. Sometimes a characteristic erythematous ring surrounding a paler center (target or halo lesion) develops around the site of the spider bite. Within 30-60 minutes of black widow envenomation, intense pain and involuntary muscle spasms may appear in abdominal muscles, with spread to limb musculature (lactrodeemm); this can be seen as many as 6-12 houts after the spider bite. Dysautonomia, piloerection, and unique sweating patterns may be present. Respiratory arrest can result from diaphragmatic muscle involvement. Other associated symptoms include priapism, salivation, sweating, bronchospasm,and bronchorrhea. Hypertension is a nearly universal finding in affected individuals (Woestman et al. 1996). Serum creatine kinase may be elevated, Treatment begins with careful monitoring of respiration and vital signs and intensive-care support if necessary, Antivenin shortens the duration of symptoms if administered early but should be reserved primarily for severe disease. Muscle spasms may be treated with slow infusion of calcium gluconate or methocarbamol. Benzodiazepines and opioids are useful for the control of anxiety and pain.

Scorpions

Although only a few of the approximately 1400 scorpion species are of neurological importance, bites by poisonous scorpions are generally more dangerous than spider bites. Scorpion envenomation is a public health problem in warm climates. In Mexico alone, there are 100,000-200,000 scorpion bites annually, resulting in 400-1000 fatalities. Small children in particular are prone to developing neurological sequelae; as many as 80% of bites to children are symptomatic. More than 14,500 scotpion bites were reported in the United States in 2001, with no mortality (Litovitz et al. 2002). All potential lethal scorpions ate **members** of the family *Butbtdae,* with the exception of *Hemiscorpious* (family *Scorpionidae).* They are characterized by a triangular sternal plate, to be distinguished from the pentagonal plate seen in less dangerous species. *Buthntus tamulus* of India, *Leiurus quinquestriatus* of North Africa and the Middle East, *Tityus serrulatus* of Brazil, *Centmroides suffusus* of Mexico and *Androctonus a us tralis* of Africa and Asia are among the most toxic species. The Arizona bark scorpion *{Centmroides exilicauda)* is found in southwestern United States and Mexico. Venom from C. *exilicauda* is relatively low in toxicity, with only one death reported in the United States since 1964 (Boyer et al. 2001). Other species of medical importance include *Butbus, Mesobuthus, Parabutbus,* and *Nebo.* The venoms of these scorpions contain a wide range of polypeptides that have a net excitatory effect on autonomic and skeletal neuromuscular systems. Effects are exerted through alteratior. ol voluj^- g.m-d ion uunnu's, panicu larly sodium ionophores (see Table 64C.1).

Venom is delivered from glands located on the lateral tip of the scorpion's tail stinger. Presenting symptoms are highly variable, from local pain (which may be secondary to serotonin found in scorpion stings) to a general state of intoxication. Paresthesias are common and are usually experienced around the site of bite but also may be felt diffusely. Autonomic symptoms of sympathetic overdrive (tachycardia, hypertension, and hyperthermia) are often present, but parasympathetic symptoms, including the SLUD syndrome (salivation, /acrimation, wrination, and defecation), may be present as well. Muscle fasciculations, spasms, dysphagia, and other cranial nerve signs arc sometimes seen, as well as dy scon jugate roving or rotary ocular movements (Bond 1999). With severe envenomation, encephalopathy may result from direct central nervous system (CNS) toxicity or secondary to uncontrolled hypertension. The constellation of symptoms has led to the misdiagnosis of seizures, particularly in infant victims of scorpion stings; although seizutes can occur, they have never been proven in *Centruroides* envenomation. Treatment is often limited to symptomatic control. Severe cases should be monitored and treated in an intensive care setting, with attention to a secure airway. Use of scorpion antivenin is controversial, but the consensus is that it should be used for significant envenomations.

NEUROTOXINS OP PLANTS **AND** MUSHROOMS

Pharmacologically active agents arc present in thousands of plants and mushtooms species. Many of these have been known since antiquity. Although fatal poisoning is relatively rare, some of the commonly encountered species are capable of inducing serious neurological symptoms. In the United States, 105,560 cases of plant poisoning and 8483 cases of mushroom poisoning were reported in 2001; only two fatalities occurred (Litovitz et al. 2002). Clinically significant toxicity happens under several circumstances. Approximately 75% of cases occur in children under the age of six, most as a result of accidental ingestion. Adult poisoning may occur when toxic plants or mushrooms are

mistaken for edible species. Undoubtedly an under-reported category is the intentional consumption among some adolescents and young adults who attempt to get "high" from so-called "natural" botanical sources.

Common names of plants are entirely inadequate for their identification; botanical names should be used whenever possible. Identification is neither easy nor accurate, even with the aid of current computer software (Lawrence 1998). Naming the plant or mushroom involved in a botanical exposure should be left to a trained botanist or mycologist. Even without a definitive identification, the history of exposure and the recognition of a characteristic syndrome are often sufficient to establish a tentative diagnosis. The best treatment is usually empiric, including gastric lavage or catharsis, supportive measures, and control of symptoms. With the exception of anticholinergic poisoning, there are few specific antidotes.

Several of the important neurological syndromes are discussed in the following sections. A comprehensive review of the many botanical toxins is impossible, and only a small selection is presented. Table 64C.2 lists several major categories and the commonly associated plants in each category. Omitted are plants that do not have direct toxicity on the nervous system, such as those containing cardiac glycosides, cournarin, oxalates, taxines, andromedotoxin, colchicine, and phytotoxins. Secondary neurological disturbances may result from these toxins because some can cause severe electrolyte abnormalities, cardiovascular dysfunction, or coagulopathy.

Jimson Weed *(Datura stramonium)*

Jimson weed, first grown by early settlers in Jamestown from seeds brought from England, was initially used to treat asthma. It is now found throughout the United States. Intoxication is not uncommon, especially among young recreational users in rural areas. The chief active ingredient is the alkaloid hyoscyamine, with lesser amounts of atropine and scopolamine. Among the 1144 intoxications by anticholinergic drugs reported in 2001, the single fatality was attributed to *Datura* ingestion (Litovitz ct al. 2002). Symptoms of anticholinergic toxicity appear within 30-60 minutes after ingestion and often continue for 24-48 hours because of delayed gastric motility (Centers for Disease Control 1995). The clinical picture can include hyperthermia, delirium, hallucinations, seizures, and coma. Autonomic disturbances such as mydriasis, cycloplegia, tachycardia, dry mouth, and urinary retention are often present. Treatment includes gastrointestinal decontamination with or without the induction of emesis. Supportive measures and symptom relief should be provided, and physostigmine should be reserved for severe or life-threatening intoxications.

Tabic 64C.2: Neurotoxicity of plants

Principal Toxins	*Plants (representative examples)*	*Main Clinical Features*
Tropane alkaloids (belladonna)	Jimson weed *(Datura stramonium),* Deadly nightshade (belladonna, *Atropa belladonna),* Matrimony vine (Lycium halimifolium), Henbane *(Hyoscyamus niger),* Mandrake *(Mandragoran officinarum),* Jasmine *[Cestrum* sp.)	Mydriasis, cycloplegia, tachycatdia, dry mouth, hyperpyrexia, delirium, hallucinations, seizures, coma
Solanine alkaloids	Woody nightshade (bittersweet, *Solanum dulcamara),* Black nightshade *{Solanum nigrum),* Jerusalem cherry *(Solanum pseudocapsicum),* Wild tomato *{Solanum gracile),* Leaves and roots of the common potato *{Solanum tuberosum)*	Mydriasis, cycloplegia, tachycardia, dry mouth, hyperpyrexia, delirium, hallucinations, seizures, coma
Nicotine-like alkaloids (e.g., Cytisine)	Tobacco *(Nkotiana* sp.}, Golden chain *{Laburnum anagyroides),* Mescal bean *(Sophora* sp.), Scotch broom (CyrisHs sp.), Poison hemlock *(Conium maculatum)*	Variable sympathetic and parasympathetic hyperactivity, hypotension, drowsiness, weakness, hallucinations, seizures
Cicu toxin	Water hemlock *(Cicuta maculata)*	Diarrhea, abdominal pain, salivation, seizures, coma
Triterpenc	China berry *{Melia azedarach)*	Confusion, ataxia, dizziness, stupor, paralysis, seizures
Anthracenones	Buckthorn *{Karwinskia humboldtiana)*	Ascending paralysis; polyneuropathy
Excitatory amino acid agonists	Chickling pea and others *[Lathyrus* sp.), Cycad *(Cycas rumpbii),* False sago palm *(Cycas circinalis)*	Neurodegenerative diseases

Poison Hemlock *(Cortiutn maculata)*

The dangers of poison hemlock have been known since ancient times. It was reportedly used to execute Socrates. The Old Testament describes rhabdomyolysis in Israelites who ate quail fed on hemlock (coturnism). The highest concentration of toxin is in the root of this ubiquitous plant, which may be mistaken for wild carrots. Alkaloid toxins structurally similar to nicotine initially cause CNS activation and general autonomic stimulation. In severe cases, a depressant phase may then ensue, presumably secondary to acetylcholine receptor tachyphylaxis. Death is usually secondary to respiratory paralysis.

Water Hemlock *{Cicuta maculata)*

Water hemlock is a highly toxic plant found primarily in wet, swampy areas and sometimes mistakenly ingested as wild parsnips or artichokes. Although related to poison hemlock, its clinical toxidrome is quite different. The principal toxin, the long-chained aliphatic alcohol cicutoxin, is a highly potent, noncompetitive GABA receptor antagonist (Uwai et al. 2000). Symptoms consist of initial gastrointestinal effects (abdominal pain, salivation, and diarrhea) followed by generalized convulsions, obtundation, and coma. Mortality is secondary to refractory status epileptieus; seizures are treated with standard protocols.

Peyote *(Lapbapbora williamsii)*

Peyote is a small cactus native to the southwestern United States and Mexico, but it can be cultivated anywhere. The principal agent is mescaline, which has actions similat to those of the hallucinogenic indoles. A peyote button, the top portion of the cactus, contains about 45 mg of mescaline; 6 to 9 buttons (5 mg/kg) are sufficient to be hallucinogenic. Dizziness, drowsiness, ataxia, paresthesias, sympathomimetic symptoms, nausea, and vomiting are frequent accompanying clinical features. Ingestions are rarely life-threatening.

Morning Glory *(Ipomoea tricolor)*

The active agents in morning glory seeds are various amides of lysergic acid. The seeds are consumed for purposes of abuse. The neuropsychological effects are similar to those of lysergic acid diethylamide (LSD) and consist of hallucinations, anxiety, mood changes, depersonalization, and drowsiness. Acute clinical effects may also include mydriasis, nausea, vomiting, and diarrhea.

Medicinal Herbs

Treatment of illness with herbal remedies, either purchased over-the-counter at health food stotes or procured from practitioners of traditional medicine, has become increasingly popular in the United States. Potentially harmful ingredients may be included in products as contaminants or intentionally added to increase a desired effect. The labels, if present, often do not fully represent the myriad of compounds contained within. Many of these can have potential GNS effects of varying severity. Gomamination of products with *Atropa belladonna* (deadly nightshade), *Datura* sp., and Mandragora officinarum (mandrake) have been reported. Common herbal preparations such as kava-kava *(Piper methysticum)* and St. John's wort *(Hypericum perforatum)* have neurotoxic potential, particularly if combined with other herbal or standard pharmaceuticals. *Podophyllum peltatum* (mayapplc), widely used in Ghinese herbal medicine, is potentially neurotoxic.

Excitatory Amino Acids

Various *Latbyrus* species, including *L. sativus* (chickling pea), L. *clymenum* (Spanish vetch), and *L. cicera* (flat-podded pea) are responsible for lathyrism (Spencer 1995). These hardy plants are an important part of the diet of people in the India subcontinent, Africa, China, and some parts of Europe. Epidemics of lathyrism often coincide with periods of famine or war, probably a result of excessive dietary dependency on these legumes. The disease, know[r]n since antiquity, is still endemic in many underdeveloped countries; astounding prevalence rates as high as 66% have been reported during famines. The putative toxin is beta-N-oxalylamino-L-alanine (L-BOAA), an amino acid with potent agonist activity at the (R.S)-a-amino-3-hydroxy-5-methyl-isoxazole-4-propionic acid (AMPA) subclass of glutamate receptors. L-BOAA is capable of inducing ncurolathyrism in several animal models.

Clinically, the affected patients present with subacute or insidious onset of spastic paraparesis, upper motoneuron signs, and gait instability. Muscle aching and paresthesias may be present, but the sensory examination is largely normal. Cognition ami tv:vbella: lumtioiis are \(\nvd. Partial recovery after discontinuation of *i.athyrus* intake is possible, but interestingly, there are reports of deterioration without further exposure many years later.

Historically the Chamorro people of Guam have had a high incidence of parkinsonism, amyotrophic lateral sclerosis, and dementia; however, the occurrence has now markedly decreased in the younger population. The etiology of this complex is uncertain; many have speculated that it is due to unique aspects of their diet, especially the consumption of flour made from the seeds of the cycad *(Cycas rumpbii).* Among other compounds, cycads contain

a toxic amino acid, ^-N-methylamino-L-alanine. (BMAA) that has heen shown to damage motoneurons in primates and cause parkinsonian and behavioral changes. [Neurodegenerative diseases in other populations have also suggested a possible link to plant-detived neurotoxins. Causal relationships are often difficult to prove in these instances.

Mushroom Poisoning

Of the more than 5000 varieties of mushrooms, approximately 100 are known to be toxic to humans. Ingestion by children comprises the majority of cases teported to poison centers. These exposures arc generally not serious, because usually only small amounts are ingested and most "lawn" mushrooms are harmless. Adults mote frequently consume mushrooms in larger quantities and more likely develop toxic symptoms. Aside from accidental ingestion, mushrooms such as *Psihcybe* sp,, *Panaeolus* sp., *Amanita mu scar la,* and *Amanita panthcrma* are popular among drug users for their psychoactive effects. Many ate used also in tribal ceremonies as an intoxicant.

The classification system most commonly adopted by clinicians divides poisonous mushrooms into groups according to clinical symptomatology. The gtoups associated with significant neurological morbidity are listed in Table 64C.3. The most lethal mushrooms belong to the *Amanita* genus and contain various cyclic polypeptides, including the amatoxins, phallotoxins, and virotoxins. Amatoxins have potent hep a to toxicity and nephrotoxicity. In significant intoxications, severe gastrointestinal symptoms appeat initially, after a characteristic latency period of 6-24 hours, followed by fulminant hepatic and renal failute *3-5* days later. Seizures, encephalopathy, and coma often accompany systemic organ failure. With the exception of poisoning by some monomethylhydrazine-containing genera (gyromitrin), toxicities ate rarely life threatening. In 2001, nearly 8500 mushroom ingestions wete reported in emergency rooms in rhe United States; thcte were no fatalities, but 38 were classified as having significant medical outcomes (Litovitz 2002),

Poisonous mushrooms often closely resemble edible varieties. A specimen may be distorted during transport or after cooking. The task of taxonomy is best left to a mycologist. Even in the absence of a positive identification, the nature of the symptoms and the time of their onset after ingestion are valuable guides to diagnosis and management. Supportive care and decontamination are the mainstays

Table 64C.3; Poisonous Mushrooms

Principal toxins	*Mushrooms {representative examples)*	*Mode of action*	*Time of onset/main clinical features*
Cyclic polypeptides (especially amatoxins)	*Amanita pballoides* ("death cap"), *Amanita mrosa, Amanita bisporigera, Amanita verria,* and others	Inhibition of mRNA synthesis; lie pa to toxicity and nephrotoxicity	6-24 hr: GI symptoms; 3-5 days: hepatotoxicity and renal failure
Monomethylhydrazines (Gyromitrin)	*Gyromitra* sp, ("false morels")	Functional pyridoxine deficiency; GABA deficiency (through decreased GAD activity)	6-10 hr: GI symptoms, hemolysis; seizures respond to pyridoxine
Coprine	*Coprinus atrame.ntarms* ("inky cap") and other Coprinaceae	Inhibition of aldehyde dehydrogenase (disulfiram-Iike)	20-120 min: flushing, palpitations, and headache after alcohol ingestion
M11.i.!	*C.lilotybc* and *btocybe* genera	Cholinergic agonist	15-120 min: cholinergic hyperactii it;
Isoxazoles (Muscimol, ibotenic acid)	*Amanita muscatia* ("fly agaric"), *Amanita gemmata, Amanita pantbenna* ("the panther"), *Amanita cotburnata*	GABA receptor agonist; glutamate receptor agonist; anticholinergic	30-90 min: ethanol-like intoxication; euphoria, hallucinations, dysarthria, ataxia, myoclonic jerks, seizures, and coma
Indoles (psilocybin, psilocin)	*Psilocybe caerullpes, Psliocybe cubensis, Panaeolus foenisecii, Gymnopbilus speclabilis, Psathyrella foenisecii*	Structural analogue of serotonin (5-HT); actions resemble LSD	30-60 min: euphoria, hallucinations, mydriasis, tachycardia, seizures (in children)

GABA = y-aminobutyric acid; GAD = glutamic acid decarboxylase; GI = gastrointestinal; 5-HT 5-hydroxytrypta mine; LSD lysergic acid diethylamide.

of treatment. This can be further supplemented by specific treatments, such as infusion of pyridoxine (gyromitrin poisoning), atropine (muscarine poisoning), or physostigmine (ibotenic acid and muscimol poisoning), as needed.

Chapter 64
Effects of Toxins and Physical Agents on the Nervous System

D. MARINE TOXINS

Neil E. Schwartz and Yuen T. So

Seafood is a vital component of the human diet worldwide and is essential fot the economic stability of many regions. Various toxic syndromes have occurred from the consumption of contaminated fish and shellfish, some of which have neurological consequences. Descriptions of marine food poisoning date back to ancient times. A carving on the tomb of the Egyptian Pharaoh Ti *(circa* 2700 KC) depicts the dangers of the toxic puffcrfish, and the Old Testament warning that forbids the eating of fish that "hath not fins and scales" may have carried the same truth. Galen claimed that moray eels, possible vectors of various marine toxins, were dangerous to eat. Ciguatera intoxication was known in China during the T'ang Dynasty (618-907 AD); it was later described by early Spanish explorers and in the journals of Captain Cook's expedition in 1774. George Vancouver recognized paralytic shellfish poisoning in the Pacific Northwest toward the end of the eighteenth century. Periodic outbreaks of marine intoxications affecting humans or wildlife continue to make news headlines. In addition to their obvious clinical concern, many of these toxins have been essential in our quest to understand cellular neurophysiology, in particular, ionic fluxes through excitable membranes. Some toxins have been exploited for other human purposes, such as tetrodotoxin-tipped darts and arrows used in the Americas for hunting purposes.

Most marine toxins originate from micro-organisms, typically unicellular flagellated algae (dinoflagellates). During periods of intense algal proliferation (blooms), high concentrations of toxins accumulate in fish or shellfish, which then act as transvectors for human disease. Typically, the toxins do not adversely affect the transvector; in fact, there is often bio-concentration of the toxin as it is consumed by larger animals further up the food chain. This chapter highlights some of the more common intoxications that occur from ingestion of contaminated seafood (Table 64D. 1), Other marine-associated intoxications, such as those that occur from venomous fish, cchinoderms, sponges, red whelks, cyanobactcria, and coelenterate stings are not covered here. Likewise, envenomation with conotoxins (predatory mollusks from the superfamily Conidac), although of tremendous interest to the research neuroscientist, is less relevant for the clinical neurologist.

The proliferation of toxin-producing microalgae depends on poorly understood interactions of a number of environmental and seasonal factors. Outbreaks of shellfish poisoning are associated with so-called "red tides," which refer to algal blooms and tile subsequent reddish-brown discoloration of the water. Red tides have great economic effects on coastal communities dependent on both tourism and fisheries; blooms can cause massive fish kills, wiping out entire fish farms within hours. Not all red tides are toxic, and shellfish contaminations do not necessarily follow red tides (Whittle and Ga Mac her 2000). Moreover, ciguatera poisoning {see Ciguatera Fish Poisoning in next section) is not associated with blooms or any other reliable forewarning.

The marine toxins arc generally colorless, tasteless, and odorless. Normal food screening and preparation procedures do not typically prevent intoxication. This heat and acid stability renders marine toxins particularly dangerous to unsuspecting consumers of contaminated seafood and poses difficulty in formulating public health strategies for prevention. Globalization of the food industry, with its efficient methods of transportation, raises the possibility of intoxication with imported fish and shellfish not typically found in the United States. The American Association of

Tabic 64D.1: Fish and shellfish poisoning

Syndrome	*'Principal toxins*	*Toxin source*	*Transvector*	*Path op hysio logy*
Ciguatera fish poisoning	Ciguatoxins; ma i to toxin; others	Dinoflagdlates *(Gambwrdiscus toxicus* and others)	Fish (multiple species of reef fish)	Na^{+} and Ca^{++} channel activation
J'uil. Irtish poisoning	Tetrodotoxins	Presumed bactetial *[}Vibrios* spp., *IPseudomonas* spp.)	Various {puffcrfish, salamanders, newt, and others)	Na^{T} channel blockade
Scombroid fish poisoning	I listamme	Presumed bacterial *[}Vibrios* spp,)	Scombroid fish (tuna, mackerel, skipjack, ere.) and non-scombroid fish (mahi-mahi, sardines, etc.)	H i stain in ergic i-l'n i ·

Neurotoxic shellfish poisoning (NSP)	Brcveioxms	Dinoflageltates *[Gymnodinuim breve)*	Shellfish	Transforms fast Na^{-t} channels into slower ones
Amnestic shellfish poisoning (ASP)	Domoic acid and its cogencrs	Diatoms *{Pseudo-nitzscbia* spp., *Nitzscbia actydrapbila, Amphora coffeifornus)*	Shellfish; fish (?)	Glutamate receptor activation
Diari hetit shellfish poisoning (DSP)	Okadaic acid and derivatives; dinophysistoxins	I (uniflagellates *{Dinophysis* sp., *Prorocentrum* spp., *Proceratium reticulatttm, Coolia* sp.)	Shellfish	Serine/threonine protein phosphatase nhibirion

Poison Control Centers (AAPCC) logged over 67,000 incidents of food poisoning in the United States in 2001; exposure data for marine intoxications, however, are not reported separately (Litovjtz et al. 2002). Physicians who treat any suspected cases should report them to public health agencies, as any index case may be the beginning of a wider outbreak. Whenever possible, the contamman d food should be retrieved and tested, and many toxin assays are currently available. Diagnosis is dependent on the history of ingestion and the recognition of the appropriate clinical features. Treatment, unfortunately, is mostly symptomatic. Although marine toxins can cause significant morbidity, most illnesses are short-lived and mortality is rare.

CIGUATERA FISH POISONING

Ciguatera is a marine food poisoning endemic to the tropics, but it is also the most common nonbacterial fish borne poisoning in the United States. The ciguatera toxins are produced by algae that thrive in the tropical or subtropical coral reef ecosystem, extending between *iS'* North and 35" South. The epiphytic dinoflagellate *Gambierdiscus toxicm* has been implicated in ciguatera, but other organisms may also play a role. The algae are consumed by small herbivorous fish that in turn arc eaten by carnivorous ones. As such, larger and older fish such as barracuda, eel, sea bass, grouper, red snapper, and amber-jack are more toxic. Practically any reef fish eaten in significant quantity, however, may cause ciguatera; more than 400 species have been implicated. Outbreaks can also occur in residents of temperate areas after travel or consumption of imported fish.

Accurate disease incidence is not available because of unavoidable undcr-rceognition and under-reporting. One estimate puts the annual number of cases between 20,000 and S0,000 among people in endemic areas, predominantly Australia, the Caribbean, and the islands of the South Pacific. A telephone survey estimated that 7% of Puerto Rico's residents might have suffered at least one episode of ciguatera in their lifetime. In the United States, most cases are encountered in Hawaii, Rhode Island, and Florida. Even in Canada, there arc an estimated 1000 cases per year from tourism and imported fish. Mortality has been reported at less than 0,5%. No deaths from ciguatera have been documented in the United States.

A number of toxins are responsible for ciguatera, including ciguatoxins and maitotoxin. Ciguatoxins are a group of lipid-solublc, highly oxygenated cyclic poly-ethyl molecules similar in structure to the brevetoxins (see Neurotoxic Shellfish Poisoning, later in this chapter). Ciguatoxins act on tetrodo toxin-sensitive voltage-gated

sodium channels in nerves and muscles, leading to increased sodium permeability at rest and membrane depolarization. This results in spontaneous neuronal firing that presumably underlies the neurological symptoms. Maitotoxin is a water-soluble bisulfated compound that increases calcium ion influx through voltage independent calcium channels; it is the most potent nonproteinaceous toxin known (LD50 = 50 ng/kg, i.p.; Yasumoto 2001). Gambierol and palytoxin, lipid- and water-soluble toxins, respectively, have also been implicated in ciguatera (Daranas, Norte, and Fernandez 2001).

Clinical Features

Symptoms of abdoiiiin.il pain, nausea, vomiting, and diarrhea are usually the first to appear and may last 1-2 days. Neurological symptoms are almost invariably present in ciguatera and arc the dominant feature in poisoning that occurs from Pacific Ocean fish (Lewis 2001). Patients develop centrifugal spread of paresthesias involving the oral cavity, pharynx, limbs, trunk, and, most disagreeably, genitalia and perineum. Particularly characteristic is a paradoxic temperature reversal; patients perceive cold as burning, tingling, or unbearable heat. A smaller proportion may sense warm objects as cold. 1 leadache, weakness, fatigue, arthralgia, myalgia, metallic taste, and pruritus are common. Bizarre symptoms such as a sensation of loose teeth are occasionally described; referrals to psychiatrists have been made by clinicians unacquainted with the disease. Curiously, symptoms are worsened by alcohol consumption, exercise, sexual intercourse, or dietary factors. The severity of symptoms is typically dose-dependent, with more severe poisonings tending to occur after consumption of the toxin-rich head, liver, and viscera of contaminated fish. Paralysis and death have occurred. Rare cases of polymyositis and peripheral neuropathy have also been reported. Irritability may be the only neurological symptoms in children, but life-threatening cases occur more frequently in this age group. Acute transient cardiovascular abnormalities are sometimes seen, and there tends to be an increase in parasympathetic tone. Most neurological symptoms remit in approximately one week, although some-degree of paresthesias, asthenia, weakness, and head-ache may persist for months to years. The long-lasting symptoms, which are often accompanied by depression, may ultimately resemble chronic fatigue syndrome. Lipid storage and slow release of toxin may underlie the prolonged nature of some symptoms (Pearn 2001).

Diagnosis

Although a commercially available immunoassay exists for ciguatoxiu detection in fresh fish, it is often impossible to find what remains of the offending species. Diagnosis is largely based on the characteristic gastrointestinal, neurological, and cardiovascular disturbances. Clustering of cases in people who consumed the same fish helps confirm the diagnosis. However, there is significant variation in individual susceptibility, even when two persons eat a similar quantity. Nerve-conduction studies may show slowing of both sensory and motor nerve-conduction velocities, with prolongation of the absolute refractory, relative refractory, and supernormal periods. These findings are consistent with prolonged opening of sodium channels in the axonal cell membranes.

Treatment

Decontamination of the gastrointestinal tract with charcoal may be beneficial if the patient presents soon after ingestion. Intravenous mannitol (20%; 1.0 g/kg at 500 mlVhour) is a specific treatment for acute ciguatera. The mechanism of action may be related to the reduction of edema in Schwann cells, but this is a matter of debate. Neurological improvement can be dramatic in over 60% of patients, especially if mannitol is given soon after symptom onset; gastrointestinal symptoms, however, are resistant to this therapy. Repeat dosages may be helpful. Fluid and electrolyte status should be assessed and corrected if necessary, because mannitol may induce severe dehydration and electrolyte derangements. Supportive care during acute disease may include fluid supplementation, control of bradycardia, and symptomatic treatment of anxiety, headache, and pain. Calcium gluconate, anticonvulsants, and corticosteroids have been tried wir'i varying results. The chronic symptoms of ciguatera arc difficult to treat. Amitriptyline or other tricyclic antidepressants may provide partial relief.

PUFFERFISH POISONING

Tetrodotoxin (TTX) is the causative agent in pufferfish poisoning. Pufferfish (family *Tetraodontidae)* have a worldwide distribution in both freshwater and saltwater but are most commonly found in the waters around Japan and China. Over 100 species are identified, known variously as pufferfish, tarn bores, porcupine fish, jugfish, and blowfish. Other sources of TTX include the ocean sun fish, toad fish, parrotfish, Australian blue-ringed octopus, gastropod mollusk, horseshoe crab (eggs), *Atelopid* frogs (skin), newts (genus *Taricba),* and some salamanders. The source of pufferfish TTX is debatable. It is thought to be marine bacteria, possibly *Vibrio,* thai colonize the fish and allow the TTX to be sequestered. Concentrations are especially IneJ'- m the skin, liver, roe, and gonads and relatively low in the muscles, *hugu* refers to a preparation of pufferfish in Japan that is considered a delicacy. Specially trained *fugu* chefs certified by the government fillet the fish

in a way that avoids contamination by the deadly viscera. A handful of these chefs prepare pufferfish in the United States. Despite these precautions, *fugu* poisoning accounts for approximately half the fatal food poisonings in Japan, with up to 50 deaths each year. Toxicity is seasonal, and pufferfish is served only from Octobet to March.

TTX is a heat-stable, water-soluble heterocyclic small organic molecule that selectively blocks voltage-gated sodium channels in excitable membranes. It interferes with the inward (excitatory) flow of sodium current that occurs during an acrion potential, 'lerrtnloroxin blocks in pulse conduction in somatic and autonomic nerve fibers, reduces the excitability of skeletal and cardiac muscles, and has profound effects on vasomotor tone and central mechanisms involved in respiration. A dose of 1-2 mg of purified TTX can be lethal. Toxicity has been documented with the consumption of as little as 1.4 ounces of *fugu.*

The clinical symptoms of TTX poisoning are similar to those of saxitoxin (STX)-induced paralytic shellfish poisoning (sec Paralytic Shellfish Poisoning, later in this chapter). Lip and tongue paresthesias appear within minutes of ingestion. Gastrointestinal symptoms such as nausea, vomiting, diarrhea, and abdominal pain are common. Progressive ascending weakness is apparent in moderately severe cases. Reflexes may be preserved early in the course of paralysis. Dysphoria, dysphagia, hypoventilation, and profound hypotension develop in more severe intoxications. Coma and seizures may be seen. Fatality rates are high, with estimates at 50-80%, mostly due to respiratory insufficiency, cardiac dysfunction, and hypotension. Treatment is supportive. Gastric lavage and charcoal are indicated if presentation is early. Anticholinesterases have variable success. Patients who survive the acute period of intoxication (approximately the first 24 hours) tend to recover without neurological sequelae, while those who succumb tend to do so within the first several hours. Fluorescent spectrometry can detect TTX, and the mouse bioassay for STX detection is also positive for TTX.

SCOMBROID FISH POISONING

Scombroid fish poisoning—also known as histamine fish poisoning, pseudoallele fish poisoning, or "mahi-mahi flush"—is among the most common causes of fish toxicity worldwide. The AAPCC does not maintain specific data on scombroid fish poisoning, but it represents 5% of food-borne disease outbreaks reported to the Centers for Disease Control and Prevention. Poisoning can occur after eating improperly stored fatty, dark-fleshed scombroid fish (family Scombri da e; e.g., tuna, mackerel, skipjack) or non-scombroid fish (e.g., mahi-mahi, marlin, sardines, .iiu hi ivies . Alleued fish typical [\ have a peppery, inei.il lie, or bitter flavor. The pathophysiology is incompletely inhk IMIIOJ, lull poisoning is believed to be caused lij bacterial decarboxylation of histidme to biogenic amines such as histamine. This occurs at temperatures above 15°G Histamine is heat-stable, so once it is formed by improper storage it cannot be inactivated by proper cooking. It is typically present at levels below 0.1 mg/100 g in normal fish but can be higher than 20-50 mg/100 g in toxic fish. Oral consumption of similar quantities of histamine does not cause symptoms to the same degree, raising the possibility that another mechanism is at play in scombroid toxicity.

The syndrome is distinctive; it closely resembles an acute allergic reaction and is often misdiagnosed as such. Clinical features include pruritus, throbbing headache, skin flushing, urticaria, oral burning or paresthesias, palpitations, and gastrointestinal disturbances. Symptoms occur within minutes after fish ingestion and are self-limited to 3-6 hours. Patients at the extremes of age and those with asthma are most vulnerable. Persons taking isoniazid or monoamine oxidase inhibitors may have more severe symptoms because of blockade of histaminasc.

Diagnosis is made by a careful history and examination. Histamine levels can be measured in fish, and urinary levels of histamine and N-methylhistidine may be elevated in affected patients, but these studies are not typically used clinically. Intravenous histamine receptor types 1 and 2 (Hj and H_2) blockers should be given promptly, as their administration often provides rapid symptomatic relief. Treatment is otherwise supportive. Epinephrine is sometimes given under the assumption that an allergic reaction is taking place; it should typically be reserved for cases with symptomatic bronchospasm.

SHELLFISH POISONING

Food poisoning caused by shellfish is more likely to be from infectious agents than toxins. Hepatitis A, Norwalk virus, and various *Vibrio* species can be transmitted through the ingestion of shellfish. Classically, four syndromes may result from consumption of shellfish contaminated by-toxins: patalytic shellfish poisoning, neurotoxic shellfish poisoning, amnestic shellfish poisoning, and diarrhetic shellfish poisoning. All arc primarily associated with bivalve mollusks (clams, mussels, scallops, oysters), filter feeders that can accumulate toxic microalgae at high levels. Outbreaks are common during the summer months, especially during periods of red tides. The World Wide Web is a good source for up-to-date information on harmful algal blooms. Although the teaching in North America and Britain is that shellfish arc safe in mouths that contain the letter "r." toxic contamination may occur in any month and in the absence of red tides. The incidence of shellfish poisoning has been on the decline in the United States, even as the incidence of harmful algal blooms is on the rise. This is probably due to greater public awareness and governmental safety measures such as forced beach closures and shellfish analysis.

Paralytic Shellfish Poisoning

Paralytic shellfish poisoning (PSP) occurs in the United States along the coast of New England, in the Pacific Northwest, and in Alaska. It is the most severe of the shellfish intoxications, with mortality rates of 1-12%>, with higher rates being in areas without advanced life support capabilities. Children appear to be more sensitive than adults. Dinoflagellates of the species *Alexandrmm* are the primary source of the saxitoxins, the agents responsible for the neurological symptoms of PSP. Blooms occur between April and October, with shellfish remaining toxic for several weeks after the bloom subsides. Saxitoxin (STX) is a heat-stable toxin that acts primarily on the peripheral nervous system, where it binds reversibly to voltage-gated sodium channels in nerve and muscle membrane. Its action is similar to TTX (see Pufferfish Poisoning, earlier in this chapter). In comparison with TTX, STX has a greater potency to cause skeletal muscle weakness but has a lesser propensity to induce severe hypotension. It also has a shorter duration of action.

Symptoms typically appear within 5-30 minutes of ingestion of contaminated shellfish. Paresthesias develop in almost all patients and initially involve the perioral areas, oral cavity, face, and neck. These symptoms spread to the limbs and trunk in severe cases. Some patients complain of an unusual floating sensation. Brainstem symptoms and signs are sometimes present; these include dysarthtia, dysphagia, dysphonia, ophthalmoplegia, nystagmus, and dilated pupils. Other neurological symptoms include headache, gait ataxia, and limb incoordination. Gastrointestinal symptoms are less common. Despite the name of this syndrome, muscle paralysis does not develop in every patient. If present, weakness may involve muscles of the face, jaw, swallowing, respiration, and upper and lower limbs. In severe cases, respiratory paralysis appears within 2-12 hours of ingestion; the incidence of required respiratory support is 3-6%. Untreated respiratory paralysis is responsible for the deaths seen in PSP. Spontaneous recovery begins to appear after 12 hours and is usually complete within a few days. Weakness, however, may persist for weeks. There is no antidote, and treatment is supportive.

Initial diagnosis is largely dependent on recognition of the history and clinical features. An enzyme-linked immunosorbent assay (El.ISA) is available for STX, but its utility is limited by the variability of toxin constituents in each outbreak. If the contaminated shellfish is available, a useful test is the mouse bioassay. A mouse unit is defined as the minimum amount necessary to induce death of a mouse in 15 minutes. The lethal dose for humans is approximately 5000-20,000 mouse units. The mouse assay is employed to monitor commercial shellfish production in many parts of the world. Nerve-conduction studies may show reduced amplitude of the sensory and motor responses and prolonged latencies with slowed nerve-conduction velocities. Unlike acute demyelinating neuropathies, in which electrophysiological abnormalities lag behind clinical findings, the electrophysiological abnormalities in PSP are most prominent at symptom onset and improve over a few days as clinical symptoms resolve.

Neurotoxic Shellfish Poisoning

Neurotoxic shellfish poisoning (NSP) is caused by the di no flagellate *Gymnodinium breve,* which is found primarily in the Gulf of Mexico, the Caribbean Sea, and the waters around New Zealand. These microalgae are known for causing the infamous Florida red tides. They elaborate a group of lipophilic polyether toxins called brevetoxins, which cause depolarization of excitable membranes, persistent activation, and repetitive firing of nerves and muscles by transforming fast voltage-gated sodium channels into slower ones. Brevetoxins are probably more toxic to wildlife than humans, and red tides from blooms of G. *breve* are typically associated with massive fish, invertebrate, and seabird kills.

Clinical presentation is characterized by the simultaneous onset of gastrointestinal and neurological symptoms within minutes to hours after ingestion. Nausea, diarrhea, rectal burning, myalgia, circumoral paresthesias, dizziness, and ataxia are common. Less common signs and symptoms include tremor, dysphagia, mydriasis, and hyporeflexia. In general, the neurological symptoms are milder than those of PSP. Temperature reversal similar to that seen in ciguatera may be reported. A separate respiratory syndrome has been attributed to inhalation of brevetoxin aerosolized by the surf. A response consisting of conjunctival irritation, rhinorrhea, cough, and bronchoconstriction can be seen in sensitive individuals. No human deaths have been associated with NSP. There is a mouse bioassay for the detection of brevetoxin; radioimmunoassay (RIA) and ELISA are also available.

Amnestic Shellfish Poisoning

In November iyS7, 107 Canadians were stricken by a novel illness after eating mussels harvested off the Prince Edward Island coast. Gastrointestinal symptoms were followed by cognitive dysfunction and headache. The syndrome, referred to as amnestic shellfish poisoning (ASP), was found to be microalgae toxin-mediated. The toxin was later identified as domoic acid, an analogue of kainic acid. It functions as a potent agonist at excitatory ionotropic glutamate receptors. A pennare diatom, *Psetidonitzschia pungens,* was the probable source of the domoic acid. Very high concentrations of the excitotoxin were found in the digestive glands of uneaten mussels and those sampled from three river estuaries in Prince Edward Island. Since the initial epidemic, domoic acid has been found in

anchovies in Monterey Bay, California; in razor clams and Dungeness crabs in the Pacific Northwest; and in the marine food web along the Texas coast (Morris 1999). Massive killing of seabirds and mammals in the waters around Baja, California, have been attributed to domoic acid (Sierra-Beltran et al. 1998).

Domoic acid acts as an excitatory neurotransmitter in animal models; it is approximately three times more potent than kainic acid and over 30 times more potent than glutamic acid. Neurological disease results from its excitotoxic actions, especially on the limbic system. Symptoms usually appear within a few hours of ingestion. Almost all patients have diarrhea, vomiting, or abdominal cramps, although the severity varies. Roughly one-half of patients have headache, and approximately 25% present with anterograde memory . loss. In those with neurological dysfunction, the findings are quite varied. They include disorientation, mutism, seizures, myoclonus, and altered state of consciousness (ranging from somnolence to coma). Reflexes may be depressed or hyperactive, and some patients may have Babinski's signs. Two patients were reported to have a unique alternating hemiparesis and complete external ophthalmoplegia.

After ASP, gradual improvement occurs over a three-month period. Those with residual deficits often have anterograde amnesia with relative preservation of intellect and other higher cortical functions. Some patients develop temporal lohe epilepsy. There also may be coexisting distal limb weakness and atrophy, and electrophysiological testing suggests a picture of either a pure motor neuronopathy or a sensorimotor axonopathy. In a few patients who have died, autopsy revealed astrocytosis and selective neuronal loss in the amygdala and hippocampus (Cendes et al. 1995). These lesions are reminiscent of those seen in the rat model of kainate-induced seizures. In the one reported outbreak, the mortality rate was 3%, all of which occurred in elderly patients.

Treatment is primarily symptomatic. Previous experience suggests that diazepam and phenobarbital, but not phenytoin, are the drugs of choice in the control of seizures. Diagnosis may be established with high-per forma nee liquid chromatography (HPLC); the mouse bioassay was deemed too insensitive. A surveillance program now exists in Canada to monitor commercial shellfish operations, with mussels and clams being analyzed regularly for domoic acid.

Diarrhctic Shellfish Poisoning

Diarrhetic shellfish poisoning (DSP) is a self-limiting gastrointestinal illness without clinical evidence of neurotoxicity. It is most common in Japan but has also been desctibed in Europe, South America, Canada, and New Zealand; there have been no confirmed cases in the United States. Okadaic acid, a polycthcr toxin that is a highly selective inhibitor of protein phosphatase type 1 (PP1) and 2A (PP2A), is responsible for the pathophysiological features. Diarrhea, nausea, and vomiting are almost universal symptoms. A mouse bioassay is available for analysis of shellfish. Complete recovery is expected within 3 days. No deaths have been reported from DSP.

OTHERS

New marine intoxications with neurological consequences continue to be described. Neurocognitive deficits have been reported in the so-called P/sesteria-associated syndrome, a recently described constellation of symptoms linked to the dinoflagellate *Pfiesteria piscicida* {the "fish killer"). Deficiencies in learning and memory, headaches, and acute confusional state have been seen. Exposure is probably mediated by aerosoli/ation or skin contact with an undetermined toxin and not shellfish consumption (Morris 1999).

An outbreak of an illness reminiscent of DSP in several people who ate mussels cultivated in Ireland led to the identification of azaspiracid. When injected into mice, the toxin causes paralysis and convulsions prior to death. The source is thought to be a dinoflagellate. Many other marine microalgae toxins found in shellfish have been characterized; the dangers and utilities of these compounds are still under investigation (Daranas, Norte, and Fernandez 2001).

Chapter 64
Effects of Toxins and Physical Agents on the Nervous System

E. EFFECT OF PHYSICAL AGENTS ON THE NERVOUS SYSTEM

Michael J. Aminoff

The nervous system may be damaged by physical agents such as kmi/.iiu; .siul nonionizing "ulialinn, r';rl nary, extreme heat or cold, and vibration. The extent of damage depends on the intensit) aiul duration ol exposure.

IONIZING RADIATION

Electromagnetic and particulate radiation may lead to cell damage and death. Radiation therapy affects the nervous system by causing damage to cells (particularly their nuclei) in the exposed regions; these cells include neurons, glia, and the blood vessels supplying neural structures. As a late carcinogenic effect, radiation therapy may also produce tumors, particularly sarcomas, that lead to neurological deficits. Neurological injury is proportional to both the total dose and the daily fraction of radiation received.

Encephalopathy

Radiation encephalopathy is best considered according to its time of onset after exposure (De Angelis et al. 2001). *Acute radiation encephalopathy* occurs within a few days of exposure and is characterized by headache, nausea, and a change in mental status. It may be related to increased intracranial pressure from breakdown of the blood-brain barrier due to the immediate effects of the energy dispersal in the nervous tissue. Treatment with high-dose corticosteroids usually provides relief.

Early delayed radiation encephalopathy is probably caused by dcmyelination and occurs between 2 weeks and 3 or 4 months after irradiation. Headache and drowsiness are features, as is an enhancement of previous focal neurological deficits. Symptoms resolve after several weeks without specific treatment. A brainstem encephalopathy, manifest by ataxia, nystagmus, diplopia, and dysarthria, also may develop if the brainstem was included in the irradiated field. Spontaneous recovery over a few weeks is usual, hut the disorder sometimes progresses to obtundation, coma, or death.

Delayed radiation encephalopathy occurs several months or longer after cranial irradiation. It may be characterized by diffuse cerebral injury (atrophy) or focal neurological deficits with signs of increased intracranial pressure. The disorder may result from focal cerebral necrosis caused by direct radiation damage or by vascular changes. Immunological mechanisms also may be involved. Occasionally patients develop a progressive disabling disorder, with cognitive and affective disturbances and a disorder of gait, approximately 6-18 months after whole-brain irradiation. Pathological examination in some instances has shown demyelinating lesions.

Myelopathy

A myelopathy may result from irradiation involving the spinal cord. *Transient radiation myelopathy* usually occurs within the first year or so after incidental spinal cord irradiation in patients treated for lymphoma and neck and thoracic neoplasms. Paresthesias and Lhermitte's phenomenon characterize the syndrome, which is self-limiting and probably relates to demyelination of the posterior columns. A *delayed severe radiation myelopathy* may occur approximately one year after completion of radiotherapy. Patients present with a focal spinal cord deficit that progresses over weeks or months to paraplegia or quadriplegia. This may

simulate a compressive myelopathy or paraneoplastic subacute necrotizing myelopathy, but the changes on magnetic resonance imaging (MRI) are usually those of a focal increased T2-weighted myelomalacia with cord atrophy. The cerebrospinal fluid is usually normal, although the protein concentration is sometimes elevated. Corticosteroids may lead to temporary improvement, but no specific treatment exists. The disorder is caused by necrosis and atrophy of the cord, with an associated vasculopathy (Okada and Okeda 2001). Occasional patients develop sudden back pain and leg weakness several years after irradiation, with MRI revealing hematomyelia; symptoms usually improve with time.

In some instances, inadvertent spinal cord involvement, usually by irradiation directed at the para-aortic nodes in cases of seminoma, leads to a focal lower-limb lower motor neuron syndrome. The neurological deficit may progress over several months or years hut eventually stabilizes, leaving a flaccid, asymmetrical paraparesis. Recovery does nor occur.

Plexopathy

A radiation-induced plexopathy may rarely occur soon after radiation treatment for neoplasms, particularly of the breast and pelvis, and must be distinguished from direct neoplastic involvement of the plexus. Paresthesias, weakness, and atrophy typify the disorder, which tends to plateau after progressing for several months. The plexopathy may develop 1-3 years or longer after irradiation that involves the brachial or lumbosacral plexus. In this regard, doses of radiation exceeding 6000 cGy, use of large daily fractions, involvement of tbc upper part of the brachial plexus, lymphedema, induration of the supraclavicular fossa, and the presence of myokymic discharges on electromyography all favor a radiation-induced plexopathy. Although radiation plexopathy is often painless, a point favoring this diagnosis rather than direct infiltration by neoplasm, pain is conspicuous in some patients. Symptoms progress at a variable rate (Fathers et al. 2002). The plexopathy is associated with small-vessel damage (endarteritis obliterans) and fibrosis around the nerve trunks (Johansson et al. 2001).

NONIONIZING RADIATION

Nonionizing radiation that strikes matter is transformed to heat, which may lead to tissue damage. Ultraviolet radiation is produced by the sun, incandescent and fluorescent light sources, welding torches, electrical arc furnaces, and germicidal lamps. Ultraviolet radiation is absorbed primarily by proteins and nucleic acids. Susceptibility to it is increased by certain drugs, such as chlorpromazine and tolbutamide, and by certain plants, such as figs, lemon and lime rinds, celery, and parsnips, which contain furocoumanns and psoralens. Short-term exposure to ultraviolet light can damage the rerina and optic nerve fibers. A severe central scotoma may result from macular injury. Prevention requires the use of goggles and face masks in work environments where exposure to high-intensity ultraviolet radiation is likely to occur.

Exposures to laser radiation can induce ocular damage. This is particularly a problem when the wavelength of the laser beam is not in the visible portion of the electromagnetic spectrum, because the patient may not be aware of the exposure.

Concern has been raised that occupational or environmental exposure to high-voltage electrical power lines may lead to neurological damage from exposure to high-intensity electromagnetic fields. However, the effects of such exposure are uncertain and require further study. Nonionizing radiation at the radio frequency used by cellular telephones has been reported to cause sleep disturbances, headache, and other nonspecific neurological symptoms. Several studies have raised concerns that such radiation may cause brain tumors or accelerate their growth, although any heating of cerebral tissue by cellular telephones is minimal, and a clear theoretical basis for such an association with brain tumors is lacking. In any event, a recent case-control study failed to identify any major increased risk associated with the use of cellular telephones, at least in the short term (Inskip et al. 2001). The neurological implications of long-term use of cellular telephones or changes in telephone technology are unknown.

High-intensin noise m the acme senmg IKLV 1CL'J lo tinnitus, vertigo, pain in the ear, and hearing impairment. Chronic exposure to high-intensity noise of any frequency leads to focal cochlear damage and impaired hearing.

ELECTRICAL CURRENT AND LIGHTNING

Electrical injuries (whether from manufactured or naturally occurring sources) are common. Their severity depends on the strength and duration of the current and the path in which it flows. Electricity travels along the shortest path to ground. Its passage through humans can often be determined by identifying entry and exit bum wounds. When its path involves the nervous system, direct neurological damage is likely among survivors. With the passage of current through tissues, heat is produced that is responsible, at least in part, for any damage, but nonthermal mechanisms may contribute also (Winkelman 2001). In addition, neurological damage may result from circulatory arrest and from trauma related to falling or a shock pressure wave.

A large current that passes through the head leads to immediate unconsciousness, sometimes associated with ventricular fibrillation and respiratory arrest. Confusion, disorientation, seizures, and transient focal deficits are common in survivors (Duff and McCaffrey 2001), but

recovery generally occurs within a few days. Some survivors develop a cerebral infarct after several days or weeks, attributed to thrombotic occlusion of cerebral blood vessels. Residual memory and other cognitive disturbances are also common. Weaker current leads only to headache or other mild symptoms for a brief period.

When the path of the current involves the spinal cord, a transverse myelopathy may occur immediately or within 7 days or so and may progress for several days. The disorder eventually stabilizes, after which partial or full recovery occurs in many instances. Upper and lower motor neuron Jetu iti .nul ii'iiMin J-.Muriuuuvs are a minion. Inn ilic sphincters are often spared. Unlike traumatic myelopathy, pain is not a feature. Autopsy studies show di-myclination of long tracts, loss of anterior horn cells, and areas of necrosis in the spinal cord.

Segmental muscle atrophy may occur also within a few days or weeks of electrical injury of the spinal cord. Whether this relates to focal neuronal damage or has an ischemic basis is uncertain. The current pathway is typically across the cervical cord from one arm to the other, and the resulting muscle atrophy in the arms may be accompanied by an upper motor neuron deficit in the legs. Sensory disturbances (in upper or lower limbs) and sphincter dysfunction also occur. Occasional reports have suggested the occurrence of a progressive disorder simulating amyotrophic lateral sclerosis after electrical injury.

Peripheral or cranial nerve injury in the region of an electrical burn is often reversible, except when high-tension current is responsible, in which case thermal coagulation necrosis is likely. Care must be taken to distinguish such neuropathies from compartment or entrapment neuropathies, which are suggested by severe pain and a delay between injury and development of the neuropathy. Compartment syndromes develop because of muscle swelling and necrosis, and entrapment syndromes because of swelling of tissues in confined anatomical spaces. Immediate decompression of the compartment is indicated in these cases.

Occasional patients have developed hemorrhagic or thrombotic stroke after electrical injuries, for uncertain reasons. Venous sinus thrombosis has also been described. Suggested mechanisms include coagulation necrosis of part of the vascular wall with aneurysmal distention and rupture ot intramural thrombosis. Intense vasospasm, acute hypertension, intramural dissections, or transient circulatory arrest may also contribute.

VI Li RATION

Exposure to vibrating tools such as pneumatic drills has been associated with both focal peripheral nerve injuries, such as carpal tunnel syndrome (Herbert et al. 2001), and vascular abnormalities, such as Raynaud's phenomenon (Byhind et al. 2001). The mechanism of production is uncertain but presumably reflects focal damage to nerve fibers.

HYPERTHERMIA

Exposure to high external temperatures may lead to heat stress disorders. *Heat stroke*, the most severe, sometimes has an exertional basis, and disturbances of thermoregulatory sweating may be contributory. Classic heat stroke occurs especially in older persons with chronic disorders such as diabetes or obesity and in hypermetabolic states such as thyrotoxicosis. Anticholinergic or diuretic drugs and dehydration predispose to heat stroke because they impair sweating and thereby limit heat dissipation.

Hyperthermia leads to thirst, fatigue, nausea, weakness, and muscle cramps and eventually to confusion, delirium, obtundation, or coma, bur coma can develop without any prodrome. Seizures are frequent, focal neurological deficits are sometimes present, and papilledema may occur. With recovery, symptoms and signs generally clear completely, but cognitive changes or focal neurological deficits may persist. Cataracts have been attributed to dehydration. Cardiac output is reduced, pulmonary edema may occur, and adult respiratory distress syndrome is sometimes conspicuous.

Other systemic manifestations include a respiratory alkalosis and often a metabolic acidosis, hypokalemia or hyperkalemia, hypoglycemia, other electrolyte disturbances, and various coagulopathies. Rhabdomyolysis is common, and acute renal failure may occur in exertional heat stroke.

The prognosis depends on the severity of hyperthermia and its duration before initiation of treatment. With proper management, the mortality rate is probably about 5%, Treatment involve control of the body temperature by cooling, rehydration of the patient, correction of the underlying cause of the hyperthermia, and prevention of complications. When excessive muscle activity is responsible, neuromuscular blockade may be necessary.

In the *malignant hyperthermia syndrome*, the responsible anesthetic agent is discontinued, the patient is vigorously cooled, oxygenation is ensured, and intravenous dantrolene is administered. Thyrotoxic crisis is treated with thyroid-blocking drugs. Patients with pheocbromocytoma are treated with a-adrenergic antagonists.

Cooling is achieved by evaporation or by direct external cooling, as by immersion of the patient in cold water. The skin should be massaged vigorously to counteract the cutaneous vasoconstriction that results from external cooling and that impedes heat removal from the cure. Antipyretic agents are unhelpful. Hypotension is treated by fluid administration rather than vasoconstrictor agents, which should be avoided if possible. High doses of mannitol and use of diuretics may be required to promote urinary output. Electrolyte and glucose abnormalities also require treatment.

Hyperthermic limb perfusion with doxorubicin or mcphalan, two widely used chemotherapeutic agents in patients with melanomas or sarcomas, may lead to a variety

of neuromuscular abnormalities related to the perfusion temperature, but this is also influenced by any pre-existing changes and awaits further clarification (Bonifati et al. 2000).

HYPOTHERMIA

A core temperature below 35°C may occur in very young or elderly persons with environmental exposure, coma, hypothyroidism, malnutrition, severe dermatological disorders (because of excessive heat loss and inability to regulate cutaneous vasoconstriction), and alcoholism. Alcohol promotes heat loss by vasodilation and may lead to coma directly or from trauma with resultant environmental exposure to cold. Hypothermia also occurs in persons exposed to low temperatures in the working environment, such as divers, skiers, and cold-room workers.

The usual compensatory mechanism for cooling is shivering, but this fails at body temperatures below approximately .WC. As the temperature declines, respiratory requirements diminish, cardiac ourput falls, and significant hypotension and cardiac arrhythmias ultimately develop. Neurologically there is increasing confusion, psychomotor retardation, and obtundation until consciousness is eventually lost. The tendon reflexes are reduced and muscle tone increases, bill extensor plantai responses are not usually found. The electroencephalogram (EEG) slows and ultimately shows a burst-suppression pattern or becomes isoelectric with increasing hypothermia. At core temperatures below 32"C, the appearance of brain death ma) be simulated clinical!) and electroencephalograph] cally, but complete recovery may follow appropriate treatment. Management involves slow rewarming of patients and the prevention of complications such as aspiration pneumonia ar.d iiKtabolie. acidosis. 1 1) potecsmn may occur from dehydration but can usually be managed by fluid replacement. Plasma electrolyte concentrations must be monitored closely, especially because of the risk of developing cardiac arrhythmias, With recover)-, -.here *AW* usually no long-term sequelae.

Nerve damage may occur as a consequence of the tissues becoming frozen by the cold (frostbite). This involves the extremities and is usually irreversible.

BURNS

Following common usage, rhe term *thermal burn* refers to a burn caused by direct contact with heat or flames. Patients with severe burns may have associated disorders such as anoxic encephalopathy from carbon monoxide poisoning, head injury, or respiratory dysfunction from smoke inhalation. Central neurological disorders may occur later during hospitalization and are secondary to various systemic complications. Thus metabolic encephalopathies may relate ro anoxia, liver or kidney failure, and hyponatremia, and central pontine myelinolysis may occur also. Infections (meningitis or cerebral microabscesses) are common, especially in the second or third week after the burn. Vascular complications, including multiple strokes, may result from septic infarction, disseminated intravascular coagulation, venous thrombosis, hypotension, or intracranial hemorrhage. Imaging studies are therefore important in clan tying die underlying disorder.

Peripheral complications of burns are also important. Nerves may be damaged directly by hear, leading to coagulation necrosis from which recovery is unlikely. A compartment syndrome may arise from massive swelling of tissues and mandates urgent decompressive surgery. In other instances, neuropathies result from compression, angulation, or stretching as a result of incorrectly applied dressings or improper positioning of the patient. A critical illness polyneuropathy and myopathy is now well recognized in patients with multiorgan failure and sepsis, including patients with burns, and is discussed in Chapter 82.

Chapter 65
Brain Edema and Disorders of Cerebrospinal Fluid Circulation

Gary A. Rosenberg

Brain cells depend on the constant delivery of oxygen and glucose by the cerebral circulation. Cerebral endothelial cells are metabolically active, selectively permeable, epithelial-like, secreting structures that are critical in maintaining a constant fluid and electrolyte environment. Adhesions between endothelial cells are tight, and only substances that are lipid soluble are able to easily cross them. These tight junctions separate brain cells from substances circulating in the blood. Brain cells are surrounded by interstitial fluid (TSF), which is contiguous with the cerebrospinal fluid (CSF). Enzymatic and osmotic processes continuously form CSF and ISF, the choroid plexuses being the main source for the CSF and cerebral capillaries and cellular metabolism the source of the ISF. Together the CSF-ISF serve the same function for brain cells that lymph provides for other cells in the body. Loss of either oxygen or glucose for even short periods causes cellular damage and may lead to cell death. Cell swelling is poorly tolerated because of the constraints imposed by the bony skull and the tough dural membranes.

The brain and spinal cord arc subject to different physical processes than other otgans in the body because they lie within the rigid bony compartments of the skull and spinal canal. The character of the CSF, with its constituents, pressure, and flow, are of great importance to the function of the central nervous system (CNS). Increased intracranial pressure results from increased tissue within the rigid bony box of the skull (space-occupying lesions, such as tumor, abscess, and hematoma}, increased fluid (cerebral edema of several types}, and impaired flow of CSF (hydrocephalus).

Brain edema is a life-threatening complication of many neurological conditions. Damaged cells swell, injured blood vessels leak, and blocked absorption pathways force fluid co enter brain tissues. F.ach of these mechanisms results in a potential increase in intracranial volume. Compensation for the potential increase occurs by displacement of CSF and venous blood from the skull. Further volume increases cause brain tissue to shift. Herniation of brain leads to a life-threatening situation, requiring rapid assessment of the cause and utgent treatment.

Because [he CSF and [SI .u/i ;>. mic 'Hid, : lumbar puncture to withdraw CSF provides insight into brain cell function that is critical in diagnosis and management of patients. The analysis of CSF gives important information on bleeding, inflammation, and infection in the brain that is not available by other methods. Proper use of the information obtained by lumbar puncture, which is central to neurological diagnosis and requires an understanding of normal CSF and ISF physiology. Cerebrospinal fluid studies show increased pressure, the presence of cells, indicating infection and inflammation, and elevated levels of protein, showing a breakdown of the normal barriers between the brain and the blood or the production of those proteins by the brain cells. Diagnosis depends on the findings of the CSF examinations in certain conditions, such as idiopathic increased intracranial hypertension, in which an elevated pressure is essential for the diagnosis. Other conditions in which the examination of the CSF is the major diagnostic test include meningitis, subarachnoid hemorrhage with a negative computed tomography (CT), and carcinomatous

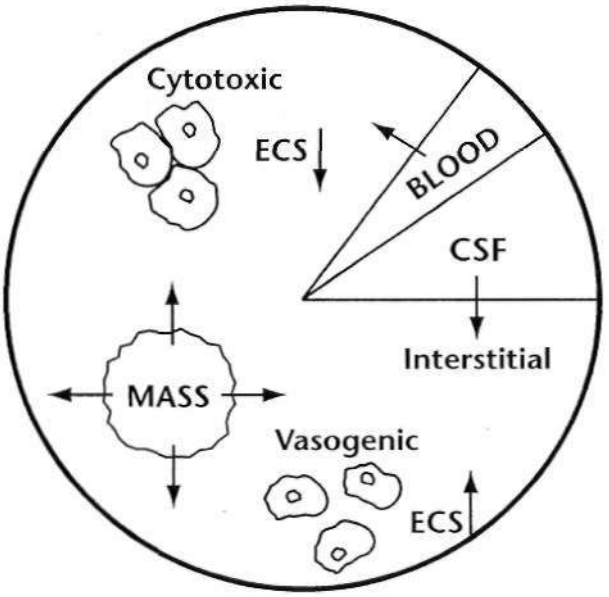

FIGURE 65.1 The rigid skull inhibits expansion of any brain compartments. An increase in blood or cerebrospinal fluid (CSF) volume directly affects CSF pressure. Masses, such as tumors, abscesses, or hematomas, increase brain tissue volume, thereby raising CSF pressure. Cell swelling causes loss of extracellular space (ECS) and cytotoxic edema. Blood-brain barrier damage increases extracellular space, particularly in the white matter with vasogenic edema.

meningitis. The examination of the CSF by lumbar puncture is one of the most cost-effective diagnostic tests, and when done properly it can provide unique information.

Brain swelling compresses the brain tissues. The recognition that the total volume of fluid and tissue contained in the rigid skull is constant is called the Monro-Kellie doctrine, which was formulated in the eighteenth century. Changes in volume of blood, CSF, or brain compartments produce compensatory changes in the others, with a resultant increase in CSF pressure (Figure 65.1). Obstruction of the CSF outflow pathways causes the enlargement of the ventricles. Hydrocephalus causes dysfunction by the movement of CSF into the tissues surrounding the ventricles, causing transependymal absorption. Masses, such as tumors or abscesses, cause an enlargement of the tissue space, compressing the CSF and blood volumes. Opening of the blood-brain barrier (BBB) due to disruption of the blood vessel wall leads to vasogenic edema with enlargement of the extracellular space by the extravasated fluid. On the contrary, damaged, swollen cells lead to cytotoxic edema with narrowing of the extracellular space. Finally, an increase in blood volume, as seen in hypercapnia and hypoxia, increases the intracranial pressure (Table 65.1).

The many surfaces in which brain tissue is exposed to the systemic circulation have evolved unique structural, metabolic, and enzymatic mechanisms to preserve the neuronal microenvironment. Fluid and electrolyte balance and

immunological protection are lost in the presence of ischemia, inflammation, infection, and tumors.

BLOOD-BRAIN INTERFACES

Cerebral Blood Vessels

Brain cells are separated from the general circulation by a complex series of interfaces that form the BBB. The large surface areas of the capillary endothelial cells form the major interface. Choroid plexuses and arachnoid granulations also have barrier surfaces that regulate the exchange of substrates between brain and blood (Table 65.2). At each of the BBB interfaces, bulk transport is restricted by high-resistance junctions (zona oceludens) between cells, which make the surface into an epithelium like structure. The epithelial sheets impede non-lipid-soluble substances, charged substances, or large molecules, whereas lipid-soluble substances, such as anesthetic gases, pass easily through the cells. Watet is unique in that it can pass through membranes with relatively little impedance.

Once substances ctoss the BBB, they have access to all brain regions through the ISF, which functions as a lymph fluid. The movement of CSF and ISF through the ventricles and brain tissues constitutes a "Third Circulation," which is analogous to the lymph fluids in other organs, Circulation of ISF begins with its fotmation at the capillaries. Flowing around cells, ISF brings nutrients, such as glucose and oxygen, to neurons and astrocytes and removes the products of metabolism. ISF is absorbed either into the blood via terminal capillaries and venules or into CSF for eventual absorption through the arachnoid granulations (Figure 65.2). A novel mechanism for ilu drainage of ISF into the cervical lymphatics has been shown in rats and rabbits, but its role in humans remains speculative.

Brain extracellular space comprises 15-20% of the total brain volume. Complex carbohydrates arc found in the extracellular space, including hyaluronic acid, chondroitin sulfate, and heparan sulfate. Hyaluronic acid forms large water domains. Othet glycosaminoglycans act as charge barriers and binding sites. A thin layer of basal lamina

Table 65.2: Characteristic features of the blood-brain interfaces

ATPase = adenosine triphosphatase; CSF = cerebrospinal fluid; ISF = interstitial fluid.

surrounds the cerebral capillaries. Type IV collagen, fibronectin, heparan sulfate, laminin, and entactin make up the various layers of the basal lamina. Entactin connects type IV collagen and laminin to add a structural element to the capillary. Fibronectin from the cells joins the basal lamina to the endothelium. Basal lamina provide structure through type IV collagen, charge barriers by heparan sulfate, and binding sites on the laminin and fibronectin molecules, but the role of the basal lamina in brain blood vessels is unclear.

During development, cerebral blood vessels acquire the characteristics that distinguish them from systemic capillaries. During embryonic life, vessels destined to form the BliB show increased expression of the cell surface protein, HT7. When quail embryonic brains are grafted into the coclomic cavity of chick embryos, chicken blood vessels growing into the grafted brain express HT7 protein, which is specific for chickens and not expressed in quails. Systemic blood vessels in the chick embryo at stages 17-20 can form a BBB when implanted into developing brain. The proximity of the astrocytic processes to the capillary cells suggests that the astrocytes provide essential substances to the capillary. A protein has been identified in the endothelial cell as the substrate for the tight junctions. Zona occludin-1 protein is anchored to the actin in the cytoskeleton, and damage to that protein leads to an increase in capillary permeability. Vascular endothelial growth factor (VF.GF), which is a factor in the increase in vascular permeability during hypoxia, alters ZO-1 protein (Fischer ct al. 2002).

Tight junctions between the endothelial cells create a high electrical resistance that limits transport of nonlipid soluble substances (Table 65.3). Carrier molecules that shuttle between the blood and brain sides of the capillaries selectively transport essential nutrients, such as glucose and amino acids. Glucose transporters are densely distributed in the capillaries. At low levels of blood glucose, the carriers function at high capacity, but at higher levels, they become saturated. Once they are saturated, any increase in uptake occurs by diffusion. Several isoforms of the glucose transporter molecule have been isolated and cloned. High concentration of one isoform, GLUT1, is found on cerebral blood vessels. GLUT3 is found on neurons and GLUT5 in microglia. GLUT2 is found predominantly in the liver, intestine, kidneys, and pancreas. Impairment of glucose transport due to lack of transporters has been described in patients with Alzheimer's disease and in other neurological disorders.

Amino acid carrier molecules are also toniul on cerebral capillaries. Substances that compete with essential amino acids for the carriers block their uptake and lead to deficiency states. For example, high-protein meals provide amino acids that compete for the carriers that transport [-dopa, which may interfere with i.-dopa uptake in the

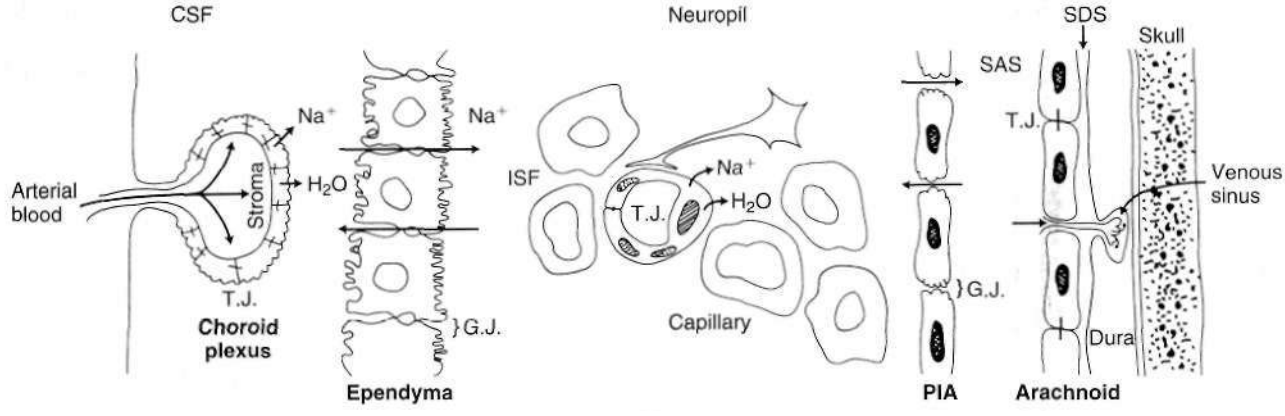

FIGURE. 65.2 Illustration of die third circulation. The cerebrospinal fluid [CSF) is formed by the choroid plexuses in the ventricles, and the interstitial fluid (ISF) is formed by cerebral capillaries. At both sites the action of the Na/K ATPase pump creates the osmotic gradient that pulls water from the blood. Tight junctions (T.J.) formed by the zona occludin-1 protein are found at each site where the blood and the brain interface. This includes the apical surface of the choroid plexus epithelial cells, the cerebral endothelial cells, and the arachnoid. Substances move between the brain and CSF across the gap junctions (G.J.) on the ependymal and pial surfaces. (Modified from Rosenberg, G, A. 1990, *Brain Fluids and Metabolism,* Oxford University Press, New York.)

treatment of Parkinson's disease. Serotonin uptake is decreased in patients with phenylketonuria.

Steady-state levels of brain electrolytes are preserved by-transport mechanisms at the BBB. Potassium is maintained at a constant level in the CSF and brain by the BBB. This prevents fluctuations of electrolyte levels in the blood from influencing brain levels. Calcium is similarly regulated. Glutamate, which is an excitotoxin, is excluded from the brain. High lipid solubility is needed for entry into the brain. Gases, such as carbon dioxide and oxygen, are rapidly exchanged across the capillary. Anesrhetic gases are effective because of rheir ease of entry into the brain. Water rapidly crosses rbe capillary wall, with only slight impedance found at faster blood flow rares.

Drugs acting on the CNS need to cross the BBB. Antibiotics, such as penicillin, have to be given in high doses because they enter the nervous system slowly. Newer generations of antibiotics, however, penetrate more readily, making them better agents for treatment of brain infections. Chemotherapy of brain tumors has been hampered by the agents' poor lipid solubility. The btain more readily takes up heroin than morphine because of its increased lipid solubility. Nicotine and alcohol are readily transported into brain, resulting in their addictive potential.

Paradoxical clinical siruations arise because of the limitations to transport across the BBB, causing different rates for equilibration of various substances between blood and brain. For example, patients with metabolic acidosis deplete bicarbonate from the brain. A compensatory respiratory alkalosis lowers carbon dioxide levels in the blood and the brain. Because of the limited transport of bicarbonate, correction of the metabolic acidosis with bicarbonate raises serum levels before those in the brain. As serum pH rises, respiratory rate falls, restoring carbon dioxide levels ro normal in brain and blood. Paradoxically, brain pH falls because the low brain bicarbonate levels fail to buffet the increased acidity due to the rise in carbon dioxide. Although treatment is necessary to correct the metabolic acidosis, patients may temporarily worsen as the treatment progresses due to brain acidosis (Figure 65.3).

Choroid Plexuses and Capillaries Produce Cerebrospinal Fluid and Interstitial Fluid

Choroid plexuses form an important interface between CSF and blood. These secretory structures protrude into the cerebral ventricles. Because the blood and the brain fluids are in contact, thctc are tight junctions. However, the tight junctions are at the apical surface of choroid plexus ependymal cells. Capillaries beneath the choroidal cells are fenestrated, and they permit substances to pass into the stroma that separate the blood vessels from the choroid plexus epithelial cells. Microvilli line the outer surface and contribute to the secretory function. The presence in the epithelial cells of many mitochondria, Golgi complexes, and endoplasmic reticulum suggests a high level of metabolic activity. The choroid plexus is the major source of CSF, with the capillaries contributing fSF at varying levels in different species. Production of CSF is constant across species when volume of fluid formed is divided by the weight of the choroid plexus. In humans, the rate of CSF production is approximately 0.35 ml. per minute. CSF production occurs at both choroidal and extrachoroidal sires, and estimates of the proportion of CSF from each site vary, depending on the species and the method of measurement. Choroidal production accounts for 60-70% of total CSF production in the cat, but it may be lower in the monkey, in which extrachoroidal sources are important. No measurements of the relative proportion of CSF produced at each source have been made in humans.

Higher levels of sodium, chloride, and magnesium and lower levels of potassium, calcium, bicarbonate, and

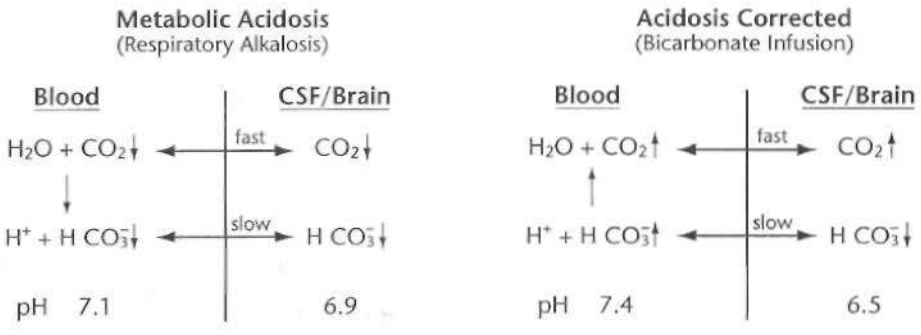

FIGURE 65.3 Illustration of the effects of metabolic acidosis with respiratory alkalosis on pH of blood and cerebrospinal fluid (CSF) and brain. Uncompensated, the blood bicarbonate and $C0_2$ are both low and art- mirrored by the levels in CSF and brain. Treatment with bicarbonate restores normal respiration, increasing CO2 levels in both compartments, but bicarbonare crosses the blood-brain barrier too slowly to compensate for the excess protons. CSF and brain pH paradoxically fall.

glucose are found in CSF than arc expected from a plasma ultrafiltrate, which suggests that the CSF is actively secreted. An adenosine triphosphatase (ATPase) pump on the apical surface of the choroidal cells secretes sodium-rich CSF that draws osmotic water into the ventricles. Carbonic ..inlndiasc enlivens cubon dioxide and water into hicar bonate, which is removed along with chloride to balance the sodium charge.

Although the steady production of CSF is difficult to decrease, several drugs have been found that reduce it. Acetazolamide, which inhibits carbonic anhydrase, reduces LSI production, as do hypothermia, hypocarbia, hypoxia, and hyperosmolality. Osmotic agents, such as mannitol and glycerol, increase serum osmolality, lowering CSI· production temporarily by about 50%. However, none of these measures is effective in the long-term reduction of CSF production. Agents that interfere with the action of ATPase reduce CSF production. Digitalis has an effect on rate of production of the CSF, but ouabain, which is a more effective agent experimentally, is too toxic for use in patients.

Capillaries, which have ATPase on the abluminal surface, are a source of extraehoroidal ISF production (Figure 65.4). Gray matter has a dense neuropil that restricts water flow, whereas white matter is more regularly arranged, making it a natural conduit for normal flow of ISF and for movement of edema in pathological conditions. Under the pressure gradient maintained by capillary ISF production, bulk flow of fluid occurs in the white matter.

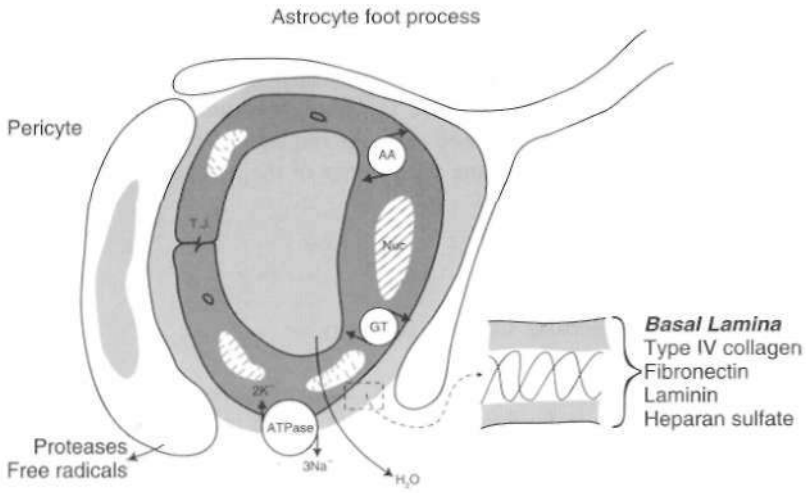
Advances in the speed of obtaining magnetic resonance images (MRI) have permitted the imaging of the diffusion of water. Normally there is a low level of water diffusion. When the cells swell and the movement of water molecules is slowed in the restricted extracellular space, the rate of water diffusion decreases. This appears as an abnormal region on the diffusion-weighted image (DWI). In cerebral ischemia, the DWI is abnormal very shortly after the onset of the ischemia, making this an excellent diagnostic test for the presence of cerebral ischemia. Another advance in nuclear magnetic resonance (NMR) technology is the development of proton NMR spectroscopy, which is a method to show biochemical abnormalities in the tissues. During an ischemic event, the signal from N-acetylaspartate falls and that from lactate increases. Combining DWI with NMR spectroscopy allows for identification of the damaged regions and increases the accuracy of spectroscopy (Carhuapoma et al. 2000).

Ependymal and Pial Surfaces

Lining the cerebral ventricles is a layer of ependymal cells with cilia. Pial cells line the surface of the brain, forming a limiting glial membrane. Cap junctions (zona adherens) are found between the ependymal cells that line the cerebral ventricles and the pial cells of the cortex. Fluid, electrolytes, and large protein molecules move through the gap junctions, allowing exchange between the CSF and ISF. Intrathecal administration of antibiotics and chemotherapeutic agents has been used to bypass the BBB. After injection into the CSF space, large proteins penetrate the perivascular spaces of Virchow-Robin, These perivascular routes may be important in the spread of infection into the brain from the subarachnoid space. Virchow-Robin spaces provide a conduit for substances in the subarachnoid space to enter brain.

Arachnoid Granulations and Absorption of Cerebrospinal Fluid

\raclrioid y,iin:i,i:inns pacchionian ;,;mnillations) are the major sites for the drainage of CSF into the blood. They protrude through the dura into the superior sagittal sinus and act as one-way valves. As CSF pressure increases, more fluid is absorbed. When CSF pressure falls below a threshold value, the absorption of CSF ceases (Figure 65.5). In this way, the CSF pressure is maintained at a constant level, with the rate of CSF production as one determining factor.



FIGURK (VS.4 The cerebral capillary is a fluid-secreting, epithelial-like cell with a high metabolic rate. The Na/K ATPase pump on the apical surface forms CSF. There are tight junctions between the endothelial cells that maintain the electrical resistance, A large number of mitochondria are seen in the capillary. Amino acid and glucose transporters are present. Around the cell is a basal lamina composed of type IV collagen, laminin, fibronectin, and heparan sulfate. Astrocytic end-feet form a glia limitans around the cells. Pericytes are maemph age-like cells that have microglia-type functions in the perivascular space.

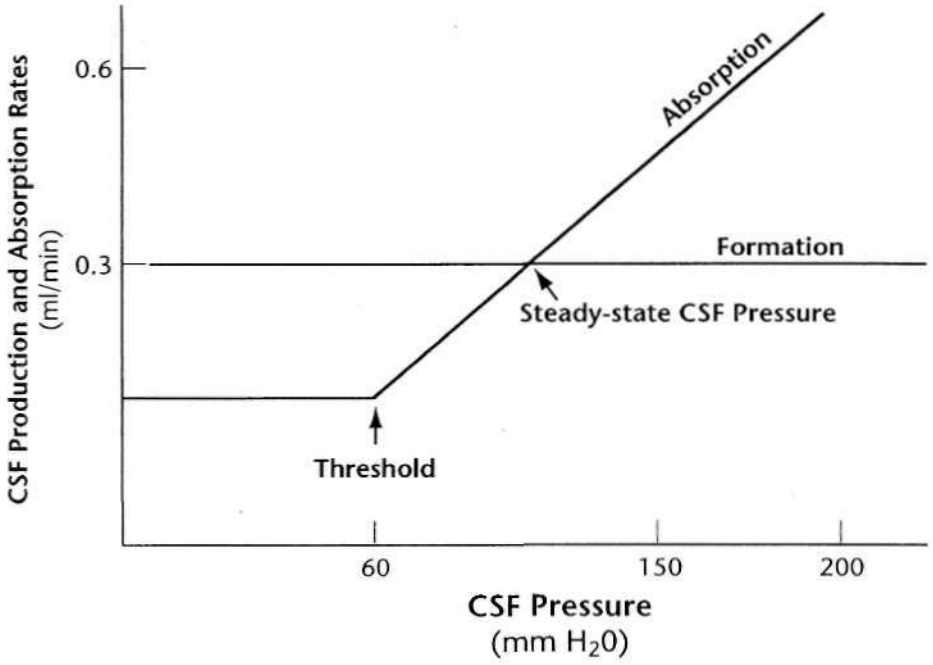


FIGURE 65.5 Schematic drawing of the relationship of cerebrospinal fluid (CSF) formation and absorption to pressure. CSF is formed at a constant rate of 0.35 mL per minute. Absorption begins above a threshold value that varies from person to person. Once CSF absorption begins, it is linear, as seen in a one-way valve. When formation tate equals absorption rate, the steady-state CSF pressure is determined. (Modified with permission from Cutler, R. W., Page, L, Galickh, J,, Waiters, G, V. 1968, "Formation and absorption of cerebrospinal fluid in man," *Brain,* vol. 91, pp. 707-720.)

Although channels are seen in the arachnoid granulations, actual valves are absent. The tissue appears to collapse around the channel as the pressure falls, and the channels enlarge as the pressure rises. Resistance to the outflow across the arachnoid granulations leads to elevation of the CSF pressure. Substances can clog outflow channels and increase resistance to CSF absorption. Blood cells are trapped in the arachnoid villi, and subarachnoid hemorrhage causes a transient increase in CSF pressure and can occasionally lead to hydrocephalus. Similarly, white blood cells from meningitis can increase CSF pressure.

Cerebrospinal Fluid Pressure

For more than 100 years, lumbar puncture has been used to measure CSF pressure, obtain CSF for diagnosis, and inject drugs. With the patient in the lateral recumbent position, a narrow-bore spinal needle is used to perform a lumbar puncture. An opening CSF pressure is measured with a manometer attached to the needle. Occasionally, the lumbar sac cannot be punctured, and the examination is done in the sitting position or under fluoroscopic guidance. Under those circumstances, the CSF pressure is difficult to measure. Normal CSF pressure is 80—I 80 mm H2O. Three components contribute to the measured pressure: volume of blood within the cranial cavity, amount of CSF, and the brain tissue. According to the Monro-Kellie doctrine, enlargement of any of these compartments causes an increase in CSF pressure due to the constraints imposed by the bony cavity of the skull.

The CS1 prewj-c recorded by [!u- manometer represents the venous pressure transmitted from the right side of the heart through the venous sinuses. Small fluctuations from the cardiac systolic pulse and larger fluctuations from respirations take place in the fluid in the manometer. Because veins are thin-walled structures, venous pulsations cause fluctuations in CSF pressure. Arteries with thick elastic walls dampen the pulsations from arterial pressures. Therefore, an increase in CSF outflow pressure at the sagittal sinuses, as occurs when pressure within the thoracic cavity increases, results in an increase in the CSF pressure. Deep respirations cause wide fluctuations in the CSF pressure, whereas changes in artetial pressure are barely visible. As intracranial pressure rises, tissue compliance falls, and reserve capacity of the intracranial contents is lost. At that point, small changes in fluid volume may lead to large increases in intracranial pressure. Patients with increased intracranial pressure have been continuously monitored with catheters placed in brain or into the cerebral ventricles or with bolts placed on the dura, Pathological elevations in intracranial pressure cause Lundberg A or B plateau waves that increase in steps to 50 mm Hg, where they persist for up to 20 minutes before returning to baseline. Treatment of patients with raised intracranial pressure is often monitored at the bedside. Monitoring is used to gauge response to the osmotic agents and to determine the severity of the head injury.

BRAIN EDEMA

Molecular Cascade in Injury

Cerebral edema occurs in many neurological diseases. Excess fluid can accumulate in the intracellular or extracellular spaces, A convenient classification separates brain edema into cytotoxic or vasogenic. Cytotoxic edema is

cellular swelling; vasogenic edema is blood vessel leakage. Another category has been proposed, namely, interstitial edema, which represents transcpcndymal flow of CSF in hydrocephalus. Rarely is the separation into distinct categories possible because there is often overlap between the various types of edema.

Vasogenic edema expands the extracellular space in the while matter. Cytotoxic edema, which results from pathological processes that damage cell membranes, constricts the extracellular spaces. Cellular and blood vessel damage follows activation of an injury cascade. The cascade begins with loss of energy ami glutamatc release into the extracellular space (Figure 65.6). This occurs during a hypoxic, ischemic, or traumatic injury and causes cytotoxic damage. Calcium and sodium entry channels on cell membranes are opened by glutamatc stimulation. Membrane ATPase pumps extrude one calcium ion in exchange for three sodium ions. Sodium builds up within the cell, creating an osmotic gradient and increasing cell volume by the entry of water. While the cell membrane is intact, the increase in water causes dysfunction but not necessarily permanent damage. Finally, hypoxia depletes the cell's energy stores, disabling the sodium-potassium ATPase pumps and reducing calcium removal from inside the cell by the sodium-calcium exchange channels. Accumulation of calcium ions within the cell activates intracellular cytotoxic processes, leading to cell death. An inflammatory response is initiated by the formation of immediate early genes, such as *c-fos* and *c-jun,* and cytokines, chemokines, and other intermediary substances. Microglial cells are activated and release free radicals and proteases, which contribute to the attack on cell membranes and capillaries. Irreversible damage to the cell occurs when the integrity of the membrane is lost. Free radicals are pluripotential substances that are produced in the ischemic brain and after traumatic injury. The arachidonic acid cascade produces reactive oxygen species, such as superoxide ion, hydrogen peroxide, and hydroxyl ion. Release of fatty acids, such as arachidonic acid, provides a supply of damaging molecules. Superoxide dismutase-1 and catalasc are the major enzymes that catalyze the breakdown of reactive oxygen species. Other defenses include glutathione, ascorbic acid, vitamin E, and iron chelators, such as the 21-amino steroids. Transgenic mice that overexpress the superoxide dismutase-1 gene have smaller ischemic lesions than controls (Gasche et al. 2001).

Nitric oxide (NO) is also a source of free radicals. NO synthetase (NOS) has three forms: neuronal NOS (nNOS), endothelial NOS (eNOS), and inducible or immunological NOS (iNOS). Macrophages and activated microglial cells form NO through the action of iNOS in response to ischemia, injury, and inflammatory stimuli. NO acts both as a normal vasodilator of blood vessels, by release of cyclic guanosine monophosphate in smooth muscle, and as a toxic compound in pathological conditions. Peroxynitrite anions (ONOO~) are formed from the reaction of NO with superoxide anions. Manipulation of the NOS gene has helped reveal the action of the enzyme. The free radical nNOS produces toxic free radicals early in ischemic injury. Deletion of the nNOS gene in transgenic mice results in smaller infarcts from middle cerebral artery occlusion. On the other hand, eNOS causes vasodilatation and increases cerebral blood flow. Removing the eNOS genes leads to increased infarct size. Inflammation induces iNOS, which reaches a maximum at 24 hours,

Vasogenic Edema and the Ncuroinflammatory Response

Capillary injury results in opening of the BBB, with leakage of protein and fluids into brain tissue. Vasogenic edema moves through the white matter. Opening of the BBB could occur by loosening of tight junctions, development of pinocytotic vesicles in the endothelial cell, or an alteration

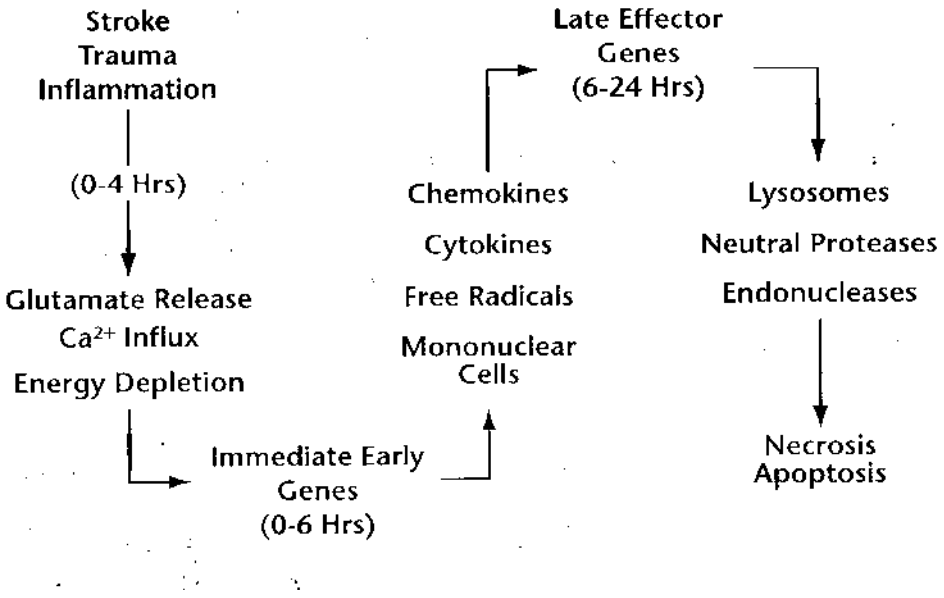

FIGURE 65.6 Mechanisms of ischemic-hypoxic injury leading to cell swelling and death. The chart shows the time course of the early events involving glutamatc release, immediate early gene production, and energy failure. This, leads to changes in electrolytes and initiation of the inflammatory response. Cytokines continue the damage that results in opening of the blood-brain barrier. Chemokines attract white blood cells to the injury site, where they release free radicals and proteases and enhance the injury. Finally, the proteases attack structural components, leading to membrane damage and cell death.

in the substrates surrounding the capillaries. Opening of tight junctions between cells has been observed after the infusion of hyperosmotic solutions. There is little evidence to support enhanced pinocytosis. Potentially toxic substances that may injure the capillary and the extracellular matrix include free radicals, cytokines, and proteases. Ftee radicals from oxygen and nitrogen can increase the permeability of the capillary. Cytokines have also been shown to have toxic effects on blood vessels, particularly tumor necrosis factor-a (TNF-a}. Several proteases damage the capillary.

Late effector genes arc activated by immediate early genes, such as *c-fos* and *c-jun,* free radicals, and cytokines. Proteases are produced that can attack substrates in the capillary and in the extracellular matrix around it. Neutrophils and macrophages enter the injury site through the blood vessel in response to a variety of injuries. The invading cells release proteases contained in the white blood cells, such as the matrix mctalloproteinases. The en/Miirs in;iK;- tlie wink[1] Mood tells In [vn-tr.ik- the capillary wall. Neutrophils release free radicals in the respiratory burst. Elastases and cathepsin are also released by neutrophils.

Astrocytic foot processes are attached by integrins to the basal lamina surround cerebral capillaries. Beneath and next to the astrocytes ate pericytes, which arc macrophage-like cells. Neutral proteases, such as serine proteases and matrix metalloprotcinascs, attack the extracellular matrix around capillaries. Brain cells make proteases. Astrocytes constitutively secrete the matrix metalioproteinase, gelatinase A or 72-kD type IV collagenase. Microglia secrete the inflammatory matrix metalioproteinase gelatinase B or 92-kD type IV collagenase. Proteases are secreted in latent forms and require activation. Free radicals and other proteases have been implicated in the activation of the gelatinases. Other proteases that may be released during the inflammatory process include elastases, plasmin, and cathepsin. Elastases are released from microglia cells and from invading neutrophils. Plasmin is generated in glia cells by plasminogen activators,

When an activated form of the 72-kD type IV collagenase is injected i ntra cere bra lly into rat brain, the BBB is opened. This reaction can be blocked by the tissue inhibitor ot metal loproteinase-2 and by synthetic metatloptoteinase inhibitors. During an ischemic injury produced by permanent occlusion of the middle cerebral artery, increased levels of gelatinase B are found around 24 hours after the occlusion. Gelatinase A increases approximately 5 days later, when the urokinase-type plasminogen activator is also elevated (Yong et al. 2001). Because of the highly disruptive properties of these hydrolytic enzymes, they arc tightly regulated by tissue inhibitors of metalioprotein-ases and plasminogen activator inhibitors (Cuzner and Opdenakker 1999). Hemorrhagic transformation occurs commonly after a stroke, particularly when ischemic tissue is reperfused. Proteolytic enzymes active in vessel regrowth, and extracellular matrix remodeling may be involved. Free radicals and proteases can damage cell membranes independently or can act in concert. Nitric oxide activates latent gelatinase B (Gu et al. 2002). Reactive oxygen species affect the production of the inflammatory matrix metallo-proteinases, whereas peroxynitrate activates gelatinase A. Because both free radicals and proteases are induced in injured brain tissue, separation of their individual effects in vivo has not been done.

Infection, Ischemia, and Inflammation

Bacterial meningitis initiates an inflammatory response in the meninges caused by the invading organisms and by the secondary release of cytokines and chemokines. The secondary, inflammatory response may aggravate the infection. Cytokines, including TNF-o and interleukin-6, are elevated in the CSF of patients with bacterial meningitis and contribute to the secondary (issue damage. Matrix metalloproteinases are increased in bacteria! meningitis, and matrix metalioproteinase inhibitors block the damage secondary to injection {Leib et al. 2001). Diagnosis of infections of the CNS has been aided by polymerase chain reaction (PCR) to detect messenger RNA from infectious agents. Herpes simplex encephalitis can be rapidly diagnosed by PCR. Patients with acquired immunodeficiency syndrome frequently have opportunistic CNS infections. Use of PCR assays helps to separate various causes, including toxoplasmosis, Epstein-Barr virus, and JC virus.

Cytotoxic Brain Edema

Cytotoxic edema is induced by stroke, trauma, and toxins. After a stroke, brain water increases rapidly due to energy failure and loss of ATP. Cytotoxic edema worsens for 24 to 48 hours, raising the danger of brain herniation (Figure 65.7). Capillary injury also takes place as part of the inflammatory phase. Vasogenic edema develops because of opening of the BBB. Reperfusion of brain after an ischemic insult increases brain edema. In animal studies of reperfusion injury after a stroke, there is a biphasic opening of the BBB. The first opening occurs several hours after reperfusion. This could be due to hyperemia, the activation of proteases, or the producrion of free radicals. The barrier then closes for an extended period before a second opening of the BBB occurs around the second day. This delayed opening is associated with activation of microglia and influx of inflammatory cells; multiple proteolytic enzymes and free radicals arc active at that time (Rosenberg et al. 1998). When oxygen is reintroduced into the tissue by reperfusion, brain edema occurs more rapidly, with a greater increase in water content. The effect of reperfusion on the capillary depends on multiple factors, including the time of occlusion and of reperfusion.

Intracerebral hemorrhage causes brain edema around the hemorrhagic mass. The edema is both cytotoxic due to the direct damage to the cells and vasogenic secondary to the inflammatory response induced by the toxic blood products. Growth of the hematoma has been seen in 38% of patients that were imaged shortly after the onset of hemorrhage and again within 24 hours. The injury that leads to the hemorrhagic mass goes through several stages. The initial stage is the disruption of the blood vessels with extravasation of the red blood cells into the brain. Upon lysis of the red blood cells, the second stage begins during which toxins are released into the surrounding tissues, amplifying the inflammatory response. Thrombin and plasminogen activators are major causes of tissue damage by rhe lysed red blood cells (Xi et al. 2001). The final stage is one of tissue compression by the fully formed mass lesion. The rate of progression through the various stages is variable and depends on the underlying pathology.

Stroke is the major cause of btain edema in the adult due lu the high incidence nl cerebral ischemia in the I'IIIITIV. Other causes include acute hepatic failure, hypoosmolality, exposure to toxins, and high altitude. In acute hepatic failure, the cerebral edema may cause death. Patients with hepatic failure are ofren young and have an acute cause for the liver failure. They may have overdosed on a drug that is toxic to the liver, such as acetaminophen, or they may have infectious hepatitis. Long-standing liver disease with cirrhosis and hepatic encephalopathy shows changes of astrocytes in the brain, but it is generally not complicated by cerebral edema. Reye's syndrome, which is seen primarily in children after an influenza infection, particularly when they are treated with aspirin, has a high incidence of brain swelling. Because of the restriction on use of aspirin in children, the number of cases of postinfluen/.a hepatic encephalopathy has dramatically declined. The mechanisms involved in the production of cerebral edema with acute hepatic disease are poorly understood (Rao and Norenberg 2001).

Rapid elevation of blood pressure causes hypertensive encephalopathy. In experimental animals, hyperemia is

present, suggesting that the blood vessels are dilated and have increased permeability. Confusion, focal findings, seizures with papilledema, and increased CSF protein are present in some patients with hypertensive encephalopathy. MRI has shown a vasogenic edema in the posterior white matter of the brain (Figure 65.8). Rapid elevations of blood pressure can occur with kidney disease and in eclampsia. The changes are transient unless hemorrhage or infarction occurs, which can be distinguished by the combination of TV weighted abnormalities on MRI with the presence of a lesion on diffusion-weighted MRI (Covarrubias et al. 2002). Rapid reduction in blood pressure is necessary. The reason for the involvement of the posterior circulation in this syndrome is uncertain. Eclamptic patients may have visual disturbances. In the rare autopsied patients, petechial hemorrhages may be seen in the occipital lobes, explaining the visual symptoms.

Another cause of cerebral edema is a rapid change in scrum osmolality. For example, parients treated for diabetic ketoacidosis, with rapid reduction of plasma glucose and sodium, are at risk for edema secondary to water shifts into the brain (Bohn and Dancmau 2002). Long-standing hyperosmolality leads to solute accumulation in brain to compensate for the hyperosmolar plasma levels. These idiogenic osmoles are thought to include taurine and other amino acids. Once formed, they are slowly removed from the brain. When blood osmolality is reduced, water follows the osmotic gradient, resulting in cerebral edema. Rapid reduction of serum hyperosmolality, as in diabetic ketoacidosis, should be avoided to prevent brain edema due to the residual idiogenic osmoles (Edge et al. 2001). Dialysis disequilibrium may also be due to an osmotic imbalance that results from urea buildup in brain tissue. Rapid correction of chronic serum hyponatremia can cause central pontine myelinolysis. In this syndrome, patients have very low sodium levels, which are usually less than 120 mEq/L, secondary to a variety of causes, including excessive water drinking, anorexia nervosa, alcohol withdrawal, and inappropriate secretion of antidiuretic hormone. Low sodium can sometimes be tolerated when it develops slowly,

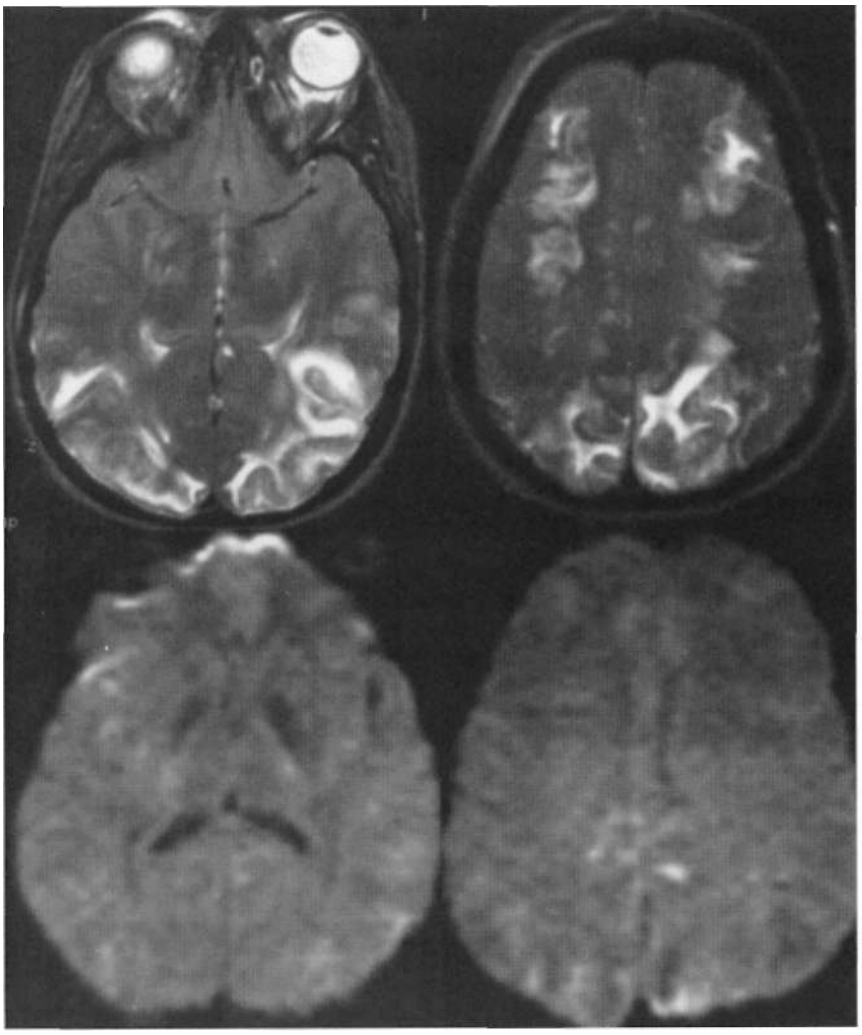

FIGURE 65.8 Patient with hypertensive encephalopathy secondary to eclampsia with the HELLP (hemolysis, elevated liver enzymes, and low platelets) syndrome. (A) A T2-weighted MRI showing the extensive cerebral edema in the posterior white matter regions with less involvement of the gray matter. (B) A higher level of the same scan sequence as in A, showing some frontal lobe involvement. (C and D) Diffusion-weighted images (DW1) with only one small area of involvement. The lack of DWI dianges is consistent with this being a vasogenic type of edema, and the patient had a good recovery without residual deficits. (Courtesy Blaine Hart, MD.)

but in the acute situation, coma may develop. As the sodium is corrected, water accumulates in the brain white matter tracts. The pontine white matter tracts are involved, and occasionally the involvement can extend into the internal capsule regions to cause a more diffuse myelinolysis.

Cerebral edema is a complication of acute mountain sickness, which in rare circumstances may be life threatening (Hackett and Roach 2001). Cerebral symptoms are prominent, and there is an increase in cerebral blood volume related to the hypoxia. Raised intracranial pressure causes headaches, ataxia, and confusion. Papilledema has been seen in people with high-altitude cerebral edema. MRI shows changes in the white matter, particularly the corpus callosum with involvement of the splenium, which may accompany high-altitude pulmonary edema. When hypoxia occurs along with extreme exertion, hyperventilation may lead to a drastic reduction in carbon dioxide, resulting in reduced blood flow and the possibility of cerebral ischemia due to vasoconstriction. Paradoxically, rebreathing carbon dioxide was shown to improve symptoms and cerebral blood flow.

Occlusion of the venous sinuses draining the brain can cause increased intracranial pressure and venous hemorrhagic infarction. When the superior sagittal sinus is involved, there may be extensive infarction in both hemispheres (Figure *65.9).* Dehydration and hypercoagulable states are often found in such patients. The early symptoms may be subtle with headache secondary to increased intracranial pressure. As the infarction develops, however, other symptoms, such as seizure, develop, leading to hemorrhagic conversion of the infarction, herniation, and death. There may be negative CT scan in the early stages thar will confound diagnosis. Some patients will recanalize the superior sagittal sinus and may have an excellent outcome (Figure 65.10).

Treatment of Brain Edema

Treatment of brain edema has not kept up with the advances in understanding the mechanisms producing the edema. Reduction of volume in one of the three compartments may be helpful. Blood volume can be reduced with hyperventilation, which lowers carbon dioxide. However, excessive hyperventilation, which can be dangerous, should be avoided. Reduction of CSF volume can he done mechanically by placing a drainage catheter into one of the ventricles. This can he difficult when the cerebral edema has compressed the ventricular system. Intraventricular drainage is mainly used in patients with head injuries, acute hydrocephalus, or postsurgically. Agents that reduce the production of CSF, such as acetazolamide or diuretics, may be used, but are of marginal benefit.

For many years osmotic therapy has been the treatment of choice to temporarily lower intracranial pressure. Initially, urea was used, but the small molecule entered the brain, causing rebound edema. Current osmotic treatment is done primarily with mannitol, which reduces brain volume, lowers CSF production, and improves cerebral blood flow. Osmotherapy with low doses of mannitol infused ovet several days lowers intracranial pressure. Earlier studies employed 3 g/kg of mannitol, which had a dtastic effect on the serum electrolytes and permitted only one or two doses to be given. More recently, it was found that low doses of mannitol (0.25-1.0 g/kg) are as effective as the higher doses without affecting the electrolytes. The lower doses taised the serum osmolality slightly, suggesting that the agent had several mechanisms of action. The effect of the small change in the osmolality is to reduce the brain tissue volume; the effect is more prominent in the noninfarcted than in the infarcted hemisphere (Videcn ct al. 2001). Other effects are that mannitol reduces CSF and ISF secretion by 50%, which may contribute to its action. Some investigators have proposed that mannitol hyperosmolality alters the theological properties of blood, whereas others have noted an antioxidant effect. Prolonged administration of mannitol results in an electrolyte imbalance that may override its benefit and that must be carefully monitored. Although mannitol is often used in acute stroke, its efficacy has not been proven.

Corticosteroids lower intracranial pressure primarily in vasogenic edema because of their beneficial effect on blood vessel permeability. They have been less effective in cytotoxic edema, howevet, and are not recommended in the treatment of edema secondary ro stroke or hemorrhage, hi fact, systemic complications of corticosteroids can worsen the patient's condition in the treatment of patients with intracerebral hemorrhage. Edema surrounding brain tumors, particularly metastatic brain tumors, responds dramatically to treatment with high doses of dexamethasonc. The corticosteroid closes the BBB rapidly. Hence, it is important to obtain contrast-enhanced MRl or CT scans before treatment with cotticosteroids; otherwise, enhancement of the lesion may be missed. High doses of corticosteroids have been shown to be effective in brain edema secondary to inflammation in multiple sclerosis.

Opening of the BBB is frequently seen on MRI with gadolinium contrast in patients with multiple sclerosis (Noseworthy ct al. 2000). The opening of the BBB is associated with elevated levels of the proinflammatory cytokine, TNF-or. Inflammatory lesions, such as those that occur in acute attacks of multiple sclerosis, respond well to high-dose methylprednisolone. Treatment with 1 gram per day of methylprednisolone for 3-5 days reduces the inflammatory changes in the blood vessels during an acute exacerbation. Dramatic reduction in enhancement on MRI may he seen after treatment. However, the effect is lost after several months.

IDIOPATHIC INTRACRANIAL HYPERTENSION

Before the advent of CT scanners, the complaint of headache and the finding of papilledema raised the suspicion of hydrocephalus or tumor. When tests were negative for either of these conditions, the condition was called otitic hydrocephalus or pseudotumor cerebri. The latter term has remained in use along with benign intracranial hypertension. None of these terms is satis-factory, and the descriptive term, idiopathic intracranial hypertension (OH) is preferred,

Clinical features

Patients with IIH have headaches that are diffuse, worse at night, and often wake them from sleep in the early hours of the morning. Sudden movements, such as coughing, aggravate headache. Headaches may be present for several months before a diagnosis is made. Some patients complain of dizziness. Transient loss of vision (transient obscuration) may occur with change of position. Visual fields may show an enlarged blind spot due to the encroachment of the swollen nerve head into the region of the macula. Prolonged papilledema may lead to sector scotomas and, rarely, vision loss. Damage to one or both sixth cranial nerves may occur as an effect of shifts of cerebral tissue; because the sixth cranial nerve is remote from the site of the process producing intracranial hypertension, the cranial neuropathy is a false localizing sign.

Diagnosis requires ruling out other causes of increased intracranial pressure. All patients require a CT or MRI scan to look for hydrocephalus and mass lesions. After a mass lesion is ruled out, lumbar puncture is needed with careful attention to accurately measuring the CSF pressure, which must be elevated by definition. Characteristic findings in the CSF include normal or low protein, normal glucose, no cells, and elevated CSE pressure. The upper limit for normal CSF pressure is above 180 mm H_20, and most IIH patients will have readings well above 200 mm H_20. Measurement of CSF pressure should be done with legs extended and neck straight. Movements of the fluid column with respiration should be seen to confirm proper placement of the needle. It is important to obtain an accurate pressure reading at the time of the initial lumbar puncture because die diagnosis is made by the presence of increased CSF pressure. Measurements of pressure in subsequent lumbar punctures may be influenced by the loss of fluid during the first puncture.

IIH occurs more frequently in women than in men. Obesity and menstrual irregularities, with excessive pre-menstrual weight gain, are often present. Headache, often worse in the morning, is the main complaint. Because many illnesses are associated with IIH, a search for an underlying cause is essential before the diagnosis is made by exclusion. MR] has rekindled interest in conditions that cause occlusions of the venous sinuses. When the sinuses draining blood Irniv. the brain are obstructed, absorption oi CS1 is reduced, causing the pressure of the CSF to increase. MR venography is better for showing the thrombosis of the sinuses than conventional MRI. The role of venous sinus obstruction in III I, although important to rule out, may be limited. Hypercoagulable states should be looked for in patients with venous sinus obstruction.

Obesity is often found in women with IIH. Endocrine abnormalities have been extensively investigated in both obese and nonobese subjects, but none has been identified. Drugs associated with the syndrome include tctracycline-type antibiotics, nalidixic acid, nitrofurantoin, sulfon-amides, and trimethoprim-sulfamethoxazole (Table 65.4). Paradoxically, the withdrawal of corticosteroids, which are used to treat increased intracranial pressure, can cause an increase in intracranial pressure. Large doses of vitamin A, which are used in the treatment of various skin conditions, may cause the syndrome. Hypcrcapnia leads to retention of carbon dioxide and increase in blood volume. Sleep apnea and lung diseases may cause headaches and papilledema due to this mechanism. Less frequent causes include Guillain-Barrc syndrome, in which IIH may be due to an increase in CSF protein or an inflammatory response. Uremic patients have an increased incidence of papilledema with IIH. Patients with renal failure have increased levels

of vitamin A, use corticosteroids, and take cyclosporine, which have all been linked to 11H.

Cerebral edema was seen in one patient with early I1H, who had a brain biopsy at the time of subtemporal decompression, .1 treatment that is no longer used. However, two IIH patients who came to postmortem examination had no histological evidence of cerebral edema. Blood volume is increased and cerebral blood flow decreased. CSF circulation is impaired. Diseases that chronically raise cerebral venous pressure often produce increased intracranial pressure without increased ventricular size. The primary sites of obstruction may be the superior vena cava, jugular veins, or large cerebral veins. Increased superior sagittal sinus or transverse sinus pressure has been reported in IIH. Many investigators favor an elevation of dural venous sums pressure as a reasonable mechanism.

Treatment

Treatment involves reducing intracranial pressure. Acetazolamide is an inhibitor of carbonic anhydrase that lowers CSF production and pressure. It is given in a dose of 250 mg twice daily, which may be increased to 1 g per day. Occasionally, higher doses may be needed. Electrolytes must be monitored to look for metabolic acidosis. Distal paresthesias are reported to occur in up to 25% of patients. The hyperosmolar agent, glycerol (0.25-1.00 g/kg two or three times daily), and the diuretic, furosemide (20-60 mg daily), have also been used to lower intracranial pressure. Corticosteroids reduce increased intracranial pressure, but the pressure may increase when they are tapered. Drug effects are often transient, and when the syndrome does not resolve spontaneously, other treatments are needed. Although the relationship of obesity to IIH is uncertain, loss of weight can lead to resolution of the syndrome, and some patients have undergone surgical stomach size reduction to control the obesity.

Visual fields should be measured and the size of the blind spot plotted. When the papilledema spreads into the region of the macula, visual acuity falls, and in extreme cases, blindness may occur. Although most patients with IIH retain normal vision, a small percentage of patients develop impairment of vision. When vision is threatened, and drugs and lumbar punctures do not lower the CSF pressure, surgical intervention is necessary. Lumboperitoneal shunting has a reportedly high success rate. However, shunt malfunction is c 01111:1011 in lui:ibopci':lnii;\il •.hmils. Fenestration of the optic nerve sheath to drain CSF into the orbital region reduces the intracranial pressure, and some consider it the treatment method of choice in medically refractory patients. In the obese patients with IIH, weight loss is an important adjunct treatment, and some authors argue that it is as important as acctazolamide.

HYDROCEPHALUS

Obstruction of drainage of the CSF causes hydrocephalus, which is defined as enlargement of the ventricles. Although detection of enlarged ventricles has been greatly aided by CT and MRI, the separation of ventricular enlargement due to hydrocephalus from that due to loss of brain tissue remains .1 challenge. In carls life, obstruction oi the ventricular outflow most commonly occurs in the aqueduct, leading to noncommunieating hydrocephalus, while in the elderly, resistance to drainage of the CSF after the exit into the subarachnoid space results in a communicating hydrocephalus. Enlargement of the cerebral ventricles in children younger than 2 years produces enlargement of the head circumference because the skull sutures are still open. Children with bead growth that is more rapid than expected for age are suspected of having hydrocephalus and are imaged. In the elderly, the onset of symptoms may be gradual, beginning with problems of gait and intellect, which can suggest many different diagnoses. Obstruction prior to the outflow of CSF at the foramina of Luschka and Magendie results in a noncommunieating type of hydrocephalus, whereas in the communicating type of hydrocephalus, enlargement of the ventricles takes place with preserved flow of CSF between the ventricles and the subarachnoid space. Obstruction of CSF circulation may result in increased CSF pressure as the cerebral ventricles enlarge.

Acute, noncommunieating hydrocephalus develops rapidly, reaching 80% of maximal ventricular enlargement within 6 hours. A slower phase of enlargement follows the initial rapid expansion, and ventricular enlargement plus continual production of CSF causes fluid accumulation in the petiventricular white matter interstitial space. When the hydrocephalus stabilizes and enters a chronic phase, the CSF pressure may decrease, resulting in normal pressure recordings on random measurements. Atrophy may occur in the chronically hydrocephalic white matter. When the rate of ventricular enlargement stabilizes in patients with incomplete ventricular obstruction, CSF production is balanced by absorption at alternate sites. This time course is unpredictable, and occasionally, patients assumed to have arrested hydrocephalus can undergo acute decompensation after many years of apparent stability.

Hydrocephalus in Children

Hydrocephalus in children is often due to a structural abnormality, such as Chiari I or II malformation, congenital aqueducts I stenosis, aqueductal stenosis due to intrauterine infection or other congenital causes, such as anoxic injury, intraventricular hemorrhage, and obstruction of the CSF pathways after bacterial meningitis. Bulging of the anterior fontancllc may be seen, along with thinning of the skull and separation of the sutures. If the diagnosis is

delayed, abnormal eye movements and optic atrophy may develop. Spasticity[7] of the lower limbs may be observed at any stage. Acute enlargement of the ventricles is associated with nausea and vomiting.

During the neonatal and early childhood period, irritability is the most common symptom of hydrocephalus. The child feeds poorly, appears fretful, and may be lethargic. In the older child, headache may be a complaint. Vomiting due to increased intracranial pressure may be present in the morning. Remote effects of the increased pressure may affect the sixth cranial nerves on one or both sides, leading to the complaint of diplopia. The enlarged ventricles affect gait. A wide-based ataxic gait may be present due to the stretching of the white matter tracts from the frontal leg regions around the ventricles.

Premature infants weighing less than 1500 g at birth have a high risk of intraventricular hemorrhage, and approximately 2.5% of these infants develop progressive ventricular enlargement, as shown by CT or ultrasound scans. Ventricular size in the neonate may be followed at the bedside with B-mode ultrasound through the open fontanellc. Long-term follow-up studies of children with intraventricular hemorrhage due to prematurity show that 5% require shunting for hydrocephalus. The survivors of a large germinal plate hemorrhage often have multiple disabilities.

Before the widespread availability of antibiotics and vaccinations, meningitis was a frequent cause of hydrocephalus in children. Often, there was concurrent cerebral infarction, resulting in brain atrophy with ventricular enlargement. Separation of the atrophy from the obstructive hydrocephalus may be difficult.

Once the sutures are closed, which generally occurs by the age of 3, hydrocephalus causes signs of increased intracranial pressure rather than head enlargement. Meningitis, aqueductal stenosis, Chiari malformations, and mass lesions may be the cause of hydrocephalus in these young children. Tumors originating from the cerebellum and from the brainstem produce acute symptomatology, including headaches with vomiting, diplopia, visual blurring, and ataxia. Symptoms are due to the acute hydrocephalus secondary to obstruction of the aqueduct of Sylvius and to pressure on brainstem structures.

Examination shows papilledema, possible sixth cranial nerve palsy, and spasticity of the lower limbs. When the hydrocephalus is more long-standing, endocrine dysfunction may occur, involving short stature, menstrual irregularities, and diabetes insipidus. Excessively rapid growth of the head is the hallmark of hydrocephalus in the child before closure of the sutures. Charts are available to plot head growth and to compare it with the standardized curves for normal children. Bulging of the anterior fontanellc is found even with the child relaxed and upright. After 1 year, the firmness of the fontanellc cannot be used because the sutures have closed. Other findings include the "cracked-pot" sound on percussion of the skull (McEwen sign), engorged scalp veins, and abnormalities of eye movements. As spasticity develops, the deep tendon reflexes are increased.

Treatment involves shunting CSE from the ventricles to drain fluid into another body cavity. In very young children, the shunt is often placed in the peritoneal cavity. hi the older child, i ventriculoperitoneal shunt is generally-used. Complications of shunt placement include malfunction and shunt infection.

Adult-Onset Hydrocephalus

In the adult, symptoms of hydrocephalus include headaches, papilledema, diplopia, and mental status changes. Sudden death may occur with severe increases in pressure. Rarely, hydrocephalus causes an akinetic mutism due to pressure on the structures around the third ventricle. Other symptoms include temporal lobe seizures, CSF rhinorrhea, endocrine dysfunction {e.g., amenorrhea, polydipsia, and polyuria), and obesity, which suggest third ventricle dysfunction. Gait disturbances are reported in patients with aqueductal stenosis, but hyper-reflexia with Babinski's sign is infrequent.

Adult-onset hydrocephalus has similar causes to those in children, but the frequencies differ. As in children, acute obstruction of the ventricles results in rapidly progressive hydrocephalus with symptoms of raised intracranial pressure. Adults are more likely than children to present with an acute blockage of CSF flow by intraventricular masses, such as a colloid cyst of the third ventricle or an ependymoma of the fourth ventricle. These tumors cause sudden headaches, ataxia, and loss of consciousness with symptoms that may be intermittent due to the ball-valve effect of the masses. CT or MRI, which reveals the structural lesion in the ventricular system, can make the diagnosis.

Cerebellar hemorrhage and cerebellar infarction with edema cause an acute hydrocephalus by compression of the brainstem, occluding the aqueduct of Sylvius and fourth ventricle outflow pathways and causing noncommunicating hydrocephalus, which can be seen on CT and results in acute elevation in intraventricular pressure. Patients with cerebellar hemorrhage usually have a history of hypertension. Increasing drowsiness and difficult)' walking often follow the acute onset of headache. Hemiparesis and brainstem findings evolve after the ataxia, providing a clue that the origin of the problem is in the posterior fossa. The expanding hemorrhagic mass in the posterior fossa, if it is encroaching on the brainstem, requires urgent neurosurgical attention, with placement of a ventricular catheter to decompress the lateral and third ventricles, followed by posterior fossa craniectomy to remove the mass effect and pressure on the brainstem. In patients with cerebellar infarction, the progression is generally slower because the maximum swelling takes place in 24-48 hours, but the consequences of the enlarging posterior fossa mass are

the same as with hemorrhage, and surgery may he necessary to remove the necrotic tissues and restore the normal flow of CSF. CT is needed in the acute setting, particularly when MRI is not readily available, but visualization of the cerebellar infarction, which may be missed on the CT, is clearly seen on the diffusion-weighted scan (Figure 65.1 1).

Treatment of hydrocephalus involves an operation to insert a tube to shunt CSF from the ventricles to another body cavity, such as peritoneum (ventriculoperitoneal shunt). These devices have one-way valves that respond to pressure. In an emergency, hydrocephalic ventricles can be assessed readily due to the increase in their size. Shunt malfunction may cause abrupt decompensation. Symptoms of acute increased intracranial pressure from a shunt malfunction resemble those seen with onset of the hydrocephalic process.

Adult-onset hydrocephalus that is communicating may be due to a tumor in the basal cisterns, subarachnoid bleeding, or infection or inflammation of the meninges, but only a small percentage of these patients require insertion of a shunt. In the preantibiotic era, syphilis, tuberculosis, and fungal infections more commonly caused chronic obstruction of the subarachnoid pathways and hydrocephalus. Cultures of the CSF are indicated in the elderly patient with enlarged ventricles, and searching for other sources of infection in lungs and other organs may be helpful in establishing the type of infection.

Normal-Pressure Hydrocephalus

Chronic hydrocephalus in the adult can produce symptoms of gait disturbance, incontinence, and memory loss, with or without symptoms and signs of raised intracranial pressure, including headache, papilledema, and false localizing signs. Causes of chronic hydrocephalus include subarachnoid hemorrhage, chronic meningeal infections, and slow-growing tumors blocking the CSF pathways.

Normal-pressure hydrocephalus (NPH) is a term commonly used to describe chronic, communicating adult-onset hydrocephalus. Typically, patients with NPH have the triad of mental impairment, gait disturbance, and incontinence.

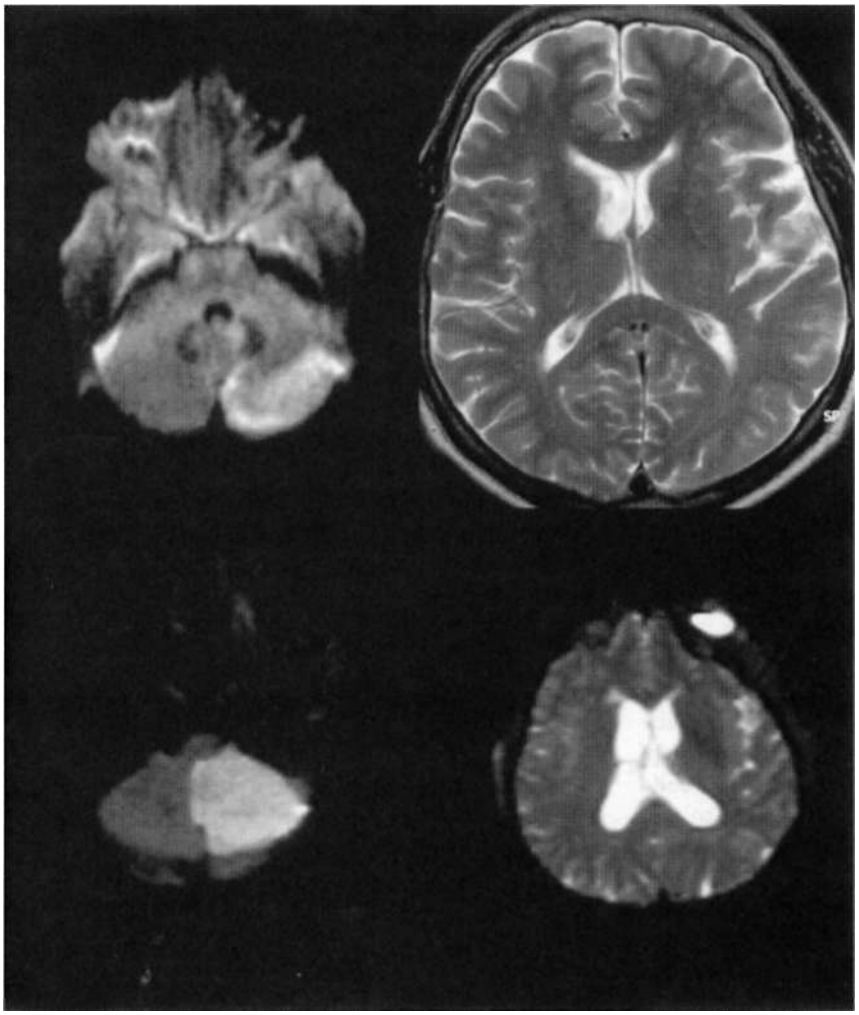

FIGURE 65.11 Cerebellar infarct with secondary hydrocephalus. (A) Initial diffusion-weighted image with cerebellar infarct in the territory of the left posterior inferior cerebellar artery. (B) Initial axial T^-weighted MR image shows n.....nil VL'iitrii ii'..ii si/.c. *C.)*] >\\ 1 3 days larer, showing swelling of the infarction in the cerebellum. ;D l.diu planar] _> .ixi.il imagu shows enlargement of the ventricles prior to surgery for hydrocephalus. (Courtesy Blaine Hart, MD.)

NPH can develop secondary to trauma, infection, or subarachnoid hemorrhage, but in about one third, no etiology is found. Enlarged ventricles ore seen on CT or MRI. By definition, lumbar puncture generally reveals a normal CSF pressure. Normal pressure is an unfortunate term because patients who have undergone long-term monitoring with this syndrome have intermittently elevated pressures, often during the night.

The presenting symptoms may be related to gait or to mental function. When gait is the presenting factor, the prognosis for treatment is better. NPH causes an apraxic gait, which is an inability to lift the legs as if they wete stuck to the floor. The motor strength is intact, reflexes are usually normal, and liabinski's sign is absent. Patients may be misdiagnosed as having Parkinson's disease because the gait disorder is similar in the two syndromes, suggesting that the etiology of the problem in the hydrocephalic patient lies in the basal ganglia. Because many of these patients also have hypertension, and some have small or large strokes, such patients may have other neurological findings, including spasticity and hyper-reflexia with Bahinski's signs. The combination of cerebrovascular disease and hydrocephalus is a poor prognostic sign for treatment with shunts.

NPH leads to a reduction in intellect, which at times may he subtle. The dementia is of the subcortical type, and involves slowing of vetbal and motot responses with preservation of cottical functions, such as language and spatial resolution. Neuropsychological testing quantitates the decline in intellect and the degree of dementia. Patients are apathetic and may appear depressed. Incontinence of urine may occur early in the coutse, particularly in patients with prominent gait disturbance. In the early stages of the illness, presumably as the ventricles are undergoing enlargement, patients can experience drop attacks ot btief loss of consciousness. Headache and papilledema are not a part of the syndrome.

Diagnosis of adult-onset NPH and selection of patients for placement of a ventriculoperitoneal shunt has been difficult (Boon ct al. 2000). Many of these patients have hypertensive vascular disease with lacunar infarcts. Featutcs of Parkinson's disease were noted in earlier reports of the syndrome, and it is now recommended that all patients with Parkinson's disease have scans to rule out hydrocephalus. CT and MRI have aided in separating Parkinson's disease, lacunar state, and NPH, although NPH may occasionally coexist with these diseases. Patients diagnosed with vascular diseases, such as lacunar state or subcortical arteriosclerotic encephalopathy (Binswanger's disease), along with the hydrocephalus respond poorly to shunting, and if there is a positive response, it may be transient as the underlying disease progresses. Selection of patients for shunting requires a combination of clinical findings and diagnostic test results, because no test can totally predict whether a patient will likely benefit from an operation.

There may be a correlation between improvement in gait after removal of CSF and improvement after shunting. Cisternography is a useful procedure that involves the injection of a radiolabeled tracer into the CSF with monitoring of its absorption for 3 days. Normally, the radiolabeled material fails to enter the ventricles, moving over the convexity of the brain and leaving the CSF space within 12-24 hours. In patients with large ventricles due to atrophy, there may be a delay in circulation time, with some isotope being seen in the ventricles during the first 24 hours. Communicating hydrocephalus with abnormal CSF circulation shows pctsistent ventricular filling for more than 48 hours. In patients with NPH, there is reflux of the tracer into the cetebral ventricles by 24 hours and retention in the ventticles for 48-72 hours. This suggests that transependymal absorption is occurring and that pcriventricular white matter has become an alternate route of CSF absorption. A positive cisteruogram is seen in some patients with hypertensive cerebrovascular disease and Binswanger's encephalopathy because of the overlap in the three syndromes.

CI and MRI in Nll'l I -hov. thai the temporal horns i>i' the lateral ventricles are enlarged and that cortical atrophy- is less than anticipated fot age. This is in contrast to patients with hydrocephalus ex vacuo due to a degenerative disease, such as Alzheimer's disease, in which there is atrophy of the cerebral gyri and enlargement of the ventricles. Another useful finding on proton density MRI is the presence of presumed transependymal fluid in the frontal and occipital periventricular regions. Quantitative cisternography using single-photon emission CT has been successfully used to predict the results of a shunt. Other proposed diagnostic methods, including measuring rate of absorption of CSF by infusion of saline or artificial CSF into the thecal sac, clinical improvement after CSF removal, or the prolonged monitoring of intracranial pressure, have been used with some success to select patients for surgery. Decreased cerebral blood flow has been reported in NPH; regional cerebral blood flow is reduced in both cortical and subcortical regions. Patients who show clinical improvement with shunting have a concomitant increase in cerebral blood flow. Removal of CSF may result in an increase in cerebral blood flow in patients in whom NPH is likely to respond to shunt therapy.

The number of patients undergoing shunt operations at most centers has fallen as the initial enthusiasm, which resulted in many shunts and a low success fate, has waned. None of the currently available tests by themselves identifies the patients that will benefit from shunting. Most helpful is a combination of clinical signs and judiciously chosen laboratory tests.

Success rates vary between investigators, with some reports describing improvement in approximately 80% of treated patients and others reporting lower rates. Shunts for presumed NPH fail about one third of the time, and as

many as one fourth of the patients may have major complications, including a high rate of infection and subdural hematomas after shunt placement. Clearly, more information is needed to aid in the management of patients with this uncommon, but treatable, syndrome.

Chapter *66*
Developmental Disorders of the Nervous System

Harvey B. Sarnat and Laura Flores-Sarnat

EMBRYOLOGICAL AND FETAL **DEVELOPMENT OF THE** NERVOUS **SYSTEM**

Congenital malformations of the nervous system are best understood in the context of embryology. The scope of modern embryology now encompasses not only classical descriptive morphogenesis, but also the molecular genetic programming of development. *Maturation* refers both to *growth,* a measurement of physical characteristics over time, and *development,* the acquisition of metabolic functions, reflexes, sensory awareness, motor skills, language, and intellect. Molecular development is the maturation of cellular function. In the case of neurons, it includes the development of an energy production system to actively maintain a resting membrane potential, the synthesis of secretory molecules as neurotransmitters, and the formation of membrane receptors. Membrane receptors respond to various transmitters at synapses, to a variety of trophic and adhesion molecules, and during development, to substances that attract or repel growing axons in their intermediate and final trajectories. The role of homeobox genes in the differentiation of neural structures is an aspect of development recognized relatively recently. Molecular genetic data are rapidly becoming available because of intense interest in this key to understanding neuroembryology in general and neural induction in particular (Sarnat and Menkes 2000). Other aspects of current investigative interest include the roles of neurotrophic factors, hormones, ion channels, and neurotransmitter systems in fetal brain development. Many genetic models of human cerebral malformations have been created by genetic manipulation in animals, and these contribute greatly to our understanding of human dysgeneses and provide insights also into the pathogenesis of epilepsy and other functional results of dysgeneses (Chcvassus-au-Louis et al. 1999).

Maturation progresses in a predictable sequence with precise timing. Insults that adversely affect maturation influence events occurring at a particular time. Some insults are brief (e.g., a single exposure to a toxin), whereas others act over many weeks or throughout gestation, such as some congenital infections, diabetes mellitus, and genetic or chromosomal defects. Even brief insults may have profound influences on later development, by interfering with processes essential to initiate the next stage of development, so that the timing of an adverse event often is difficult.

The anatomical and physiological correlates of neurological maturation reflect the growth and development of the individual neuron and its synaptic relations with other neurons. The mature neuron is a secretory cell with an electrically polarized membrane. Though endocrine and exocrine cells are secretory, and muscle cells possess excitable membranes, only neurons embrace both functions. The precursors of neurons arc neither secretory nor excitable. The cytological maturation of neurons is an

aspect of ontogenesis that is as important as their spatial relations with other cells for future function and also for the pathogenesis of some functional neurological disorders of infancy, such as neonatal seizures. Neuroblasts are defined as postmitotic neuroepithelial tells committed to neuronal lineage. These cells have not yet achieved all functions of mature neurons such as membrane polarity, secretion, and synaptic relations with other neurons, and often they are still migratory. The term *blast* thus is used differently for neural development than for hematopoieses, in which blast cells are still in the mitotic cycle.

The events of neural maturation after initial induction and formation of the neural tube are each predictive of specific types of malformation of the brain and of later abnormal neurological function. These are (1) mitotic proliferation of neuroblasts, (2) programmed death of excess neuroblasts, (3) neuroblast migration, {4) growth of axons and dendtites, (5) electrical polarity of the cell membrane, *(6)* synaptogencsis, (7) biosynthesis of neurotransmitters, and (8) myelinstion of axons.

Malformations of the nervous system are unique. No two individual cases are identical, even if they can both be categorized as similar, such as alobar holoprosencephaly, agenesis of the corpus callosum, or type 2 lissencephaly. Functional expression of anatomically similar cases also may vary widely. For example, two cases of holoprosencephaly with nearly identical imaging findings and similar histological patterns of cortical architecture and subcortical heterotopia at autopsy may differ in that one infant may have epilepsy refractory to pharmacological control, whereas the other may have no clinical seizures at all. The difference may be at the level of synaptic organization and the relative maturation of afferent input and neuronal maturation (Sarnat and Born 1999).

NEURAL MATURATION

Mitotic Proliferation of Neuroblasts (Neuronogenesis)

After formation of the neural tube, neurons and glial cells are generated by proliferation of neuroepithelial cells in the ventricular zone with mitoses at the ventricular surface. The rate of division is greatest during the early first trimester in the spinal cord and brainstem and during the late first and early second trimester in the forebrain. "Within the ventricular zone of the human fetal telencephalon, 33 mitotic cycles provide the total number of neurons required for the mature cetebral cortex. Most mitotic activity in the ncuroepithelium occurs at the ventricular surface, and the orientation of the mitotic spindle determines the subsequent immediate fate of the daughter cells. If the cleavage plane is perpendicular to the ventricular surface, the two daughter cells become equal neuroepithelial cells preparing for further mitosis. If, however, the cleavage is parallel to the ventricular surface, the two daughter cells are unequal (asymmetrical cleavage). In that case, the one at the ventricular surface becomes another neuroepithelial cell, whereas the one away from the ventricular surface separates from its ventricular attachment and becomes a postmitotic neuroblast ready to migrate to the cortical plate. Furthermore, the products of two genes that determine cell fate, called *numb* and *notch,* are on different sides of the neuroepithelial cell. Therefore, with symmetrical cleavages, both daughter cells receive the same amount of each, but with asymmetrical cleavage, the cells receive unequal ratios of each, which also influences their subsequent development (Mione et al. *1997).* The orientation of the mitotic spindle requires centractin.

Active mitoses cease well before the time of birth in most parts of the human nervous system, but a few sites retain a potential for postnatal mitoses of neuroblasts. One recognized site is the periventricular region of the cerebral hemispheres (Kendler and Golden 1996). The best-documented site is the external granular layer of the cerebellar cortex, where occasional mitoses persist until I year of age. Postnatal regeneration of these neurons after most are destroyed by irradiation or cytotoxic drugs is demonstrated in animals and may occur in humans as well. Primary olfactory receptor neurons also retain a potential for regeneration. In fact, if a constant turnover of these neurons did not occur throughout life, the individual would become anosmic after a few upper respiratory infections, which transiently denude the intranasal epithelium. Recently, a population of "stem cells'[1] with mitotic potential has been demonstrated in the suliventncular /.one anil hippocampa! dentate gyrus (Johansson etal. 1999). These have generated a great deal of interest because of a potential for regeneration of the damaged adult brain and because they may be induced to mature as neurons (Schuldiner et al. 2001).

Disorders of Neuronogenesis

Destructive processes may destroy so many neuroblasts that regeneration of the full complement of cells is impossible. This happens when the insult petsists for a long time or is repetitive, destroying each subsequent generation of dividing cells. Inadequate mitotic proliferation of neuroblasts results in hypoplasia of the brain (Figure 66.1). Such brains are small and grossly malformed because neuroblast migration is affected directly or by destruction of the glial cells with radial processes that guide migrating nerve cells. The entire brain may be affected, or portions may be selectively involved. Cerebellar hypoplasia is often a selective interference with proliferation of the external granular layer. In some cases, cerebral hypoplasia and microcephaly are the result of precocious development of the ependyma before all mitotic cycles of the neuroepirhelium are complete because ependymal differentiation arrests mitotic activity at the ventricular surface (Sarnat 1992). The mutation of a gene that programs neuronogenesis may

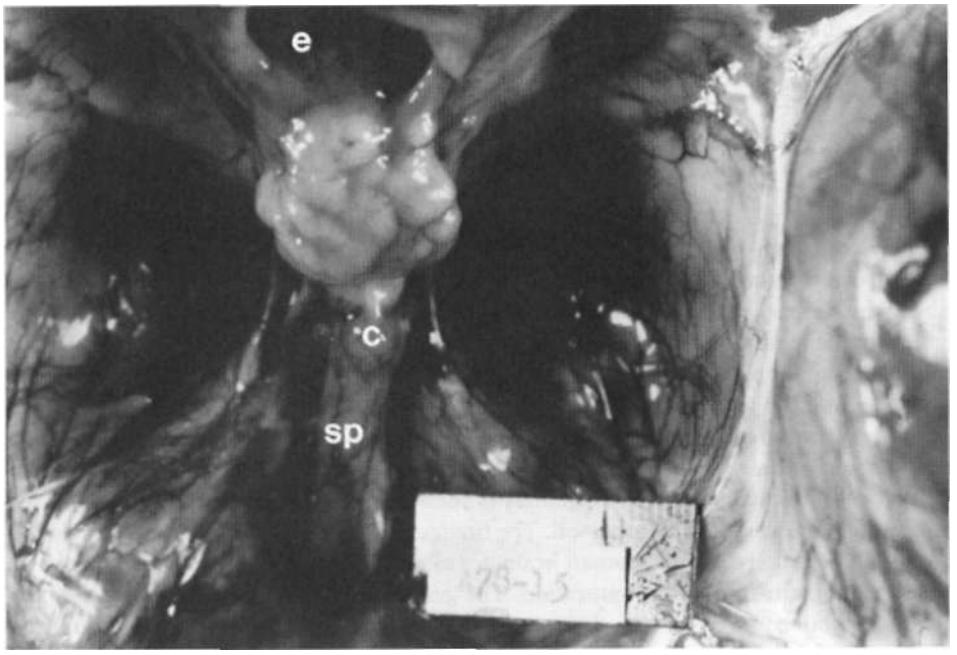

FIGURE 66.1 Severe cerebral hypnphsi;!. The brain of this term neonate weighed only 12.6 g (normal mean is 350 g), although the cranium was closed and mainly filled with fluid, The dysplasia architecture of the telencephalon. incluJ-iu', dysplasia cerebellar tissue, extended into a frontal encephalocele (e) and was not that of a neural tube defect or fetal infarction. The spinal cord (sp) is well formed except for the absence of descending tracts. The cerebellum (e) is small but normally laminated. This brain probably represents lack of neuronal proliferation. Note the well-formed fossae at rhe base of the skull, despite the absence of cerebri I development. (Reproduced with permission from Sarnat, H. B., de Mello, D. E., Blair, J. D., ct al. J 9S2, "Heterotopic growth of dysplastic cerebellum in frontal encephalocele in an infant of a diabetic mother," *Can j Neurol* So, vol. 9, pp. 31-35.)

he another explanation for generating insufficient neuroepithelial cells, although this pathogenesis remains hypothetical in humans.

Programmed Cell Death (Apoptosis)

Excessive neuroblasts are formed in every part of the nervous system by normal mitotic proliferation. This abundance is reduced by a programmed process of cell death until the definitive number of immature neurons is achieved. The factors that arrest the process of programmed cell death in the fetus are multiple and are in part genetically determined. Cells that do not match with targets are more vulnerable to degeneration than are those that achieve synaptic contact with other cells. Kndocrine hormones and neuropeptides modulate apoptosis. Some homeotic genes, such as *c-fos* arc important in the regulation of programmed cell death in the nervous system, and other suppressor genes stop the expression of apoptotic genes.

Two phases of apoptosis are distinguished. One involves yet undifferentiated neuroepithelial cells or neuroblasts with incomplete differentiation; another phase involves fully differentiated neurons of the fetal brain.

Disorders of Programmed Cell Death

Spinal muscular atrophy (see Chapter 79) is an example of a human disease caused by programmed cell death not stopping at the proper time. In this disorder, continued loss of spinal motor neurons (SMN) after all surplus embryonic neuroblasts are deleted is expressed as a progressive denervating process. Genetic factors are crucial in determining the arrest of cell death, which accounts for the hereditary character of spinal muscular atrophy. The SMN defective gene at the chromosome 5ql3.1 locus has now been isolated and is normally responsible for arresting apoptosis in motor neuroblasts (Roy et al. 1995),

Other neurodegenerative diseases of fetal life and infancy arc more widespread within the central nervous system (CNS) rather than limited to one type of neuron, such as the motor neuron. They also are characterized by progressive neuronal loss that is apoptotic rather than necrotic in character: There is no inflammatory or glial reaction, and the features of the DNA degradation differ from ischemic necrosis. An example is pontocerebellar hypoplasia, a group of progressive degenerative diseases that begin prenatally and continue postnatally. Despite the name, they involve much more than the cerebellar system. These diseases are associated with extensive cerebral cortical and basal ganglionic abnormalities, even in motor neurons, which cause a clinical presentation at birth resembling spinal muscular atrophy. This autosomal recessive group of diseases, all genetically distinct from olivopontocerebellar atrophy, exemplifies a semantic difficulty: If an atrophic process begins before development is complete, it results in both hypoplasia and superimposed atrophy.

In the CNS, glial cells also undergo programmed cell death. Glial necrosis is intimately linked to the interhemispheric passage of commissural fibers in the corpus

callosum. In a murine model of callosal agenesis, glial cells that do not degenerate act as a barrier to crossing axons and prevent the corpus callosum from forming.

Neuroblast Migration

No neurons of the mature human brain occupy the site in which they were generated from the neuroepithelium. They migrate to their mature site to establish the proper synaptic connections with appropriate neighboring neurons and to send their axons in short or long trajectories to targets. The subependymal germinal matrix (Figure 66.2) is the subventricular zone of the embryonic concentric layers and consists of postmitotic, premigratory neuroblasts and glioblasts. In general, the movement of maturing nerve cells is centrifugal, radiating toward the surface of the brain. The cerebellar cortex is exceptional in that external granule eel Is first spread over the surface of the cerebellum and then migrate into the folia. Migration of neuroblasts begins at about 6 weeks' gestation in the human cerebrum and is not completed until at least 34 weeks of fetal life, although the majority of germinal matrix cells after midgestation are glioblasts. Glioblasts continue to migrate until early in the postnatal period. Within the brainstem, neuroblast migration is complete by 2 months' gestation. Cerebellar external granule cells continue migrating throughout the first year of life.

Neuroblast migration permits a three-dimensional spatial relation to develop between neurons, which facilitates the formation of complex synaptic circuits. The timing and sequence of successive waves of migrating neuroblasts are precise. In the cerebral cortex, immature nerve cells reach the pial surface and then form deeper layers as more recent arrivals replace their position at the surface. Neurons forming the most superficial layers of neocortex are thus the last to have migrated, although in the three-layered hippocampus, the most superficial neurons represent the earliest migratory wave.

The laminated arrangement of the mammalian cerebral cortex requires a large cortical surface area to accommodate increasing numbers of migrating neuroblasts and glioblasts, Convolutions provide this large surface area without incurring a concomitant increase in cerebral volume. The formation of gyri and sulci is thus a direct result of migration (Figure 66.3). Most gyri form in the second half of gestation, which is a period of predominant gliogenesis and glial cell migration. Therefore, the proliferation of glia in the cortex and subcortical white matter may be more important than neuroblast migrations in the formation of convolutions, but the growth of dendrites and synaptogenesis also may influence gyration by contributing mass to the neuropil. The timing and sequence of gyral formation in the human brain arc as predictable as other aspects of cerebral maturation. The gestational age of a premature infant may be determined to within a 2-week period or less from the convolutional pattern of the brain at autopsy.

THE MAJOR MECHANISM OF NEUROBLAST MIGRATION: RADIAL GLIAL FIBER GUIDES

The majority of neuroblasts arriving at the cortical plate do so by means of radial glial guides from the subventricular zone. A second route, that of tangential migration, uses axons as the guides for the migratory neuroblasts. The genetically determined programming of neuroblast migration begins when cells are still undifferentiated neuroepithelial cells and even before all their mitotic cycles are complete. Neuroepithelial cells express the gene products of the lissencephaly gene (LIS1), as do ependymal cells and

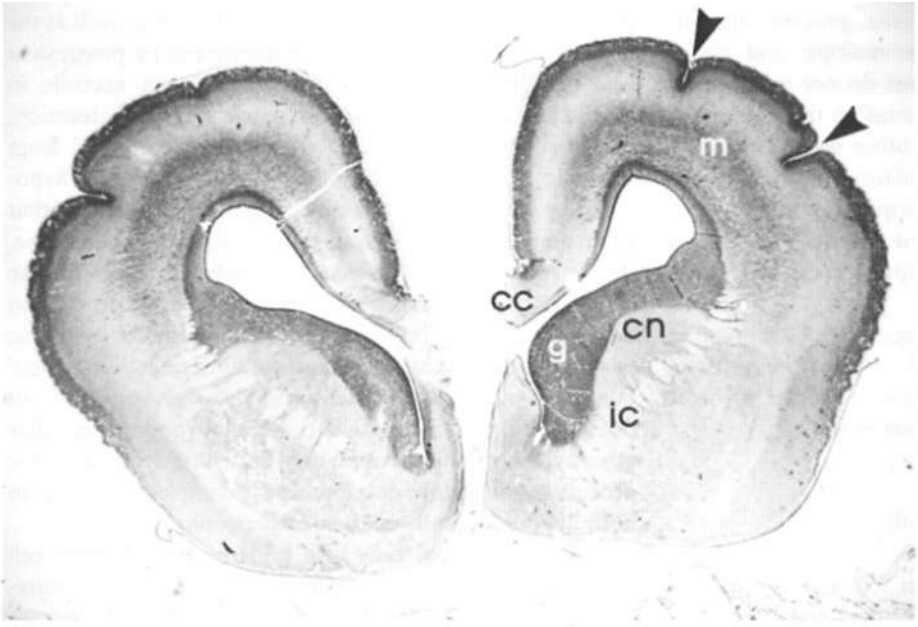

FIGURE 66.2 Coronal section of forebrain of 16-week normal fetus, showing extensive subependymal germinal matrix (g) of neuroblasts and glial precursors that have not yet migrated. The surface of the brain is just beginning to develop sulci *(arrowheads).* Migrating neuroblasts (m) are seen in the subcortical white matter. The corpus callosum (ce) is artifaetually ruptured and the two hemispheres should be closely approximated. (en = caudate nucleus; ic = anterior limb of internal capsule.) (Hematoxylin-eosin stain.)

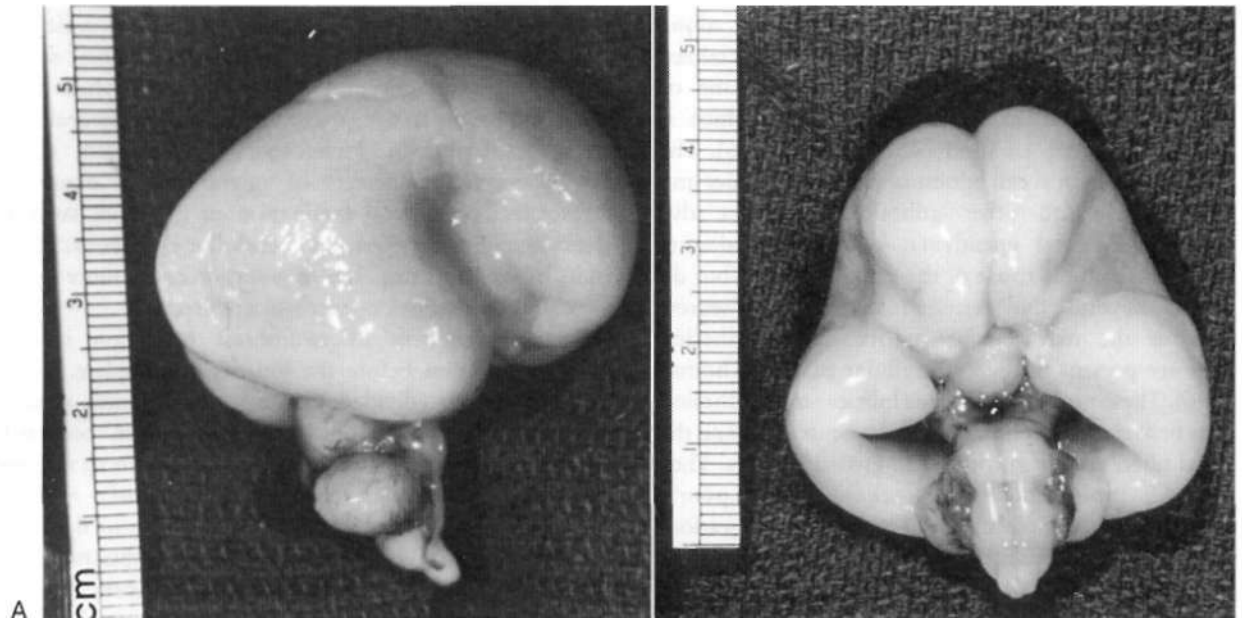

FIGURE 66.3 Lateral (A) and ventral (B) views of a normal brain of a 16-week ferus. The primary sulci, such as the sylvian fissure, calcarine fissure, and central sulcus, are forming, hut secondary and Tertiary sulci and gyri are not yet developed, and the Surface of the brain is smooth.

Cajat-Retzius cells of the molecular layer of cerebral cortex, This gene is defective in type 1 tissencephaly (Miller-Dieker syndrome), a severe disorder of neuroblast migration (Clark et al. 1997). How it functions in migration is not fully understood. Most neurons of the forcbrain are guided to their predetermined site from the germinal matrix (embryonic subventricular /one) by long, radiating fibers of specialized fetal astrocytes (Figure 66.4). The entire wall of the fetal cerebral hemisphere is spanned by the elongated processes of these glial cells, whose cell bodies are in the periventricular region and terminate as end-feet on the limiting pial membrane at the surface of the brain (see Figure 66.4), Radial glial cells are the first astroglial cells of the human nervous system converted into a mature fibrillary astrocyte of the subcortical white matter; some are still present at birth. Mature astrocytes are present throughout the CNS by 15 weeks' gestation, and gliogenesis continues throughout fetal and postnatal life. Several types of glial cells are recognized between 20 and 36 weeks' gestation.

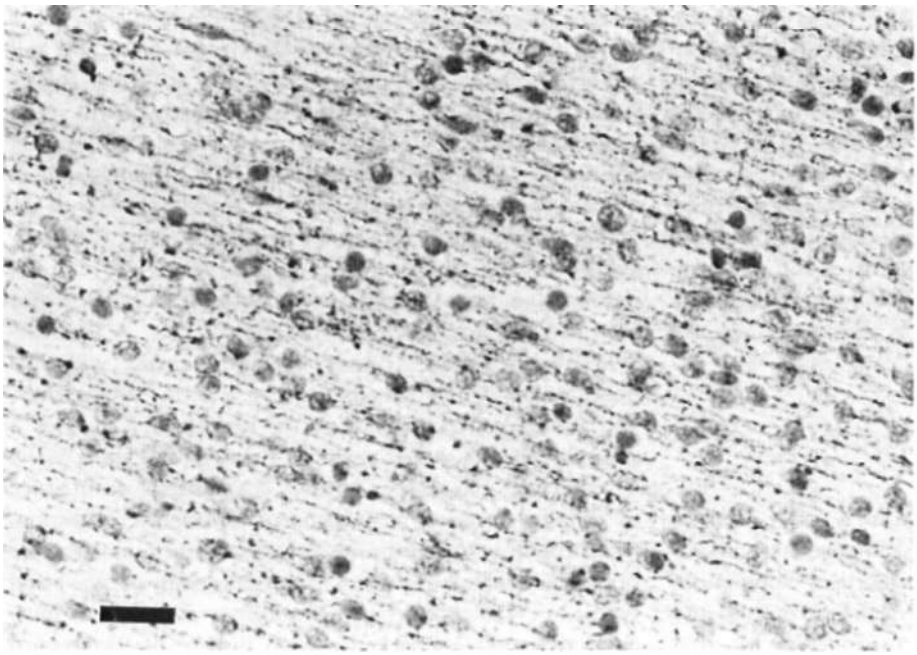

FIGURE 66.4 Radial glial fibers extending from subependymal region (*right*) toward cerebral cortex (*left*), guiding migrating neuroblasts in a 16-week fetus. (Glial fibrillary acidic protein reaction. Bar = 10 μm.)

The mechanical process of neuroblasts gliding along a radial glial fiber is facilitated by a number of specialized proteins at the radial glial fiber surface membrane or extracellular space. An example is astrotactin, which is secreted by the neuroblast itself (Zheng et al. 1996). The glial cell (e.g., LI neural cell adhesion molecules [Jouet and Kenwrick 1995| and orhc" adhesion molecules also facilitate gliding. Fetal ependymal cells have radiating processes that resemble those of the radial glial cell but do not extend beyond the germinal matrix and secrete molecules in the extracellular matrix. Some adhesion molecules are present in the extracellular matrix (Thomas et al. 1996). These molecules serve as lubricants, as adhesion molecules between the membranes of the neuroblast and the radial glial fiber, and as nutritive and growth factors. They stimulate cell movement by a mechanism still poorly understood. Deficient molecules lead to defective migration, For example, the abnormality of the LI adhesion molecule is the defective genetic program in X-linked hydrocephalus accompanied by poly microgyria and pachygyria.

The process of transformation of radial glial cells into astrocytes and ependymal cells begins during the first half of gestation and is completed postnatal ly. During mid-gestation, when neuronal migration is at a peak, many radial glial cells remain attached to the ventricular and pial surfaces, increasing in length and curving with the expansion and convolution of the cerebral wall. From 28 weeks' gestation to 6 years of age, astrocytes of the frontal lobe shift from the periventricular to the subcortical region. The centrifugal movement of this band of normal gliosis marks the end of neuronal migration in the cetebral mantle. Ependyma does not completely line the lateral ventricles until 22 weeks' gestation (Sarnat 1992}.

In addition to the radial migration to the cerebral cortex, tangential migration also occurs, but the number of neuroblasts is far smaller (Rakic 1995). These migrations perpendicular ro the radial fibers probably use axons rather than glial processes as guides for migratory neuroblasts, which explains why all cells in a given region of cortex are not from the same clone or vertical column. Most of the tangentially migrating neuroblasts in the cerebral cortical plate are generated in the fetal *gangltonic eminence,* a deep relecephalic structure that later becomes the basel ganglia. Tangential migrations occur in the brainstem and olfactory bulb as well as in the cerebrum. The subpial region is another site of neuroblast migration that docs not use radial glial cells.

Disorders of Neuroblast Migration

Nearly all malformations of the brain are a direct result of fauln- neuroblast migration or at least involve a secondary impairment of migration. Imperfect cortical lamination, abnormal gyral development, subcortical heterotopia, and other focal dysplasias are related to some factor that interferes with neuronal migration, whether vascular, traumatic, metabolic, or infectious. The most severe migrational defects occur in early gestation, often associated with events in the gross formation of the neural tube and cerebral vesicles. Heterotopia of brainstem nuclei also occurs. Later defects of migration are expressed as disorders of cortical lamination or gyration, such as lissencephaly, pachygyria, and cerebellar dysplasias. These insults of the third trimester of gestation cause more subtle or focal abnormalities of cerebral architecture.

Most disturbances of neuroblast migration involve arrested migration before the journey is complete. These disorders may be divided into three anatomical phases, depending on where the migratory arrest occurred. An example of neuroblasts never having begun to migrate from the periventricular region is *periventricular nodular heterotopia* an X-linked genetic disorder due to defective expression of the gene *Filamin-A.* If neuroblasts began migrating, but became arrested in the subcortical white matter and did not reach the cortical plate, *subcortical laminar* heterotopia may result, another X-linked recessive trait, but due to a different gene called *Dnublecortin (DCX).* If the neuroblasts reached the cortical plate but did not arrange themselves with correct lamination, this abnormal architecture of the cortical plate often is accompanied by abnormalities of gyration, such as lissencephaly or pachygyria. Several different genes, including *LIS!* and *Reelin* (RTN), are important in cortical plate organization (Curran and D'Arcangelo 1998) and are mutated in malformations of the terminal phase of neuroblast migration.

Lissencephaly is a condition of a smooth cerebral cortex without convolutions. At midgestation, the brain is essentially smooth; only the interhemispheric, sylvian, and calcarine fissures are formed. Gyri and sulci develop between 20 and 36 weeks' gestation, and the mature pattern of gyration is evident at term, although some parts of the cerebral cortex, such as the frontal lobes, are still relatively small. In lissencephaly type 1 (Miller-Dieker syndrome), the cerebral cortex remains smooth. The histopathological pattern is that of a four-layer cortex in which the outermost layer (1) is the molecular layer, as in normal six-layered neocortex. La yet 2 corresponds ro layers 2 through 6 of normal neocortex, layer J3 is cell-sparse as a persistent fetal subplate zone, and layer 4 consists of incompletely migrated neurons in the subcortical intermediate zone. In lissencephaly type 2 (Walker-Warburg syndrome), poorly laminated cortex with disorganized and disoriented neurons is seen histologically, and the gross appearance of the cerebrum is one of a smooth brain or a few poorly formed sulci (Figure *66.5),* The cerebral mantle may be thin, suggesting a disturbance of cell proliferation as well as of neuroblast migration, Malformations of the brainstem and cerebellum often are present as well (see Figure *66.5).* Lissencephaly of type 1 and type 2 (Walker-Warburg syndrome, Fukuyama muscular dystrophy, muscle-eye-bra in disease of Santavuori)

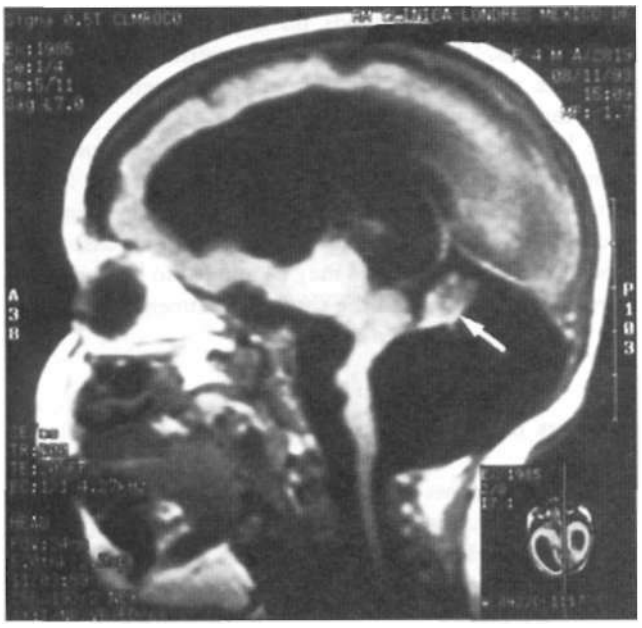

FIGURE 66.5 Sagittal Tl-weighted magnetic resonance image of a 10-month-old girl with lissencephaly type 2 and Dandy-Walker malformation. The cerebral mantle is thin, and the latetal ventricle is greatly enlarged. A few abnormal shallow fissures at the cerebral surface may indicate abortive gyration or pachygyria. The cerebellum is severely hypoplastic {*arrow* indicates anterior vermis), and the posterior fossa contains a large, fluid-filled cyst. The brainstem also is hypoplastic, and the basis pontis is nearly absent. A differential diagnosis of this image is pontocerebellar hypoplasia, but the high position of the toreula indicates a Dandy-Walker malformation.

are genetic diseases, but lissencephaly also may occur secondary to nongeneric disturbances of neuroepithelial proliferation or neuroblast migration, including destructive encephaloclastic processes, such as congenital infections during fetal life.

Other abnormal patterns of gross gyration of the cerebral cortex also occur secondary to neuroblast migratory disorders. *Pachygyria* signifies abnormally large, poorly formed gyri and may be present in some regions of cerebral cortex with lissencephaly in other regions. *Poly microgyria* refers to excessively mi men HIS and abnormally small gyri that similarly may coexist with pachygyria; it docs not necessarily denote a primary migratory disorder of genetic origin. Small, poorly formed gyri may occur in zones of fetal ischemia, and they regularly surround porencephalic cysts due to middle cerebral artery occlusion in fetal life. Schizencephaly is a unilateral or bilateral deep cleft usually in the general position of the sylvian fissure but is not a sylvian fissure: This cleft is the full thickness of the hemispheric wall, and no cerebral tissue remains between the meninges and the lateral ventricle (the pial-ependymal seam). If the cerebral cortical walls on either side of the deep cleft are in contact, the condition is called *closed lips,* and if a wide subarachnoid space separates the two walls, it is known as *open lips,* but these two variants do not provide a clue to pathogenesis. Schizencephaly occurs both as a genetic trait (the defective gene is *EMX2)* and sporadically; in some cases, it is a form of porencephaly due to fetal cerebral infarction.

In the cerebral hemisphere, most germinal matrix cells become neurons during the first half of gestation, and most form glia during the second half of gestation. Nonetheless, j small ium::KT o: gerir.sual matrix cells arc neuronal precursors, migrating into the cerebral cortex in late gestation. Because the migration of the external granular layer in the cerebellar cortex is not completed until 1 year of age, a potential for acquired insults to interfere with late migrations persists throughout the perinatal period. Anatomical lesions, such as periventricular leukomalacia, intracerebral hemorrhages and abscesses, hydrocephalus, and traumatic injuries, may disrupt the delicate radial glial guide fibers and prevent normal migration, even though the migrating cell itself may escape tin- focal destructive lesion.

Damaged radial glial cells tend to retract their processes from the pial surface. The migrating neuron travels only as far as its retracted glial fibers carry it. If this fiber is retracted into the subcortical white matter, the neuroblast stops there and matures, becoming an isolated hetcroropic nodule composed of several nerve cells that were migrating at the same time in the same place. In these nodules, neurons of various cortical types differentiate without laminar organization and with haphazard orientations of their processes, but a few extrinsic axons may prevent total synaptic isolation of the nodule.

Interference with the glial guide fibers in the cerebral cortex itself results in neurons cithet not reaching the pial surface or not being able to reverse direction and then descending to a deeper layer. The consequence is imperfect cortical lamination, which interferes with the development of synaptic circuits. These distutbances of late neuroblast migration do not ptoducc the gross malformations of early gestation and may not be detected by imaging techniques. They may account for many neurological sequelae after the perinatal period, including seizures, perceptual disorders, impaired coordination of gross or fine motor function, learning disabilities, and mental retardation.

In sum, disorders of neuroblast migration may be due either to defective genetic programming or may be acquired secondary to lesions in the fetal brain that destroy or interrupt radial glial fibers. Cells may not migrate at all and become manire neurons in the periventricular region, as occurs in X-linked periventricular nodular heterotopia (Eksioglu et al. 1996) and in some cases of congenital cytomegalovirus infection. Cells may become arrested along their course as heterotopic neurons in deep subcortical **white matter,** as occurs in many genetic syndromes of Iissencephaly-pachygyria and in many metabolic diseases, including cerebrohepatorcnal Zellweger syndrome and in many aminoacidurias and organic acidurias. The same aberration may occur in acquired insults to the radial glial cell during ontogenesis. Cells may overmigrate beyond

B

the limits of the pial membrane into the meninges as ectopic neurons, either singly or in clusters known as *marginal glkmeurnnal heterotopia* or *brain warts.* Rarely, herniation of the germinal matrix into the lateral ventricle may occur through gaps in the ependyma; those cells mature as neurons, forming a nonneoplastic intraventricular mass that may or may not obstruct cerebrospinal fluid (CSF) flow. Whether disoriented radial glial fibers actually guide neuroblasts to an intraventricular site or are physically pushed into a direction of less resistance is uncertain.

Growth of Axons and Dendrites

During the course of neuroblast migration, neurons remain largely undifferentiated cells, and the embryonic cerebral cortex at midgestation consists of vertical columns of tightly packed cells between radial blood vessels and extensive extracellular spaces. Cytodifferentiation begins with a proliferation of **organelles,** mainly endoplasmic reticulum and mitochondria in the cytoplasm, and clumping of condensed nuclear chromatin at **the** inner margin of the nuclear membrane. Rough endoplasmic reticulum becomes swollen, and ribosomes proliferate,

The outgrowth of the axon always precedes the development of dendrites, and the axon forms connections before the differentiation of dendrites begins. The projection of the axon toward its destination was first recognized by Ramon y Cajal, who named this growing process the *cone d'accroissetnent* (growth cone). The tropic **factors** that guide the growth cone to its specific terminal synapse, whether chemical, endocrine, or electrotaxic, have been a focus of controversy for many years. However, it is now well demonstrated that growth cones are guided during their long trajectories by diffusible molecules secreted along their pathway by the processes of fetal ependyma! cells and perhaps some glial cells. Some molecules, such as brain-denved neurotrophic growth factor, netrin and -100 protein, attract growing axons, whereas others, such as the glycosaminoglycan *keratan sulfate* (not to be confused with the protein *keratin),* strongly repel them and thus prevent aberrant decussations and other deviations. Matrix proteins, such as laminin and fibronectin, also provide a substrate for axona! guidance. Cell-to-cell attractions operate as the axon approaches its final target. Despite the long delay between the migration of an immature nerve cell and the beginning of dendritic growth, the branching of dendrites eventually accounrs for more than 90% of the synaptic surface of the mature neuron. The pattern of dendritic ramification is specific for' each type oi neuron. Spines form on the dendrites as short protrusions with expanded tips, providing sites of synaptic membrane Jitii-i-nliation.

The Golgi method of impregnation of neurons and their processes with heavy metals, such as silver or mercury, has been used for more than a century and continues to be one of the most useful methods for demonstrating dendritic arborizations. Among the many contributions of this technique to the study of the nervous system, beginning with the elegant pioneering work of Ramon y Cajal, none has surpassed its demonstration of the sequence of normal dendritic branching in the human fetus. Newer immunocytochemieal techniques for demonstrating dendrites also are now available, such as microtubule-associated protein 2. These techniques may be applied to human tissue resected surgically, as in rhc surgical treatment of epilepsy, and to the tissue secured at autopsy.

Disorders of Neurile Growth

If a neuron becomes disoriented during migration and faces the wrong direction in its final site, its axon is capable of reorienting itself as much as 180 degrees after emerging from the neuronal cell body. Dendrites, by contrast, conform strictly to the orientation of the cell body and do not change their axis. The dendritic tree becomes stunted if axodendritic synapses are not established.

Because so much dendritic differentiation and growth occurs during the last third of gestation and the first months of the postnatal period, the preterm infant is particularly vulnerable to noxious influences that interfere wirh maturation of dendrites. Extraordinarily long dendrites of dentate granule cells and prominent basal dendrites of pyramidal cells have been described in term infants on life-support systems. Retardation of neuronal maturation in terms of dendrite development and spine morphology has been described in premature infants, compared with term infants of the same conceptional age, possibly as a result of asphyxia. Infants with fetal alcohol syndrome also have a reduced number and abnormal geometry of dcmlnric opines oi conical neurons.

Traditional histological examination of the brains of mentally retarded children often shows remarkably few alterations to account for a profound intellectual deficit. The study of dendritic morphology by the Golgi technique has revealed striking abnormalities in some of these cases. The alterations are best documented in chromosomal diseases, such as trisomy 13 and Down syndrome. Long, thin, tortuous dendritic spines and the absence of small, stubby spines are a common finding. Children with unclassified mental retardation but normal chromosomal numbers and morphology also show defects in the number, length, and spatial arrangement of dendrites and synapses.

Abnormalities of cerebellar Purkinje's cell dendrites occur in cerebellar dysplasias and hypoplasias. They consist of cactus-like thickenings and loss of brauchlet spines. Abnormal development of the dendritic tree is also a common finding in many metabolic encephalopathies, including Krabbe's disease and other leukodystrophies, Menkes' kinky hair disease, gangliosidoses, ceroid lipofuscinosis, and Sanfilippo's syndrome. Among genetically

determined cerebral dysgeneses, aberrations in the structure and number of dendrites and spines are reported in cerebrohepatorenal (Zellweger) syndrome and in tuberous sclerosis.

Electrical I'olariu of llic Cell Membrane

The development of membrane excitability is one of the important markers of neuronal maturation, but little is known about the exact timing and duration of this development. Membrane polarity is established before synaptogenesis and before the synthesis of neurotransmitters begins. Because the maintenance of a resting membrane pfiriT.ri.il rviiuin"-. considerable energ\ expenditure to fuel the sodium-potassium pump, the undifferentiated neuroblast would be incapable of maintaining such a dynamic condition as a resting membrane potential. The development of ion channels within the neural membrane is another important factor in the maturation of excitable membranes and the maintenance of resting membrane potentials.

Disorders of Membrane Polarity

Epileptic phenomena are largely due to inappropriate membrane depolarizations. They represent a complex interaction of excitatory and inhibitory synapses that modulate the resting membrane potential, metabolic alterations, and many unknown factors that also contribute to the discharge threshold of neural membranes. Cerebral malformations ate often associated with seizures because of abnormal synaptic circuitry, and the role of abnormal resting membrane potentials in development is largely speculative at this time. Electrolyte imbalances in the serum certainly influence the depolarization threshold, and hypothalamic disturbances may alter endocrine function and electrolyte balance.

Synaptogenesis

Synapse formation follows the development of dendritic spines and the polarization of the cell membrane. The relation of synaptogenesis to neuroblast migration differs in different parts of the nervous system. In the cerebral cortex, synaptogenesis always follows neuroblast migration. In the cerebellar cortex, however, the external granule cells develop axonal processes that become the long parallel fibers of the molecular layer and make synaptic contact with Purkinje cell dendrites before migrating through the molecular and Purkinje cell layer to their mature internal position within the folium.

Afferent nerve fibers reach the neocortex early, before lamination occurs in the cortical plate. The first synapses are axodendritic and occur both external to and beneath the cortical plare in the future layers I and VI, which contain the first neurons that have migrated.

An excessive number of synapses form on each neuron, with subsequent elimination of those that are not required. Outside the CNS, muscle fibers also begin their relation with the nefvous system by receiving multiple sources of innervation from multiple motor neurons, later retaining only one. Transitory synapses also form at sites on neurons where they are not found in the matute condition. The spinal motor neurons of newborn kittens display prominent synapses on theit initial axonal segment, where they are never found in adult cats. Somatic spines are an important synaptic site on the embryonic Purkinje cell, bur these spines and their synapses disappear as the dendritic tree develops.

A structure-function correlation may be made in the developing visual cottex. In preterm infants of 24-25 weeks' gestation, the visual evoked potentials (VEPs) recorded at the occiput exhibit an initial long-latency negativity, but by 28 weeks' gestation, a small positive wave precedes this negativity. The change in this initial component of the VEP corresponds to dendritic arborization and the formation of dendritic spines that occurs at that time.

The electroencephalogram (KEG) of the premature infant follows a predictable and time-linked progression in maturation that has been extensively studied. The EEC reflects synaptogenesis more closely than any other feature of cerebral maturation and thereby provides a noninvasive and clinically useful measure of neurological maturation in the preterm infant. Fetal EEC may even detect neurological disease and seizures in utero.

Disorders of Synaptogenesis

Because the formation of dendritic spines and the formation of synapses are so closely related, the same spectrum of diseases already discussed is equally appropriate for consideration in this section. The rate of maturation of the EECi is often slow in preterm infants, who are generally unwell, even if they do not have specific neurological disease, which may reflect an impairment of synapse formation. Chronic hypoxemia particularly delays neurological maturation.

Biosynthesis of Neurotransmitters

The synthesis of neurotransmitters and ncuromodulating chemicals is based on the secretory character of the neuron, without which synaptic transmission is impossible. Several types of substances serve as transmitters: (1) acetylcholine (ACh); (2) monoamines, including dopamine, norepinephrine, epinephrine, and serotonin; (3) neuropeptides, including substance P, somatostatin, and opioid-conraining

peptide chains, such as the enkephalins; and (4) simple amino acids, including glutamic acid, aspartic acid, *y*-aminobutyric acid (GABA), and glycine. Some transmitters are characteristically inhibitory (such as glycine, GABA, and ACh in the CNS). Each neuronal type produces a characteristic transmitter (motor neurons produce ACh, cerebellar Purkinje cells produce GABA, and granule cells produce glutamic acid in the adult). Neuropeptides may coexist with other types of transmitters in some neurons.

In some parts of the brain, transitory fetal transmitters may appear during development and then disappear. Substance 1' and somatostatin are present in the fetal cerebellum at midgestation, but these neuropeptides are never found in the mature cerebellum. In the cerebral cortex of the frontal lobe, there is laminar distribution of cholinergic muscarinic receptors of the mature brain that is the inverse of the pattern in the fetus. The functions of these transitory transmitter systems are unknown. Some serve as trophic molecules rather than transmitters in early development. Even amino acid transmitters, such as GABA, may serve mainly a trophic function at an early stage in development. In situ hybridization and new immunocytochemical Technique cki nor. M:\IIY r.eiirorransir-trci^ in neurons of the developing brain of experimental animals and may be applied to human tissue under some circumstances (Dupuy and Houser 1997).

The ontogeny of neurotransmitter systems depends not only on the mechanisms of synthesis of chemical transmitters, but also on the development of highly specific receptors of these chemical signals and the ability of these receptors to modify excitability of neuronal membranes and to trigger action potentials after the recognition of specific molecules (Rho and Storey 2001; Simeone et al. 2003).

Disorders of Neurotransmitter Synthesis

Ischemic and hypoxic insults impair RNA transcription and result in arrest of the synthesis of secretory products. Many of the clinical neurological deficits observed in neonates who underwent birth asphyxia are probably the result of neurotransmitter depletion and functional synaptic block. Some amino acid neurotransmitters, by contrast, arc neurotoxic when released in large quantities. The excitatory amino acids glutamic acid and aspartic acid induce transsynaptic degeneration when released in this way, as might occur with hypoxic stresses, and may be a major source of irreversible brain damage in asphyxiated neonates,

Developmental disorders due to inborn errors of metabolism that block the chemical pathway of transmitter synthesis may hypothetically occur bur are probably incompatible with survival if they interfere with the synthesis of a major transmitter, such as ACh, monoamines, or an essential peptide. Defects in the metabolic pathways of particular amino acids are known, and many of these are associated with mental retardation, epilepsy, spastic diplegia, and other chronic neurological handicaps. Phenylketonuria (a disorder of phenylalanine metabolism) and maple syrup urine disease (a disorder of the metabolism of the branched-chain amino acids leucine, isoleucine, and valine) are we 11-documented examples. However, it is not cettain whether absence of the product of the deficient enzyme or toxicity of high levels of precursors upstream from the enzyme deficiency is the principal insult to the nervous system,

Myelination

Myelin insulates individual axons and provides greatly increased speed ot conduction. It is not essential in all nerves, and many autonomic fibers of the peripheral nervous system remain unmyelinated throughout life. Conduction velocity in central pathways is important in coordinating time-related impulses from different centers that converge on a distant target and in ensuring that action potentials arc not lost by synaptic block. The nervous system functions on the basis of temporal summation of impulses to relay messages across synapses.

Myelination of pathways in the CNS occurs in a predictable spatial and temporal sequence. Some tracts myelinate as early as 14 weeks' gestation and complete their myelination cycle in a few weeks. Examples include the spinal roots, medial longitudinal fasciculus, dorsal columns of the spinal cord, and most cranial nerves. Between 22 and 24 weeks' gestation, myelination progresses in the olivary and cerebellar connections, the ansa lenticularis of the globus pallidus, the sensory trigeminal nerve, the auditory pathways, and the acoustic nerve as well as the trapezoid body, lateral lemniscus, and brachium of rhe inferior collicuius. By contrast, the optic nerve and the geniculocalcarine tract (i.e., optic radiations) do not begin to acquire myelin until near term.

Some pathways are late in myelinating and have myelination cycles measured in years. The corpus callosum begins myelinating at 4 months postnatally and is not complete until midadolescence. Some ipsilateral association fibers connecting the frontal with the temporal and parietal lobes do not achieve full myelination until about 32 years ol age.

Myelination can now be accurately measured in specific central pathways of the living patient by using T2-weigh ted magnetic resonance imaging sequences, but the time at which myelination can be detected is somewhat later than with traditional myelin stains of brain tissue sections, such as Luxol fast blue. Newer neuropathologies! methods, using gallocyanin and immunoreactiviry to myelin basic protein, may detect myelination even earlier than the traditional strains. Electron microscopy remains the most sensitive method of demonstrating the earliest myelination in tissue sections.

Disorders of Myclination

Many metabolic diseases impede the rate of myelination. Hypothyroidism is a classic example. Menkes kinky hair disease, a disorder of copper absorption and metabolism, is another example. Many aminoacidurias, including phenylketonuria, are also associated with delayed myelination. Cerebrohepatorcnal (Zellweger) syndrome is well documented with neuropathological findings that include disorders of neuroblast migration and of myelination. Some leukodystrophies, such as Krabbc disease and perinatal sudanophilic leukodystrophy, are already expressed in fetal life with defective myelination.

Chronic hypoxia in premature infants is probably the most common cause of delayed myelination and contributes to the delay found in clinical neurological maturation, Myelination depends on fatty acids that must be supplied by the maternal and infant diet; nutritional deficiencies during gestation or in postnatal life may result in delayed myelination and are clinically expressed as developmental delay. Unlike disorders of neuronal migration, delay in myelination is not necessarily irreversible if **the** insult is removed; myelination may catch up to reach the appropriate level of maturity.

Cajal-Retzius Neurons of the Fetal Brain

Cajal-Retzius cells arc large, mature, stellate neurons in the marginal (outermost) zone of the fetal cerebral cortex. They are the first cells to appear at the surface of the embryonic cerebrum, preceding the first wave of radial migration from the subventricular zone and forming a plexus in the marginal (later the molecular) zone. They migrate to the surface either lrom the ganglionic cmiiiciKV or from the midbrain neuromere (Sarnat and Flores-Sarnat 2002). The first afferent processes to enter the marginal layer are dendrites of pyramidal cells of layer VI; synapses between Cajal-Retzius and pyramidal neurons of layer VI form the first intrinsic cortical circuits (Marin-Padilla 1998). They eventually have synaptic contacts with cortical neurons in all layers.

Cajal-Retzius cells contain acetylcholinesterase and oxidative enzymes and secrete GABA and probably also ACh as neurotransmitters. Their long axons extend parallel to the surface of the brain, plunging short branches into layer II (Figure 66.6). Cajal-Retzius neurons are sparse by term but persist even in the adult, though their function after maturity is uncertain. Cajal-Retzius neurons strongly express the transcription product of the I .IS I gene, which is defective in X-linkcd hydrocephalus associated with polymicrogyria and defective neuroblast migration, and they also **strongly** express Reelin (RLN), another gene essential for radial neuroblast migration {Clark et al. 1997; Sarnat and Flores-Sarnat 2002). No other specific diseases involving Cajal-Retzius neurons are yet described.

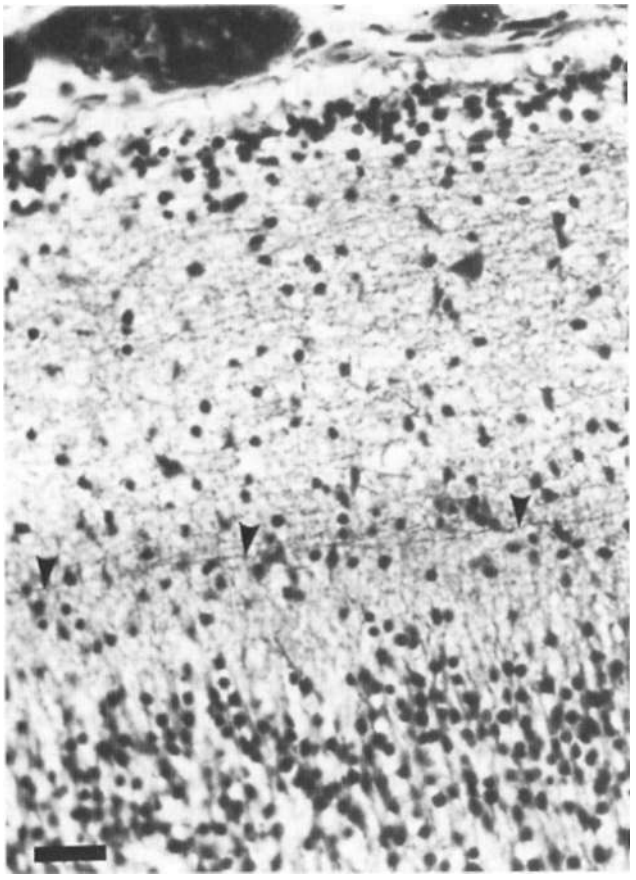

FIGURE 66.6 Silver stain of molecular layer of motor cortex in a 20-wcek fetus. The long fibers *[arrowheads]* extending parallel to the surface of the brain are axons of Cajal-Retzius neurons. They disappear with further cerebral maturation. (Bielschowsky stain. Bar= 10 urn.)

The fetal cerebral cortex has a subpial or external granular layer that histologically resembles that of the cerebellum but is of quite a different character. Cells of the cerebral cortex rise in columns from the germinal matrix of the hippocampus to form a thin layer on the surface of the archicortex at 12 weeks' gestation. They rapidly spread over the neocortex in a predictable sequence to cover the entire convexity by the sixteenth to eighteenth week, with the layer reaching the greatest thickness by 22 weeks' gestation. Subsequent involution of the external granular layer results from migration of these cells into the cerebral cortex, where they can no longer be distinguished. Only remnants of this once-prominent layer persist at term, confined to the inferior temporal and orbital surfaces. These surfaces are the last sites from which they finally disappear from the neocortex, although a few may persist over the paleocortex even into adult life. Their fate within the cerebral cortex is unknown, but it is speculated that they mature into glial cells because they lack ultra structural features of neurons, and they stain immunocytochemically for glial fibrillary acidic protein but not for vimentin.

The subpial granular layer of the cerebral hemispheres is partially or totally absent in most cases of holoproscn-ccphaly, even at the gestational period when it is expected to be most prominent; this absence may contribute to the marginal glioncural heterotopia found in the meningeal spaces and superficial cortical layers. The layer of the subpial granule cells may serve as a barrier to reverse the direction of migration in neuroblasts reaching the surface. In the Fukuyama type of congenital muscular dystrophy associated with cerebral cortical dysplasia, a heterotopic layer of stellate glial cells forms at the surface of the cerebral cortex, into which migrating neurons accumulate as they reach the surface rather than reversing direction and entering deeper layers of the cortex.

Suprasegmental Influences on Muscle Maturation

The motor unit is capable of developing normally in the absence of suprasegmental modification, as in infants with severe hypoplasias of the brain (see Figure 66.1). Malformations of the brainstem and cerebellar hypoplasia in particular are associated with a variety of aberrations in histochemical differentiation. These aberrations include (1) delayed maturation; (2) more than 80% predominance of type 1 or type 2 myofibers, with or without uniform hypoplasia of one or the other type {Figure 66.7); and (3) classic congenital muscle fiber-type disproportion. Malformations limited to the cerebral cortex do not cause fiber-type predominance. Muscle biopsy of children with cerebral palsy from birth asphyxia or other perinatal insults shows only nonspecific type 2 muscle fibct atrophy, with preservation of the normal ratios of fiber types, similar to the changes that follow disuse or immobili/ation of muscle.

It is speculated that many of the small bulbospinal "subcorticospinal" tracts (i.e., vestibulospinal, reticulo-spinal, olivospinal, tectospinal, and rubrospinal) are more important than is the larger corticospinal tract during the stage of histochemical differentiation of muscle between 20 and 28 weeks' gestation. These small descending pathways are generally well myelinated and functional at that time, whereas the corticospinal tract does not even begin its inyelination cycle or proliferation of axonal terminals until after muscle development is complete.

Etiologies of CNS Malformations

The causes of cerebral malformations generally fall into one of two categories. The first category is genetic and chromosomal disease in which there is defective program-ming of cerebral development. This genetic category also includes many inborn metabolic diseases, in which cerebral dysgenesis may be due to biochemical insults during devel-opment rather than, or in addition to, primary errors in molecular genetic codes for neural programming. The second category includes all induced malformations in which a teratogenic influence acts at a particular time in ontogenesis; the malformation depends on the timing of the insult in relation to brain development at that moment. The timing may be brief, as with a single exposure to a toxic drug, a dose of radiation, or a traumatic injury of the fetal lira in. It may be repeated two or more times or may

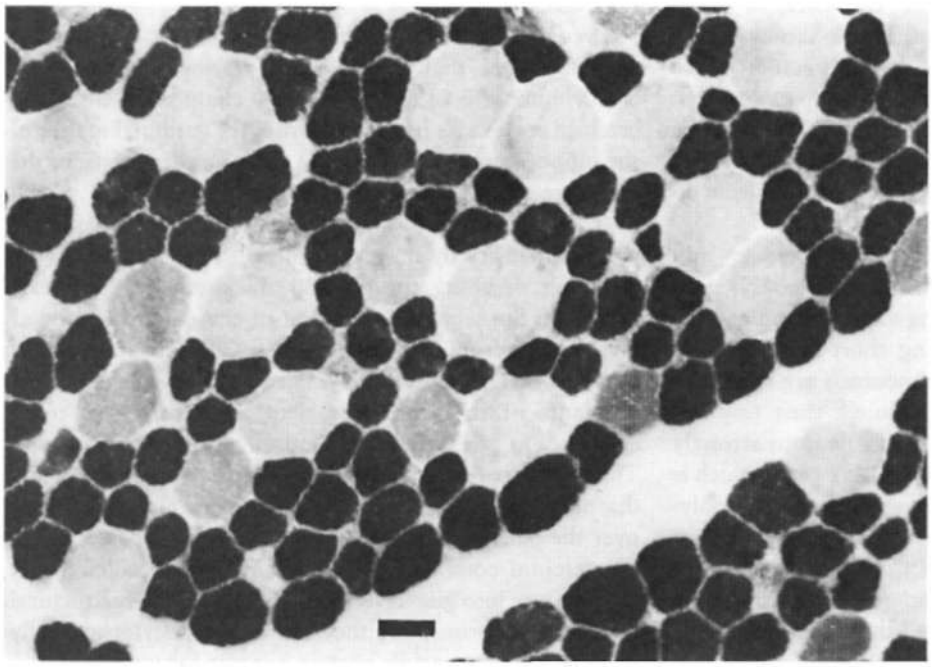

FIGURE *66.7* Histochemical type 2 myofiber numerical predominance and relative smallness of type 2 fibers. Type I fibers are stained lightly; type 2 fibers are dark. The small type 2 fibers do not show the angular contour characteristic of denervated muscle fibers in the adult or of those atrophic secondary to disuse. This muscle biopsy was taken from a 3-year-old boy with generalized hypotonia and cerebellar hypoplasia. (Myosin ATPase stain preincubated at pH 10.4. Bar=15 urn.)

be prolonged and involve the fetus at several stages of development. Examples of die latter include certain congenital infections, such as toxoplasmosis and cytomegalovirus disease, which may be active throughout most of gestation, even into the postnatal period. Genetic factors are the most frequent causes of malformations during the first half of gestation; environmental factors are more important in late gestation and may cause disturbances of late neuroblast migrations, particularly in premature infants. In some cases, no definite inductive factor is identified despite intensive clinical investigations during life and meticulous postmortem studies.

Ischemic Encephalopathy in the Fetus

Among the environmental factors that may interfere with the developmental process in utero or postnatally, cither briefly or more chronically, none is more important as a cause of morbidity than ischemic or hypoxic encephalopathy, Circulatory insufficiency or hypoxemia may interfere with migrations by causing infarction, which interrupts glial guide fibers.

Ischemia also affects the fetal cerebrum by producing watershed infarcts between zones of artetial supply because of poorer collateral circulation compared with the mature brain. Thin-walled vessels radiate perpendicular to the surface of the brain. The precursors of these radial vessels originate from leptomeningeal arteries and are evident at 15 weeks' gestation in the human embryo; horizontal branches appear in deep cortical layers at 20 weeks' gestation and increase to supply the superficial cortex by 27 weeks' gestation. The capillary network of the cortex proliferates mainly in the postnatal period, as radial arterioles dectease in number. Severe ischemia of the immature brain may result in cuffs of surviving nerve cells surrounding the radial arterioles, with vertical columns of necrotic tissue between these zones related to immaturity of the vascular bed, Alternating radial zones of viable cerebral tissue and infarctcd tissue thus occur in the cerebral cortex. Infarcts not only destroy maturing nerve cells that have already completed their migration hut also interfere with continuing and future migrations into those regions. The zones of infarction eventually become gliotic, and the geometric architecture of the cortex is disrupted.

The existence of fetal watershed zones of the cortical vascular bed is important in the pathogenesis of ulcgyria an atrophy of gyri that grossly resembles polymicrogyria. Focal areas of cortical atrophy and gliotic scarring after perinatal ischemic or hypoxic encephalopathy have been known for many years. The four-layered cortex of polymicrogyria is traditionally consideted quite a different lesion than ulegyria, resulting from a primary disturbance of neuroblast migration. Some authors question this interpretation, however, and provide evidence of postmigratory laminar necrosis of the cortex. Polymicrogyria is frequently distributed in vascular territories of fetal brain and often forms a rim surrounding a porencephalic cyst in the territoty of the middle cerebral artery. Multicystic encephalomalacia and hydranencephaly arc end-stage sequelae of massive cerebral infarction in the developing brain. Watershed zones also exist in the brainstem, between the territories supplied by paramedian penetrating, short circumferential, and long circumferential arteries, which all originate from the basilar artery. Transient hypoperfusion in the basilar artery in fetal life may produce watershed infarcts in the tegmentum of the pons and medullar oblongata. This is a probable pathogenesis of Mobius' syndrome and probably also of "failure of central respiratory drive" in neonates with hypoventilation not due to pulmonary or neuromuscular disorders. The cause is involvement of the tractus solitarius, which receives afferents from chemoreceptors, such as the carotid body, and provides efferent axons to motor neurons that innervate the diaphragm and intercostal muscles.

MOLECULAR GENETIC CLASSIFICATION Of MALFORMATIONS OF **THE** NERVOUS SYSTEM

Classification is a fundamental human thought process, allowing us to organize data in a systematic manner and understand relations. The classification of the malformations of the CNS traditionally is based on descriptive morphogenesis, but the new insight into the molecular genetic programming of neural development **in the last** decade (Simeonc 2002) requires that rhese new data be integrated with anatomical criteria to be etiological!)' relevant and clinically useful. For example, lissencephaly and holoprosencephaly are two important malformations, each formerly thought to be distinctive dysgeneses, but we now recognize many different genetic defects that cause each; hence they are end stages of ontogenetic errors with diverse etiologies (see following). A pure genetic classification to replace anatomical criteria, by contrast, would not be useful to clinicians, radiologists, ot pathologists and would be incomplete because many genetic mutations remain imkr.owr. A ;<impn imise (h;ii addresses the deficiencies of both pure analoinic.il and pure genetic schemes of classification is one based upon *patterns of genetic expression* in which the precise generic mutation may or may not be known but is stated while preserving anatomical criteria (Sarnat 2000; Sarnat and Flores-Sarnat 2001b), The upregulation or down regulation of a dorsalizing or ventraliziug gene thus may be recognized by its anatomical effect on neural tube development, even if the precise gene is not yet identified.

The traditional categories of CNS development that allow categoties of ontogenetic processes, such as ncuronogenesis, neuroblast migration, and synaptogenesis, and their disturbances in malformations, may -be preserved in the proposed new scheme of classification, bur are

"•In holoprosencephaly, anatomical varieties do not correspond to genetic defect and correlate poorly with midfacial hypoplasia.

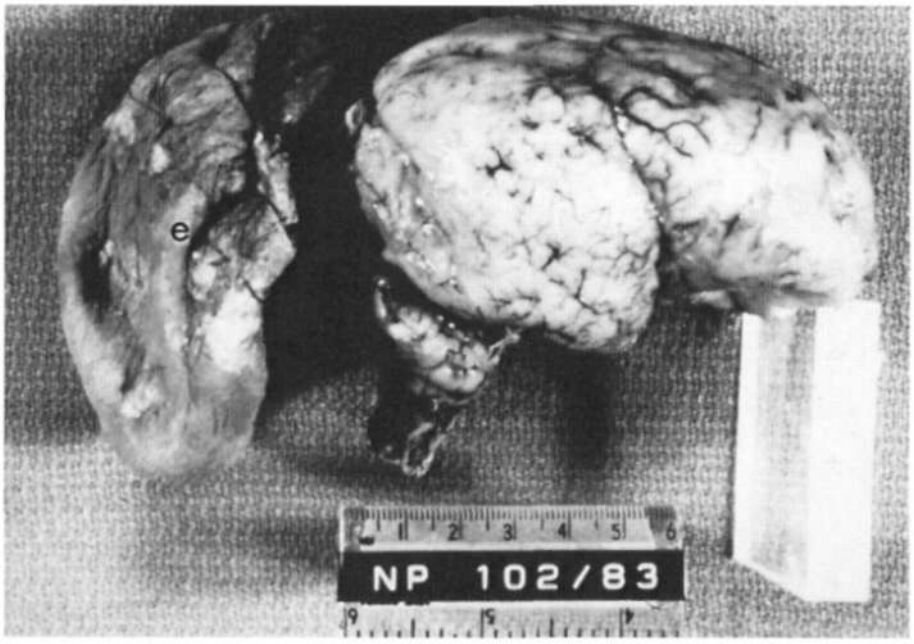

FIGURE 66.8 Lateral view of the brain of a term neonate with Meckel-Gruber syndrome. This dysplasia is a large occipital encephalocele (e) and lissencephaly. The brain is smooth and shows only a sylvian fissure and a few shallow abnormal sulci near the vertex. The encephalocele contains disorganized neural tissue, angiomatous malformations, focal hemorrhages, and zones of infarction.

surrounding countries. They nearly always include olfactory tissue.

The cerebral tissue in the encephalocele sac is usually extremely hamartomatous without recognized architecture. It may include heterotopia from an unexpected site, such as cerebellar tissue in a frontal encephalocele. Zones of infarction, hemorrhage, calcifications, and extensive proliferations of thin-walled vascular channels are common, approaching the disorganized tissue of the area cerebrovasculosa of atelencephaly. The remaining intracranial brain is often dysplastie as well. The ventricular system may be partially herniated into the encephalocele sac, at which point hydrocephalus ensues.

Kncephaloceles may be completely covered with skin, or lln:i, diMorlcd im rim;',„•.!I membranes may he expired. Leaking CSh' rapidly becomes infected. Some encephalocclcs, particularly those of the occipital midline, may become so large that they exceed the size of the infant's head. Nasopharyngeal encephaloccles arc rare but may be a source of meningitis from CSF leak through the nose. Malformations of the visceral organs often coexist with encephaloceles, and other congenital anomalies of the eyes and face, cleft palate, and Polydactyly also are common. The entire brain may be severely hypoplastic {see Figure 66.1).

Clinical neurological handicaps may be severe because even if the herniated tissue within the encephalocele is small and easily excised, concomitant intracranial malformations of the brain often result in epilepsy, mental retardation, motor impairment, and often cortical blindness in the case of occipital encephaloccles. The treatment of choice of small encephaloccles is surgical excision and closure of overlying cutaneous defects. Seizures and hydrocephalus are common but treatable complications.

Meningomyelocele (Spinal Dysrapbism, Rachiscbisis, Spina Bifida Cystica)

Spinal dysraphism involving the caudal end of the neural tube results from the posterior neuropore not closing at 26 days postnatal. The hypothesis that meningomyelocele .iiul .ik-lnvcplia'\ arc due to increased pressure and volume of fluid within the primordial ventricular system of the developing neural tube, which causes rupture at one end and prevents reclosure, has not been widely embraced. This is true because the choroid plexuses are not yet formed at the time of neural tube closure, and embryological evidence of hydrocephalus at that stage in experimental animals is lacking. Although many theories have been proposed, and several teratogenic drugs, hypervitaminosis A, and genetic models are able to produce neural tube defects and hydrocephalus in experimental animals, none explains the pathogenesis of faulty neurulation in humans.

The spina bifida syndromes are classified on one of two bases: the bony vertebral deformity or the neurological lesion and associated clinical deficit. The latter can cause a range of problems, including no deficit in the case of spina bifida occulta without herniation of tissue or mild spina bifida cystica with herniation of meninges alone. Deficits resulting from herniation of nerve roots and consequent motor, sensory, and autonomic neuropathy (meningomyelocele) also occur, as do extensive defects that also involve the parenchyma of the spinal cord (myelodysplasia). Most lesions are lumbosacral in location, but meningomyelocele also may occur in the thoracic or even the cervical region, usually as an extension rostrally of lumbosacral lesions. The level of involvement determines much of the clinical deficit. Type II Chiari malformation is consistently

present, and aqueductal stenosis coexists in 50% of cases. Hydrocephalus is a common complication, involving most patients with meningomyelocele and causing neurological deficit.

The tteatment of meningomyelocele is controversial and enters the arena of medical ethics. Small defects are easily closed surgically in the neonatal period, but large defects that cause complete paraplegia and flaccid neurogenic bladder, often accompanied by hydronephrosis, severe hydrocephalus, and other cerebral malformations, are associated with poor quality of life. A decision not to treat such infants or not to prolong survival poses a moral question to be addressed by the physicians in consultation with parents, hospital ethics committees, and other individuals whom the parents may identify.

The most important immediate complications of large meningomyeloceles are hydrocephalus and infection from leaking CSF. Long-term complications include chronic urinary tract infections, decubiti, hydrocephalus, paraplegia, and other neurological deficits. Mental retardation is common but may be mild.

Midline Malformations of the Forebrain (4-8 Weeks' Gestation)

A series of developmental malformations of the prosencephalon are embryologically related to the lamina tcrminalis not differentiating into telencephalie structures. The lamina terminalis is the rostral membrane of the primitive neural tube that forms with closure of the anterior neuropore. Disorders of the lamina terminalis are expressed mainly as midline defects, not only because of its location in the midline but also because lateral growth of the cerebral hemispheres is affected due to deficient or abnormal cellular migration centrifugally to form the cerebral cortex. The series of midline prosencephala malformations is related to the cmbryological time of the beginning of each and includes alobar, semilobar, and lobar hi^(prosencephaly, arhinencephaly, septo-optic dysplasia, colpocephaly, and agenesis ol [lie corpus , illnsum.

The lamina terminalis itself, after differentiating the forebrain structures, becomes the anterior wall of the third ventricle in the mature btain, extending between the optic chiasm ventrally and the rostrum of the corpus callosum dorsally. Some authors contend that a defective cephalic notochord induces midline forebrain defects. The complex embryological relationships of neuroectoderm and mesoderm in early ontogenesis arc incompletely understood.

Ho loprosencephaly

Holoprosencephaly is a malformation in which the two cerebral hemispheres appear to be fused in the midline, but is really a failure of cleavage in the midsagittal plane of the embryonic cerebral vesicle at 33 days" gestation and thus a paramedian hypoplasia of the forebrain. Holoprosencephaly (HPF.) has a frequency of 1:16,000 live births, but 1:250 spontaneously aborted fetuses in the first trimester, hence is among the most common of the major cerebral malformations.

HPF. was traditionally thought to be a single malformation, and four variants were defined: alobar, semilobar, lobar, supplemented more recently by the middle interhemisphcric varianta) (Hahn and Pinter 2002; Simon ct al, 2002). Recent molecular genetic data redefines HPF. as a common end-stage malformation with six known different genetic iiint.Hions Jrmnnsl r.iiiil in various cases iflnklcii 1998), and 12 other chromosomal defects also are known in which the specific genetic mutation is not yet identified (Table 66.2).

All six known defective genes together account for only about 20% of cases studied, so that many more genetic etiologies are undiscovered. Furthermore, each of the traditional anatomical variants ol holoprosencephaly is demonstrated in each of the six known genetic forms, signifying that these merely represent degrees of severity without etiological implication.

A defect in the ZIC-2 gene is associated with chromosome 13q deletions, and holoprosencephaly is frequent in infants with trisomy 13 (Brown et al. 1998}. One of the most studied of the genetic mutations is the strong vcntralizing gene, Sonic hedgehog (SI II I); the lack of expression of this gene in the ptechordal mesoderm ventral to the rostral end of the neural tube results in no neural induction (Roessler et al. 1996). Abnormal SHH expression also may be altered in metabolic diseases with impaired cholesterol synthesis and high serum levels of the cholesterol precursor molecule 7-dehydrocholcsterol, as in the Smith-Lemli-Opitz syndrome, associated with holoprosencephaly (Kelley et al. 1996).

After chromosomal defects, the most common association of holoprosencephaly is maternal diabetes mellitus;

sacral agenesis is another common malformation in infants •;il di ilx'tk mothers. hoth involve dowuregulation <•I SI li I. A defect at the same chromosome 7p36.2 locus associated with an autosomal dominant form of HPE also affects SHH at the posterior, rather than the anterior, end of the neural tube and results in sacral agenesis (Lynch et al. 1995). Disturbed insulin metabolism may affect SHH in programmi ng the neural tube.

Olfactory bulbs and tubercles differentiate a few days after forebrain cleavage, but olfactory agenesis almost always accompanies all but the mildest forms of holoprosencephaly; therefore the term *arb'mencephaly* has often been used interchangeably (and incorrectly). Callosal agenesis also is a uniform feature except in the mildest forms, and the cerebral mantle is grossly disorganized, with multiple heterotopia, poorly laminated cortical gray matter, and heterotopic neurons and glial cells in the overlying meninges. Extensions of germinal matrix into the lateral ventricles through gaps in the ependyma are common. Thus, although holoprosencephaly can be dated to about 33 days' gestation at onset, the pathological process extends throughout most of fetal life.

The anatomical variants of holoprosencephaly have been classified into four types, reflecting different degrees ol abnormal cerebral architecture. Alobar holoprosencephaly is characterized by a brain with a single midline telencephalic ventricle, rather than paired lateral ventricles, and continuity of the cerebral cortex across the midline frontally. The roof of the monoventriele balloons into a dorsal cyst. The corpus sttiatum and thalamus of the two sides are uncleaved, and the third ventricle may be obliterated, with rudiments of ependymal tosettes in its place. In semilobar holoprosencephaly, an incomplete intcrhemispheric fissure is formed posteriorly, and the occipital lobes, including the occipital horns of the ventricular system, may approach a normal configuration, despite noncleavage of the frontal lobes across the midline. Lobar holoprosencephaly is a less severe dysgenesis; the hemispheres are well formed but are in continuity through a band of cortex at the frontal pole or the orbital surface, and the indusium griscum and cingulate gyri overlying the corpus callosum are in continuity. The corpus callosum is incompletely formed but not totally absent, as in alobar and semilobar holoprosencephaly. The middle inrerhemispheric variant consists of hypoplasia of the middle part ol the corpus callosum and associated structures of the medial side of the hemispheres. In the more severe forms of holoprosencephaly, the optic nerves are hypoplastic or fused to enter a single median eye. Midline cerebellar defects, absent pyramidal tracts, and malformed brainstem structures accompany the more severe form-, ol [his malformation. Meningeal heterotopia or marginal gtioneuronal nodules commonly result from overmigration, perhaps associated with absence of the transitory external granular layer of rhe fetal brain in HPE.

Holoprosencephaly often is diagnosed at the time of delivery because 93% of patients exhibit midline facial dysplasias. Midfacial hypoplasia is present in most patients with I IPE, but others have a normal face. The facial dysmorphism ranges from mild hyporelorism and vomer bones to severe forms, including cebocephaly with a single nare, severe hypotelorism and absence of the premaxilla and vomer bones to produce a midline cleft lip and palate, or cyclopia with a midline proboscis dorsal to the single median eye, The severity of the facial dysmorphism does not correlate as well with the anatomical variant as originally thought, expressed in the often-cued statement, "The face predicts the brain," Midfacial hypoplasia does correlate, however, with the rostrocaudal extent of the defective genetic expression. If the gradient extends to the embryonic mesencephalic neuromerc and causes hypoplasia of the midbrain, neural crest formation and migration are affected (Sarnat and Flores-Sarnat 2001a). The mesencephalic neural crest is the most rostral origin of neural crest and this tissue forms not only peripheral neural structures such as the ciliary ganglion, but also most of the membranous bones of the face, globe of the eye (except the retina and choroid), and much of the facial connective tissue.

The various forms of holoprosencephaly are well demonstrated h\ must imaging tei ;i:ui[ik -s [figure d(i.[l]>), including prenatal ultrasound. The imaging features of each anatomical variant are distinctive (Halm and Pinter 2002) and correspond well ro the gross neuropathological findings (Golden 1998). The anterior cerebral artery is usually a single azygous vessel coursing just beneath the inner table of the skull, a pathognomonic finding. The sagittal sinuses are deformed or replaced by a network of large abnormal veins that resembles the early embryonic pattern of venous drainage.

The EEG in holoprosencephaly shows multifocal spikes that often evolve into hypsarrhythmia. In the neonatal period, the waking EEG is characterized by almost continuous high-voltage alpha-thcta monorhythmic activity, becoming discontinuous in sleep. VEPs also arc abnormal or altogether absent,

The clinical cotttse of holoprosencephaly is characterized by severe developmental delay and mental retardation and by a mixed pattern of seizures that often are refractory ro anticonvulsant medications. The presence or absence of seizures docs not correlate with the anatomical severity or variant of the defective forebrain and also correlates poorly with the genetic mutation (Hahn and Pinter 2002). A better correlation may be with the degree of mediolateral extension of genetic expression in disrupting the histological architecture of the cortex, or may relate to an abnormal sequence of maturation of axosomattc (inhibitory) and axodendritic (excitatory: synapses in relation to the maturation of the neuron innervated by these axonal terminations (Sarnat and Elores-Sarnat 2001a).

Some patients develop hydrocephalus and require shunting, and this condition is paradoxically more common in

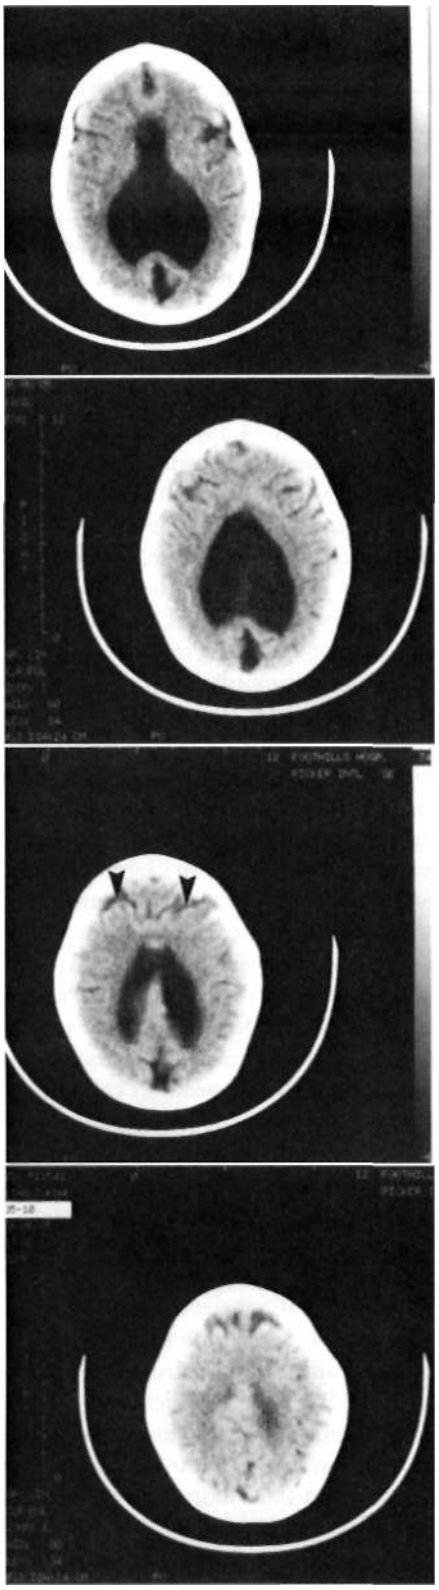

FIGURE 66.9 Unenlianced computed tomographic scan of a 6-year-old boy with semilobar holoprosencephaly. The lateral ventricles are fused, particularly frontally, but show some division into two occipital horns. A deep abnormal sulcus is seen across the fused frontal lobes *(arrowheads).* This is one of several radiological variants of holoprosencephaly.

the less severe anatomical forms of the malformation. In the severe, alobar form, a "dorsal cyst" occupies the entire posterior half to two thirds of the intracranial space and occasionally even protrudes through the anterior fontanelle as a unique encephaloeele that may be larger than the rest of the head. No other type of encephalocele is found at the anterior fontanelle. The dorsal cyst seems to originate from a dilated suprapineal recess of the third ventricle and later is a dorsal membrane that includes the roof of the forebrain, extending from the hippocampi (Sarnat and Flores-Sarnat 2001a).

Hndocrine dysfunction may be present, associated with hypothalamic or pituitary involvement, and vasopressin-sensitive diabetes insipidus occurs in about K6% of cases, other hypothalamic-pituitary dysfunction being much less frequent (Plawner et al. 20021. The basis of this specific involvement of the paraventricular and supraoptic hypothalamic nuclei may be hypoplasia in some cases in which the midline hypoplasia involves the diencephalon as well as the forebrain (most patients), hut also occurs in some children without hypothalamic noncleavage. One hypothesis is that the expression of the gene Orthopcdia (OTP) is secondarily suppressed by the primary genetic defect; OTP and downstream genes, such as SIM1 and BRN2, are essential for terminal differentiation of neuroendocrine cells of these hypothalamic nuclei (Sarnat and Flores-Sarnat 2001a).

The treatment of HPF is directed toward the complications, such as seizures, hydrocephalus, and endocrine disturbances. Educational potential and needs depend on the degree of mental retardation, speech, and visual impairment.

Isolated Arhinencepkaly and Kallmann's Syndrome

Absence of olfactory bulbs, tracts, and tubercles commonly accompanies more extensive malformations, such as holoprosencephaly and septo-optic dysplasia, but may occur with callosal agenesis or as an isolated cerebral anomaly. Kallmann's syndrome is an X-linkcd or autosomal dominant condition limited to males, in which anosmia secondary to arhinencephaly without other forebrain malformations is associated with lack of secretion of gonadotropic hormones. The genetic defect is KALI at the chromosome Xp22..'? locus, but the FMX2 gene also is implicated, though schizencephaly does not occur with Kallmann's syndrome (Taylor et al. 1999). Olfactory reflexes may he elicited in the neonate consistently after 32 weeks' gestation and provide a useful supplement to the neurological examination of newborns suspected of cerebral dysgenesis.

Septo-Optic-Pituitary Dysplasia

The association of a rudimentary or absent septum pellucidum with hypoplasia of the optic nerves and

chiasm was first recognized hy De Mosier in 1956. Underdevelopment of the corpus callosum and anterior commissure and detachment of the fornix from the ventral surface of the corpus callosum are additional features. Patients with this combination of anomalies overlap others with semilobar holoprosencephaly, and some children with septo-optic dysplasia also have arhinencephaly.

Disturbances of the hypothalamic-pituitary axis often occur in septo-optic dysplasia, ranging from isolated growth hormone deficiency to panhypopituitarism and deficient secretion of antidiuretic hormone. Hypothalamic hamartomas, gliosis, and the absence of some hypothalamic nuclei may he associated with a histologically normal pituitary. Absence of the neurohypophysis is demonstrated at autopsy in some cases.

Midline cerebellar defects and hydrocephalus occur inconsistently in septo-optic dysplasia. One cerebellar lesion, called *rhombencephalosynapsis* is aplasia of the vermis and midline fusion of the cerebellar hemispheres and of the dentate nuclei, probably the downrcgulation of a dorsalizing gene at the level of rhombomere 1 (Samat 2000).

Clinical manifestations relate mainly to the endocrine deficiencies and vision impairment. Ataxia may be compensated if the cerebellar vermis is mildly involved. Seizures are uncommon. Intellectual development usually is normal. Hypertelorism is nor a constant finding. Chromosomes are invariably normal. The gene HESX1 is defective in at least some cases (Dattani et al. 1998). Familial cases are not reported. There is, however, a high incidence of teenage pregnancy and drug abuse in early gestation in mothers of affected infants. Septo-optic-pituitary dysplasia has been described in an infant of a diabetic mother.

Rbmnbmneiic Deletions and Ectopic Genetic Expression

Rare patients with absence of certain parts of the brain have long been known, but only recently, with the understanding of the families of genes responsible for neural tube segmentation (e.g., HOX, WNT, PAX), have these medical curiosities been understood at the level of molecular embryology. Agenesis of the midbrain and upper pons (metencephalon) with cerebellar hypoplasia is attributed to the FN2 gene, which produces an almost identical malformation in the knockout mouse model (Sarnat ct al. 2002). EN1 and WNT1 genes also are essential for development of the mesencephalic and rhombomere 1, but the annual models of these genetic defects produce rotal agenesis of the cerebellum. Absence of the corpus striatum might be due to mutation of the EMX1 gene, which is essential in the programming of the basal telencephalon but not the cerebral cortex (Sarnat and Flores-Sarnat 2001a). The Chiari malformations, particularly type II, are traditionally but incompletely explained by mechanical theories of pathogenesis, but a molecular genetic hypothesis of ectopic expression provides a more complete and reasonable explanation (see following; Sarnat and Flores-Sarnat 2001). Whereas many of these genetic malformations are well demonstrated in experimental animal models, none are yet definitively confirmed in humans.

Agenesis of the Corpus Callosum

A commissural plate differentiates within the lamina terminalis at day 39 of embryonic life. The plate acts as a bridge for axonal passage and provides a preformed glial pathway to guide decussating growth cones of commissural axons. The inter hemispheric projection of the first axons is preceded by microcystis- degeneration m the commissural plate and physiological death of astrocytes. The earliest callosal axons appear at 74 days in the human embryo, the genu and the splenium are recognized at 84 days, and the adult morphology is achieved by 115 days.

The pathogenesis of callosal agenesis is related to two aspects of the commissural plate. If this plate is not available to guide axons across, the corpus callosum does not develop. However, failure of physiological degeneration of a portion of the plate results in a glial barrier to axonat passage, and primordial callosal fibers are deflected posteriorly to some other destination within their hemisphere of origin (bundle of Probst) or disappear.

Agenesis of rhe corpus callosum is a common malformation, having a 2..'!% prevalence m computed tomographic (CT) scans in North America and 7-9% prevalence in Japan. Most cases are isolated malformations, hut callosal agenesis is an additional feature of many other prosencephala dysplasias; it also occurs with aplasia of the cerebellar vermis and anomalous pyramidal tract. Simple callosal agenesis may involve the entire commissure or may be partial, usually affecting only the posterior fibers. Hypoplasia or partial agenesis of the commissure is much more common than total agenesis. In callosal agenesis, the anterior and hippocampal commissures are always well formed or large.

A rare genetic form of callosal agenesis is associated with defective neural crest migration causing aganghonic megacolon (Hirschsprung's disease) is due to a defective human gene, Smad-interacting protein-1 (SMAD1), at the chromosome 2q22-q23 locus (Cachcux ct al. 2001).

In the absence of a corpus callosum, the lateral ventricles are displaced laterally and the third ventricle rises between them (Figure 66.10). The ventricles also are often mildly dilated, but intraventricular pressure is normal. The anomaly may be demonstrated by most imaging techniques. The varying degrees of partial callosal agenesis produce several radiographic variants,

Clinical symptoms of callosal agenesis may be minimal and unrecognized in children of normal intelligence, although detailed neurological examination discloses deficits in the intcrhemispheric transfer of perceptual information for verbal expression. Mental retardation or learning disabilities arc found in some cases. Epilepsy is common, particularly in patients who are diagnosed early in life.

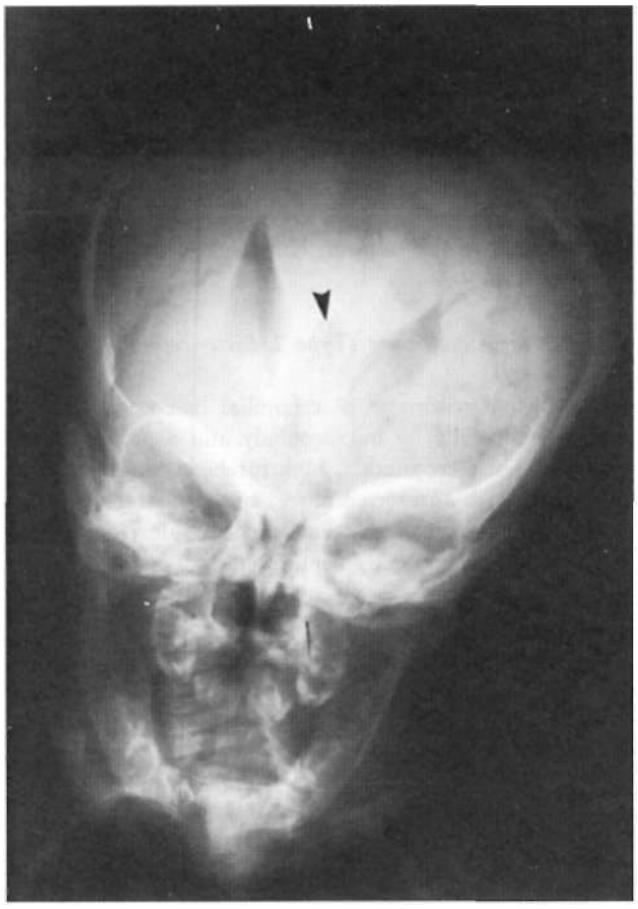

FIGURE 66.10 Pneumoencephalogram, from the pre-imaging period, of an lH-month-old boy with agenesis of the corpus callosum associated with an inter hemispheric arachnoidal cyst, a complication of some cases of callosal agenesis. The lateral ventricles are widely separated from the medial side of each hemisphere by the bundle of Probst; the third ventricle rises between them. The brainstem, cerebellum, and cerebral cortical convolutions appear normal. The patient has mental retardation and epilepsy.

Seizures may relate more to minor focal cortical dysplasias than to the callosal agenesis itself. Hypertelorism is present in many but not all cases and often is associated with exotropia and inability to converge.

The EEG characteristically shows interhemispheric asynchrony or poor organization, with or without multifocal spikes, but is not specific enough to establish the diagnosis. Asynchronous sleep spindles after 18 mouths of age arc a good clue.

Several hereditary forms of callosal agenesis are described besides its occurrence as an additional anomaly in some cases of tuberous sclerosis and various genetic syndromes. An autosomal recessive syndrome of callosal agenesis, mental deficiency, and peripheral neuropathy is known as Andermann's syndrome. Aicardt's syndrome consists of.agenesis of the corpus callosum, chorioretinal lacunae, vertebral anomalies, mental retardation, and myoclonic epilepsy. This disorder is found almost exclusively in girls and is thought to be X-linked dominant (chromosomal locus is Xp22) and generally lethal in the male fetus. The EEG shows a typical asymmetrical and asynchronous burst-suppression pattern. Neuropathologies! findings in Aicardi's syndrome include a variety of minor dysplasias in addition to agenesis of the corpus callosum and anterior commissure and nonlaminated polymicrogyric cortex with abnormally oriented neurons. I inllosal agenesis is a common compouail m main . limnm somal disorders, particularly trisomies 8, 11, and 13. Lipoma replacing part of the corpus callosum is associated with a high incidence of epilepsy.

Colpocephaly

Colpocephaly is a selective dilatation of the occipital horns, not due to increased intraventricular pressure but rather due to loss of white matter. Three conditions may cause colpocephaly: (1) it may appear as a primary malformation, histologically associated with poorly laminated striate cortex, subcortical heterotopia, and defective ependymn lining the occipital horns; (2) it is common in many cases of agenesis of the corpus callosum because of absence of the splenium and hypoplasia of white matter; and (3) it may be the acquired result of periventricular leukomalacia, especially in premature infants, because of loss of periventricular white matter in the posterior half of the cerebral hemispheres.

Clinical findings are usually those of mental retardation, spastic diplegia, epilepsy, and vision loss, but it does not always cause complete blindness. Most cases have been demonstrated by CT in the neonatal period or early infancy. Isotope cisternography shows normal CSF dynamics in most cases. Colpocephaly is associated with a number of syndromes and systemic disorders, including cerebro-hepato-renal (Zellweger) disease, hemimcgalcnccphaly, and several chromosomal disorders.

The EEG in colpocephaly ranges from normal in mild cases to near-hypsarrhythmia in infants who develop myoclonic epilepsy. Bilateral posterior slowing of low voltage with occipital spikes is common.

Colpocephaly also develops late in fetal life because of infarction and cystic degeneration of the deep white matter of the posterior third of the cerebral hemispheres, rather than as a developmental disorder of neuroblast migration. It should not be confused with hydrocephalus.

Disorders of Early Neuroblast Migration (8-20 Weeks' Gestation)

Lissencephaly (Agyria)

Lisscncephaly is a failure of development of convolutions in the cerebral cortex because of defective neuroblast

migration. The cortex remains smooth, as in the embryonic brain (see Figure 66.8). The migrations of the cerebellum and the brainstem also are usually involved, but the embryonic corpus gangliothalamicus pathway is not distutbed, so the thalamus and basal ganglia are well formed. Structural and metabolic abnormalities of the fetal ependyma may be important factors in disturbing the normal development of radial glial cells.

The cytoarchitecture of the neocortex in lissencephaly takes one of two forms. In the first, a four-layered sequence develops. The outermost layer is a widened molecular zone; layer 2 contains neurons corresponding to those of normal laminae III, V, and VI; layer 3 is cell-sparse; and layer 4 contains heterotopic neurons that have migrated incompletely. Decreased brain size leads to microcephaly, with widened ventricles representing a fetal stage rather than pressure hydrocephalus and an uncovered sylvian fossa representing a lack of opcrculation. The second form of cortical architectural abnormality- in lissencephaly is disorganized clusters of neurons with haphazard orientation, forming no definite layers or predictable pattern. Type 2 lissencephaly is associated with several closely related genetic syndromes: Walker-Warburg syndrome, Fukuyama muscular dystrophy, muscle-eye-brain disease of Santavuori, and Meckcl-Gruber syndrome. Encephalocele may be associated with some cases of lissencephaly (see Figure 66.8}.

Miller-Dieker Syndrome (Type 1 Lissencephaly)

Miller-Dieker syndrome is a familial lissencephaly characterized clinically by microcephaly and a peculiar facics that includes micrognathia, high forehead, thin upper lip, short nose with antevcrtcd nares, and low-set ears (Figure 66.11). Neurologically, the children are developmentally delayed in infancy and mentally retarded, lack normal

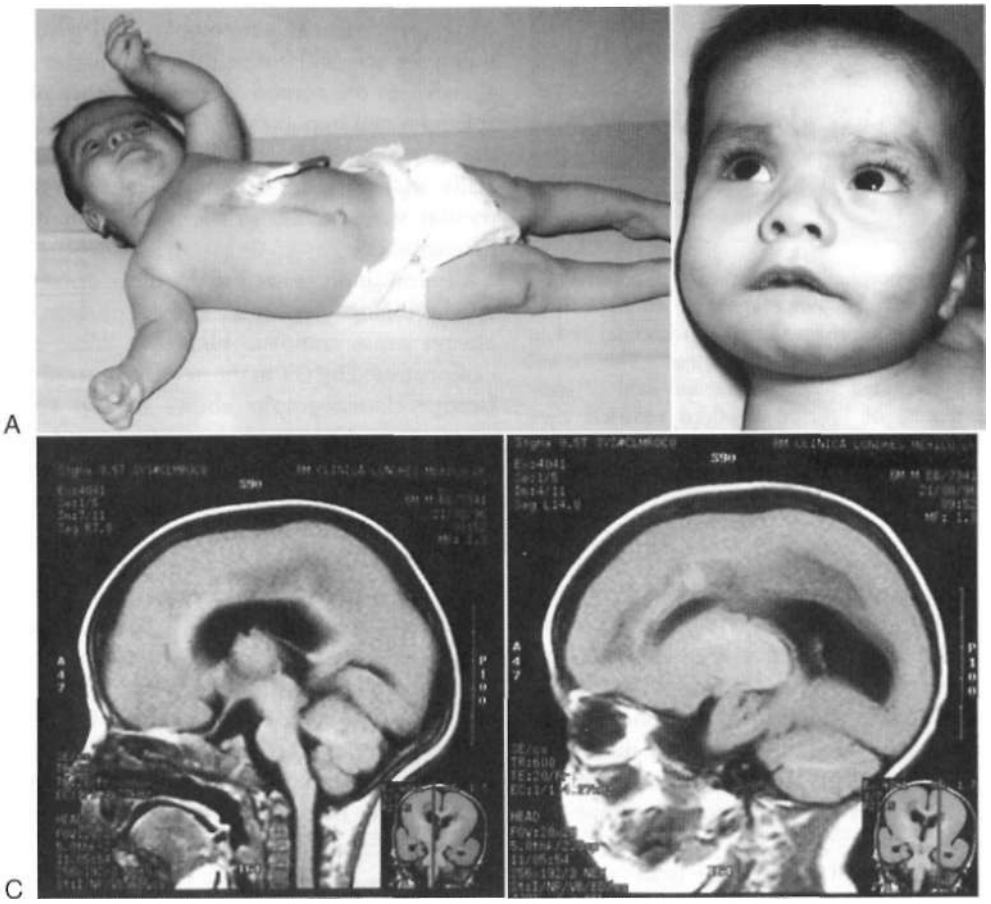

FIGURE 66.11 (A) This 7-month-old boy has Miller-Dieker syndrome. He has unusual postures of the extremities and opisthotonus, which are not seen in all patients with this genetic disorder. Note the gastrostomy that he required. (B] He has the typical facies of this genetic syndrome, with a high brow, upturned nares, and long phiitrum (upper lip). His gaze is dysconjugate, but there is no paresis of extraocular muscles. (C) Sagittal and (D) parasagittal views of Tl-weightcd magnetic resonance images, showing type I lissencephaly with only mild ventriculomegaly. The cerebellum and brainstem, including the basis pontis, are grossly well formed. The corpus callosum is very thin. Kxtra-fixial (i.e., subarachnoid) spaces are wide over rhe convexities of the cerebral hemispheres and in the cisterns surrounding the brainstem.

responsiveness to stimuli, initially exhibit muscular hypotonia that later evolves into spasticity and opisthotonos, and develop intractable seizures. Death before 1 year of age is common. The EEC often shows focal or multifocal spike-wave discharges that later become bisynchronous bursts of diffuse paroxysmal activity and extremely high-voltage diffuse rhythmic theta and beta activity.

At autopsy, the original cases showed lack of gyral development in the cerebral cortex, but later patients were found with the typical craniofacial features and clinical course but with gyral development, although the convolution-. were almoin:,il ;.rij pachygyria predominated. I he term *Miller-Dieker syndrome* was proposed to distinguish this syndrome from other cases of lissenccphaly without the clinical and dysmorphic facial features. A microdcletion at the chromosome 17pl3.3 locus is demonstrated by high-rcsolution studies in most patients with Miller-Dieker syndrome, and family members of the original patients also show the defect (Chong et al. 1997). The responsible gene is LIS1. Histological examination of the brain in Miller-Dieker syndrome confirms the presence of a severe disorder of neuroblast migration, as in other cases of lissencephaly.

Walker-Warburg and Related Syndromes (Type 2 Lissencephaly)

Type 2 lissencephaly/pachygyria includes several distinctive disorders of different genetic origin, but all of which involve the terminal organization and architecture of the cortical plate and most of which include a dystrophic myopathy. In Fukuyama muscular dystrophy, a congenital muscular dystrophy is associated with cerebral dysgenesis of this type, due to mutation in the gene Fukutin. Though common in Japan, where it is the second most common muscular dystrophy (after Duchenne type dystrophy), it is rare in othet ethnic populations. The muscle-eyc-brain disease of Santavuori is most common in Finland, but also exists in other northern European ethnic groups. Walker-Warburg is another congenital muscular dystrophy found in diverse ethnic groups. An autosomal recessive type 2 lissencephaly associated with cerebellar hypoplasia is due to defective expression of Reel in, and X-l inked congenital hydrocephalus (usually due to aqueductal atresia) is associated with pachygyria and mutation of the cell adhesion gene *L1CAM.*

Subcortical Laminar Heterotopia (Band Heterotopia, Double Cortex) and Bilateral Periventricular Nodular Heterotopia

Subcortical laminar heterotopia and bilateral periventricular nodular heterotopia both result from X-l inked recessive traits that occur almost exclusively in females. Both disorders present clinically as severe seizure disorders in childhood, although they arc often associated also with mental retardation and other neurological deficits. In subcortical laminar heterotopia, a band of gray matter heterotopia within the subcortical white matter lies parallel to the overlying cerebral cortex but separated from it by white matter. Histologically, it is not laminated, as is the normal cortex, and consists of disoriented neurons and glial cells and fibers with poorly organized architecture. The few male fetuses that have not spontaneously aborted have been born with lissencephaly in addition and even more severe neurological deficits. The defective gene and its transcription product in subcortical laminar heterotopia have been identified; the latter is called *dotiblecortin* ((ileeson et al. 1999). In bilateral periventricular nodular heterotopia, islands of neurons and glial cells occur in the subependymal regions around the lateral ventricles and are neuroepithelial cells that have matured in their site of origin without migrating (Eksioglu et al. 1996). The gene responsible is Filamin-1. Both conditions are best demonstrated by MRI, but also are detected by CT,

Scbizencephaly

Deep or shallow clefts in the region of the Sylvian fissure, with open or closed lips, is a configuration termed *scbizencephaly.* Schizencephaly is associated with defective expression of the gene EMX2 (Granata et al. 1997). It may be associated with a variable degree of lissencephaly/pachygyria and may be bilaterally symmetrical or asymmerrical, more severe on one side or even unilateral.

llemtm egalen cephaly

This is one of the most enigmatic cerebral malformations because it is a severe dysgenesis limited to one cerebral hemisphere or, less commonly, includes the ipsilatcral cerebellar hemisphere and brainstem ("total hemimegalencephaly"). Though traditionally regarded as another disorder of neuroblast migration, this feature is probably only secondary to involvement of radial glial cells and perhaps the neuroblasts themselves, and the primary process is a disturbance of cellular lineage and also involvement of genes of symmetry expressed as early as gastrulation (Flores-Sarnat 2002a; Elores-Sarnat et al. 2003). Individual neural cells exhibit both glial and neuronal proteins and have abnormal growth and morphology. Some cases of hem lm egalen cephaly are isolated malformations, but others are syndromic, particularly associated with epidermal nevus syndrome, Proteus syndrome and Klippel-Trenaunay-Wcber syndrome. Clinical features and neuropathological findings are virtually identical in isolated and syndromic forms. The principal clinical manifestation is severe partial epilepsy, often refractory to medical treatment and abolished only by hcmisphcrcctomy or other surgical resections. Other less constant features include variable mental retardation and contralateral motor deficit. Mild as well as severe forms

occur. Syndromic forms additionally include the features of the particular syndrome, such as lipoma formation in the ipsilatcral face in epidermal nevus syndrome.

Disturbances of Late Neuroblast Migration (after 20 Weeks' Gestation)

Although major neuronal migrations in the developing human brain occur in the first half of gestation, late migrations of immature nerve cells continue. A few neuronal precursors continue to migrate to the cerebral cortex after 20 weeks' gestation. Perinatal disorders of cerebral perfusion, small intraparenchymal hemorrhages in premature infants, intracranial infections, and hydrocephalus are examples of common perinatal complications that may interfere with the late neuronal migrations, either by destroying migrating neuroblasts or by disrupting their radial glial fiber guides. Reactive gliosis is detected as early as 20 weeks' gestation in the fetal brain, and proliferation of astrocytes is already evident 4 days after an insult. Neurons may be blocked from traversing a gliotie plaque.

Disorders of Cerebellar Development (32 Days' Gestation to 1 Year Postnatally)

The cerebellum has the longest period of cmbryological development of any major structure of the brain. Neuroblast differentiation in the cerebellar plates (rhombic lips of His) of the dorsolateral future medulla oblongata and lateral recesses of the future fourth ventricle are recognized at 32 days. Neuroblast migration from the external granular layer is nol complete until 1 year postnatally. As a result of this extended ontogenesis, the cerebellum is vulnerable to teratogenic insults longer than arc most parts of the nervous system. Malformations of the cerebellum may be focal, confined to the cerebellum, or associated with other brainstem or cerebral dysplasias. The cerebellar cortex is especially susceptible to toxic effects of many drugs, chemicals, viral infections, and ischemic-hypoxic insults.

Selective Vermal Aplasia

Selective hypoplasia or aplasia of the vermis, with intact lateral hemispheres, occurs in some genetic disorders, in association with other midline defects involving the forebrain, as in some cases of hoioprosencephaly and of callosal agenesis. A specific autosomal recessive disease, Joubert's syndrome, is characterized clinically by episodic hyperpnea, abnormal eye movements, ataxia, and mental retardation and has a variable but often progressively worsening course, with improvement in some cases. Anomalies of visceral organs and Polydactyly may be associated.

Selective Cerebellar Hemispheric Aplasia

Selective agenesis of the cerebellar hemispheres is much less common than aplasia of the vermis alone. Other components of the cerebellar system, such as the dentate and inferior olivary nuclei, may also be dysplastic. The lateral hemispheres and the inferior olivary and pontine nuclei more commonly arc selectively involved in certain degenerative diseases of genetic origin, such as olivopontocerebellar alropin and nllli-i spirincciYJvllar' degenerations.

Dandy-Walker Malformation

The Dandy-Walker malformation consists of a ballooning of the posterior half of the fourth ventricle, often but not always associated with nonopening of the foramen of Magcndie. In addition, the posterior cerebellar vermis is aplastic, and there may be heterotopia of the inferior olivary nuclei, pachygyria of the cerebral cortex, and other cerebral and sometimes visceral anomalies. Hydrocephalus from obstruction almost always develops, but if it is treated promptly, the prognosis may be good. Neurological handicaps, such as spastic diplegia and mental retardation, probably relate more to the associated malformations of the brain than to the hydrocephalus.

Chiari Malformations

The Chiari malformation is a displacement of the tonsils and posterior vermis of the cerebellum through the foramen magnum, compressing the spinomedullary junction. This simple form is termed *Chiari type I malformation.* Type II involves an additional downward displacement of a distorted lower medulla and dysplasia of medullary nuclei and is a constant feature of lumbosacral meningomyelocele. Chiari type III malformation is actually a cervical spina bifida with cerebellar encephalocele. Chiari originally identified a type IV in 1896, but this type is now recognized as cerebellar hypoplasia having no relation to the other types, and the term *Chiari malformation type IV* should now be used only in its historical context. Hydrocephalus is commonly associated with Chiari malformations.

The pathogenesis has been a matter of controversy for many years. Mechanical theories have dominated since the time of Chiari: (1) the traction theory, a result of a tethered spinal cord with traction as the vertebral column grows; (2) the pulsion theory of fetal hydrocephalus pushing the cerebellum and brainstem from above; and (3} the crowding theory in which a small posterior fossa provides insufficient room for the growth of neural structures and causes a "toothpaste tube effect." The torcula is indeed too low and the volume of the posterior fossa small, so that this latter explanation is probably a true contributory factor, but only in late gestation as a superimposed secondary

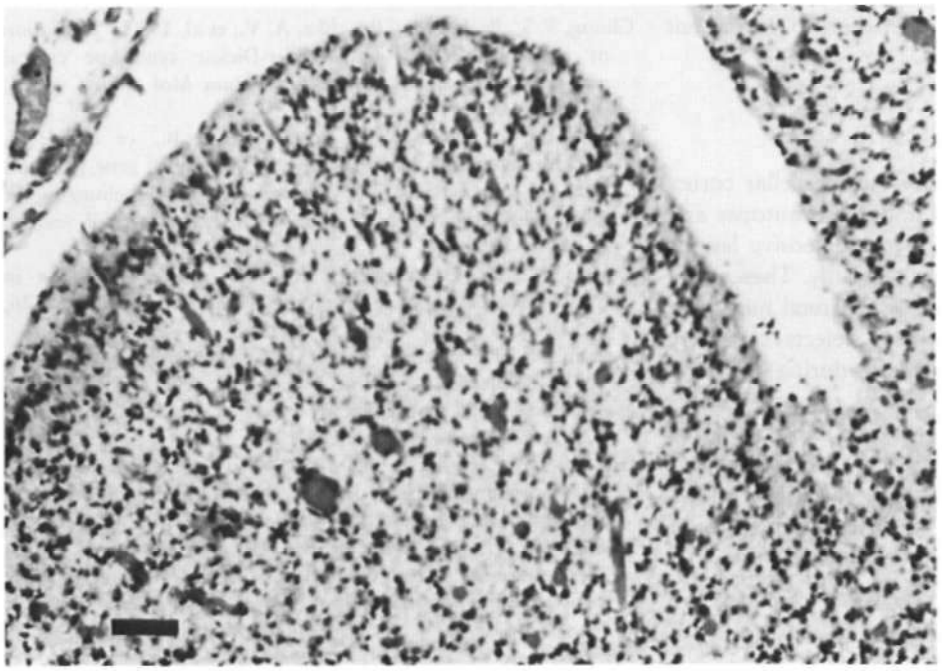

FIGURE 66.12 Cerebellar cortex of infant with cerebellar hypoplasia shows extensive gliosis and loss of ill neuronal elements. This histological appearance resembles that of cerebellar sclerosis secondary to acquired injury, but in the latter condition there arc usually a few neurons still surviving. Some cases of cerebellar hypoplasia show selective loss of granule cells and preservation of l'urkinje's cells. (Hcmatoxylin-eosin stain. liar = 100 urn.)

influence. A molecular generic hypothesis of ectopic expression of a segmentation gene in the rhombomcrcs explains not only the Chiari malformation, but also the brainstem anomalies, the myelodysplasia, and the defective basioccipital and suptaoccipital bone formation that tcsults in a too small posterior fossa (Sarnat 2001a, 2003).

Global Cerebellar Hypoplasia

Global cerebellar hypoplasia has diverse causes, which include chromosomal and genetically detennincd diseases, Tay-Sachs disease, Menkes' kinky hait disease, some cases of spinal muscular atrophy, and sporadic cases of unknown cause. Histologically, there may be a selective depiction of granule cells or a loss of Purkinje cells and other neuronal elements in addition to granule cells (Figure 66.12). In selective granule cell depletion, the axons and dendtites of Purkinje cells are deformed.

Clinically, the most constant features of cerebellar hypoplasia in infancy are developmental delay and generalized muscular hypotonia. Truncal titubation and ataxia become evident after several months, and nystagmus and intention tremor may appear in severe cases. Tendon stretch reflexes usually are diminished but may be

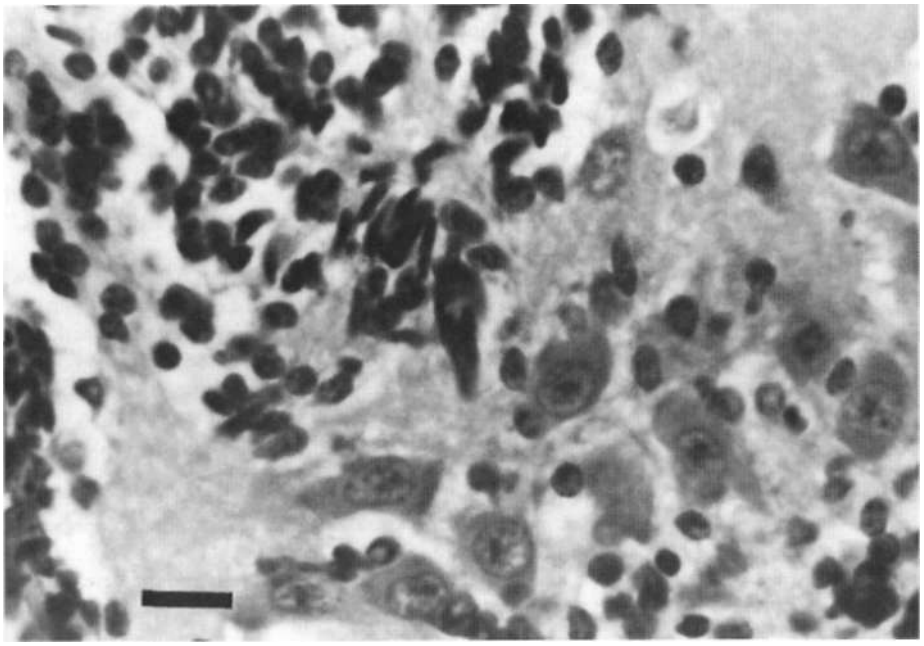

FIGURE 66.13 Focal dysplasia of cerebellar eorrcx. The normal laminar architecture is disrupted, and •IMI'IIK- .liul I'uikinjf cells show .L haphazard orientation and array. Some granule ceils arc spindle shaped, resembling the shape assumed during transit from the external granular layer in normal development. This dysplasia is due to faulty neuronal migration and probably occurred at midgestation. (Hematoxylin-eosin stain. Rar= 15 urn.)

hyperactive if corticospinal tract deficit also is present because of cerebral involvement.

Focal Cerebellar Dysplasias

Focal dysplasias and hamartomas of the cerebellar cortex (Figure 66.13} are often incidental findings at autopsy and are often clinically asymptomatic. More extensive lesions present abnormal cerebellar findings clinically. These small **focal** malformations are a disorder of neuronal migration that may be programmed as genetic defects or, more commonly, acquired from brief insults during the long period of cerebellar development. Focal ischemic insults and exposure to cytotoxic drugs or viruses are among the more common causes. The granule cells of the cerebellar cortex retain a regenerative capacity lost early in gestation by most other neurons, but the regenetative pattern of lamination in the cerebellar cortex may be imperfect.

Craniosynostosis

The development of the cranium and sutures is now recognized as closely related to neuromeric formation in the neural tube. More than 100 syndromes that include a component of craniosynostosis have been identified. Several have a genetic basis, including the syndromes of Apert, Crouzon, Pfeiffer, and Saethre-Chotzen; these are related to fibroblast growth factor receptor defects and, in some, specific causative genes such as TWIST are recognized (Flores-Sarnat 2002b). The genetic basis of the mure coniiiuin isolated craniostenoses "1 the coronal and sagittal sutures are not yet known. Once thought to be only a cosmetic defect, it is now known that neurological impairment may result in untreated cases. Advances in imaging have enhanced both prenatal and postnatal diagnosis, and parallel advances in craniofacial surgery makes treatment more effective from both a neurological and cosmetic perspective. True craniosynostosis must be distinguished from positional deformities of the head resulting from abnormal prenatal compression by the maternal pelvis and postnatal effects of head position, particularly in premature infants.

Chapter 67
Developmental Disabilities

Ruth Nass

CEREBRAL PALSY

Diagnosis

Cerebral palsy (CP) is a static encephalopathy of prenatal or perinatal origin that affects motor function and tone. Spasticity, hypotonia, ataxia, and/or dyskinesias are the possible motor outcomes. A history of delayed motor milestones and the clinical features are the basis of diagnosis. CP occurs in approximately 2 per 1000 children. Low birth weight/pre term infants currently comprise more than 50% of children with CP. The prevalence is about 60 per 1000 among children weighing less than 1000 grams at birth. In a population-based study of births in the 1990s, the types of CP encountered were hemiplegia (33%), diplegic (44%), quadriplegic (6%), dyskinetic (12%), and ataxic (4%) syndtomes. Diplegic CP is the most common type in the preterm infant. Children with CP may or may not have intellectual problems, and seizures are a concurrent problem in about 40%. The likelihood of each is directly proportional to the severity of the motor impairment and the degree of brain damage.

Etiology

The National Perinatal Collaborative Project monitoring more than 50,000 pregnancies documented the following important risk factors among the 200 children with CP; maternal mental retardation (MR), birth weight less than 2000 grams, a malformation of any organ system, and breech presentation or delivery. Commonly used signs of perinatal hypoxic ischemic insults, such as an abnormal fetal heart rate, the presence of meconium, and low Apgar scores, did not predict CP and were relatively common in infants who were ultimately normal. Even when the Apgar score is low, the risk of CP appears to be minimal unless the infant continues to have neurological problems (e.g., lethargy, hypotonia, poor suck, seizures) in the newbotn nursery. Moreover, almost *95%* of infants with 5-minute Apgar scores of 3 do not have CP. In a population-based study of births in the early 1990s (Hagberg et al. 2001), the etiology of CP was established in 75% of preterm newborns and in about 85% of term infants. Most were due to perinatal problems. Among term babies with a known etiology of the CP, half were prenatal and half were perinatal. In addition to intraventricular hemorrhage (IVH) and periventricular leukomalacia (PVL) in premature infants and perinatal hypoxic ischemic encephalopathy (HIE) in term newborns, documented causes of CP include brain malformations, small size for gestational age, congenital infections, maternal infection during pregnancy and labor, and genetic and metabolic disorders. Twin gestation is a risk factor, and a vanishing twin is a proven risk factor for CP in the survivor. Although most metabolic and genetic disorders ultimately cause progressive disability, some may be static for years and have a phenotype that suggests CP. Atypical features of CP and a history of other affected family members should indicate the need for further evaluation. Genetic disorders are the most common

cause of "ataxic CP syndromes." Dopamine-responsive dystonia, .111 r.ir-,;l\ diagnosed **arid :i\-;.ik'd** disorder, **mimics** CP. Other genetic or metabolic disorders that potentially mimic CP include metachromatic leukodystrophy, Krabbe's disease (spastic diplegia CP), Lesch-Nyhan syndrome, glutarie aciduria 1 (dyskinetic CP), ataxia telangiectasia, Leigh disease, and subacute sclerosing panencephalitis (ataxic CP).

Brain imaging is extremely useful in determining the etiology and prognosis of cerebral palsy. Brain malformations are relatively common in term infants with CP, whereas PVL is the most common cause of CP in preterm infants (Barkovich 2002). PVL is associated with even more severe disability in term-born children (Krageloh-Mann et al. 1999). HIE is associated with bilateral cerebral infarctions, whereas most unilateral infarctions arc prenatal, not perinatal, in origin (Volpe 2000). Ultrasound abnormalities are different in preterm newborns that develop disabling rather than nondisabling CP (Paneth 2001). Hypothyroidism of prematurity has twice the risk of echolucencies on ultrasound as compared to euthyroid newborns and has an increased risk of cerebral palsy (Leviton et al. 1999). Recent outcome studies of children and adolescents born prematurely suggest a correlation between the presence of magnetic resonance imaging (MRI) abnormalities and greater cognitive difficulties (Rushe et al. 2001). A reduction in cortical and cerebellar volumes among newborns with CP may result from enhanced apoptosis or excitotoxic damage to highly susceptible immature neurons (Bhurta and Anand 2001).

Treatment

The prevention of prematurity, respiratory management of preterm infants during the perinatal period, and the development of neuroprotective agents is the focus of CP prevention. Cesarean section and rapid initiation of supportive care may decrease the frequency of CP in the preterm newborn. Most IVH occurs within the first 6 hours after birth and possibly during labor and delivery. Infections during pregnancy as well as chorioamnionitis at delivery appear to be risk factors for CP. Elevated cytokines are the presumed agent toxic to the brain (Gilstrap and Ramin 2000).

Rehabilitative therapy influences outcome. The main goals of treatment are to improve motor function and to modify the environment to improve mobility. Orthopedic surgery is sometimes required. Dorsal rhizotomy has been used to decrease spasticity and improve gait or make children who are wheelchair-confined more comfortable. Botulinum toxin has had an important role in the treatment of spasticity. The factors that shorten life expectancy are immobility, profound retardation, and feeding difficulty (Hutton et al. 2000). Children with CP may otherwise live well into adulthood.

MENTAL RETARDATION

Mental retardation (MR) is not an absolute condition, but a construct that assists in educational planning and determining activities of daily living needs. The diagnosis therefore requires both low 1Q (less than 70) and difficulties in at least two areas of adaptive functioning: communication, self-care, home living, social skills, community use, self-direction, health and safety, functional academics, leisure, and work. The definition of mental retardation (American Association of Mental Retardation) links degree of severity to the degree of community support required to achieve optimal independence. In this context, mild retardation means intermittent support, moderate retardation indicates limited support, severe retardation indicates extensive support, and profound retardation indicates pervasive support. When IQ defines mental retardation, 100 is the mean and 15 is the standard deviation. Subdivided by severity, an 10 *55-70* is mild, an IQ of 40-55 is moderate, an IQ of 25—40 is severe, and below 25 is profound. A significant variability exists in the level of functioning among children with an IQ around 70; about half require special education and half attend regular school. Those in special schools are more likely to have a personal or family history of language delay. Such differences in functional level of children with the same IQ highlight the need to examine the specific cognitive profile of those with MR (Table 67.1).

In industrialized countries, the prevalence of MR is 1-3%. Mild MR represents the majority (75%). In general, individuals with severe retardation are more likely to have a definable biological cause, whereas those with mild retardation tend to come from socially disadvantaged backgrounds and often have a family history of borderline IQ or mild retardation (Opitz 2000; Stromme and Magnus 2000). Recent genetic studies demonstrate submicroscopic deletions in the subtclomcric chromosomal regions in about 3.5% of previously undiagnosed cases of MR (Leonard and Wen 2002).

Environmental factors play a role. For example, smoking during pregnancy is associated with more than a 50% increase in the prevalence of MR. The risk of recurrence of severe MR is 3-10% and of mild MR is 5-40%. The diagnosis of MR is more common in hoys than in girls (1.4:1). Male excess is present m those with autism, those with undiagnosed nonsyndromic mental retardation, and those with X-linked monogenic disorders. X-linkcd inheritance is responsible for more than 150 known mental retardation syndromes (Partington et al. 2000). Within the last 5 years specific X-linkcd gene abnormalities have been identified in 15 syndromes causing severe MR and in eight causing moderate MR (Leonard and Wen 2002), Fragile X syndrome has been considered the most frequent known X-linked disorder among the moderately handicapped and has been thought to occur with even greater frequency in mild MR. The prevalence of nonspecific (genetic etiology

as yet unknown) X-linked MR (XLMR) (2.5/10,000), however, is three times greater. But diagnosis may be difficult because most males with XLMR have no specifiable phcnorypical, neurological, or biochemical features as yet identified. Advances in genetic technology will clearly change this.

Several iH'in-f)l(i;n'ail and neuropsyehianic problems *M'v* associated with MR. Epidemiological studies (Airaksinen et al. 2000) suggest that one fifth of children with MR are epileptic by 10 years of age. The probability of developing epilepsy is fivefold higher in severely MR children *(35%)* than in children with mild MR (7%). Cerebral palsy is a concurrent disorder in 6-8% of the mildly retarded and in *MV'A,* of the severely retarded. Blindness or deafness occurs in 2% of the mildly retarded and 11% of the severely retarded. An increased prevalence of psychopathology and maladaptive behavior occurs in children with MR, and almost 40% have a psychiatric disorder (Stromme and Disedi 2000). The most common diagnoses are hyperactivity and autistic spectrum disorders. Overall, autistic features are reported in 9-15% of the mildly retarded and 12-20% of the severely retarded. Table 67.1 details specific psychopathology and behavioral problems in several genetically defined MR syndromes.

Treatment

Treatment focuses on finding the appropriate educational setting and vocational training for the mildly and moderately retarded and determining home or institutional placement for the severely and profoundly retarded.

AUTISTIC SPECTRUM DISORDERS

Diagnosis

The triad of impaired sociability, impaired verbal and nonverbal communication skills, and restricted activities and interests, all of early onset, are the diagnostic features of autistic spectrum disorders (ASD) (Rapin 2002) (Figure 67.1). The presence or absence of social disabilities distinguishes *developmental language disorders* (DLD) from ASD. IQ, language, and social normalcy distinguish *nonautistic mental retardation* (NAMR) from DLD and ASD (figure 67.2). The range of disabilities seen among children in the spectrum is considerable. Asperger's disorder (Table 67,2) probably represents the high-functioning end of the ASD spectrum. Paralinguistic[1] rather than linguistic problems are characteristic. The iivideiice ol ASD varices from 0.4 to 70.0 per 10,000 children, depending on how the

'Paralinguistic skills include pragmatics—communicarive intent rather than content; prosody - tone of voice to express emotions, for example; understanding humor, sarcasm, and irony.

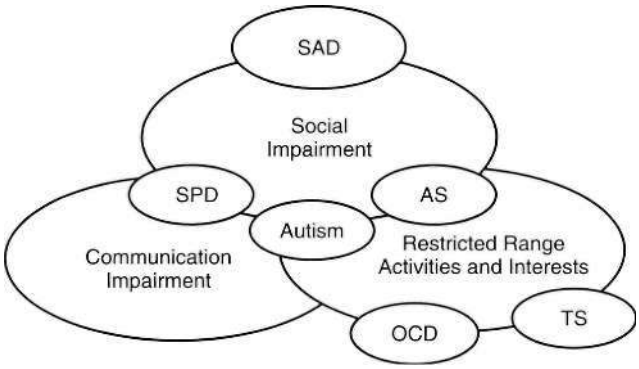

FIGURE 67.1 This Venn diagram shows the overlap of all three symptom areas in autism, of two areas in AS, and of disorders involving a single symptom often reported in ASD families. TS = Tourette syndrome; OCD = obsessive-compulsive disorder; AS = Asperger's disorder; SAD = social anxiety disorder; SPD = semantic pragmatic disorder. (Modified from N'ass and Leventhal, in press.)

term is used (Gillberg and Coleman 2000). A hereditary basis is probable in many cases because of (1) a high concordance in monozygotic twins (90%), (2) a 4.5% increased risk for dizygotic twins and siblings, (3) a broader autistic phenotype in families (Piven and Palmer 1999), and (4) an association with several genetic disorders (Spencer 2001). The dramatically diminished risk in relatives who share 50% versus 100% of their DNA is most consistent with an oligogenic inheritance pattern, where more than two and as many as 100 genetic variants may contribute to susceptibility to developing autism. Each gene may make a different contribution to the disorder, with gene A more important for the development of repetitive stereotyped behaviors and gene B mote important for language acquisition (Alarcon et al. 2002; Veenstra-Vanderweele and Cook 2003). Chromosomal abnormalities have been reported on chromosomes 2q37, 7q, and 22ql3,13q among others. Both fragile X and the Rett syndrome mutation can

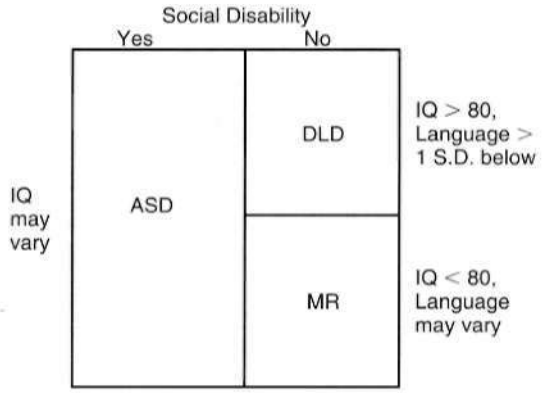

FIGURE 67.2 'The presence or absence of social disabilities distinguishes developmental language disorders (DLD) from ASD. IQ, language, and social normalcy distinguish nonautistic mental retardation (\'AMR) from DLD and ASD.

Tabic 67.2: Asperger's disorder diagnostic criteria

A. Qualitative impairment in social interaction, manifested by at least two of the following:
   1. Impairment in use of nonverbal behaviors to regulate social interaction
   2. Failure to develop peer relationships
   3. Lack of spontaneous seeking to share enjoyments and interests
   4. Lack of social or emotional reciprocity
B. Restricted repetitive and stereotyped behavior, interests, and activities, manifested by at least one of the following:
   1. Encompassing preoccupation
   2. Inflexible adherence to nonfunctional routines
   3. Stereotyped and repetitive motor mannerisms
   4. Persistent preoccupation with parts of objects
C. Disturbance causes significant impairment in functioning
D. No clinically significant language delay
E. No clinically significant cognitive deficit
F. Criteria not met for diagnosis of another pervasive developmental disorder or schizophrenia

Source: Modified from *Diagnostic and Statistical Manual of Mental Disorders,* 4th ed. Washington, D.C.: American Psychiatric Association, 1994.

present with an autistic spectrum phenotype. However, the most common specific cause of autism appears to be maternally inherited duplications of chromosome 15qll-13, accounting for 1% to 3% of cases {Vcenstra-Vanderweele and Cook 2003).

The symptoms of ASD, like other developmental disorders, often change with age. Approximately one third of autistic children regress between the ages of 1 and 3 years. Conversely, some toddlers and preschoolers, with typical symptoms of autism, may not appear autistic by school age, but may seem a bit odd, have peculiarities of language prosody and pragmatics, and show tenuous social skills. Nonverbal learning disabilities (NVLD) or attention-deficit hyperactivity disorder (ADHD) is often the school-age diagnosis. Most retain the typical features of autism, particularly those who are mentally retarded. The natural history of Asperger's disorder is less well documented, and the diagnosis is often delayed until late childhood, adolescence, or even adult life because by definition early language development is normal. Nonverbal learning disabilities (LD) or ADI ID may be the apparent presenting complaint (Klin et a I. 2000). The characteristic overfocus in a particular, or sometimes peculiar, interest area may escalate with time, but may be the key to a special form of adult success.

Outcome studies suggest that among children with ASD, ovetall improvement occurs in approximately 40% during adolescence and deterioration occurs in as many as one third (Cillberg and Coleman 2000). The onset of seizures or mood disorders (depression and bipolar disorder) usually underlies the deterioration. Some adolescents may even become catatonic. A minority of children, usually the higher functioning group, improves significantly during adolescence, reaching adulthood with no significant problems. Approximately two thirds of adults with autism show poor social adjustment (limited independence in social relations), and one half require institutional care. Autistic individuals who are not retarded tend to improve more than those who are. Higher functioning people with autism and Asperger's disorder have the best outcome. Although fair-to-good outcomes are reported in 15-30%, only 5-15% become competitively employed, lead independent lives, marry, and raise families. Psychiatric problems are common even in this group. Some adults with Asperger disorder are probably undiagnosed in childhood and adolescence; therefore the percentage of adults with ASD that ultimately functions in the mainstream may be higher than reported. Some adults with ASD are highly productive and original in their work. Bartok, the composer, and Wittgenstein, the philosopher, are believed to have had ASD (Cillberg 2002).

Specific Clinical Features

Intelligence and Cognition

The presence of language and social deficits defines ASD, nor the IQ level (see Figure 67.2). Although 70-85% of children with ASD are mentally retarded, some have average or even superior intellectual ability. IQ is a key-predictor of long-term outcome in autism, especially when the IQ is less than 50 (Stevens et al. 2000). Those with low IQ generally fare poorly. If Asperger disorder is included as an autism spectrum disorder, the rate of mental retardation in ASD drops considerably. Some consider the core cognitive deficit of ASD to be an inability to grasp other people's thoughts or a failure to develop a theory of mind (Baron Cohen et al. 2001). "Mindblindness" manifests differently at different stages of development (Table 67.3).

Language

Communication difficulties are a cardinal feature of ASD. The extent of the language deficit generally parallels IQ. In lower functioning ASD children, language if present is echolalic; repetitive and stereotyped phrases are common. Some children fail to process language and despite normal hearing can appear deaf (verbal auditory *agnosia).* Higher functioning children sometimes talk too much; they talk to talk (semantic and pragmatic deficits). These children are often extremely literal and concrete. Prosody is frequently impaired as evidenced by mechanical, excessively rapid, monotonic, high pitched, or poorly modulated speech. Language skills at age 5 to 6 years are predictive of long-term prognosis. Children with conversational language will do significantly better than children who have little or no language.

Abnormalities of play are part of the autistic child's communication disorder. The range of play includes

repetitive Stereotypic and indiscriminate sensory use of objects (mouthing, rubbing, etc.); functional object use and imitation, mechanical play with puzzles and the like; interactive play with adults like running, catching, and tickling games; and activities involving their circumscribed areas of interest (e.g., board games, computers, electronic games, or high-level word and number tasks). These activities, when engaged, may provide pleasure. Pretend play is often rudimentary even in higher functioning children, involving, for example, simple role taking (Whitehouse et al. 1996).

Social Skills

The hallmark of ASD is social dysfunction. The *aloof* child most resembles the popular notion of autism. Such children do not follow their parents around, run to greet them, or seek their comfort. Such children tend to have low intelligence, have poor verbal and nonverbal communication skills, and show little symbolic play. *Passive* children are generally somewhat higher functioning overall. They do not make social approaches, but will accept them when made by others. They engage in some pretend play and join in games, but take a passive role (e.g., the baby in the game of mothers and fathers). Children who are *interactive but odd* make spontaneous social approaches to others, but do it in a peculiar way. They tend to talk at other people, and their persistence may become annoying. Pragmatic language skills are impaired. Conversation is started with a question. Many persons on the autistic spectrum are relatively unaware of their social ineptitude except to the extent that others tease them, but some are not (Whitehouse et al. 1996). Several books written by high functioning people with ASI) highlight this lack of awareness (Willey 1999).

Restricted Range of Behaviors, Interests, and Activities

A restricted range of behaviors, interests, and activities is the third cardinal feature of autism. In lower functioning children, these consist of repetitive, stereotyped behaviors like twirling, rocking, flapping, licking, and opening and closing doors. Overlap and comorbidity with tic disorders and obsessive-compulsive disorders are seen in higher functioning children (Gillberg and Coleman 2000; Nass and Leventhal, in press) (see Figure 67.1, Venn diagram). Many of these children have great difficulties with transitions. Not only do they not focus, but they also become overfocused. Some individuals with exceptional artistic, musical, or mathematical talents may meet other criteria for a diagnosis of an ASH or Asperger's disorder. Some of these children grow up to be single-minded, perhaps peculiar, nunsocial chess or mathematics geniuses.

Evaluation and Etiology

The standard neurological examination is generally normal. The skin must be careful examined for evidence of tuberous sclerosis, the most common diagnosable disease associated with autism (Gillberg and Coleman 2000). Formal audiological assessment is required to exclude a hearing impairment. An electroencephalogram (EEG), including a sleep record or overnight video-EEG monitoring, is appropriate to exclude subclinical seizures, especially when language comprehension is impaired or developmental regression has occurred. Mild-to-severe epilepsy, partial and generalized, occurs in up to one third of patients with autism *h* early adulthood, Ir.l.ino uniantile spasinsi .ind puberty are particularly vulnerable periods. The onset of

seizures may play a role in adolescent deterioration. Those who arc retarded are at higher risk, hut epilepsy occurs in high-functioning children as well. Epileptiform patterns on EEG and early epilepsy occur more frequently in children who show early regression. Studies using magnetoencephalography suggest that diffuse epileptiform activity is common in children with autistic regression (Rumsey and Ernst 2000).

Three major types of neuropathology have been reported in autism (Rumsey and Ernst 2000): (1) decreased development of forebrain limbic system structures {e.g., cingulate, hippocampus, amygdala), substrates for memory and emotion; (2) a decreased number of Purkinje cells in the cerebellum; and (3) age-related differences in cell size and number in cerebellar and brain stem nuclei, suggestive of a dynamic developmental process. Structural abnormalities reported in autism based on imaging studies include increased brain volume (especially males), increased ventricular volume, increased white matter volume, thin splcnium of corpus callosum, hypoplastic cerebellum (vermian lobules VI and VII), hyperplastic cerebellum (10%), and hypoplastic parietal lobes (Sparks et al. 2002). Recent imaging findings suggest that there may be differential effects driving white matter to be larger and cerebral cortex and hippocampus-amygdala to be relatively smaller (Herbert et al. 2003). Brain imaging is rarely productive in clinical practice. However, a recent meta-analysis of imaging in children with developmental delay, including autism, does demonstrate that MRI may show abnormalities in one third, especially when the neurological examination is abnormal (Shevell et al. 2003}. Most metabolic imaging studies show hypometabolism in the frontal lobes and to a lesser extent in the temporal lobes and cerebellum. Activation studies suggest an altered localization of language and cognition (theory of mind). Positron emission tomography (PET) studies suggest abnormalities of both serotonergic and dopaminergic function. Overall, the extent of metabolic workup depends on the clinical suspicions and the relevance to family counseling. Table 67.4 lists some specific causes of ASD/PDD (pervasive developmental disorder).

Treatment

Preschool children with ASD should receive special education in a therapeutic nutsery or in a home-based behavioral modification piogram. Table 67.5 lists medications that have proven helpful in some cases (Towbin 2003).

LEARNING DISABILITIES

Approximately 10% of school-aged children have learning disabilities (LD), and these can affect one or more cognitive skills. The common LDs involve reading (dyslexia), motor function (dysgraphia and dyspraxia), the spectrum of specific nonverbal LDs (mathematics, written composition, visuospatial skills, socioemotional abilities, paralinguistic communication, executive function), and attention deficit disorder (ADD) with or without hyperactivity (ADHD).

Dyslexia

Ditignosis

Dyslexia is the best studied and probably the most common of the learning disabilities, occurring in as many as l()% of school-aged children. This disability often has a genetic basis, and several different chromosomal loci are suspect (Fisher and DeFries 2002). The definition of *developmental dyslexia,* an unexpected difficulty in learning to read, has both exclusive and inclusive criteria. As with other I D, the dyslexic child should not have majot neurological abnormalities. The detection of minor abnormalities (soft signs) on examination is usual (Table 67.6). Although majot sensory function must be normal, studies of disturbed cortical visual functioning in children with reading disability are ongoing. Processing by a slow lateral geniculate magnocellular system (impottant for monitoring motion,

stereopsis, spatial localization, depth, and figure-ground perception) may not appropriately modify the information received from the fast parvoccllular system (crucial for color perception, object recognition, and high-resolution form perception) (Amity et aI. 2002; Angelique et aI. 2002). Normal intelligence and exposure to a social and educational environment conducive to learning to read is required for diagnosis. Studies ot iiuicr-city eleinemary school children show that enrichment programs can help some nonteaders become readers.

With respect to inclusive criteria, reading two grades behind actual or expected grade level is generally required for a diagnosis of dyslexia by educational institutions. The *two-grades-behind criterion* does not take into account the fact that different reading tests yield different reading levels and may be more or less reliable measures and predictors of reading ability at different ages and grade levels because of ilu complex dynamics of reading acquisition. Hie agi of the child affects the inclusive criteria. Because we do not expect children to read until first grade, the strict definition makes a diagnosis of dyslexia impossible before the third grade. Yet a history of language delay or a family history of reading disabilities is often predictive of dyslexia, and strict adherence to the definition should not preempt consideration of early intervention. In addition, a 2-year discrepancy reflects n greater disability for the younger than for the older child. Whether or not to factor intelligence into the diagnosis of teading disability is debatable. Spelling difficulties may be a mild form of dyslexia that persists into adulthood or that are present In good readers in dyslexic families *(forme fruste).*

Sensory	Extinction on double simultaneous stimulipoor finger localization
DTK	Minor reflex asymmetries

Evaluation and Etiology

Children with dyslexia deserve a formal neuropsychological evaluation to determine their cognitive strengths and weaknesses and to identify comorbid problems that might affect treatment. For example, dyslexia and ADHD can coexist. Deficits in phonological awareness frequently underlie reading difficulties and may petsist into adolescence (Shaywitz *\999).* Measures that assess phonological functioning best differentiate dyslexic from normal readers (e.g., segmenting words, saying cowboy without the boy, saying smack without the *m,* word and nonword blending, and sound matching of first and last syllables). Few children fail to read because of visual perceptual difficulties. The standard neurological examination is generally normal. Routine imaging is tarely abnormal and generally unnecessary, except perhaps in children with atypical features (Table 67.7). Pathological studies suggest that those with dyslexia have both atypical planum temporale asymmetries and areas of cortical dysplasia, particularly in the left hemisphere. Specialized imaging has corroborated the macroscopic pathological findings. In about two thirds of normal adults, the left planum temporale is larger than the right. By contrast, only 10-50% of dyslcxics show a left greater than right posterior asymmetry (Eckert and Leonard 2000). Dyslexics with atypical asymmetry patterns tend to have more sevete language and/or reading deficits. Theoretically, fluent reading requires the functional

Table 67.7: Atypical features in dyslexia

integrity of two left-hemisphere posterior systems: a tem-pt)[•(jp;iru-taI system .slid a ventral occipitotemporal system, Developmental^', the temporoparietal system predominates initially and is required for learning to integrate the printed word with its phonological and semantic features. The occipitotemporal system constitutes a hue-developing rapid sight-word identification system that underlies word recognition in skilled readers. In developmental dyslexia, both posterior systems may be disrupted causing reliance on the left inferior frontal and right posterior regions of the cortex (Pugh et al. 2000). The corpus callosum, which has a role in inrerhemispheric information transfer, may he structurally different in normal versus dyslexic readers. Theoretically, the splenium is critical hecause it contains axons linking the planum temporale and angular gyrus. Metabolic imaging confirms that the left temporal lobe and the cerebellum, an area that other studies suggest is crucial for language functioning, are involved in reading (Fulbrigbt etal. 1999). Measures demanding phonological processing activate the left temporal tegion in normal conttols, but not in dyslcxics.

Treatment

Although dyslexia is permanent, most children with early reading problems, when identified by 8-9 years (third to fourth grade) and provided with evidence-based reading instruction, can learn to read at average to above average levels. Children diagnosed later, even when provided remediation, are likely to continue having reading problems. Seventy-five percent of children with reading problems at the end of third grade are still having trouble in seventh gtade. Dyslexic children, identified after third grade, never catch up to average or superior high school readers (Shaywitz ct al. 1999). Early identification and provision of evidence-based reading instruction reduces the percentage of children reading below grade level in fourth grade from 37% to 6%.

Nonverbal Learning Disabilities

Diagnosis

No generally accepted definition is available for the term *nonverbal learning disabilities* (NVLD), and although the diagnosis of NVLD does not yet appear in the *Diagyiostic and Statistical Manual,* anywhere from 1-10% of school-aged children are thought to have problems that fall under this rubric. Many children with Asperger's syndrome have difficulties in the nonverbal domain that may manifest as learning issues in school,

In contrast to children with dyslexia, children with NVLD generally have significantly higher verbal than performance IQ scores. Problem areas include:

1. Social-emotional functioning
2. Nonvcrbal/paralinguistic communication
3. Sensorimotor functioning
   - Tactile perceptual
   - Gross and/or fine motor (clumsy, dysgraphia, dyspraxia)
   - Slow processing speed
4. Visuospanal processing
   - Perceptual, motor, visual-spatial-organizational, visual-spatial working memory, visual imagery, getting gestalt

.5. Executive functioning
   - Problems in planning, organization, working memory, processing speed
   - Attention difficulties/attention deficit hyperactivity disorder
   - Deficits in problem solving, reasoning, concept formation, hypothesis testing, seeing the gestalt, guessing
   - Difficulty adapting to novel (inflexible) or complex situations
   - Motivation
6. Academics
   - Problems with handwriting, reading comprehension, written expression, math operations and concepts, science

further complicating the diagnosis of NVLD is a changing pattern of deficits with time as school demands escalate (Rourke et al. 2002). In the elementary school years, the predominant problems are social difficulties, inflexibility, writing disturbances, poor gross motor coordination, sensorimotor problems, and inattention. In junior and senior high school, academic problems become apparent in mathematics, reading comprehension, and written composition despite good verbal skills. Social skills issues continue, and problem-solving and organizational skills are relatively impaired. In young adults, emotional problems may become prominent.

Evaluation and Etiology

In general, NVLD reflect right hemisphere dysfunction, particularly the frontal and parietal regions. Based on children at high risk for NVLD (e.g., children with closed head injuries, those treated for leukemia, and those with

hydrocephalus), Rourke (Rourke et al. 2002) has suggested that NVLD result from white matter abnormalities, but imaging studies to confirm this hypothesis have yet to be done.

Treatment

The basic management strategy is the use of verbal strengths to compensate for the visuospatial disability. Because these children have difficulties dealing with novel or complex situations, the educational process emphasizes systematic learning and appropriate strategies for troublesome, frequently occurring situations. Generalization of learned strategies should be encouraged. Appropriate nomerba; behavior to facilitate peer' interactions is learned and not instinctual. Social groups are often helpful in this regard. Sensorimotor deficits can be managed by occupational therapy, early instruction in keyboarding and minimization of the written load in school.

Developmental Disorders of Motor Function

Diagnosis

Among 7-year-old children, moderate coordination disturbances occur in *9%* and severe disturbances in *5%* (Kadesjo and Gillberg 1999). Hadders-Algra's (2002) longitudinal study suggests that the frequency of developmental coordination disability (DCD) changes with age and is affected by the presence or absence of early neurological problems. ADHD (Landgrcn et al. 2000), visual perceptual problems, and reading comprehension problems are often comorbid conditions. Several discrete types of motor skill disorders may coexist. These include clumsiness, dyspraxia, dysgraphia, adventitious movements, and anomalous dominance or handedness. Clumsiness is defined as "a slowness and/or inefficiency in performing elementary fine motor and sometimes gross motor movements.[1'] Clumsiness is more common in children with learning disabilities (LD), and for this reason, the combination was inappropriately termed *minimal brain dysfunction.* Children with *developmental dyspraxia* have difficulty with motor learning and motor execution. Dyspraxia may be associated with clumsiness, alone or in combination with other l.D. Ideomotor and ideational dyspraxia occurs in children. Dysgraphia (difficulty with writing) can be a primary disturbance, a manifestation of clumsiness or dyspraxia, or be secondary to dyslexia as a higher order cognitive disorder (Table 67.8). Adventitious movements (i.e., synkinesis, chorea, tremor, and tic) occur normally on a developmental basis and are designated *developmental soft signs* when they persist beyond the age when they normally cease (Table 67.9). With regard to handedness (manual dominance), most ultimately right-handed children declare handedness after 1 year of age and before age 5 years. Strong dominance when

Tripod (static) 50% by 3 yr, 80% by 4 yr
Tripod (dynamic) 5-6 yr

established belorv age 1 year should raise concern that handedness is pathological and indicates disturbed use of the other hand. Many infants may appear to be left-handed and then become right-handed. The percentage of right-handed children, and probably the strength of handedness, increases through age 5 years. Eventually, more than 90% of children are right-handed. Most right-handed people are strongly right-handed, whereas most left-handed people are ambidextrous. Dexterity in left-handed and right-handed people is equal. However, the frequency of LD is greater in left-handed than right-handed people, and the frequency of left-handed people is greater among the learning disabled.

Evaluation and Etiology

Developmental coordination disorders, because of their heterogeneity, can only be fully evaluated using a battery that taps the gamut of motor skills. In one study (Geuze et al. 2001) about 75% of children who were]udged to have DCD by a team of specialists (rehabilitation doctor, occupational therapist, and physical therapist), performed below the fifteenth percentile on a comprehensive motor battery. The remaining 25%, had handwriting problems or low muscle tone issues not measured by the particular battery used. Adventitious movements arc generally assessed separately. Synkinesia is best elicited by finger tapping, finger sequencing, and stressed gait testing. Choreiform movements are best elicited by having the child stand with eyes closed, tongue out and pronated arms extended with fingers spread.

Some investigators suggest that children with developmental coordination disorders have difficulty representing internally the visuospatial coordinates of intended movements. Such a deficit implicates parietal lobe dysfunction. The parietal lobe is involved in processing *feed-forward* information from downstream motor areas by comparing it with local visuospatial representations that specify the coordinates of the prospective actions (Wilson et al. 2002).

Treatment

Children with significant disorders of motor control may benefit from process-oriented occupational therapy, motor imagery intervention, and perceptual motor training (Wilson et al. 2002), Computers can facilitate output for those with poor graphomotor skills. Sometimes, these difficulties are sufficient to require a scribe in the classroom.

Visuospatial Disabilities

Diagnosis

Visuospatial disabilities (perceptual, organizational, memory, and motor) occur in the context of NVI.D and in isolation. They may be the underlying cause of academic difficulties in reading, writing, and mathematics. Visuospatial difficulties are usually apparent on traditional IQ testing as a large verbal performance split as several performance IQ subtests measure visual perceptual processing.

Evaluation and Etiology

Difficulties in the visuospatial domain that are suggested by a large verbal performance split can be corroborated by specific neuropsychological measures such as design copy and memory, picture memory, and mental rotation. Visuospatial abilities are easily assessed in the office by the simply administered "draw a person test" (Table 67.10).

Studies of visuospatial disabilities have not been as extensive as studies of specific academic disabilities. Visuospatial difficulties are, however, hallmark deficits in such genetically divergent syndromes as Turner syndrome, Williams syndrome (WS), velocardiofacial (VCF) syndrome, and neurofibromatosis (see Table 67.1). WS is perhaps the best studied by neuroimaging. Affected individuals have decreased overall brain volume, particularly in the cerebrum and brainstem with relative preservation of cerebellar and superior temporal gyrus volumes. The ratio of frontal to posterior (parietal + occipital) tissue is greater than in controls. WS has relative preservation of cerebral gray matter volume and disproportionate reduction in cerebral white matter volume. However, within the cerebral gray matter tissue compartment, the right occipital lobe shows excess volume loss, a feature that could underlie the visuospatial difficulties (Reiss et al. 2000).

Table 67.10: "Draw a person test" scale

Humpty-Dumpty or better 50% at 3 yr, 80% at *1*>\ yr
Intermediate man or better 50% at 4 yr, 80% at 4/4 yr
Mature man 50% at 4/4 yr
I 0 part person at 5 *A*_ yr

Treatment

The treatment of visuospatial disabilities emphasizes the use of verbal strategies to navigate situations demanding visuospatial solutions. It is important to realize that visuospatial disabilities may seriously impair one's perception of the world. Insignificant tasks, like navigating the hallways at school, become difficult. Visuospatial misperceptions may lead to serious social errors.

Dyscalculia

Diagnosis

Dyscalculia can involve any or all aspects of mathematics from computation to conceptualization. The prevalence of dyscalculia is approximately 6%, a figure similar to that of dyslexia and ADHD. Both genders are equally affected. Indeed, the only clear gender difference in mathematical skills is in the extremely superior range (scoring over 700 on

the math SAT in seventh grade); within this group, males out-number females by mure than 10 to 1. A developmental Gerstmann's syndrome (right-left disorientation, finger agnosia, dysgraphia, and dyscalculia) occurs in as many as 2% of school-aged children. The mean IQ of children with dyscalculia is generally normal; ADHD occurs in 25% and dyslexia in 20%. Dyscalculia is common in children with NVLD (Shalev and Gross-Tsur 2001).

Evaluation and Etiology

Children with neuropsychological evidence of either left- or right-hemisphere dysfunction can have dyscalculia. Both groups have similar problems on arithmetic batteries, but those with left-hemisphere dysfunction perform significantly worse in addition, subtraction, complex multiplication, and division and make more visuospatial errors (Shalev and Gross-Tsur 2001). Imaging studies in children with dyscalculia who had been born prematurely suggest that left-parietal abnormalities predominate (Grafman and Romero 2001).

Treatment

Math remediation is appropriate for the child with isolated dyscalculia or with math difficulties in combination with other learning difficulties.

Attention Deficit Hyperactivity Disorder (ADHD)

Diagnosis

The reported prevalence of ADHD in school-aged children ranges from 1% to 20%. This wide range reflect-, (h_L- lack of a biological marker for the disorder. The variation in prevalence is secondary to differing technique of ascertainment (parent, child, or teacher perspective), the diagnostic questionnaire used, age at ascertainment {standards are most clear-cut for the elementary school-aged child), and even the country of study (e.g., ADHD is more common in the United States than in the United Kingdom). Although complete recovery used to be thought the rule, it now appears that ADHD persists in *60-70%* of adults diagnosed with ADHD in childhood. Almost half of such adults show significant social-emotional difficulties, and 10% show serious psychiatric or anrisocial disabilities. Assuming a prevalence of childhood ADHD of 6-10%, the prevalence **of ADHD** in adults may be 2-7%. **ADHD** is diagnosable in toddlers and may be four to eight times more common in males than females. Females, when affected, have less hyperactivity and more severe general cognitive deficits. This suggests that females with ADHD may have a gteater genetic load. Other learning difficulties as well as psychiatric disorders are commonly comorbid with ADHD (Brown 2000).

Clinical Features

Practically speaking, the following symptoms define ADHD: inappropriate inattention, impulsivity, disttactibility, and hyperactivity for chronological and mental age. The current standard for diagnosis is the *Diagnostic and Statistical Manual of Mental Disorders,* 4th edition (Table 67.11). Table 67.12 lists the characteristics of ADHD in preschoolers. The physical examination of **the ADHD** child is generally normal. Minor signs on neurological examination may include synkinesis and choreiform movements. The neuropsychological profile reveals normal IQ but low scores on the Wechsler IQ subtests that demand attention or rapid processing: digit span, coding, arithmetic, and symbol search. Also often compromised are executive-frontal lobe functions tapping the ability to initiate, inhibit, sustain, and shift attention.

Evaluation and Etiology

Although many medical causes of ADHD exist, ADHD has a substantial genetic component. Genetic factors may account for 70-90% of cases. Approximately one quarter of the first-degree relatives of a child proband with ADHD also have or have had ADHD, generally the father or a maternal uncle. As many as 10% of ADHD children probably carry the Tourette gene, but may not have tics at the time of diagnosis or indeed ever. Girls with the Tourette gene more often have obsessive-compulsive disorder, whereas the combination of ADHD and tics predominate in boys. Structural imaging studies suggest atypical asymmetry

patterns in the basal ganglia, whereas metabolic imaging studies suggest dysfunction of frontal lobes and the right sided prefrontal-striatal systems (Ernst and Rtimsey 2000). Dopaminergic dysfunction appears to be the biochemical basis of ADHD. Genetic studies have focused on candidate genes involved in dopaminergic transmission, dopamine transport, and dopamine receptors (Solanto 2002).

Treatment

Medication, in particular psychostimulants, is the mainstay of treatment (Table 67.13). Approximately 75% of children respond to stimulants. In .5-10%, side effects, such as weight loss, rebound depression or irritability, or flat affect limit treatment. Neither tics nor Tourette's syndrome are contraindications to stimulant use in ADHD (Nass and Bressman 2002). Comorbid mood or anxiety disorders influence medication choice (Brown 2000). Atomoxetine (Strattera) a nonstimulant medication has recently been marketed for treating ADHD and may prove effective (Ktatochvil et ah 2002) and useful especially in stimulant nonrespondcrs. Other factors requiring attention are parent skills training, educational accommodations (extended time, separate testing site), cognitive behavioral therapy, social skills training, and behavioral modification. Behavioral modification requires setting goals, defining progress, and determining the incentives.

DEVELOPMENTAL LANGUAGE DISORDERS

Developmental language disorder (DLD) is the failure to develop language in an age-appropriate fashion in a child with normal intelligence and heating. Most children have good receptive language by age 2 years, along with a 50- to 100-word {ot more) vocabulary and some two-word phrases. Keen children w nil S'LHHI receptive skills who speak late may be at risk for continuing subtle language difficulties and later reading and language-based academic difficulties (Rescotla et al. 1997). Lack of well-developed expressive language by age 3 years is definitely abnormal. Table 67.14 lists additional warning signs that suggest DID duni it; [he m si 3 wnrs. \rnjuur basis lor diagnosis is a discrepancy between nonverbal intelligence and language capabilities (Klcc et al. 2000). However, both over- and underdiagnosis occur even when the best available discrepancy criteria are used. The difficulty in applying criteria and the need for strict discrepancy-based diagnostic criteria reflect, in part, the large degree of individual variability in rate of language acquisition (Toppleberg and Shapiro 2000). It is sometimes difficult to distinguish DLD from miti.il idiosyncratic delay in acquisition with eventual catch-up and ultimately notmal language. This probably accounts in part for the wide range (1-25%) in the reported prevalence of DLD in preschool children.

Risk factors for DLD identified by the National Collaborative Perinatal Project include low birth weight or prematurity and parental mental retardation. Another risk factor is a family history of developmental language disorders. Increased monozygotic versus dizygoric twin concordance rates indicate that heredity, not just shared environment, is the cause of the familial clustering (Bartlett et al. 2002). A number of gene loci have been implicated including: 13q, 16q, 19q (SLI Consortium 2002). In the three-generation KE family, half the members are affected with a severe speech and language disorder that is transmitted as an autosomal dominant monogenic trait—the gene responsible is the FOXP2 forkhead-domain gene. The first description of the language deficit in the KE family was of a severe form of developmental verbal apraxia. However, most recently investigatots argue in favor of a core deficit in sequencing and learning of verbal and

nonverbal associations (Watkins et al. 2002a). A recent screening of 270 4-year-olds with DLD was negative for the FOXP2 mutation (Meaburn et al. 2002).

Erring on the side of overdiagnosis in the young child and initiating therapy is probably better than underdiagnosis. Hearing impairment should be ruled out by formal audiological assessment in most children presenting with language delay. The current availability of brainstem-evoked responses (in addition to behavioral audiometry) makes possible an assessment of even an uncooperative young child. In view of the frequent concurrence of language disorders and epilepsy, an KEG, including a sleep record, to rule out subclinical seizures {see Verbal Auditory Agnosia, later in this chapter) is often appropriate, especially for those with impaired language comprehension.

Subtypes of Developmental Language Disorders

Depending on subtype, DLD vary in their characteristic features, etiology, prognosis, and treatment response. The subtypes listed in Table 67.15 focus on psycholinguistic features that most closely approximate the adult aphasias (see Chapter 12).

Articulation and Expressive Fluency Disorders

Pure Articulation Disorders

Articulator)' skills improve with age and, as with language development, the normal range is considerable. Most children (70%) speak intelligibly by age 2 years. Unintelligible speech is the exception at age 3 years (15%). However, almost 50% of children at age 4 years still have articulation difficulties. A com moo problem is defective use of *th* or *r.* At kindergarten entry, one third of children still have minor to mild articulation defects, but speech is unintelligible in less than 5%.

Stuttering and Cluttering

Stuttering is a disorder in the rhythms of speech. The speaker knows what to say, but is unable to say it because of an involuntary, repetitive prolongation or cessation of a sound. Some degree of dysfluency is common as language skills evolve during the preschool years, particularly as mean length of utterance (MLU) reaches 6-8 words between ages 3 and 4 years. However, stuttering in contrast to developmental dysfluency is probably a linguistic disorder {errors occur at grammatically important points in the sentence). Sniftering is often a genetic trait. Although the cause of developmental stuttering is unknown, the main theories are anomalous dominance and abnormalities of iuterhemisphcric connections (Eoundas et al. 2001). Stuttering occurs more frequently in children with other DLD and with mental retardation. Cluttering, by contrast, as seen in fragile X syndrome, is characterized by incomplete sentences and short outbursts of two- to three-word phrases, along with echolalia, palilalia (compulsive repetition reiterated with increasing rapidity and decreasing volume), perseveration, poor articulation, and stuttering.

Phonological Programming Disorder

Children with the phonological programming disorder are fluent, and MLU approaches normal. Despite initial poor intelligibility, the achievement of serviceable speech is

Nl = normal.
Source: Modified from Rap in, i. 1996, *Preschool Children with inadequate Communication.* London: Mackeith Press.

expected. Language comprehension is relatively preserved. Most such children show delayed rather than deviant phonology, with improvement at 1 and 7 years after preschool diagnosis. It is debatable whether this disorder is a severe articulation problem (see Pure Articulation Disorders, earlier in this chapter) or a mild form of verbal dyspraxia (see Verbal Dyspraxia, latet in this chapter). The fact that patients witli the phonological programming disorder have more trouble learning manual signs and Bliss symbols than controls supports an association with dyspraxia. A prcrcmediation paired associate learning task may help select the best remediation method for each child because some arc better with symbols and some with signs. An adult aphasia equivalent does not exist.

Verbal Dyspraxia

The speech of children with verbal dyspraxia, also called *dilapidated speech,* is extremely disfluent. Utterances are short and laboriously produced. Phonology is impaired and includes inconsistent omissions, substitutions, and distortions of speech sounds. Syntactic skills are difficult to assess in the face of dysfluency. Language comprehension is relatively preserved. Many require speech and language therapy fot prolonged periods. Children with vetbal dyspraxia who do not develop intelligible speech by age 6 years are unlikely to acquire it later. The frequency with which nonverbal praxis deficits—buccal-Ungual dyspraxia (e.g., positioning muscles of articulation) and generalized dyspraxia or clumsiness—coexist with verbal dyspraxia is unknown. The presence of a more diffuse disorder of praxis has significant therapeutic implications because children with verbal dyspraxia may depend on signing and writing skills for communication.

The etiology of verbal dyspraxia is unknown. The excess of males and a familial tendency support a genetic basis. Postmortem studies show either hypoplasia of the motot tract running from the Rolandic region to cranial nerve nuclei X and XII or bilateral opercular lesions. In a few patients studied decreased cerebral blood flow in the frontal regions and failure of verbal activation to increase profusion in Broca's area have been found. Although often accompanied by more neurological symptoms, verbal dyspraxia most resembles the adult aphasia called *aphemia* (see Chapter 12A}.

Disorders of Receptive and Expressive Language

Phonological Syntactic Syndrome

Phonological syntactic syndrome (also called *mixed receptive expressive disorder, expressive disorder,* and *nonspecific formulation-repetition deficit)* is probably the most common DLD. The phonological disturbances consist of omissions, substitutions, and distortions of consonants and consonant clusters in all word positions. The production of unpredictable and unrecognizable sounds makes speech impossible to understand. The syntactic impairment consists of a lack of small grammatical words (e.g., *and, but)* and an absence of appropriate inflected endings (e.g., *-ed, -ing).* The syntactic deficit is not just a developmental lag. Whereas a normal young child may say "baby cry" or "a baby crying," these children create deviant constructions, such as "the baby is cry." Telegraphic speech is common. The presence or absence of difficulties in other language areas is variable. Overall, comprehension is relatively, although not wholly, spared. Semantic skills tend to be intact. Repetition, pragmatics, and prosody may be normal. Autistic children with this DLD subtype produce a significant amount of jargon.

Neurological dysfunction is especially frequent in this developmental language disorder subtype. Feeding problems related to sucking, swallowing, and chewing difficulties are common, and drooling is often persistent. The neurological examination may reveal signs of pseudobulbar palsy,

oromotor apraxia, hypertonia, and incoordination. A single patient with the phonological syntactic syndrome and oromotor apraxia had an atypical asymmetry of the planum region and a dysplastie gyrus in the left frontal cortex. Bilateral anterior and posterior perisylvian hypoperfusion has been demonstrated in a few children with this disorder. This DLD most resembles Broca's aphasia in adults.

Verbal Auditory Agnosia

Despite intact hearing, meaningful language is not understandable in verbal auditory agnosia {VAA). VAA may occur on a developmental basis and as an acquired disorder, the Landau-Kleffner syndrome (sec Chapter 73). *Generalized low performance* and *global dysfunction* are other names tor die developmental form. VAA is common in low-functioning children with autism. VAA best supports the theory that DI.D result from difficulty with processing basic sensory information entering the nervous system in rapid succession.

The outcome from the developmental form of VAA is generally poor. *1* be outcome from tin- acquired disorder is better in approximately one third of patients. VAA is seen in adults with acquired bitemporal lesions.

Higher Order Language Disorders

Semantic Pragmatic Syndrome

Children with the semantic pragmatic syndrome (also called *repetition strength and comprehension deficit* and *language without cognition)* are fluent speakers, even verbose. The tetm *cocktail party syndrome* describes the semantic pragmatic syndrome in children with hydrocephalus. Vocabulary is often large and somewhat formal. Parents are often encouraged by the child's sizable vocabulary only to find later that the verbosity did not indicate superior cognitive skills. Such children fall short in basic semantic skills required for meaningful conversation and informative exchange of ideas. *They talk to talk.* Phonological and syntactic skills arc generally intact, but comprehension is impaired. Pragmatic skills arc lacking and the rules that govern the use of language in conversation arc never learned. Finally, children with semantic pragmatic syndrome often show deficits in prosody. Their speech has a monotonous, mechanical, or singsong quality. They cannot convey the additional pragmatic intentions that prosody affords, such as speaking with the proper emotion or indicating by tone of voice that they are asking a question. Semantic pragmatic syndrome is often seen in higher functioning autistic children.

The neuroanatomical basis of this disorder is unknown. It is reported in patients with agenesis of the corpus callosum and with hydrocephalus, which supports a possible localization in the subcortex and its connections or a disconnection effect. Repetition strength in the setting of fluent speech with impaired comprehension characterizes the adult aphasia syndrome of transcortical sensory aphasia. Difficulties with prosody and pragmatics suggest right hemisphere dysfunction in addition to left.

Lexical Syntactic Syndrome

The lexical syntactic syndrome is seen in approximately 15% of children with DLD. Speech is generally dysfluent, even to the point of stuttering, because of word-finding difficulties and poor syntactic skills, with many hesitancies and false starts. Both literal and semantic paraphasias are common. Syntax is immature, not deviant. Phonology is spared, and therefore speech is intelligible. Repetition is generally better than spontaneous speech. In conversation, idiom use is better than spontaneous speech. Pragmatics may be impaired, particularly when this syndrome occurs in autistic children. Comprehension is generally acceptable, although complex questions and other linguistic forms taxing higher level receptive syntactic skills are often deficient.

The neuroanatomical basis of this disorder is .llso unknown. No clear counterpart for the lexical syntactic syndrome exists among the acquired aphasias of adulthood, despite similarities with anomic aphasia, conduction aphasia, and transcortical aphasia.

Ncurobtological Basis of Developmental Language Disorders

Structural Anatomy

Adult aphasia data and neurobiological theory implicate the left perisylvian regions in the processing of phonemes and linguistic information. Very few group studies have used neuroimaging to assess language-impaired children per se, other than those originally ascertained because of dyslexia. Perisylvian abnormalities of varying degrees and associated with varyingly severe language disorders are reported. Complete opercular agenesis has been reported in association with suprabulbar palsy (Worster-Drought syndrome). Poly microgyria has also been reported in the perisylvian region. Patients with the most extensive disease have the greatest language impairments, whereas those with posterior parietal polymicrogyria have milder symptoms (Nevo et a I. 2001; Gucrreiro ct al. 2002). Some children and adults with DLD (as well as relatives of DLD probands) do not have the typical planum temporale asymmetry pattern. The absence of the typical planum asymmetry may be the result of aberrant neurogenesis, which leads to reduced cell development in the perisylvian regions or atypical patterns of cell death. Caliosal si/e may be decreased in some children with DLD (Prcis ct al. 2000). An extra sulcus in the inferior frontal gyrus was statistically associated with a history of DLD (Clark and Plante 199S)

in a group of 41 neurological!)' normal adults. In one recent series one third of 35 children with DLD had nonspecific MRI abnormalities including ventricular enlargement (5), central volume loss (3), and white matter abnormalities (4) (Trauner et al. 2000). Rare reports document right hemisphere abnormalities in the DLD child suggestive of a right-hemisphere contribution to language acquisition {Plante et al. 2001). In the KL; family (see earlier) the caudate nucleus and inferior frontal gyrus are reduced in size bilaterally, whereas the left frontal opercular region (pars triangularis and anterior insular cortex) and the putamen bilaterally have a greater volume of grey matter (Watkins et al. 2002b), An insufficient dosage of a critical forkhead transcription factors during embryogenesis, may lead to maldevelopment of brain speech and language regions of the brain (Lai et al. 2001). Despite these research results, there is no reason to image the typical DLD child in clinical practice.

Metabolic Anatomy

Lew studies have specifically assessed children with primary DLD (as opposed to dyslexia) (Table 67.16). In addition, the comorbidity of attention deficit hyperactivity disorder (ADHD) in many of the subjects makes interpreting the results more difficult. However, finding differences in the temporal regions may be specific for the DLD or dyslexic groups because most areas implicated in ADHD research involve the caudate, frontal, and rerrocallosal white-matter regions. Moreover, some of these metabolic studies suggest that different pathological systems may be involved, depending on the DLD subtype,

F.lectropbysto logy

In addition to the EEG studies mentioned in the discussion of the VAA DLD subtype, several investigators have assessed evoked responses and auditory processing speed as markers of language development, normal and abnormal. Atypical patterns of brain activity are documented in children with DLD. Lateralization patterns of electrophysiological activity may predict outcome in late talkers.

Outcome of Developmental Language Disorders

The occurrence of a DLD, even when it appears to resolve, may affect later social emotional adjustment, educational achievement, and vocational choices. Short- and long-term behavioral, social-emotional and psychiatric problems are associated with early language problems (Irwin et al. 2002; Jerome et al. 2002). In one group of 5-year-olds with speech and language problems, the frequency of ADHD

ADHD = a i tent ion-deficit hyperactivity disorder; DLD = developmental language disorder; K = expressive; E/R — expressive/receptive; MR = mental retardation; PS = phonological syntactic syndrome.

Source: Modified wirh permission from Semrud Clikeman, M. 1997, "Evidence from imaging on the relationship between brain structure and developmental language disorders," vol. 4, pp. 117-124; Lee et al. 2002.

was 30%, and the frequency of emotional problems was approximately 10%. In preschool children with DLD, nonverbal intelligence is the best single predictor of overall long-term outcome, and expressive syntactic abilities arc the best predictor of adolescent language skills. Preschool language skills are the best single predictor of later reading ability and disability. Thus both screening and follow-up studies of children with DLD is important. Persisting language problems at adolescence have been reported as high as 90% (Conti-Ramsden et al. 2001; Rcscorla 2002). Communication problems may continue into adult life in 50-70% (Young et al. 2002).

Remediation

Whether intensive early therapy changes the long-term outcome to \in appreciable degree remains to be determined. Different theoretical frameworks drive the various approaches to intervention. One approach involves identifying specific linguistic deficits and targeting them for remediation (Tyler 201)21. Another involves identifying specific DLD subtypes and addressing them in remediation (Forrest 2002). This approach means, for example, that selecting a strategy for improving language producrion must account for a child's level of comprehension. A third approach aims to detect and target a core cognitive processing deficit for intervention. A fourth approach emphasizes the neuropsychological profile. In contrast CO the other approaches, which focus on the deficit, the neuropsychological approach defines and uses children's strengths t:[1] remediate their weaknesses. 11 also takes mio account the child's temperament and neurodevelopmental status to determine learning styles and to develop optimal methods for remediating targeted deficits. To date, no formal study has compared the efficacy of these approaches.

Chapter 68
Inborn Errors of Metabolism of the Nervous System

Gregory M. Pastores and Edwin H. Kolodny

Archibald Garrod developed and introduced the concept of inborn errors of metabolism (IEM) in the 1908 Croonian Lectures and a 1927 Huxley Lecture given at Charing Cross Hospital in London. The IEM are now recognized as a heterogeneous group of disorders resulting from abnormalities of the synthesis, transport, and turnover of dietary and cellular components. Although individually uncommon, collectively they represent a significant cause of morbidity and mortality. In aggregate, approximately 1 per 1000 individuals is born with a metabolic disorder. IEM are estimated to account for 20% of all deaths from genetic diseases; hereditary neurological or storage disorders account for 38% (Yang et al. 1997). The cost of care associated with the acute critical and chronic care of patients with IEM is substantial. Early diagnosis and intervention may influence patient quality of life and lead potentially to health care cost savings.

Defects of intermediary metabolic pathways cause disease either by the accumulation of a toxic metabolite or depletion of a metabolic by-product required to maintain proper cellular function. When an enzyme deficiency blocks normal catabolic routes, metabolism is diverted to alternative pathways that may disrupt cellular integrity. Deficient enzyme activity may arise from (1) mutations in the primary gene sequence for the protein, (2) abnormal processing {i.e., defects of posttranslational modification), or (3) mistaken intracellular localization or improper folding of the enzyme. Metabolic defects may also result from defects of a structural or transport protein.

Most IEM are multiorgan disorders that usually involve the nervous system. The clinical course can be acute, subacute, or chronic. Disorders characteti/ed by intoxication or energy depletion usually present acutely as altered mental status. Seizures and hypotonia may be associated. Other clinical features of acute intoxication are vomiting and hepatic and renal dysfunction. Some IEM follow an insidious course characterized by developmental delay or mental retardation, sensory-motor impairment, or dementia. From a pathophysiological perspective, it is helpful to categorize the various IEM into one of three diagnostic groups: (1) disorders involving complex molecules (e.g., *lysosomal storage disorders, peroxisomal diseases, congenital defects of glycosylation (CDG),* and *defects of cholesterol synthesis);* (2) disorders involving "small molecules" (e.g., *amino and organic acidurias, hyperammonemias,* and *lactic acidemias);* and (3) disorders associated with disruption of cellular energy metabolism (e.g., *mitochondrial respiratory-chain defects, disorders of carbohydrate metabolism, and disorders of fatty acid oxidation* [FAOJ). Metabolic defects involving complex molecules are usually progressive and not related to food intake, whereas those involving small molecules and cellular energy metabolism may be temporally related to food intake. The latter relationship accounts for the importance of dietary manipulation in the management of patients with certain IEM.

IEM are most often inherited as an autosomal recessive trait that results in the deficiency of an enzyme or its

cofactor. This may account for the absence of a family-history when the sibship size is small. A few IEM arc transmitted as autosomal dominant traits (e.g., acute intermittent porphyria, familial hypercholesterolemia), as X-linked traits (e.g., Fabry's disease, Lesch-Nyhan syndrome, ornithine transearbamylase deficiency, phosphorylase kinase deficiency), or segregate in a matrilincal fashion {e.g., mitochondrial DNA defects).

The early diagnosis of an IEM is important not only for prognostication and genetic counseling, hut also to provide treatment. A major goal of newborn screening is to reduce **the** burden of learning and functional impairment of affected children through early diagnosis and intervention. Most families may not be aware of their a priori risk, and early diagnosis of an affected child may enable consideration of prenatal diagnosis (.hiring future pregnancies. Therapeutic advances in recent years are considerable, and early diagnosis provides the best opportunity for a favorable outcome. Furthermore, treatment of secondary disabilities (e.g., seizures, sensory impairments, and behavioral, slccp-wake cycle or communication problems) has a positive impact on quality of life and helps address some sources of parental frustration.

This review covers the major IEM, except for the mitochondrial disorders. Most clinicians are neither metabolic specialists nor bi< >,hcir.val ;vr.oric:srs, and they are not expected to be knowledgeahle of the details of all biochemical pathways. The current chapter provides a general approach to diagnosis and management of IEM.

GENERAL CONSIDERATIONS

Diagnostic Approach

When an IEM is suspected, the clinical features help focus the approach to diagnosis. In the setting of acute illness, IEM should be considered in parallel with more common disorders even when the family history is not informative. The blood and urine of patients with acute neurological deterioration should be examined for signs of acidosis, ketosis, hypoglycemia, and hyperammonemia (Table 68,1 and Table 68.2). Screening tests for abnormalities of amino or organic acids should also he considered. Abnormal metabolites may not be present during stable periods or when samples are obtained after tile acute illness is over.

Analyses of cerebrospinal fluid (CSF) may be indicated in certain cases. For example, determination of CSF levels of biogenic monoamines and GABA may be diagnostic in severe neonatal/infantile epileptic encephalopathy due to neurotransmitter defects. Such defects should be suspected in infants and children with (fluctuating)

Table 68,1: Commonly requested tests for the evaluation of a patient suspected to have an IEM

Tests	*Clinical utility*
Ammonia	Urea cycle defects, organic acidemia
Carnitine, plasma or serum total and free (unesterified) urine levels	Deficiency may develop in carnitine transport defects, disorders of fatty acid oxidation and branched chain amino acid metabolism, and valproic acid treatment
Acy lea mi tine profile	Normal plasma acyl/frcc carnitine ratio: < 0.25
Ccruloplasmin	Decreased in Wilson's and Menkes' disease, a ce miopias mi nemia
Cholesterol	Low plasma levels in Smith-Lemli-Opitz syndrome, cerebrotendinous xanthomatosis; abnormal profile in the dyslipidemias
Free fatty acids (FFA); ketone bodies (KB): 3-OHbutyrati', acctoacetate	Disorders of fatty acid oxidation and kccolysis; supervised fasting and assessment of FFA/Kli ratio and glucose and ketone levels enable distinction of hypo- and hyperketotk disorder
Lactate[1,]	Defects of glycogen metabolism, gluconeogenesis and fatty acid oxidation (often seen with hypoglycemia); defects involving the electron transport chain, Krebs cycle, and pyruvate dehydrogenase (absence of hypoglycemic episodes) LactateVpyruvate ratio (Nl: <20:1) provides insight into oxidariomreductation status Normal Blood lactate <1.8 mmol/L Normal CSF lactate < 2.2 mmol/L
VLCFA (Very-long-chain fatty acid);	Disorders of peroxisomal metabolism
Phytanic acid	Elevated in Refsum disease and rhizomelic chondrodysplasia punctata
Uric acid	Elevated in Lesch-Nyhan syndrome and other defects of purine metabolism and glycogen storage disorders; Decreased in molybdenum cofactor deficiency and defects of pyrimidinc metabolism
CSF: Plasma ratio	
Glucose	<0.35 Glucose transport defect
Glycine	>0.6 Nonketotic hyperglycinemia
Serine	<0.2 Serine synthesis defects (3-phosphoglycerate dehydrogenase and phosphoseune phosphatase deficiency)

^Presence or absence of hypoglycemia can be a useful aid to differential diagnosis of disorders that lead to lactic acidemia,
'Hyperuricemia may lead to formation of nephrolithiasis, obstructive nephropathy and gout.

Table 68.2: Clinical findings characteristic of an IEM

Disorder	*Acute metabolic encephalopathy*	*Metabolic acidosis*	*Hyperammonemia*	*Hypoglycemia*
Aminoacidopathies	•/			
Organic acidemias*	-/-		+/-	
Urea cycle defects	+/-		+	
THAN[1:]			+	
Fatty acid oxidation defects'			+	1/
Defects of ketolysis				1/
Defects of pyruvate metabolism and respiratory chain*			+/-	
Glycogen storage disorders		+		
Defects of gluconeogenesis				

'Additional findings include increased anion gap and ketonuria.
[f]Usually associated with hypoketosis and may lead to secondary carnitine deficiency,
[1] Normal lactate/pyruvate ratio (< 25) found with defects of pyruvate dehydrogenase or gluconeogenesis; elevated ratio suggests pyruvate carboxylase deficiency or mitochondrial disorder.
Transient hyperammoncnia of the newborn.

extrapyramidal disorders, in particular parkinsonism-dystonia or more general "athetoid cerebral palsy", and vegetative disturbances.

Neurological deterioration is a characteristic feature of acute intoxication disorders (e.g., certain aminoacidopathies [MSUD], organic acidemias [MMA, PA, IVA, MCD] and the urea cycle defects). Abnormal urine odor is present in diseases associated with the excretion of volatile metabolites (maple syrup in maple syrup urine disease [MSUD]; sweaty feet in IVA and glutaric acidemia type II), Isolated seizures are often the initial features of vitamin-responsive disorders (e.g., defects of pyridoxinc and folinic acid metabolism, biotin-responsive multiple carboxylase deficiency), and \w ;i prominenl feature in nonketotic hyperglycinemia, sulfite oxidase deficiency, and congenital malabsorption of magnesium. Congenital lactic acidosis and central hypotonia are features of deficiencies of pyruvate carboxylase (PC) and pyruvate dehydrogenase (PD) and disorders of the Krebs cycle and mitochondrial respiratory chain. Recurrent hypoglycemia typically occurs in the glycogen storage disorders and defects of FAO, which are also associated with signs of cardiac involvement (cardiomyopathy, arrhythmias).

Ophthalmological examination often provides a clue to the diagnosis of 1KM. Evidence of coloboma (congenital malformation of the optic nerve head or iris) may suggest an underlying brain abnormality. Vertical supranuclear ophthalmoplegia is noted in Niemann-Pick C, and saccadic initiation failure and defective optokinetic nystagmus can be found in Gaucher's disease type III. Kayser-Fleisher rings (orange or greenish deposits around the lirnbus of the cornea due to copper deposition within the Descemet's membrane) are seen in Wilson's disease. Additional eye findings characteristic of IEM arc shown in Table 68.3.

Hepatosplenomegaly and other signs of storage (e.g., coarse facies, nonimmune hydrops fetalis, dysostosis multiplex) occur with the lysosomal disorders. Liver dysfunction and/or hepatomegaly usually occur in defects of carbohydrate metabolism (galactosemia and hereditary fructose intolerance) and bile acid synthesis and in tyrosinemia and CDG. Unconjugated hyperbilirubinemia associated with liver dysfunction and/or hemolysis in infancy may lead to permanent brain damage due to kernicterus.

Cardiomyopathy may develop in IEM associated with infiltrative (storage) disorders and defects of energy

Table 68.3: Ophthalmologic findings associated with IEM

CatLiratis	Cherry red spot	Lens dislocation
Cerebrotcndinous xanthomatosis	Galactosialidosis	Homocystinuria
Cholesterol synthesis defects	GM1-gangliosidosis	Molybdenum cofactor deficiency
Galactokinase deficiency	Niemann-Pick disease A	Sulfite oxidase deficiency
Galactosemia	Sandhoff disease	
Lowe syndrome	Sialidosis type 1	
Menkes' syndrome	Tay-Sachs disease	
Mucopolysaccharidoses		
Peroxisomal disorders	Optic atrophy	Retinopathy
Serine deficiency disorders	Vlivnnk-iiktidvstnipliy	Carbohydrate-deficient glycoprotein syndrome
Tyrosinemia type II	Canavan's disease	Neuronal ceroid lipofuscinosis
	Hyperomithinetnia with gyrate atrophy	Mitochondrial defects
	Lafora's disease	Peroxisomal disorders

metabolism (Schwartz et al. 1996). The presence of hepatomegaly and other signs of systemic involvement (e.g., cataracts, coarse facics, dysostosis multiplex) may suggest storage disorders of glycogen or glycosaminoglycans. Defects of energy metabolism may be associated with acute or chronic encephalopathy, hepatic dysfunction and several biochemical abnormalities (e.g., hypoglycemia, lactic acidosis ± ketosis, and elevated liver transaminase levels).

Some disorders may have a later age at onset or follow .111 aiypsca; course. 'I lie diagnosis ma; be delayed until adolescence or adulthood. Examples include acid maltase deficiency (muscle weakness and respiratory problems in the absence of cardiomyopathy), fatty acid oxidation defects (myoglobinuria and rhabdoinyolysis after extreme exercise), X-linked adrenomyeloncuropathy (spastic paraparesis secondary to demy duration of the spinal **cord and** peripheral nerves), glycogen brancher enzyme deficiency (adult polyglucosan body disease with progressive upper and lower motor neuron disease, sensory loss, neurogenic bladder, and dementia), and acute intermittent porphyria (abdominal pain, psychosis).

Tandem mass spectrometry (TMS) analysis of blood spots on filter paper is an effective means of screening for some defects of amino and organic acid metabolism and FAO defects (Table 68.4) (Scaglia and Longo 1999; Rashed 2001; Zytkovicz et al. 2001). The main advantages of TMS over previous methods of newborn screening are improved accuracy, sensitivity and specificity, and suitability for cost-effective multi-IEM screening. Furthermore, the need for potentially harmful procedures (i.e., fasting or substrate loading) is avoided.

Assessment of carnitine profile (total and csterified carnitine levels and urinary carnitine excretion patterns) may also prove useful, when a primary or secondary carnitine deficiency is suspected (Kerner and Hoppel 1998). Carnitine plays an essential tole in the transfer of long-chain fatty acids across the inner mitochondrial membrane, in the detoxification of acyl moieties and in the maintenance of free Coenzyme A levels. It is primarily derived from dietary sources. Primary carnitine deficiency due to defective transport leads to increased urinary loss and cardiac and skeletal muscle disease. Secondary carnitine deficiency occurs in several II'.M and may be partially responsive to oral carnitine supplementation. A differential diagnosis of disorders involving carnitine metabolism is shown in Table 68.5.

Brain magnetic resonance imaging (MRI) has significantly advanced the diagnosis and management of patients with DEM (Kaye 2001; Faerber and Poussaint 2002). MR] also allows visualization of structural brain anomalies in children with mental retardation and seizures. For example, MRI images of patients with adrenoleukodystrophy typically show symmetrical areas of hypomyelination in the occipital lobes that extend to the splcnium of the corpus

Table 68.4: Metabolic disorders detected through Tandem Mass Spectrometry (MS-MS)*

Disorder	*Enzyme deficiency*	*Primary metabolic indicator*
Amino audopalhy		
Phenylketonuria	Phenylalanine hydroxylase	Phe
Maple syrup urine disease	Branched chain oxo- (or keto) acid dehydrogenase	Leu/Ile, Val
Homocystinemia	Cystathionine /?-synthase	Met
Hypermethioninemia	Methioninc-S-Adenosyltransferase	Met
Citrullinemia	Argininosuecinate synthetase	Cit
Argiiiinosuccinic aciduria	Argininosuecinate lyase	(ll
Tyrosinemia type I	Fumarylacetoacetase	Tyr
Organic acidemia		
Glutaric acidemia type 1	Glutaryl-CoA dehydrogenase	C5DC
Propionic acidemia	Pro pinny]-(!oA carhnx; lase	C3
Methylmalonic acidemia	Methylmalonyl-CoA mutasc	C3
Isovaleric acidemia	Isovaleryl-CoA dehydrogenase	C5
3-OH-3-methylglutary! CloA lyase deficiency		(MHI
3-methylcromonylearboxylase deficiency		CSOH
Fatty acid oxidation defects		
Medium-chain-acyl-Co A dehydrogenase deficiency		C8, CIO, C10:l, C6
Very-long-chain acyl-CoA dehydrogenase deficiency-		**C14:1,C14,** C16
Short chain acyl-CoA dehydrogenase deficiency		C4
Multiple acyl-CoA dehydrogenase deficiency		C4, C5, C8, C12, C14, C16, C5DC
Carnitine palmitoyl transferase deficiency		CIS, C18:1,C18
C a rnitine/acy (carnitine translocase deficiency		C160H, C18:10H, C180H
Very-long-chain hydroxyacyl-CoA dehydrogenase deficiency		C160H, C18:10H, C180H
Tri functional protein deficiency		C160H, C18:10H, C180H

*MMWR: Recommendations and reports. April 13, 2001.

Table 68.5: Useful measures as an aid in the differential diagnosis of 1EM involving carnitine*

Disorder	*Plasma total (ftmoI/L)*	*Carnitine esterified (% of total)*	*Urinary carnitine*
Control	40 *M*	**<30**	Normal
Carnitine transporter deficiency (CTD)	<5	**<30**	Paradoxically high free
Carnitine palmitoyl transferase-! (CPT-1) deficiency	60-100	**<20**	Normal or high
Carnitine translocase deficiency	5-30	80-100	High ester
Carnitine palmitoyl transferase-2 (CPT-2) deficiency	10-40	40-80	Normal or high ester
Defects in ^-oxidation	**lo ;o**	30-60	High ester
3-OH-3-mcthylglutaryl-CoA-lyasc deficiency	10-30	30-60	High ester

callosum. Disease progression is associated with extension of white matter involvement from central to peripheral and from posterior to anterior, contiguously within the centrum semiovale and internal and external capsule. Reversal of early changes has been observed following bone marrow transplantation (BMT). Abnormalities of both white and gray matter arc observed with mitochondrial disorders that affect the centra! nervous system (CN5).

Proton magnetic resonance spectroscopy (MRS) is a useful adjunct to brain MRI and allows the determination of specific metabolites (e.g., elevated levels of N-aceroacetate in Canavan's disease, and lactic acid in mitochondrial disorders, defects of gluconeogenesis, and biotin-responsive multiple carboxylase deficiency). MRS is also useful in monitoring response to treatment. Recently, MRS has enabled definition of the creatine deficiency syndromes (secondary to guanidinoaceiaie methyltransferase deficiency), a newly discovered group of disorders causing mental retardation and other neurological problems (i.e., extrapyramidal movement abnormalities, hypotonia) (Stockler-Ipsiroglu *1997).* The common feature is severe depletion of brown creatine/phosphocrcatine.

Histological examination of appropriate tissue samples can provide clues to the nature of the storage materials found in certain IEM (e.g., lysosomal disorders) (Warren and Alroy 2000). When a skin biopsy is performed, it is advisable to obtain samples for microscopic examination and for tissue culture, which can be used as a source material lor subsequent biochemical or molecul.;i :i;ciictic) testing. Disorders of amino and organic acid metabolism are not associated with deposition of storage material, although nonspecific histological changes may be found. For this group of disorders, skin fibroblasts are used for confirmatory diagnosis by enzymatic assays. For some disorders, biochemical testing is not accurate for carrier detection because residual enzyme activity in a significant proportion of carriers overlaps with values obtained from the general population. In certain IEM, molecular assays may be available for diagnostic purposes and carrier testing.

A listing of diagnostic laboratories that perform the specialized genetic tests can be found in the GeneTests Web site (www.genetests.otg). Careful attention to sample requirements and shipping/handling considerations is imperative. Clinical information must be sent along with the specimen to receive expert advice in the evaluation of patients. In cases where the diagnosis is established, detailed information may be obtained from several Web sites, including Mendcliau Inheritance in Man (OMIM), GeneClinics, and the National Organization for Rare Disorders (NORD). Several support and patient advocacy groups also provide information about community resources and ongoing clinical trials.

Mutation Analysis in the Diagnosis of IEM

Molecular genetic techniques offer an alternative means for the diagnostic confirmation of IEM (Hill 1993; Baric et al. 2001). This is particularly true for diseases associated with common mutations in which one or a few alleles account for a significant proportion of cases. When the causal mutation is known, testing of other family members permits accurate carrier identification. Furthermore, DNA analysis for prenatal diagnosis provides .1 more rapid it lean-, of diagnosis bec.i use n is performed on chorionic villi or amniocytes without the need for culture (although in practice, most laboratories insist on subsequent confirmatory testing of cultuted cells).

Examples of disorders for which DNA testing has proven useful include MCAD deficiency, myophosphorylase deficiency (McArdle's disease), and Gaucher's disease (Gregersen et al. 2000; Mairc 2001; Madonna et al. 2002). Among patients with MGAD of northwestern European descent, 80% are homozygous for a single mis sense mutation (A985G), and 17% carry this mutation in combination with another less common defect. This finding iias unproved tin reliahb ot Mt.Al) earner ideii; iiic.inoii and diagnosis, particularly of siblings who may be affected but asymptomatic at the time of family screening. In hereditary fructose intolerance, screening for the disease mutation in blood obviates the need for liver biopsy. However, in mitochondrial disorders that cause myopathy, muscle biopsy is still required because the mutant gene may not be expressed in blood or skin fibroblasts.

IEM Associated with Abnormal Brain Development and Encephaloclastic Lesions

Structural brain anomalies are often thought of as developmental anomalies, and IEM are not considered as causative. However, several metabolic disorders can cause a disruption of the normal sequence of brain development and lead to encephalocele, dysgenic corpus callosum, and neuronal migration defects (Tables 68.6 and 68.7) (Gelineau-van Waes and Finnell 2001; Jeng et al. 2001; Nissenkorn et al, 2001). For instance, cystic necrosis of white matter (± basal ganglia involvement) has been described in deficiencies of PDH, PC, and molybdenum cofactor. The mechanisms proposed to explain abnormal brain development and encephaloclastic lesions in IEM include the production of a toxic or energy-deficient intrauterine milieu, modification of the content and function of membranes, and disturbance of the normal expression of intrauterine genes responsible for morphogenesis.

Imminent Death Prior to Diagnosis in a Child with a Suspected IEM

Samples needed for diagnosis nuisi In- obtained when a child develops acute fatal metabolic decompensation. A correct diagnosis may help families as they cope with their loss and enables appropriate counseling and prenatal diagnosis for subsequent pregnancies. Plasma (separated from whole blood) and urine should be frozen (Chace et al. 2001; Chakrapani et al. 2001). A skin sample should be obtained under sterile technique (using alcohol swabs and not iodine, which can interfere with cell growth) and stored at room temperature in tissue culture medium. When a storage disorder is suspected, a small snip of skin should be obtained and placed in glutaraldehyde for subsequent electron microscopic studies.

Management Considerations

The appropriate management of a patient with an IEM is determined by the particular metabolic derangement. Therapeutic strategies may include one or more of the following approaches: (1) substrate reduction by dietary manipulation or precursor synthesis inhibition; (2} removal (or enhanced clearance) of the toxic metabolites; (3) replenishment of depleted metabolites and/or cofactor supplementation; (4) enzyme (replacement) therapy; and (5) cellular replacement (e.g., bone marrow, liver, or kidney transplantation) (Chakrapani and Wraith 2002; Ogier de Baulny 2002). Gene therapy had been actively explored but the recent unexpected death of a study subject with OTC deficiency has prompted reexamination of this approach, with greater caution demanded for future clinical trials (Hsich et al. 2002). Other approaches under consideration are liver repopulation, chaperon-mediated therapy for diseases associated with residual enzyme activity, and the transplantation of stem cells with directed differentiation along specific lines (Gregersen et al. 2001; Grompe 2001, 2002). These advances have changed the attitude toward patients with IEM away from nihilism and hopelessness.

Table 68.6: Developmental brain malformations associated with an IEM*

Disease	*Neural tube defects*	*Holoprosencephaly*	*Cerebellar malformations*	*Hypoplastic temporal lobes*

[+]Pseudo-2ellwcger and pseudo-neonatal adrenoleukodystrophy have normal appearing cortcxes.
•The perirolandic distribution of pachygyria in Zellweger syndrome may help in the differential diagnosis of infants with hypotonia. Pattern is mainly occipital in congenital muscular dystrophy.

An individualized approach is needed for each patient; some disorders require more than one management option. The clinical response to most treatment plans may vary, and residual disturbances are common. Patients may remain at risk for metabolic decompensation when stressed by infection, trauma, or surgery. Reducing energy expenditure and promoting anabolism arc immediate management goals. Emergency measures may prevent further deterioration, but most measures are nutritionally incomplete and should not be extended beyond 48 hours without dietary review. In most situations, symptomatic treatment must be ptovided in specialized care units with expertise in the specific disease.

When using special diets, attention must be given to caloric requirements and balanced nutrition that includes needed minerals and supplements. Diseases managed with dietary restriction include the aminoacidopathics: PKU, MSUD, and homocystinuria. In classic Refsum disease, reduction in dietary phytanate results in normalization of the biochemical and clinical phenotype.

In some disorders alternative dietary sources may be necessary. Thus, medium-chain triglycerides are given to patients with VLCAD and LCHAD as a lipid source. In Smith-Lemli-Opitz syndrome (3^-hydroxysterol-A^7-reductase deficiency), the use of a high cholesterol diet (± bile acids) improves growth and neurodevelopmental status, although clinical response is variable. In children with glycogen storage disorders (GSD), carbohydrates are given to prevent hypoglycemia and suppress secondary metabolic derangements (i.e., hyperlipidcmia, hyperuricemia). In the urea cycle disorders, arginine or citrulline is given to make up for compounds that are not synthesized secondary to the metabolic block.

Methods in enhance excretion or detoxification ol toxic metabolites ate employed when theit accumulation cannot be corrected by dietary manipulation. In patients with hyperammonemia, sodium benzoate and sodium phenylbutyrate, which conjugate with glycine and glutamine, are given to facilitate nitrogen excretion (Figure 68.1). In isovaleric acidemia, oral glycine conjugates with the highly

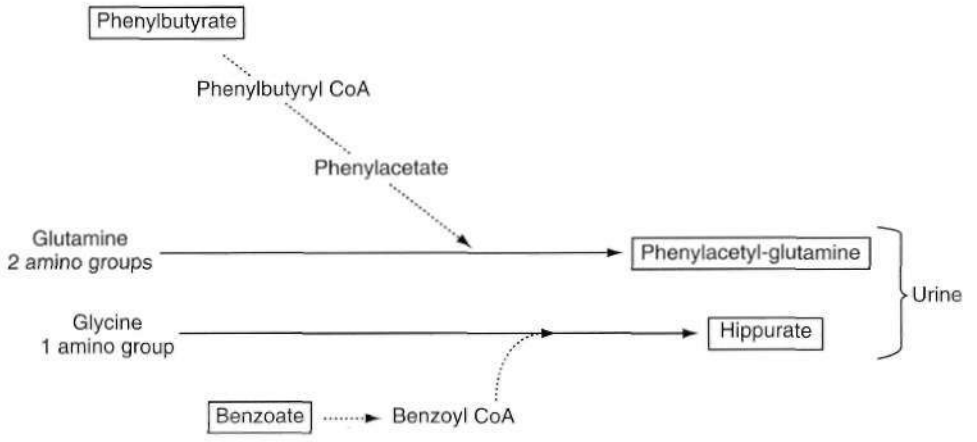

FIGURE 68.1 Alternative pathways to reduce accumulation of ammonia.

toxic isovaleric acid to form a harmless by-product excreted in the urine. Administration of cysteminc to patients with cystinosis promotes the formation of cysteine, which is subsequently excreted in the urine. Carnitine supplementation is given to patients with organic acidemia to prevent carnitine deficiency secondary to the formation and renal excretion of acylcamitinc compounds. During acute metabolic decompensation, dialysis and hcmofiltration may be used to facilitate rapid clearance of roxic metabolites. These techniques have been applied in the treatment of MSUD and carbamoylphosphate synthetase deficiency (Schaefer et al, 1999; Daschner and Schaefer 2002).

Novel therapeutic strategies for IEM are directed at blocking the production of toxic metabolites through the use of substrate synthesis inhibitors. In tyrosinemia type I (fumaroylacetoacetate hydrolase deficiency), NTBC (2-nitro-4-trifluoro-methylbenzoyl-l,3-cyclohexanedione) reduces the production of downstream metabolites of tyrosine degradation by inhibiting the enzyme 4-OH-pl'iLTi} jpyruvate citix^LiKisc. 'lit.- enzyme imolved in a

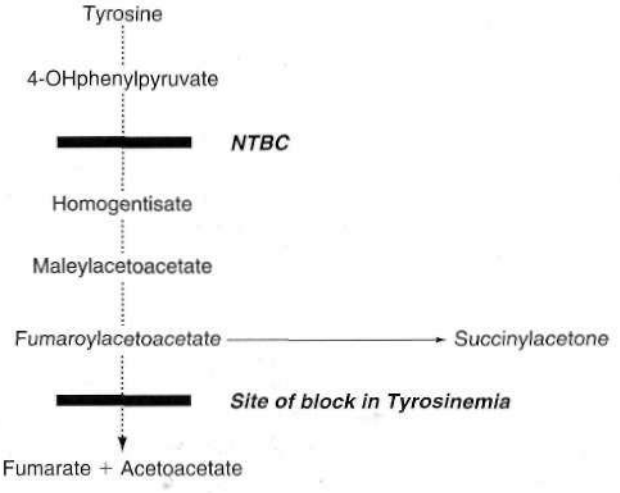

FIGURE 68.2 Substrate reduction therapy.

reaction preceding the block (Figure 68.2). In one study of NTBC in more than 300 patients with tyrosinemia type 1, 95% showed improvement of hepatic and kidney function (Grompe 2001). In Gaucher disease type I, NB-DNJ (N-butyldcoxynojirimycin) administration leads to decreased liver and spleen volumes and a gradual but significant improvement in hematological parameters with a decline in the levels of disease activity markers (Cox et al. 2000). NB-DNJ inhibits glucosyltransferase, the first enzymatic step in glycosphingolipid (GSL) biosynthesis. Metabolic homeostasis is achieved by limiting the accumulation of substrate to a level that can be sufficiently catabolized by a mutant but partially active enzyme. Given this mechanism of action, NB-DNJ may be potentially useful for other disorders of GSL metabolism (e.g., late-onset Tay-Sachs and Sandhoff disease).

The underlying defect in some IEM may be partially corrected by replenishing depleted substrates. In carnitine-transport defect, the use of carnitine results in the resolution of cardiomyopathy and prevention of further episodes of hypoketotic hypoglycemia. In other disorders, the production or binding affinity of a cofactor required for enzyme activity is impaired. These defects can be corrected by administration of pharmacological doses of the required supplement. Biotin given to children with biotinidase or holocarboxylase deficiency has led to good clinical outcomes, except in the most severe forms with neonatal-onset (Wolf 2002). Vitamin B12 given for late-onset forms of methylmalonic acidemia (MMA) caused by defects of adenosylcobalamin metabolism leads to a sustained decrease of toxic metabolites and a favorable developmental prognosis (Nicolaides et al. 1998). Suppression of gut microbial propionate production (through the use of metronidazole to inhibit anaerobic colonic flora) and dietary protein restriction are complementary approaches provided to children with MMA.

Additional examples of pharmacological correction include the use of tetrahydrobiopterin (BH_4) to treat disorders of biopterin synthesis, rare variants of the hyperphenylalaninemia. Although BH4 reduces elevated

plasma phenylalanine levels by its action on liver phenylalanine hydroxylase, access to the CSE is minimal. Response has been observed in those with a peripheral type of defect. Tetrahydrofolate prevents demyelination in children with folate deficiency and dihydroptcridinc reductase deficiency (Steinfeld et al. 2002). Responsiveness to cofactor administration can be assessed by controlled enzyme assays involving the patient's cultured skin fibroblasts. A list of the cofactors used in various metabolic disorders and the recommended doses are shown in Table 68.8.

Enzyme replacement therapy (ERT) has been shown to reverse the hematological and visceral manifestations of Gaucher's disease. This approach has been considered for the treatment of lysosomal storage disorders (LSD) due to single enzyme deficiencies. The relevanl enzymes are produced from genetically manipulated mammalian cells in culture and subsequently modified to expose the appropriate sugar residues to facilitate targeted cell uptake. Once purified, the recombinant enzyme is given intravenously on a regular basis. Beneficial effects have been noted in patients with Fabry's disease, MPS type I (Hurler-Scheie syndrome), and GSD II (Pompe's disease) (Pastores and Thadhani 2002). Enzyme therapy is also being explored for other LSD including Niemann-Pick disease type B, MPS II (the mild variant of Hunter's syndrome), and MPSVI (Maroteaux-I.amy syndrome) (Schiffmann and Brady 2002).

Metabolic correction through cellular replacement by BMT has been performed in patients with LSD (e.g., MPS I, Gaucher's disease type III) (Krivit et al. 1999). In X-hnked adrcnoleukodystrophy, BMT has resulted in prolonged remission with reversal of MRI abnormalities and stabilization or improvement of motor function (Shapiro et al. 2000). Although BMT has altered the natural course of these diseases, donor limitation issues, procedural risks and long-term care considerations (e.g., immunosuppression) exist. Advances in the methods of conditioning (e.g., non-myeloablative procedures) prior to BMT and utilization of umbilical cord blood have addressed some of these concerns. Patients with IEM who may be suitable candidates for BMT should have serial follow-up visits incorporating neuropsychological and neuroradiological studies so that intervention can be timed prior to significant disease progression to allow an outcome with minimal neurological sequelae. BMT is not appropriate for disorders characterized by rapid neurodegeneration, such as MPS II (severe Hunter syndrome) and MPS III (Sanfilippo syndrome).

For disorders where the metabolic defect is confined to the liver (e.g., Crigler-Najjar syndrome, Hyperoxaluria type I) or leads to single organ failure (e.g., end-stage renal insufficiency in Fabry's disease and Hyperoxaluria type I, and liver failure in OTC deficiency, ryrosinemia, and GSD-IV), organ transplantation may be appropriate (Burdelski and Rogiers 1999; Khanna et al. 1999). In patients with tyrosinemia who do not respond ro NTBC therapy or have evidence of hepatic malignancy, orthotopic liver transplantation is the treatment of choice. Microchimerism (the migration of donor-derived cells from the allograft) has been reported in a few patients following livet transplantation. However, this phenomenon is probably not sufficient to correct the systemic metabolic defect.

Symptomatic treatment remains a vital component of patient care. Indeed, several palliative measures have been shown to improve quality of life and reduce the incidence and severity of disease-related complications. For instance, i-dopa improves motor function in patients with tyrosine hydroxylase deficieocv. DDAVP (dcamino-arginine-vasopression) has been used to reduce the tendency for abnormal bleeding during surgery of patients with GSD type 1A (von Gierke's disease). G-CSF (granulocyte colony-stimulating factor) has been administered to patients with GSD IB and neutropenia to minimize the risk of recurrent bacterial infection and gastrointestinal tract ulceration. Steroid and mineralocorncoid replacement is essential in patients with adrenoleukodystrophy and adrenal insufficiency.

In addition to dealing with the medical problems of an affected child, families should be provided with genetic counseling. Approximately 90% of the IEM are inherited

as autosomal recessive traits. Of the remaining 10%, approximately two thirds are X-linked and one third arc autosomal dominant traits. Prenatal diagnosis is available for most IEM. A tecent study that looked at teproductive decisions made by parents of children with IEM noted 56% were receptive to future prenatal diagnosis, and 41% would choose to take measures to prevent another affected pregnancy (Read 2002). The study also found that parents of children with IEM have higher scores on a stress index, lower scotcs on an adaptive behavior scale, and have fewer persons in their social support network. Furthermore, the parents expressed greater worry about their child's future and perceived difficulty in meeting the child's extra care needs. These observations underscore the importance of early intervention, supportive care and appropriate genetic counseling.

The Adolescent with an IEM and Transition to Adulthood

As a tcsult of early diagnosis and intetvention, many affected children have achieved longer survival. The overall prognosis and quality of life for these individuals in adolescence and adulthood is greatly influenced by the care they receive as children. An important goal is for societal integration and life-fulfillment, which may be possible in certain cases.

In most instances, patient care has been provided by pediatricians and metabolic specialists. Often, the majority of adult physicians are not ptepared to assume the management of these patients as they grow older. Familiarity with the natural history of the disease may lead to anticipatory guidance and appropriate monitoring, with early intervention at the first sign of trouble (Eons and Packman 2002). Several examples can be cited. Hepatic adenomas, which may become malignant, develop in the second and third decade of life in patients with GSD IA. Patients with tyrosinemia are also at risk for hepatocellular carcinoma, which can be monitored by serial <*-fetoprotein measurements and livct imaging.

Other complications to watch for include acute and chronic recurrent pancreatitis, which occurs in association with the hyperlipidemias, disorders of hranched-chain amino acid degradation, homocystinuria, and acute intermittent porphyria (Simon et al. 2001). Atherosclerosis and thromboembolism are potential causes of morbidity in homocystinuria and methylcnetctrahydrofolate reductase deficiency. LCHAD may be complicated by cardiomyopathy and retinopathy. Renal insufficiency/failure may develop in patients with cystinosis, Fabry's disease, GSD I, and MMA. Metabolic stroke with bilateral globus pallidus .ihi.iim.i In :;-S .in J i-xii,;pyramidal signs m.i\ Iv .i scqiu l.i oi metabolic decompensation in MMA.

As most IEM affect multiple systems, the involvement of a multidisciplinary team with central coordination by a primary physician is essential. Patients and family members usually appreciate being included in the decision-making process. These moments of interaction can also be used as an opportunity to assess the family's understanding of the disease and its management, and their coping mechanisms.

Efforts should be directed at ensuring the child reaches his/her maximum potential. Educational programs for the affected child must be adapted to developmental level and cognitive strengths to minimize frustration and associated behavioral problems. It is important to prepare for development of increasing handicap and take appropriate steps to facilitate individual performance during activities of daily living. Special attention should be given to self-care, communications skills, and mobility issues.

All individuals become increasingly self-conscious of their body image during puberty. Support may be needed to enhance self-esteem in adolescents who feel stigmatized by theit physical appearance, particularly when the IEM is associated with facial dysmorphic features and skeletal deformities. Dysarthria impedes communication, and disturbances of bowel and bladder continence undermine self-confidence and social interaction. Some disorders are associated with delayed puberty (GSD IA, galactosemia) and CDG-la or premature ovarian failure (hypergonadotropic hypogonadism). Osteoporosis is often under-recognized as an associated condition of IEM. It most often occurs in those conditions that cause poor mobility because of cognitive or neuromuscular impairment, or characterized by chronic acidosis and renal insufficiency. When dietary regimens are required for disease control, the adolescent should be expected to manage the diet without parental assistance. Peer pressure may lead to noncompliance, and the patient must understand the potential implications of this course of action.

Pregnancy is a critical time when measures are needed to ensure a good maternal-fetal outcome (Walter 2000), Women of childbearing age with an IEM must be well controlled before conception. Close follow-up is required during labor and delivery and postpartum. Children born to women with poorly controlled PKU are at risk for microcephaly (70%), attention deficit disorder and mental retardation (>90%), intrauterine growth retardation (40%), and congenital heart disease (12%). Risk to the fetus correlates with maternal p:ii.-iiy].il.minr k'vcls. Outcomes are optimal if maternal blood phenylalanine of < 10 mg/dL (600 uM) is achieved by 8-10 weeks of gestation and maintained throughout the pregnancy.

Women with liomocyslinisria **icvslalliioiniu ;> synthasr** deficiency) may have an increased risk for spontaneous abortion and preeclampsia. Pregnancy may exacerbate the cutaneous lesions of porphyria cutanea tarda during the first trimester. Women who are carriers of OTC deficiency may develop a hyperammonemia encephalopathy during the postpartum period. Postpartum metabolic decompensation also occurs in MSUD.

Psychiatric symptoms arc primary features of some disorders or may develop secondary to metabolic decompensation (Gray et al. 2000). For instance, behavioral changes are seen in individuals with X-linked adrenoleukodystrophy, late-onset GM2 gangliosidosis, and porphyria. Cognitive and behavioral problems also occur in children with PKU, especially in those who are not compliant with dietary restriction. Children subjected to BMT are at risk for neuropsychological complications secondary to chemotherapy and irradiation.

DISORDERS INVOLVING COMPLEX MOLECULES

The metabolism of complex molecules in lysosomes and peroxisomes involves different biochemical pathways than those responsible for the processing of dietary constituents. This explains why dietary manipulation and vitamin or cofactor supplementation are not effective. An overview of the distinctive characteristics of these organelles and the associated general features are summarized in Tables 68.9 and 68.10. LSDs involve tissues and organs that develop normally but later malfunction. In contrast, early-onset peroxisomal disorders arc often expressed as severe developmental malformations,

Lysosomal Storage Disorders

The lysosome is a membrane-hound intracytoplasmic vacuole that contains enzymes required for the degradation of complex lipids, proteins, and nucleotides. Its acidic milieu (pH-^5.4) is required for optimal activity of the contained hydrolytic enzymes and their cofactors/activators. More than 40 different LSDs are described (see Table 68.10).

H.G. Hers first proposed the LSD concept in 1963 based on the detection of glycogen-filled vesicles of lysosomal origin in cells obtained from a patient with Pompe's disease. Progressive lysosomal storage of incompletely metabolized substrates occurs either because of primary hydrolase deficiency, deficiency of a protective protein that aids in the lysosomal targeting and prevention of premature degradation of enzymes, or the absence of an "activator protein" necessary for enzyme-substrate interaction and degradation. Additional disease mechanisms include abnormal protein/enzyme processing, defects of posttranslational modification in the endoplasmic reticulum, failure to attach the appropriate targeting signals (e.g., mannose-6-phosphate) in the Golgi apparatus, and defective removal or transport of the substrate from lysosomes (e.g., Niemann-Pick type C and sialic acid storage disease) (Aula et al, 2002; Carver and Heidcnrcich 2002). Abnormalities in endocytosis, vesicle fusion, and the processing of autophagic elements are identified in Danon disease from defects of lysosomal associated membrane protein 2 (LAMP2). LAMP2 is an integral membrane protein of endosomes and lysosomes. Other syndromes of intracellular vesicle damage chat causes abnormal lysosomal formation and storage are Hermansky-Pudlak syndrome and Chediak-I Iigashi syndrome.

Clinically, the LSDs are a heterogeneous group of disorders involving multiple organ systems. The clinical features reflect the cellular sites of substrate storage and resultant organ dysfunction. In rapidly progressive forms, the onset of clinical features is in the newborn or in early infancy. With later-onset forms, the initial features are delayed until adolescence or adult life, and the course may be acure, subacute, or chronic. Acute and subacute courses are usually associated with primary CNS involvement, developmental delay, and mental retardation.

Unlike the small molecule diseases, the clinical features of LSD are often characterized by a subacute or chronic encephalopathy. Myoclonic seizures are seen in the following disorders: GMj-gangliosidosis, sialidosis type 1, Schidler's disease (a-N-aeetylgalactosaminidase deficiency), Gaucher's disease types IT and III, and fucosidosis. Some LSDs do not have primary CNS involvement (e.g., Fabry disease, Gaucher's disease type I, Niemann-Pick type B, MPS I-Scheie' syndrome, MPS IV-Morquio syndrome and mild MPS VI-Maroteaux-Lamy syndrome).

Tabic 68.9: Characteristic biochemical features of the major cellular organelles

Lysosome	*Peroxisome*	*Mitochondria*
Acidic compartment, actively maintained (proton ATPase)	Metabolic functions: ^-oxidation of fatty acids and derivatives, Ether phospholipid synthesis	Site of coupling of oxidation and phosphorylation, generation of ATP
Terminal compartment in en doc y tic pathway	Increased VI.CFA	Symptoms reflect tissue specificity for aerobic metabolism: Btain > Skeletal, Cardiac Muscle > Kidney > Eye
Rich in acid hydrolases (protease, glycosidase, sulphatase)	Disease often classified based on loss of single or multiple peroxisomal enzyme hi action	Has unique DNA, which replicates independently of nuclear DNA
Enzymes use M-6-P targeting into pre lysosome	Due ro defects of biogenesis and targeting thru PTS 1 and 2	Occur re 1 let- may be sporadic, matrilineal or autosomal (dominant or recessive) inheritance
Autosomal recessive, except Fabry's disease, Hunter's syndrome (MPD-II), and Danon disease which are X-linked traits	Autosomal recessive, except for X-l inked ad rem leukodystrophy

MLD = metachromatic leukodystrophy; MPS = mucopolysaccharidosis.
*Three types imply infanrile, childhood, and adulthood presentations.

Rare variants of some sphingolipid storage disorders are caused by defects in the enzyme cofactor/activator required for complete substrate hydrolysis instead of a primary-enzyme defect. Two categories of sphingolipid activators exist. One represents the GM_2-activator and the other a group of four molecules (saposin A, B, C, and D) derived by proteolytic cleavage of a common precursor, prosaposin. The gene localization for prosaposin is chromosome 10. Deficiency of the G_{M2}-activator results in the AB variant of GM2-gangliosidosis. Saposin B activates arylsulfatase A. Deficiency of saposin B gives rise to a variant of metachromatic leukodystrophy (MLD variant). Saposin C activates glucocercbrosidase and /i-galactocerebrosidasc; its deficiency leads to a clinical picture often referred to as an atypical form of Gaucher's disease (GD) because of the clinical overlap with the type 3 variant (subacute neuropathic GD). Disorders resulting from cofactor deficiencies are characterized by normal enzymatic activities in vitro when using the synthetic (artificial) substrate. Therefore the diagnosis can be missed by routine biochemical testing. Molecular analysis may reveal the presence of mutations in the relevant encoding genes.

LSDs are usually transmitted as autosomal recessive traits, except for Fabry's disease, Hunter's syndrome (MI'S-II), and Danon disease. These are inherited as X-linked recessive Traits. Biochemical assays are generally available for prenatal diagnosis. Care should be taken in the interpretation of certain enzyme assay results (e.g., arylsulfatase activity) because low values may be obtained in the presence of pseudo-deficiencies. Diagnostic confirmation is also available by molecular (DNA) testing. In families where the causal mutation is known, molecular testing enables accurate assignment of carrier or affected status. Prenatal diagnosis is possible for almost all LSD.

Neufeld and colleagues (1968) showed that an exchange of medium from fibroblasts with different disease gene mutations, MPS I (Hurler syndrome) and II (Hunter's syndrome), results in the clearance of intracellular storage material. The metabolic cross correction was due to secretion of the functional enzyme from one cell line followed by intracellular uptake by the deficient cells. These studies provided the rationale for treatment of the LSD by ERT. Today, cellular correction is achieved in certain clinical LSD subtypes through BMT and ERT. Other therapeutic strategies under consideration include the use of substrate synthesis inhibitors, chaperon-mediated agents, and gene therapy.

Peroxisomal Disorders

The peroxisome is an organelle involved in ^-oxidation of very-long-chain fatty acids (VLCFA), the synthesis of plasmalogen and bile acids, and oxidation of pipecolic, phytanic, and dicarboxylic acids. Peroxisomal disorders are generally classified according to the presence of single or multiple enzyme deficiencies (Table 68.11). Most peroxisomal matrix proteins are targeted using one of two targeting sequences in a unique system allowing the importation of oligomerized proteins through a specific shuttle involving a receptor and its cargo. Defects of these cellular mechanisms lead to disruption of peroxisomal metabolic functions (Baumgartner and Saudubray 2002).

The spectrum of clinical findings in peroxisomal disorders includes craniofacial abnormalities, encephalopathy. limb malfotmations, ocular abnormalities, and hepatic and intestinal dysfunction. In the late-onset types, the features are nonspecific and include behavioral changes and deterioration of intellectual function, Demyelination occurs in X-linked adrenoleukodystrophy, visual and hearing deficits in Refsum disease, and peripheral neuropathy and gait abnormality in the atypical peroxisomal biogenesis defects,

Screening for peroxisomal disorders is facilitated by demonstrating elevated plasma VLCEA levels and/or impaired erythrocyte plasmalogen synthesis. Increased phytanic acid levels are found in Refsum disease and rhizomelic chondrodysplasia punctata.

DISORDERS INVOLVING SMALL MOLECULES

Disorders of intermediary metabolism often result in the accumulation of compounds that cause acute progressive neurological disorders. The term "defects of small molecules" is used because the compounds that build up proximal to the metabolic block are often elevated in blood and CSF and may be excreted in the urine or potentially cleared by dialysis. Diagnosis is enabled by detection of these compounds in blood, CSF, and urine. Serin I measurements i a n lie used in monitor the eftccth etiess of disease control. Treatment often requires the elimination of the accumulating toxic compounds by dietary restriction and/or the provision of vitamins or cofactors. During episodes of acute decompensation, metabolic homeostasis may be rapidly achieved by exchange transfusion or by peritoneal or hemodialysis. Chronit control necessitates the use of compounds that bind with the toxic molecules and facilitate alternative pathways of clearance.

Included in this group are the aminoacidopathies, organic acidemias, and the urea cycle defects. Examples for each category and their estimated incidence are listed in Table 68.12.

Disorders of Amino and Organic Acid Metabolism

ll-.;' iii.iiii cluneal feature "I lliese c n:uli(inns i– .1 symptom free interval followed by an acute catastrophic event (e.g., vomiting, lethargy, and coma). The acute episodes arc characterized by metabolic acidosis, hypoglycemia, and/or hyperammonemia (Burlina et al. 1999; Ogier dc Baulny and Suadubray 2002). These metabolic disorders can lead

Table 68.11: Peroxisomal disorders

1. Defects of Biogenesis I	Craniofacial dysmorphic fearures: large anterior fontanel, high forehead
Spectrum:	Psychomotor retardation

to progressive developmental regression and spasticity. A specific diagnosis relies on the pattern of abnormalities displayed on the amino and organic acid screening profile and by detection of the relevant acylcarnitine compounds in plasma and urine. These disorders are usually treated by dietary restriction, elimination of the toxic compounds, and adjunctive treatments using specific cofactor or vitamin supplements and carnitine as indicated.

Hyperammonemia

Blood ammonia is derived from protein catabolism and as a metabolic by-product of bacterial reactions in the gastrointestinal tract. It is a neurotoxic metabolite that promotes excessive glutamine production in the cytosol of astrocytes by its action on glutamine synthetase. Ammonia can promote cellular swelling and brain edema by its osmotic effect. Blood ammonia concentrations may be elevated from a primary defect of the urea cycle (UCD) or secondarily in disorders of amino and organic acid metabolism. In the organic acidemias, intraniitochondria) accumulation of acyl-CoA esters causes secondary inhibition of the urea cycle enzymes. The clinical diagnosis is made by assessment of the plasma amino acid and ammonia levels and analysis of urine organic acid profile. Measurement of orotic acid levels in urine is useful in the differential diagnosis (Table 68.13). Defects of the urea cycle are all inherited as autosomal recessive traits excepl for ornithine transcarbamylase deficiency, which is inherited as an X-linkcd trait.

The clinical features arc variable; newborns may exhibit rapidly progressive neurological deterioration, with

Argininosuccinic lyase	Moderately elevated citrulline, argininosuccinic acid; decreased arginine	Increased
Arginasc	Increased glutamine, alanine	Increased

irritability or lethargy, seizures, coma, and respiratory arrest (Burton 2000; Stciner and Cederbaum 2001). Transitory hyperammonemia of the newborn (THAN) must also be considered. Neonates with THAN have significantly lower birth weights for gestational age, and chest radiographic findings are usually abnormal. Affected newborns are managed with exchange transfusion and peritoneal dialysis if necessary. Most THAN survivors have normal neurological and developmental examinations on follow-up and do not experience recurrent episodes of hyperammonemia.

Later-onset clinical UCD manifestations include developmental delay, behavioral problems, hepatomegaly, and gastrointestinal symptoms. Affected children and adults may show behavioral problems, confusion, irritability, and cyclic vomiting, with deterioration in mental status during metabolic stress. Of the UCD, arginasc deficiency is uniquely characterized by spastic diplegia, dystonia, ataxia, and seizures.

Two disorders of amino acid metabolism, lysinuric protein intolerance (I.SI) and hypcrainmoncmia-hyperormthinemia-homocitrLillinemia (HHH syndrome), are associated with hyperammonemia' encephalopathy. LSI presents with growth retardation, hepatic and renal dysfunction, and hematological and pulmonary abnormalities. It is caused by a defect in dibasic amino acid transport that leads to an increased urinary excretion of arginine, ornithine, and lysine. HHH syndrome is associated with an elevation of plasma ornithine and increased urinary excretion of homocitrulline {a derivative of lysine). The clinical features include intolerance to protein feeding, vomiting, seizures, and developmental delay. Ornithine administra-i-.nn improves urea cycle function m the Ml II I •»yndronie by providing the required precursor for uninterrupted completion of the sequential metabolic steps (Summar 200 1:•. Progressive spastic paraparesis is a late complication.

DISORDERS 01: ENERGY METABOLISM

The energy requirements of cellular metabolism are derived from carbohydrates in the nourished state and from glycogen and fatty acids stores during fasting. Cellular energy is stored in the form of ATP, generated in the cytoplasmic and mitochondrial compartments from glucose and fatty acid oxidation. The relevant metabolic pathways are to a great extent hormonally mediated. Tissues with high aerobic metabolic rates, in the brain, skeletal muscle, and cardiac muscle are most vulnerable to defects of energy metabolism.

Several clinical presentations suggest an underlying defect of energy metabolism (Sim et al. 2002). Acute or recurrent exercise intolerance and myoglobinuria, with or wirhout cramps, are features of the glycogen and fatty acid oxidation (FAO) disorders. Progressive neuromuscular weakness and hypotonia are features of the glycogenoses (acid maltase, debrancher enzyme, and brancher enzyme deficiencies), FAO defects, involving carnitine uptake and carnitine acylcarnitine translocasc detects, and mitochondrial disorders (cytochrome oxidase deficiency). Acute or chronic weakness occurs in long-chain or very long-chain acyl coenzyme A (CoA) dehydrogenase, short-chain 1-3-hydroxyacyl-CoA dehydrogenase, and trifunctional protein deficiencies.

Avoidance of fasting is an important consideration in the management of patients with disorders of carbohydrate metabolism (glycogenolysis), fatty acid oxidation, and ketogenesis. In some cases, the calories for energy metabolism must be maintained by nasogastric or gastrostomy tube feedings.

Glycogen Storage Diseases

The glycogen storage diseases (GSD) are caused by enzyme defects of glycogen degradation. The GSD are usually designated by a type number that reflects the historical sequence of their clinical characterization. Several subtypes are also designated in tecognition of the individual who called attention to the condition. For instance, Pompe's disease is the eponymous designation for GSD type II. GSD that result from liver enzyme defects are characterized by hepatomegaly and hypoglycemia. GSD that result from muscle enzyme defects are characterized by cramps on exertion and progressive weakness. Disorders of carbohydrate metabolism are inherited as autosomal recessive

traits, except for the X-linked form of phosphorylase kinase deficiency (GSD type VI).

Disorders of Gluconeogenesis

Defects of gtuconeogenesis result in recurrent hypoglycemia with lactic acidosis, with or without ketosis. Neurodegenerative features are found in deficiencies of pyruvate carboxylase (PC) and phosphoenolpyruvate carhoxykinasc (PEPCK).

batty Acid Oxidation Defects

The oxidation of fatty acids involves four components: the carnitine cycle, mitochondrial ^-oxidation, electron transfer, and the synthesis of ketone bodies (KB), Fatty acids and KB are used by some tissues as an alternative energy source to spare the consumption of glucose. In contrast to muscle, the brain is unable to fully oxidize fatty acids but can utilize KB synthesized by the liver. In early-onset cases, the clinical disease course is characterized by episodes of hypoketotic, hypoglycemic coma and periods of metabolic decompensation during prolonged fasting, operations, or infections K ioares 1998). Rhabdomyolysis, cardiomyopathy, and skeletal muscle weakness are features of chronic late-onset cases. Carrier women, hetcrozygoLis for a mutation associated with LCHAD deficiency and possibly other disorders of fatty acid oxidation, who arc pregnant with a homozygous (affected) fetus may be at risk for acute fatty liver.

Medium-chain acyl-CoA dehydrogenase (MCAD) deficiency is the most common FAO defect. The initial crisis is fatal in up to 25% of cases. The diagnosis of MCAD is based on organic acid profile showing elevated levels of 5-OHhexanoate, 7-OHoctanoate, hexanoylglycine, suberylglycine, and phenylpropionylglycine.

Disorders of Ketogenesis and Ketolysis

Excess acetyl Co A, a by-product of FAO, is converted in the liver to ketones (3-OHbutyrate and aeetoaeetate) that are subsequently transported to and oxidized in the peripheral tissues. Ketone utilization by the brain spares other tissues, such as erythrocytes, which cannot meet their energy requirements from nonglucose substrates. Ketoacidosis is a prominent secondary feature of several defects of in tcrme di a r y mcta b ol i sm.

Primary disorders of ketogenesis and ketolysis are rare. Mitochondrial /i-ketothiolase deficiency leads to severe episodes of ketoacidosis and encephalopathy, which shows a rapid response to intravenous glucose administration. Urine organic acid analysis reveals the presence of 2-methyl-3-OH-butyrate, 2-methylacetoacetate, 2-butanone, and tiglyglycine (derived from the metabolism ul isok'uciiie). Cytosolic aceloncetyl-CoA ihiol.isc deficiency is a rare cause of psychomotor retardation and hypotonia, features that reflect the importance of the involved enzyme in sterol and isoprenoid synthesis.

MISCELLANEOUS METABOLIC DISORDERS

Dyslipidemias

Lipids arc transported in plasma on lipoproteins (consisting of a hydrophobic core of triglycerides and cholesterol esters), wrapped in an am phi phi lie coating of apolipoproteins, phospholipids, and unesterified cholesterol. Diseases associated with abnormal lipid absorption and metabolism can lead to low blood levels of the fat-soluble vitamins (A, D, E, and K). This is correctable by oral or parenteral supplementation.

Abetalipoproteinemia and Hypobetalipoproteinemia

Abctalipoproteinemia and hypobetalipoproteinemia are disorders of reduced low-density lipoprotein (LDL)-eholesterol metabolism. In abetalipoproteinemia, a rare autosomal recessive disorder also known as Bassen-Kornzweig syndrome, plasma apolipoprotein-B (apoB) levels are undetectable, and total cholesterol levels are low (usually <50 mg/dL). The defect is caused by absence of microsomal triglyceride transfer protein (MTP), and not by mutations in the apoB gene. MTP is a heterodimcric protein involved in the transfer of lipid to apoB. Patients with abetalipoproteinemia have fat malabsorption and neurological disturbances that include dysmctria, cerebellar ataxia, and spastic gait. Ocular disturbances are common and include retinitis pigmentosa, impaired night vision, nystagmus, and ophthalmoplegia. Failure to thrive and steatorrhea occurs in infancy, whereas the neurological complications appear during adolescence. Other features include anemia (acanthocytosis) and arrhythmia. Acantbocytosis is a consequence of reduced erythrocyte membrane fluidity. It is also seen in vitamin E deficiency and neuroacanthocytosis (Rampoldi et al. 2002).

Hypobetalipoproteinemia, due to mutations in the apoB gene, causes a clinical syndrome similar to Friedreich's ataxia (ataxia and peripheral neuropathy). It is transmitted as an autosomal dominant trait. Most patients have low LDL-cholesterol concentrations (usually < 60 mg/dL). Rare patients homozygous for the defect have clinical features indistinguishable from those of abetalipoproteinemia. Vitamin supplements (A and E) have a beneficial influence on the neurological and ocular symptoms. Care should be taken to avoid vitamin A toxicity by serial monitoring of vitamin levels.

Tangier Disease

Tangier disease is a rare autosomal recessive disorder caused by mutations in a cell-membrane protein called

ABCAl. ABCAl normally mediates the secretion of excess cholesterol from cells into the HDL metabolic pathway. It belongs to a family of ATP-binding cassette (ABC) transporters. These proteins are involved in the recognition of substrate and their transport across, into, and out of cell membranes. Cystic fibrosis, age-related macular degeneration, and X-linked adrenoleukodystrophy are othet disorders associated with defects of genes that encode this class of proteins. Tangier disease is characterized by severe deficiency of high-density lipoproteins (HDL) and tissue stotage of cholesterol estets. Clinical features include enlarged, orange-yellow tonsils (filled with foam cells representing deposits of ^-carotene cholesterol estets), splenomegaly, and a relapsing sensorimotor neuropathy. Patients may develop distal weakness, hyporeflexia, decreased pain, and temperature sensation with relative preservation of position and vibration sense.

Smith-Lemh-Opitz Syndrome

Smith-Lemli-Opitz syndrome is a disorder characterized by multiple malformations, growth and psychomotor retardation, and behavioral disturbances (Nowaczyk and Waye 2001). It is a disorder of cholesterol biosynthesis caused by mutations of the 7-dehydrocholestrel (DHQ-A -reductase gene, inherited as an autosomal recessive trait. Biochemical tests reveal low total cholesterol and elevated serum levels of 7DHC. Sterol abnormalities that result from deficiencies of cholesterol biosynthesis also explain other recently recognized disorders of morphogenesis (mevalonic aciduria [MVA], desmosterolosis, X-Hnked chondrodysplasia punctata, and CHILD syndrome). Sterol synthesis (SS) takes place partly in the peroxisome, and explains why SS defects show some overlap in clinical features with the peroxisomal biogenesis disorders. The diagnosis of MVA is based on determination of mevalonic acid in urine and the determination of residual enzyme (mevalonate kinase) activity. The diagnosis of other disorders secondary to distally located defects of cholesterol biosynthesis requires sterol analysis in blood or tissues by GC-MS.

Cerebrotendinous Xanthomatosis (Cholestanolosis)

Cholestanolosis is transmitted as an autosomal recessive trait. The condition is caused by mutations in the stetol 27-hydroxylase gene. The primary feature is the formation of xanthomatous lesions in the brain and tendons. Neurological impairments include mental retardation, progressive spasticity, pseudobulbar palsy, and cerebellar dysfunction (Moghadasian et al. 2002). Brain MRI shows hyperintense signals that involve the corticospinal tracts in the brainstem, the white matter of both internal capsules, and the peritrigonal white matter. Bilateral cataracts and chronic diarrhea may precede the neurological deterioration. Biochemical findings include elevated plasma and bile cholestanol levels and increased urinary excretion of bile alcohol glucuronides associated with diminished biliary chenodeoxycholic acid (CDCA). Therapy with CDCA reverses the neurological features. In one study of CDCA therapy in 17 patients, dementia cleared in 10, pyramidal and cerebellar signs resolved in 5 and improved in another 8. In addition, cerebral CT scans improved in 7 (Samenuk and Koffman 2001).

Lowe Oculocerebrorenal Syndrome

Lowe syndrome is transmitted as an X-linked trait and is characterized by bilateral congenital cataracts, mental retardation, and a renal ion-transport defect (Fanconi's syndrome) (Schneider et al. 2001). Disease results fiom mutations in the OCRL gene. This gene encodes a Golgi-associated protein (inositol polyphosphate-5-phosphatase) that regulates the cellular levels of a metabolite (phosphatidyl inositol 4,5-biphosphate) involved in vesicular transpon. female carriers ean be ulenlilieil by detrciion through slit-lamp examination of lens opacities. Symptomatic treatment with phosphate and vitamin D prevents the development of severe rickets. Patients are at risk for glaucoma and should have serial monitoring of intraocular pressure.

Nonketotic Hyperglycinemia (NKH)

Glycine encephalopathy is caused by a defect in the P-protein (glycine decarboxylase) gene, which encodes a component of the mitochondrial glycine cleavage system (Toone et al. 2002). NKH is clinically charactetized by a neonatal encephalopmlu . I'anenrs develop Iclhargy, hypo tonia, myoclonic seizures, and apnea. The electroencephalogram shows a burst suppression pattern. CSF glycine is elevated, and the ratio of CSK to plasma glycine concentration (normally below 0.4) is above 0.6. Brain MRI reveals a hypoplastic or absent corpus callosum and gyral malformations; cerebellar hypoplasia is an associated feature. The excitatory effects of glycine on the NMDA receptor may cause the neurological symptoms. Dextromethorphan and ketamine inhibit receptor excitation and are used fot tteatment. Prognosis is poor, and most affected children are mentally retarded.

Molybdenum Cefaclor Deficiency

Molybdenum cofactor is essential for xanthine oxidase, sulfite oxidase, and aldehyde oxidase activity. Deficiency of the cofactor causes refractory seizures, axial

hypotonia, and limb rigidity (Aukett et al. 1988), Urinary excretion of xanthine and sulfite is increased. Brain imaging shows multiple cystic cavities in the white matter. This autosomal recessive disorder should be considered in the differential diagnosis of ischemic/anoxic perinatal Icukomalacia.

Sulfite Oxidase Deficiency

Sulfite oxidase deficiency is transmitted as an autosomal recessive trait. SUOX, the gene encoding the enzyme that catalyzes the terminal reaction in the sulfur amino acid degradation pathway, is defective (Johnson et al. 2002). Clinical features include seizures and progressive neurological deterioration, features similar to that encountered with molybdenum cofactor deficiency. Dislocated ocular lens is characteristic.

Disorders of Copper Metabolism

Copper is an essential element for the activity of several enzymes (cytochrome c oxidase, Cu/Zn-su peroxide dismutasc, dopamines-hydroxylase). Menkes' disease and Wilson's disease result from mutations in highly homologous copper transportets (P-rype ATPases).

Menkes' syndrome: Menkes' syndrome is transmitted as an X-linked trait. The membrane copper transporter ATP7A is defective, causing a functional copper deficiency and low levels of serum copper and ceruloplasmin. Progressive neurodegcncration and marked connective tissue abnormalities are characteristic. The disease is usually lethal in infancy or childhood. Neuropathologies! findings include neovascularization and extreme reduplication of the cerebral arteries, in conjunction with cystic medial degeneration, bilateral cerebellar hypoplasia, focal cortical dysplasia, and cerebellar heterotopias (Strausak et al. 2001). Daily intravenous copper histidinc administration in Menkes' syndrome restores scrum copper and ceruloplasmin levels, and leads to favorable clinical results when started prior to neuro degeneration (Sarkar 1997). Occipital horn syndrome, formerly known as Ehlers-Danlos syndrome type IX or X-linked cutis laxa, is an allelic variant of Menkes' syndrome.

Wilson's disease: Wilson's disease is an autosomal recessive disorder caused by mutations in the copper transporter (ATP7B) gene. Excessive copper accumulates in the liver and brain. Neurological features include tremors, loss of fine motor control and poor coordination, rigid dystonia, dysarthria, and swallowing difficulties (Schilsky 2002). Diagnostic findings include the presence of Kayser-Fleischer rings, increased urine copper excretion, with low serum ceruloplasmin and increased liver tissue copper content. Basal ganglia degeneration is evident on MRI as increased T2 intensity in the caudate and putamen. The results of therapy by liver transplantation have been mixed.

Disorders of Purine and Pyrimidine Metabolism

Purine and pyrimidine nucleotides are essential cellular components involved in energy transfer and the regulation and synthesis of DNA and RNA. Defects of purine and pyrimidine metabolism can result from disruption of biosynthetic, catabolic, and salvage pathways.

Lesch-Nyhan syndrome is transmitted as an X-linked recessive rrait. Hypoxanthinc-guanine phosphoribosyltransferase (HGPRT), required in the purine salvage pathway, is deficient causing hyperuricemia. Clinical features include chorea and athetosis, dysarthria, hyperreflexia and hypertonia, cognitive impairment, and behavioral disturbances (including impulsive and self-injuring activity) (Schretlen et al. 2001). Dopamine concentrations in the basal ganglia and CSF are reduced and may account for some of the neurological features. Patients with partial HGPRT deficiency always have hyperuricemia and often have neurological abnormalities, but do not show self-injuring behavior and usually have normal intelligence.

Adenylosuccinate lyase deficiency is transmitted as an autosomal recessive trait. *De novo* purine and AMP synthesis are defective, and SAICA riboside and adenylosuccinate accumulate in cells and can be detected in CSF and urine. Severe developmental delay, seizures, and growth retardation are characteristic. Psychomotor retardation with autistic-like behavior occurs in about half of the cases (Ciardo et al. 2001).

Porphyrias

Porphyrins play an important role in the formation of metalloporphyrin complexes, including hemoglobin, myoglobin, cytochromes, peroxidases, oxidases, and catalases. The porphyrias are caused by deficiencies of specific enzymes involved in the heme biosynthctic pathway. This pathway occurs in bone marrow elements (85%) or in the liver. The porphyrias are characterized by the accumulation and excess excretion of by-products of intermediary heme metabolism and their oxidized products. A diagnosis of porphyria should be considered in patients with unexplained neuropsychiatry signs, visceral (gastrointestinal and hepatic) symptoms, or cutaneous photosensitivity (Ahmed 2002), Cutaneous manifestations are prominent in hereditary coptoporphyria and variegate porphyria, but the neurovisceral disturbances may be indistinguishabU from those of acuie :iuci'iniircill porphyria iAII'j. Porphyrias with neurological features have either a constant or an intermittent excretion of aminolevulinic acid and porphobilinogen. The elimination of precipitating

Table 68.14: Medications patients with porphyria should avoid and permissible alternatives

Contraindicated	*Alternative*
Sedatives, tranquilizers	Chloral hydrate
Barbiturates	Chlor promazine
Anticonvulsants (ethosuximide, clonazepam, sodium valproate, phenytoin, primidone)	
Anticoagulants	\spirin
Centrally acting agents (imipramine, nikethamide, metoclopramide, methyldopa)	Droperidol, methadone (physeptone), chlorproma/.inc, promethazine
Anaigesics/aiiti-infla matory (diclofenac, pentazocine, phcnylbutoazone, phenazone)	Morphine and derivatives

factors is an important method to reduce the frequency and intensity of acute exacerbations.

Acute intermittent porphyria: AIP is transmitted as an autosomal dominant trait. Mutations occur in the porphobilinogen deaminase (PBD) gene. Deficient activity of erythrocyte PBD activity is used to confirm the diagnosis. Bouts of abdominal pain, paresthesias, seizures, and peripheral neuropathy are prominent clinical features. Neurotic or psychotic behavior is also reported. Certain drugs can precipitate acute attacks and patients should be provided with a list of medications to avoid (Table 68.14). Carbohydrate loading and administration of heme analogues arc used to manage the acute crises.

Congenital Disorders of Giycosylation

The carbohydrate-deficient glycoprotein (CDG) syndromes are a heterogenous group of autosomal recessive disorders resulting from defects of the N-linked giycosylation pathway. Many proteins undergo giycosylation (a posttranslational modification step) to render them functional. The initial features of CDG syndromes may include ataxia, strabismus, unusual fat distribution, severe liver dysfunction, seizures, and strokelike episodes. All of these disorders, except for CDGTb (phosphomannose isomerase deficiency), show some degree of developmental and psychomotor retardation and many have gastrointestinal dysfunction (Freeze 2001). Severe brain involvement occurs in phosphomannomurase deficiency (CDG-Ia), which accounts for —80% of CDG cases, and *N*-acetylglucosaminyl ttansferase-H deficiency, a disorder with craniofacial abnormalities (Pearl and Krasnewich 2001), Testing for abnormal protein giycosylation is done by isoelectric focusing analysis of serum transferrin. Treatment is not available. Ota) mannose given to two children with CDG-Ib provided clinical improvement and normalization of blood glucose, aminotransferases, and coagulation factor levels in one child and resolution of gastrointestinal bleeding in another (Rush et al. 2000).

Canavan Disease (CD)

CD is transmitted as an autosomal recessive trait. It is caused by deficiency of aspartoacylase. N-acetyl-aspartic acid (NAA), a neurotoxic compound, accumulates in the brain and is excreted in urine, CD mainly occurs in Ashkenazi Jews (carrier frequency 1:37-58). Clinical features include hypotonia, delayed development, optic atrophy, and seizures (Matalon and Ma talon 2002). CD shares several features (e.g., progressive macrocephaly, demyelination) with Alexander's disease, a rare, progressive, leukoencephalopathy characterized by the widespread accumulation of Rosenthal fibers. However, Alexander's disease has a later onset and slower course. Missense mutations in the coding region of the glial fibrillary acidic protein (GFAP) gene occur in patients with Alexander's disease.

Neurotransmitter and Small Peptide Defects

Neurotransmitters are divided im« the following groups: inhibitory (GABA, glycine), excitatory (aspartate, glutamare), cholinergic (acetylcholine), monoaminergic (epinephrine, norepinephrine, dopamine, serotonin), and purinergic (adenosine, AMP, ADP, ATP), Inherited defects of neurotransmission may be caused by deficient synthesis, release, breakdown or re-uptake of neurotransmitters. In addition, disease may be caused by defects of receptors and failure of signaling pathways of glial cells to maintain an appropriate milieu. Clinical features vary from mild to severe and are characterized by psychomotor retardation, developmental delay, oculogyric crises, hypotonia, and ataxia.

Succinic semialdehyde dehydrogenase deficiency disrupts the normal metabolism of GABA, and y-OHbutyrate, a compound with neuromoclulatory properties, accumulates in plasma, CSF, and urine {Gibson et al. 1998). Vigahatrin inhibits GABA transaminase and causes variable improvement of the ataxia and behavioral disturbances.

Aromatic i -amino acid decarboxylase deficiency causes deficiency of serotonin and catecholamines. Pterin and phenylalanine metabolism are normal. The diagnosis is based on demonstrating low CSF homovanillic (HMV), 5-OHindoleacetic acid (.5HIAA), and 3-methoxy-4-OHphenyl-ethyleneglycol, associated with increased levels of i-dopa (Mailer et al. 1997). Combined treatment with pyridoxine {vitamin BJ, tranylcypromine (a MAO inhibitor), and bromocriptine promotes clinical improvement.

The 3-phosphoglycerate dehydrogenase deficiency, a disorder of i.-serinc biosynthesis, is characterized by

congenital microcephaly, intractable seizures, and severe psychomotor retardation (De Koning et al. 2002). Oral supplementation of the deficient amino acids reduces seizure frequency and can prevent psychomotor delay if given at an early age.

Defects in Leukotriene Synthesis

Leukotrienes are a group of highly active biological compounds that are synthesized by brain tissue and a limited number of other cells. Cysteinyl leukotrienes have neuromodulator functions apart from their role in the mediation of inflammation and host defense. Leukotriene synthesis defects results in severe muscular hypotonia, psychomotot retardation, failure to thrive, microcephaly, and the absence of cysteinyl leukotrienes in body fluids (Mayatepek 2000).

Animal Models of Human TEM

Several spontaneous animal models of human IEM exist; only a lew have been bred successfully. ()\ ••.-: the List decade, recombinant genetic techniques have enabled the generation of animal (primarily mice) models of disease. In a genotype-driven approach, mouse (knockout) models are generated by homologous recombination in embryonic stem cells incorporating a null allele. Alternatively, single-point mutations have been introduced, resulting in mice with partial rather than complete deficiencies. These animal models have proven useful in investigations of the natural history of the disease and in the preclinical testing of various drugs. In some cases, these investigations have provided the rationale for further clinical trials in humans. Although similarities exist between affected mice and men, species-specific differences in phenotypical expression result from alternative pathways of substrate processing. These considerations highlight the need for caution in carrying over observations made in the animal models to human trials.

presence of increased SWS after sleep deprivation. The critical role of REM sleep for CNS development in young organisms and increased protein synthesis in the brain during REM sleep may support the theory of restoration of hmin function by REM sleep. Although d/iu remain ^;im and controversial, studies of brain basal metabolism that suggest an enhanced synthesis of macromolccules during sleep, such as nucleic acids and proteins in the brain, provide an argument in favor of the restorative theory of sleep.

The energy conservation theory is somewhat inadequate. The fact that animals with a high metabolic rate sleep longer than those with slower metabolism has been cited in support of this theory. It should, however, be noted that during 8 hours of sleep, only 120 calories are conserved.

The adaptive theory suggests that sleep is an instinct that allows creatures to survive under a variety of environmental conditions.

The memory reinforcement and consolidation theory suggests that memory reinforcement and consolidation take place during REM sleep. This theory has been strengthened by the observation that, after REM and SWS sleep-deprivation experiments in six young adults, perceptual learning during REM deprivation was significantly less than it was with SWS deprivation. These data suggest that REM deprivation affected the consolidation of the recent perceptual experience.

The synaptic neuronal network integrity theory is an emerging thcor; proposing thai the primary tunciiun oi sleep is the maintenance of synaptic and neuronal network integrity. Intermittent stimulation of neural network synapses is necessary to preserve CNS function. The concept of dynamic stabilization (repetitive activation of brain synapses and neural circuitry) suggests that REM sleep maintains motor circuits, whereas NREM sleep maintains nonmotor activities.

The thermoregulatory function theory is based on the observation that thermoregulatory homeostasis is maintained during sleep, whereas severe thermoregulatory-abnormalities follow total sleep deprivation.

The preoptic anterior hypothalamic neurons participate in thermoregulation and NREM sleep. These two processes-are closely linked by preoptic anterior hypothalamic neurons but arc clearly separate. Thermoregulation is maintained during NREM sleep but suspended during REM sleep. Thermoregulatory responses such as shivering, piloerection, panting, and sweating are impaired during REM sleep. There is a loss of thermosensitivity in the preoptic anterior hypothalamic neurons during REM sleep,

PHYSIOLOGICAL CHANGES IN SLEEP

Various physiological changes occur during NREM and REM sleep that are different from those noted during wakefulness (Chokroverry 2002). These changes are observed in somatic and autonomic nervous systems and include respiratory, cardiovascular, and gastrointestinal systems; endocrine, renal, and sexual function; and thermoregulation (Table 74.6).

Table 74.6: Physiological changes during wakefulness, NREM sleep, and REM sleep

Physiology	*Wakefulness*	*NREM sleep*	*REM sleep*
Parasympathetic activity	++	+++	4-4-4-4-
Sympathetic activity	++	+	Decreases or variable (++)
Heart rate	Normal sinus rhythm	Bradycardia	Urady tachyarrhythmia
Blood pressure	Normal	Decreases	Variable
Cardiac output	**Normal**	Decreases	Decreases further
Peripheral vascular resistance	Normal	Normal or decreases slightly	Decreases further
Respiratory rate	Normal	Decreases	Variable; apneas may occur
Alveolar ventilation	Normal	Decreases	Decreases furthet
Upper airway muscle tone	++	+	**1)uir;hi> n[** absi'lll
Upper airway resistance	4-4-	++4-	4-+++
Hypoxic and hypercapnie ventilatory responses	Normal	Dcercases	1 :v, !V;LM-, further
Cerebral blond flow	++	++ or -H-+	4-4-4-4-
Thermoregulation	4-+	+	—
Gastric acid secretion	\i i-'iiial	Variable	Variable
Gastric motility	**Noi null**	1)t creases	Decreases
Swallowing	Normal	Decreases	Decreases
Salivary flow	Normal	1 (ecreases	Decreases
Migrating motor complex (a special type of intestinal motor activity)	Normal	Slow velocity	Slow velocity
Penile or clitoral tumescence	Normal	Normal	Markedly increased

NREM = non-rapid eye movement; REM = rapid eye movement; + = mild; ++ = moderate; +++ = marked; ++++ = very marked. - = absent.

Somatic Central Nervous System

Firing rates of many neurons in the CNS decrease during NREM sleep but increase during REM sleep.

Autonomic Nervous System

During sleep, the autonomic nervous system undergoes several changes that may have implications for the pathophysiology of autonomic failure and sleep disorders in humans. Most of the autonomic changes involve respiration, circulation, thermoregulation, and the pupils (e.g., pupilloconstriction during sleep). During NREM sleep, there is an overall tonic increase in parasympathetic activity, which increases further during tonic REM sleep. In addition, during phasic REM sleep, sympathetic activity decreases. Sympathetic activity during REM sleep, however, increases intermittently, which results in swings of blood pressure and heart rhythm, causing bradytachyarrhythmias.

Respiratory Changes

Two systems—metabolic (or automatic) and voluntary (or behavioral)—control respiration during sleep and wakefulness. Both metabolic and voluntary systems operate during wakefulness, whereas only the metabolic system operates during NREM sleep. The wakefulness stimuli that act through the ARAS also act as tonic stimuli to ventilation. Activity decreases in the respiratory neurons in the parabrachial and Kolliker-Fuse nuclei in the pons, the nucleus tractus solitarius, nucleus ambiguus, and nucleus retroambigualis in the medulla. Respiratory muscle activity decreases slightly during NREM sleep but markedly during REM sleep. A marked decrement or even temporary suppression of intercostal muscle tone occurs during REM sleep, whereas tonic activity of the diaphragm diminishes and phasic activity continues. Muscle tone in the upper airway decreases in NREM sleep and disappears in REM sleep, resulting in an increase in upper airway resistance. The decreased sensitivity of the respiratory neurons to carbon dioxide, inhibition of the reticular activating system, and alteration of metabolic control of respiratory neurons during sleep result in a decrement of tidal volume, minute ventilation, and alveolar ventilation, In normal individuals, diminished alveolar ventilation causes arterial carbon dioxide tension (Pco_2) to rise by 2-8 mm Hg, the arterial oxygen tension (P02) to decrease by 3-10 mm Hg, and oxygen saturation (So_2) to decrease by less than 2% during sleep. These blood -as changes are noted despite a fall in oxygen consumption and carbon dioxide production during sleep. Both hypercapnic and hypoxic ventilatory responses decrease during REM and NREM sleep, with a more marked decrease during REM sleep. These decrements result from a combination of factors: fewer functional medullary respiratory neurons during sleep, decreased sensitivity of the central chemorcccptors subserving medullary respiratory neurons, and increased resistance in the upper airway. Arousal responses also decrease, particularly during REM sleep. The voluntary respiratory control system may be active during some portion of REM sleep. Respiration is therefore vulnerable during sleep in normal individuals. Mild respiratory irregularity- with few apneic episodes (apnea index <5) may occur at sleep onset and during REM sleep. In disease states, however, apneas may become more frequent, prolonged, and pathologically significant.

Cardiovascular Changes

Heart rate, blood pressure, cardiac output, and peripheral vascular resistance decrease during NREM sleep and decrease still **tun her diLiiiie. REM** sleep. **Dunne,** phasic REM, blood pressure and heart rate are unstable because of phasic vagal inhibition and sympathetic activation caused by alterations in brainstem neural activity. Heart rate and blood pressure fluctuate during REM sleep. Cerebral blood flow and cerebral metabolic rate for glucose and oxygen decrease by 5-2.3% during stages 1 to IV of NREM sleep, whereas these values inctease by 10-41% above waking levels during REM sleep. These data indirectly suggest that NREM sleep is the state of resting brain, with reduced neuronal activity, decreased synaptic transmission, and depressed cerebral metabolism. The data also are consistent with the assumption that REM sleep represents an active brain state with increased neuronal activity and increased brain metabolism. The largest increases during REM sleep are noted in the hypothalamus and the brainstem structures, and the smallesl increases are in the cerebral cortex and white matter.

Because of all the hemodynamic and sympathetic alterations, REM sleep, which is prominent during the third part of the night's sleep, could initiate increased platelet aggregation, plaque rupture, and coronary artery spasm. These increases may act as triggering mechanisms tor thrombotic events, causing myocardial infarction, *vol* tricular arrhythmias, or even sudden cardiac death.

Gastrointestinal Changes

Gastric acid secretion shows a variable response during sleep in normal individuals, but patients with duodenal ulcers show a striking increase in acid secretion and no inhibition of secretion during the first 2 hours of sleep. Swallowing is suppressed during sleep, and there is prolonged acid clearance; these factors are important in the pathogenesis of esophagitis caused by nocturnal gastroesophageal reflux. Esophageal motility is also reduced during sleep. Results of studies of intestinal motility during sleep are contradictory. A special pattern of motor activity, called the migrating motor complex,

shows a circadian rhythm in its propagation with the slowest velocity during sleep.

Endocrine Function

Profound changes in neuroendocrine secretions are found during sleep (Figure 74,4), Growth hormone secretion exhibits a pulsatile increase during NREM sleep in the first i-.nc third of 'lie night. Prolactin secretion also rises 30-90 minutes after the onset of sleep. Sleep inhibits Cortisol secretion. Secretion of thyroid-stimulating hormone reaches a peak in the evening and then decreases throughout the night.

Testosterone levels in adult men continue to be highest during sleep, but no clear relationship has been demonstrated between levels of gonadotropic hormones and the sleep-wake cycle in children or adults. During puberty, gonadotropin levels increase in sleep. Melatonin, which is synthesized and released by the pineal gland and derived from serotonin, begins to rise in the evening, attaining maximal values between 3:00 AM and 5:00 AM, and decreases to low levels during the day.

Other endocrine changes include a maximum rise of aldosterone jusl before awakcnmi" in the carl; hours oi the morning and a marked decrease of plasma renin activity during REM sleep.

Sexual Function

The most striking finding is increased penile tumescence in men during REM sleep. In women, there is increased clitoral tumescence during REM sleep.

Them toregulatio n

iVuk rcMnuT.mnv has kvn linked intimately to the sleep-wake cycle, but it follows a circadian rhythm that is independent of the sleep-wake rhythm. At the onset of sleep, body temperature begins to fall. Body temperature reaches its lowest point during the third sleep cycle. Thermoregulation is maintained during NREM sleep but is nonexistent in REM sleep, and experimental animals become poikilothcrmic. Thus physiological responses (e.g., shivering, panting, sweating, and piloerection) to thermal stimuli are depressed or absent during REM sleep.

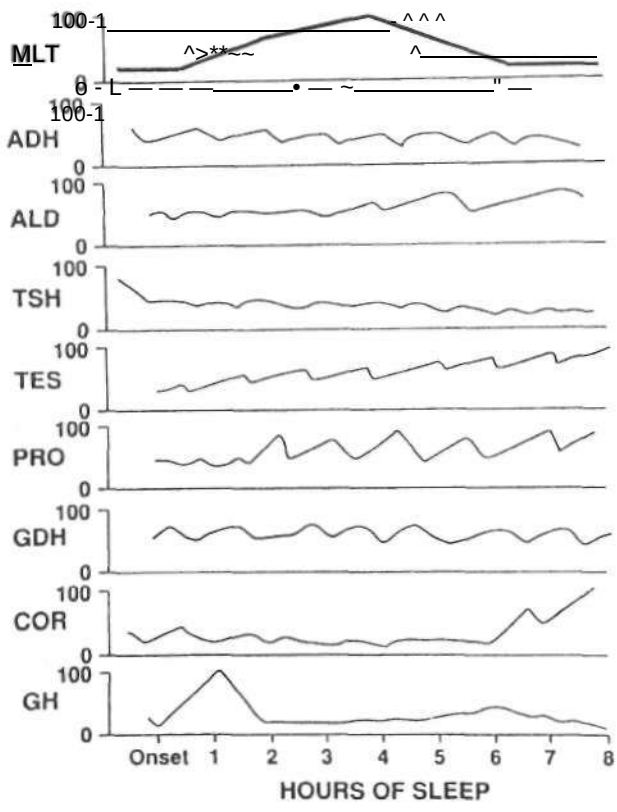

FIGURE 74.4 Schematic diagram to show plasma levels of hormones during 8 hours of sleep in an adult. {ADH = antidiuretic hormone; ALD = aldosterone; COR = Cortisol; GDI! = gonadotropic hormone; GH = growth hormone; MLT = melatonin; PRO = prolactin; TES = testosterone; TSH = thyroid-stimulating hormone. Zero indicates lowest secretory episode, and 100 indicates peak secretion.J (Reproduced with permission from Chokrovcrty, S. 1999, "Physiological changes in sleep," in *Sleep Disorders Medicine: Basic Science, Technical Considerations, and Clinical Aspects,* ed S. Chokrovcrty, Butterworth-Heinemann, Boston.)

Sleep Deprivation and Sleepiness

Sleepiness is determined by both circadian and homcostatic factors. The circadian phase is determined by the supra-chiasmatic nuclei, and it works in a biphasic manner. There arc two phases when an individual has the maximal sleepiness propensity: One phase that is intense is around 3:00-5:00 AM, and the other, which is less intense, is around 3:00-5:00 PM. In addition, there are two forbidden or dead zones. The individual is wide awake and is unable to sleep, noted around late morning and early evening. Homeostasis refers to a balance between sleep and wakefulness. After prolonged wakefulness, there is an intense desire to sleep. REM sleep is influenced by the circadian rhythm, whereas SWS is influenced by homeostasis. Much is known about the physiology of circadian rhythm, but the neurobiology of the homeostatic influences remains largely unknown. Excessive sleepiness, therefore, may result from both circadian dysrhythmia and disruption of homeostasis of the body.

A large segment of the population working different shifts and having irregular sleep-wake schedules is chronically sleep deprived (Bonnet and Arand 1995). The at-risk groups include doctors, nurses, firefighters, interstate truck drivers, police officers, overnight train drivers, and high school and college students. Compared with a survey conducted in the beginning of the last century and another

toward the end of the century, modern America is sleep deprived by approximately 1.5 hours of sleep (Harrison and Home 1995). This does not necessarily mean that the sleep requirement is less today, but, simply, it means that people are sleep deprived. However, there may be a sampling error in these two surveys: for example, 2000 people were sampled in the earlier survey versus 311 in the later survey. Increased environmental light and sound, industrialization. increasing r, umber i of people work in L: in various shifts, and the advent of television and radio are cited as some of the factors responsible for this reduction of total sleep hours. Harrison and Home (1995), however, argued that most people are not chronically sleep deprived but have the capacity to take more sleep. In one epidemiological study, sleepiness in Western society was estimated to be found in *5-36%* of the total population.

Experiments have been conducted to study the consequences of total, partial, and selective sleep deprivation. These experiments have shown clearly that in animals sleep is necessary for survival, but studies of complete sleep deprivation for prolonged periods (e.g., weeks to months) cannot be conducted in humans from a practical point of view. Experiments in rats using a carousel device have provided evidence that sleep is essential for survival. All rats deprived of sleep for 10-30 days died after having lost weight despite increasing food intake. The rats also lost temperature control. It took longer for rats deprived of REM sleep to die than those deprived of SWS.

Total Sleep Deprivation

One of the earliest experiments in sleep deprivation in humans was in 1896 (Chokroverty 1999a). The effects of a 90-hour period of sleep deprivation were studied in three healthy young men. All subjects had difficulty staying awake, hut they felt totally refreshed and rested after they were allowed to sleep for 10 hours. One of them, however, had sensory illusions that disappeared completely after icon, LTV i>' sleep period, hi I Vfi.S, a spectacular experiment was conducted when a 17-year-old California college student named Randy Gardner (Chokroverty 1999a) tried to set a new world record for staying awake. He remained awake for 264 hours and 12 minutes and then slept for 14 hours and 14 minutes, after which he recovered fully. Thus the conclusion of the experiment was that it was possible to deprive people of sleep for a prolonged period without causing serious mental impairment. Other important observations include frequent occurrence of "microsleep[1]' episodes (i.e., brief episodes of NREM sleep) and loss of performance that may have been caused by the loss of molivation. Several order cvpcriiticnls Liter in humans showed no permanent adverse effects after sleep deprivation. However, sleep deprivation increases the daytime tendency to sleep as proven by multiple sleep latency tests in such subjects. The percentage of SWS increases considerably during the tccovery sleep period after sleep deprivation. The REM sleep percentages also increase during the recovery sleep after a prolonged period of sleep deprivation, but this increment of REM sleep percentage was not shown after short periods of sleep deprivation for 4 days. These facts might suggest that different mechanisms regulate NREM and REM sleep.

Partial and Selective Steep Deprivation

Measurements of mood and performance after partial sleep deprivation (e.g., restricting sleep to 4.5-5.5 hours for 2-3 months) showed minimal deficits in performance, which may have been related to decreased motivation. After selective REM deprivarion, PSC studies showed increased REM pressure (i.e., earlier and more common onset of REM sleep during successive nights) and REM rebound (i.e., quantitative increase of REM pcrcenrages during recovery sleep). The observation of a psychotic reaction after REM deprivation as noted by Dement was proved to be inaccurate in subsequent investigations. Similar ro REM deprivation, after stage IV NREM sleep deprivation for two consecutive nights, there is an increase in stage IV sleep during the recovery night. It is more difficult to deprive a person of stage IV NREM sleep than of REM sleep.

In summary, these experiments have proven conclusively that sleep deprivation causes sleepiness and impairment of performance, vigilance, attention, and concentration but does not cause permanent memory or other CNS changes,

Consequences of Excessive Daytime Sleepiness

Consequences of EDS (Table 74.7) are discussed under the following four headings: (1) performance and productivity ,u work and school; *;1* Imnur cerebral functions; (3) quality of life and social interactions; and (4) morbidity and mortality (Roth and Roehrs 1996).

Performance and Productivity at Work and School

Impaired performance and reduced productivity at work for shift workers, reduced performance in class for school and college students, and impaired job performance in patients with narcolepsy, sleep apnea, circadian rhythm disorders, and chronic insomnia are well-known adverse effects of sleep deprivation and sleepiness. Sleepiness and .issoi.-i.ilcd rn irhuiil v are worse- in niejit sliiti workers, older workers, and female shift workers.

Table 74,7: Consequences of excessive daytime sleepiness

Impaired performance and productivity
Impaired short-term memory, attention, conception, and cognition
Impaired quality of life
Psychological stress
Increased morbidity and mortality: i.e., increased likelihood of accidents

Higher Cerebral Functions

Sleepiness interferes with higher cerebral functions, causing impairment of short-term memory, concentration, attention, cognition, or intellectual performance. Psychometric tests document increased reaction time in patients with excessive sleepiness. These individuals make increasing numbers of errors, and they need increasing time to reach the target in reaction time tests (Dinges 1995). Sleepiness also can impair perceptual skills and new learning. Insufficient sleep and excessive sleepiness may cause irritability, anxiety, and depression. Learning disabilities and cognitive impairment due to impaired vigilance also have been described (Roth and Rochrs 1996).

Quality of Life and Social Interaction

People complaining of F.DS are often under severe psychological stress. They are often wrongly perceived as dull, lazy, and downright stupid. Excessive sleepiness may cause severe marital and social problems. Individuals with this problem have serious difficulty with interpersonal relationships. In a survey of 180 narcoleptic patients, one third thought that they were misunderstood because of their symptoms.

Shift workers constitute approximately 20-25% of the work force in America (i.e., approximately 20 million). A majority of them have difficulty with sleeping, and sleepiness as a result of insufficient sleep and circadian dysrhythmia. Many of them have an impaired quality of life, marital discord, and gastrointestinal problems.

Increased Morbidity and Mortality

Persistent daytime sleepiness causes individuals to have an increased likelihood of accidents. Estimates by the U.S. National Highway Traffic Safety Administration showed that approximately 56,000 police-reported crashes per year resulted from drivers who were "asleep at the wheel" (Knipling and Wang 1994). New York police estimate that 30% of all fatal crashes along the New York Thruway occur because the driver fell asleep at the wheel. Approximately 1 million crashes annually (one sixth of all crashes) are thought to be produced by driver inattention or lapses. Sleep deprivation and fatigue make such lapses more likely to occur. Truck drivers are especially susceptible to fatigue-related crashes (Lyznicki et al. 1998). Many truckers drive during the night while they are sleepiest. Truckers also may have a high prevalence ol sleep apnea. The I ".S. Department of Transportation estimates that 200,000 automobile accidents each year may be related to sleepiness. Nearly one third of all trucking accidents that are fatal to the driver are related to sleepiness and fatigue.

The presence of sleep disorders (see Primary Sleep Disorders Associated with Excessive Daytime Sleepiness, later in this chapter) increases the risk of crashes. Individuals with untreated insomnia, sleep apnea, and narcolepsy and shift workers, all of which cause excessive sleepiness, have more automobile crashes than other drivers (Costa de Silva et al. 1996). A 1991 Gallup organization national survey found that individuals with chronic insomnia report 2.5 times as many fatigue-re la ted automobile accidents than did those without insomnia. The same 1991 Gallup survey found serious morbidity associated with untreated sleep complaints as well as impaired ability to concentrate and accomplish daily tasks, impaired memory, and interpersonal difficulties.

A 1994 telephone survey of drivers by the New York State Task Force estimated that approximately 25% reported that they had fallen asleep at the wheel at some time. Young male drivers are especially susceptible to crashes caused by falling asleep as documented in a study in North Carolina in 1990, 1991, and 1992 (e.g., in 55% of the 4333 crashes, the drivers were predominantly male and 25 years of age or younger). In the October 1995 Gallup poll, 52% of all adults surveyed said that in the past year they had driven a car or other vehicle while feeling drowsy, 31% of adults admitted dozing off while at the wheel of a car or other vehicle, and 4% reported having had an automobile accident because of tiredness during driving. A number of national and international catastrophes involving industrial operations, nuclear power plants, and all modes of transportation have been related to sleepiness and fatigue (Dinges 1995): for example, the Exxon Valdez oil spill in Alaska; the nuclear disaster at Chernobyl in the former Soviet Union; the near-nuclear disaster at Three Mile Island in Pennsylvania; the gas leak disaster in Bhopal, India, resulting in 25,000 deaths; and the Challenger space shuttle disaster.

Causes of Excessive Daytime Sleepiness

Excessive sleepiness may result from both physiological and pathological causes (Table 74.8).

Physiological Causes of Sleepiness

Sleep deprivation and sleepiness because of lifestyle and habits of going to sleep and waking up at irregular hours can be considered to result from disruption of the normal circadian and homeostatic physiology. Groups who are excessively sleepy because of lifestyle and inadequate sleep include young adults and elderly individuals, workers at irregular shifts, health care professionals (e.g., doctors, particularly the house staff, and nurses), firefighters, police officers, train drivers, pilots and flight attendants, commercial truck drivers, and those individuals with competitive drives to move ahead in life, sacrificing hours of sleep and accumulating sleep debt. Among young adults, high school and college students are particularly at risk for sleep deprivation and sleepiness. The reasons for excessive

  - Brain tumors or vascular lesions affecting thalamus, hypothalamus, or brainstem
  - Post-traumatic hypersomnolence
  - Multiple sclerosis
  - Encephalitis Icthargica and other cnccphalitidcs and encephalopathies including Wernicke's encephalopathy
  - Cerebral trypanosomiasis (African sleeping sickness)
  - Neurodegenerative disorders
    - Alzheimer's disease
    - Parkinson's disease
    - Multiple system atrophy
  - Myotonic dystrophy and other neuromuscular disorders causing sleepiness secondary to sleep apnea
  - Medication-related hypersomnia
    - Benzodiazepines
    - Nonbcnzodiazepine hypnotics, e.g., phenobarbital, Zolpidem
    - Sedative antidepressants, e.g., tricyclics, trazodone
    - Antipsychotics
    - Nonbcnzodiazepine anxiolytics, e.g., buspirone
    - Antihistamines
    - Narcotic analgesics including tramadol (Ultram)
    - Beta blockers
    - Toxin and alcohol-induced hypersomnolence

sleepiness in adolescents and young adults include both biological and psychosocial factors. Some of the causes for later bedtimes in these groups include social interactions Willi peers, homework in the evening, sports, employment or other extracurricular activities, early wake-up times to start school, and academic obligations requiring additional school or college work at night. Biological factors may play a role but are not well studied. For example, teenagers may need extra hours of sleep. Also, the circadian timing system may change with sleep phase delay in teenagers. EDS associated with shift work is described (see Primary Sleep Disorders Associated with Excessive Daytime Sleepiness, later in this chapter).

Pathological Causes of Sleepiness

Neurological Causes of Excessive Sleepiness. Tumors and vascular lesions affecting the ascending reticulat activating arousal system and its projections to the posterior hypothalamus and thalamus lead to daytime sleepiness (Aldrich 1993). It should be noted that lesions of this system often cause coma rather than just sleepiness. Brain tumors (e.g., astrocytomas, suprasellar cysts, metastases, lymphomas and hamartomas affecting the posterior hypothalamus, pineal tumors, and astrocytomas of the upper brainstem) may produce excessive sleepiness. Prolonged hypersomnia may be associated with tumors in the region of the third ventricle. Symptomatic narcolepsy resulting from craniopharyngioma and other tumors of the hypothalamic and pituitary regions has been described (Aldrich 1993). Cataplexy associated with sleepiness, sleep paralysis, and hypnagogic hallucinations has been described in patients with rostral brainstem gliomas with or without infiltration of the walls of the third ventricle. Narcolepsy-cataplexy also has been described in a HLA DR2 antigen-negative patient with a pontine lesion documented by magnetic resonance imaging (MRI).

Other neurological causes of EDS include bilateral paramedian thalamic infarcts (Bassctti et al. 1996), post-traumatic hypersomnolence, and multiple sclerosis. Narcolepsy-cataplexy has been described in occasional patients with multiple sclerosis and arteriovenous malformations in the diencephalon (Calvelou ct al. 1995).

EDS has been described in association with encephalitis lethargica and other encephalitides as well as encephalopathies including Wernicke's encephalopathy. It was noted that the lesions of encephalitis Icthargica described by Von Economo in the beginning of this century, which severely affected the posterior hypothalamic region, were associated with the clinical manifestation of extreme somnolence.

These lesions apparently interrupted the ascending arousal systems projecting to the posterior hypothalamus. Encephalitis lerhargica is now extinct. Cerebral sarcoidosis involving the hypothalamus may cause symptomatic narcolepsy. Whipple's disease of the nervous system involving the hypothalamus may occasionally cause hypcrsomnolence.

Cerebral trypanosomiasis, or African sleeping sickness, is transmitted to humans by tsetse flies: *Trypanosoma gambiense* causes Gambian or West African sleeping sickness, and *Trypanosoma rbodesiense* causes East African sleeping sickness.

Certain neurodegenerative diseases such as Alzheimer's disease, Parkinson's disease, and multiple system atrophy also may cause EDS. The causes of EDS in Alzheimer's disease include degeneration of suprachiasmatic nucleus resulting in arcadian dysrhythmia, associated sleep apnea-hypopnea, and periodic limb movements in sleep, In Parkinson's disease, excessive sleepiness may be due to the associated periodic limb movements in sleep, sleep apnea, and depression. EDS in multiple system atrophy associated with cerebellar parkinsonism or parkinsonian-cerebellar syndrome and progressive autonomic deficit (Shy-Drager syndrome) may be caused by the frequent association with sleep-related respiratory dysrhythmias and possible degeneration of the reticular activating arousal systems (Chokrovcrty 1999b).

Sleep disorders are being increasingly recognized as a feature of Parkinson's disease and other parkinsonian disorders. Although some studies have attributed the excessive daytime drowsiness and irresistible sleep episodes ("sleep attacks") to anti-parkinsonian medications (Ondo et al. 2001), sleep disturbances are also an integral parr of Parkinson's disease (Arnulf et al. 2002). In one study of 303 patients with Parkinson's disease, 21% reported falling asleep while driving (Ondo et al. 2002). Several studies also reported a relatively high incidence (10-20%) of symptoms of restless legs syndrome in patients with Parkinson's disease (Ondo et al. 2002; Krishnan et al. 2003). There is also increasing awareness about the relationship between parkinsonian disorders and REM sleep behavior disorder (RBD), and RBD may be the presenting feature of Parkinson's disease, multiple system atrophy, and other parkinsonian disorders (Gagnon et a I. 2002).

These and other studies provide evidence supporting the notion that dopamine activity is normally influenced by circadian factors (Rye and Jankovic 2002). For example, tyrosine hydroxylase levels fall several hours before waking and their increase correlates with motor activity. The relationship between hypocretin and sleep disorders asso ciated with Parkinson's disease is currently being explored (Overeem et al. 2002).

Myotonic dystrophy and other neuromuscular disorders may cause EDS due to associated sleep apnea-hypopnea syndrome and hypoventilation. In addition, in myotonic dystrophy, there may be involvement of the ARAS as part of the multisystem membrane effects noted in this disease.

Excessive Daytime Sleepiness Associated with General Medical Disorders. Several systemic diseases such as hepatic, renal, or respiratory failure and electrolyte disturbances may cause metabolic encephalopathies that result in FDS. Patients with severe EDS drift into a coma. The other medical causes for EDS include congestive heart failure (CHE) and severe anemia. Hypothyroidism and acromegaly also may cause EDS due to the associated sleep apnea syndrome. Hypoglycemic episodes in diabetes mellitus and severe hyperglycemia arc additional causes of EDS.

Primary Steep Disorders Associated with Excessive Daytime Sleepiness. A number of primary sleep disorders cause excessive sleepiness (Tables 74.8 and 74.9). The most common cause of FJDS in the general population is insufficient sleep syndrome associated with sleep deprivation. The next most common cause is obstructive sleep apnea syndrome (OSAS); narcolepsy and idiopathic hypersomnolence are other common causes of EDS. Most patients with EDS referred to the sleep laboratory have OSAS. Other causes of EDS include circadian rhythm sleep disorders, periodic limb movement disorder, and restless legs syndrome, some cases of chronic insomnia, and inadequate sleep hygiene (sec later).

Many sedatives and hypnotics cause EDS. In addition to the benzodiazepine and nonbenzodiazepine hypnotics and sedative anti-depressants (e.g., tricyclic antidepressants and trazodone) as well as nonbenzodiazepine neuroleptics {e.g., buspirone), antihistamines, antipsychotics, and narcotic analgesics including tramadol (Ultram) cause EDS. Beta blockers for treatment of the hypertension also may cause excessive sleepiness.

Toxin and alcohol-related hyper somnolence can occur as well. Many industrial toxins such as heavy metals and organic toxins (e.g., mercury, lead, arsenic, and copper) may cause EDS. These may sometimes also cause insomnia. Individuals working in industrial settings using toxic chemicals routinely are ar risk. These toxins also may cause systemic disturbances such as alteration of renal, liver, and hematological function. There may be an impairment of nerve conduction. Chronic use of alcohol ar bedtime may produce alcohol-dependent sleep disorder. Usually, this causes insomnia, but sometimes the patients may have excessive sleepiness in the daytime. Many of these patients suffer from chronic alcoholism. Acute ingestion of alcohol causes transient sleepiness.

CLASSIFICATION OF SLEEP DISORDERS

The original diagnostic classification of sleep and arousal disorders by the Association of Sleep Disorder Centers categorized sleep-wake disorders into four classes: (1) disorders of initiating and maintaining sleep, (2) disorders of excessive somnolence, (3) disorders of sleep-wake schedule, and (4) dysfunctions associated with sleep,

Tabic 74.9: International classification of sleep disorders

- Dyssomnias
  - Intrinsic sleep disorders
    - Psychophysiological insomnia

sleep stages, or partial arousals (parasomnias). Tbis classification has been supplanted by the 1990 *International Classification of Sleep Disorders (ICSD),* which was revised slightly in 1997. The ICSD system is the one used by sleep specialists; it lists 84 sleep disorders in tour broad catcgories: dyssomnias, parasomnias, sleep disorders associated with medical or psychiatric disorders, and proposed sleep disorders (see Table 74.9).

Dyssomnias are subdivided into intrinsic, extrinsic, and circadian rhythm sleep disorders. Intrinsic disorders result from causes in the body, whereas extrinsic disorders are primarily caused by environmental factors. Circadian

rhythm disorders result from disruption of sleep-wake schedule changes.

Parasomnias arc characterized hy abnormal movements and behavior intruding into sleep without necessarily disturbing sleep architecture. These consist of arousal and sleep-wake transition disorders, REM-related parasomnias, and others.

Medical or psychiatric sleep disorders include those attributable to another condition; they are caused by mental (psychiatric), neurological, and other medical disorders.

Proposed sleep disorders include disorders for which inadequate or insufficient information is available to substantiate with certainty the existence of that particular disorder.

The *ICSD* includes descriptive details, specific diagnostic criteria, severity, and duration. There is also coding information for clinical and research purposes.

In addition to the *ICSD* two other systems are used: the *International Classification of Diseases (ICD),* ninth revision, clinical modification, and the *ICD,* tenth revision *[ICD-10).* The *1CD-10NA* is an expansion of *ICD-10* with alphanumeric codes for every neurological disease, including specific sleep disorders. There has been no study to assess the validity and reliability of any classification of sleep disorders.

Approach to a Patient with Sleep Complaints

The approach to a patient with a sleep complaint must begin with a clear understanding about sleep disorders as listed in the *ICSD.* Some common sleep complaints are trouble falling asleep and staying asleep (insomnia); falling asleep during the day (daytime hypersomnolence); and inability to sleep at the right time (circadian rhythm sleep disorders). Other common complaints are thrashing and moving about in bed with repeated leg jerking (parasomnias and other abnormal movements, including nocturnal seizures) and restless legs syndrome (RLS).

Cardinal manifestations in a patient complaining of insomnia include all or some of the following: difficulty falling asleep; frequent awakenings, including early-morning awakening; insufficient or total lack of sleep; daytime fatigue, tiredness, or sleepiness; lack of concentration, irritability, anxiety, and sometimes depression and forget fulness; and preoccupation with psychosomatic symptoms, such as aches and pains.

Cardinal manifestations of hypersomnia include EDS, falling asleep in an inappropriate place and under inappropriate circumstances, no relief of symptoms after additional sleep at night, daytime fatigue, inability to concentrate, and impairment of motor skills and cognition. Additional symptoms depend on the nature of the underlying sleep disorder (e.g., snoring and apneas during sleep witnessed by a bed partner in patients with OSAS; attacks of cataplexy, hypnagogic hallucinations, sleep paralysis, automatic behavior, and disturbed night sleep in patients with narcolepsy).

Sleeplessness and EDS are symptoms; therefore, every attempt should be made to find a cause for these complaints. Insomnia may be due to a variety of causes. The etiological differential diagnosis for EDS may include OSAS; central sleep apnea (C'SAt; narcolepsy; idiopathic hypersomnia; several psychiatric, neurological, and other medical illnesses; drug or alcohol abuse; and periodic hypersomnolence (e.g., Kleine-Levin syndrome, idiopathic recurrent stupor, and caramenial hypersomnolence). Sometimes a patient with RES may complain of f'.DS. Abnormal movements and behavior during sleep include REM and NREM sleep parasomnias and other abnormal movements (e.g., periodic limb movements in sleep [PLMS]), some daytime movement disorders that persist during sleep, and nocturnal seizures.

The physician must evaluate the patient first on the basis of the history and physical examination before undertaking laboratory tests, which must be determined by the clinical diagnosis (Chokroverty 1999a). The first step in the assessment of a sleep-wakcfulncss disturbance is careful evaluation of the sleep complaints. The history should include information on the patient's entire 24 hours and must include a detailed sleep history, with a sleep questionnaire as well as a sleep log or diary. It must also include psychiatric, neurological, medical, drug alcohol, and family and past histories. The history must be followed by a physical examination to uncover medical or neurological causes of insomnia, hypersomnia, and parasomnias. Physical examination of patients with OSAS may uncover upper airway anatomic abnormalities.

It is advisable to interview the bed partner, caregiver, or parents of children to get an adequate history, particularly the history during sleep at night, which may have an effect on daytime functioning. A sleep questionnaire containing a list of pertinent questions relating to sleep complaints; sleep hygiene; sleep patterns; medical, psychiatric, and neurological disorders; and drug and alcohol use may be filled out by the patient to save time during the history taking. A sleep log kept over a 2-weck period also is a valuable indicator of sleep hygiene. Such a log should include information on bedtime, arising time, daytime naps, amount of time needed to go to sleep, number of nighttime awakenings, total sleep time, and feelings on arousal. $0^{LlL,st}i^{o ll}s$ should be asked regarding the patient's mood and naps during the daytime, hi women, the relation of sleepiness to the menstrual cycle also should be ascertained.

Pertinent questions can help diagnose primary sleep disorders. For example, a history of snoring and apneas witnessed during sleep at night would suggest OSAS. Unusual movements during sleep at night may suggest periodic limb movement disorder. A history of short sleep attacks, cataplexy, hypnagogic hallucinations, sleep paralysis, and disturbed night sleep in a young adult suggests narcolepsy. Nonrefreshing sleep or no benefit from

additional sleep may suggest sleep apnea syndrome and idiopathic hypersomnolence. Identification of an irregular sleep-wake schedule and delayed sleep onset and awakening and inquiry into the patient's lifestyle to uncover sleep deprivation and insufficient sleep are important for the diagnosis of sleepiness. Paresthesias and uncontrollable limb movements at sleep onset or in the early evening may suggest RLS. A family history is important in primary sleep disorders such as narcolepsy, RLS, and OSAS, which may be responsible for EDS.

Subjective Measures of Sleepiness

A variety of scales have been developed to assess the subjective degree of sleepiness. The Stanford Sleepiness Scale (Table 74.10) is a seven-point scale to measure subjective sleepiness but may not be reliable in patients with persistent sleepiness (Robinson and Guilleminault 1999).

Another scale is the visual analogue scale of alertness and well-being. In this scale, subjects are asked to indicate their feelings on an arbitrary line. This scale has been used successfully in circadian rhythm disorders. The Epworth Sleepiness Scale evaluates general level of sleepiness (Johns 1998). The patient is rated on eight situations with a score of 0-3 (3 being the highest chance of dozing off). The maximum score is 24, and a score greater than 10 suggests the presence of excessive sleepiness (Table 74.11). This scale has been weakly correlated with the multiple sleep latency test (MSIT) scores.

CLINICAL PHENOMENOLOGY

In this section, the clinical characteristics of selected sleep disorders arc described.

Insomnia

Insomnia is a symptom rather than a disease and is characterized by an inadequate amount of sleep or impaired quality of sleep (Chesson et al. 2000; Satei et al. 2000).

Table 74.10: Stanford sleepiness scale

1. Wide awake, active, and alert
2. Awake and able to concentrate but not functioning at peak
3. Relaxed, awake, and responsive but not fully alert
4. Feeling a little foggy
5. Difficulty staying awake
6. Sleepy, prefer to lie down
7. Cannot stay awake; sleep onset is imminent

People with insomnia complain of difficulty initiating or maintaining sleep, which causes sleep that does not restore or refresh and impairment of daytime functioning. The National Institute of Mental Health (NIMH) consensus conference in 1984 divided insomnia (Chokroverty 2003b) into transient (1 week), short-term (1—3 weeks), and chronic (>3 weeks). The *ICSD* includes 14 categories that may have insomnia as a prominent complaint (included under the category of dyssomnias) and can occur in intrinsic, extrinsic, and circadian rhythm sleep disorders.

Insomnia is the most common sleep disorder in the population. In one survey, 35% of adults between the ages of 18 and 79 years complained of insomnia in the past year (Chokroverty 2003b). In the NIMH Epidemiological Catchment Area Study (1981-1985), 10% of the subjects responding to a sleep questionnaire had had problems sleeping for 2 weeks or more in the preceding 6 months; the problems were not related to neurological or psychological conditions. Other surveys have confirmed that insomnia affects about one third of the adult population in the United States at one time or another, and in 10%, it is a persistent problem {Leger et al. 2000; Ohayon and Guilleminault 1999). The prevalence of insomnia increases with age, and symptoms were more prevalent in women than in men. There is also a higher prevalence of insomnia among persons of lower socioeconomic status; in divorced, widowed, or separated individuals; and in those experiencing recent stress, depression, drug or alcohol abuse and anxiety disorder (Kirsti et al. 2003).

Clinical Manifestations of Insomnia

The symptoms of insomnia often interfere with interpersonal relationships or job performance. Decrements in daytime task performance and prolonged reaction times have been reported in patients complaining of insomnia (Chokroverty 2003b). Formal cognitive and motor skill

tests generally do not detect objective evidence of impairment. The NIMH Epidemiological Catchment Area Study, however, indicated an increased risk of major depression in those with chronic insomnia. A 1991 Gallup survey found that patients who report sleep deprivation due to chronic insomnia have 2.5 times as many automobile accidents as those who report fatigue from other causes. Some of these excessive risks may relate to the increasing proportion of drug or alcohol abuse with insomnia. Long-term detrimental health effects due to insomnia have not been documented, but one prospective study reported an increased chance of deaths from cancer, stroke, or heart disease among persons who reported sleeping for less than 4 hours or more than 10 hours per night (Chokroverty 1999a). These results have not been corroborated and may have been confounded by several factors. Objective tests for sleepiness (e.g., the MSI.T) document that people with insomnia are no more sleepy than age-matched normal control subjects; in fact, those with insomnia are less sleepy than normal control subjects, which suggests a hyperarousal state. These findings may also be due to an impaired perception of sleep. In one study, more than 70% of patients with chronic insomnia and more than 30% of normal subjects reported being awake if awakened from stage II NREM sleep (Mahowald et al. 1997) and patients wirh insomnia tend to overestimate sleep latency (the deviation of time between lights-out and the onset of sleep) after nocturnal awakenings. Patients with insomnia also tend to mispcrceive prior sleep as wake time, thus underestimating total sleep time (Mercer et al. 2002).

Causes of Insomnia

Insomnia is a heterogeneous condirion that may result from a wide variety of factors. Multiple causes may contribute to insomnia in an individual, and different causes may be responsible for different types of insomnia (transient, short-term, and chronic).

Transient and Short-Term Insomnia. Factors that can result in transient or short-term insomnia are similar, but the disturbances that produce short-term insomnia are of greater magnitude. Causes of transient and short-term insomnia arc listed in Table 74.12.

Tabic 74,12: Causes of transient and short-term insomnia

A change of sleeping environment (the most common cause of transient insomnia, the so-called first night effect)
Jet lag
Unpleasant room temperature
Stressful life events (e.g., loss of a loved one, divorce, loss of employment, preparing to take an examination)
Acute medical or surgical illnesses (including intensive care units)
Stimulant medications (e.g., theophylline, beta blockers, corticosteroids, thyroxine, bronchodilators, or withdrawal of central nervous system depressant medications)

Jet lag is experienced after travel through several time zones, which disrupts the synchronization between the body's inner clock and external cues (Bearpark 1994). Some of these sleep problems result from "jet" factors and others from "lag" factors. Jet factors that may be detrimental to sleep include long periods of travel with limited mobility, dryness of the eyes, headache, fatigue, gastrointestinal disturbances, and nasal congestion. Lag factots result in dyssynchrony berween the body's internal clock and the sleep schedule of the new environment. Symptoms are usually most pronounced when travel is from west to east and are more severe in elderly individuals. Readjustment and resynchronization occur at a rate of about 1 hour per day when one travels eastward and *1.5* hours per day when one travels westward (Bearpark 1994).

Shift work may affect up to 5 million workers in the United States; it can cause sleep disruption, chronic fatigue, gastrointestinal symptoms (including peptic ulcer), an increased chance of traffic accidents, and increased errors on the job. Drug-related insomnia includes rebound insomnia on discontinuation of short- and intermediate-acting hypnotics. Other drugs that may be responsible for insomnia are listed in Table 74,12.

Chronic Insomnia. Chronic insomnia can be caused by the chronic use of drugs or alcohol; various medical, neurological, or psychiatric disorders; or a variety of primary sleep disorders (Table 74.13).

Persistent insomnia can result directly from a medical illness (Table 74.14) or indirectly from the medications required for treatment of that illness. For example, sleep disruption may be caused by paroxysmal nocturnal dyspnea in patients with untreated CHF, whereas treatment with diuretics may disturb sleep by causing nocturia. Similar situations occur with nocturnal angina, chronic obstructive pulmonary disease (COPD), and bronchial asthma. Asthma may be exacerbated at night, with coughing and wheezing, which is related to several circadian factors {Chokroverty 1999c).

Table 74.13: Causes of chrome insomnia

General medical disorders
Neurological disorders, including fatal familial insomnia and post-traumatic insomnia
Psychiatric disorders
Drug- or alcohol-related insomnia
Primary sleep disorders
Primary or idiopathic (used to be called childhood-onset insomnia)
Psychophysiological insomnia
Circadian rhythm disorders associated with insomnia
Sleep-state misperceprion
Restless legs syndrome
Periodic timb movements in sleep
Inadequate sleep hygiene
Altitude insomnia
Insufficient sleep syndrome
Central sleep apnea-insomnia syndrome

Tabic 74.14: Medical causes of insomnia

Congestive heart failure
Ischemic heart disease
Nocturnal angina
Chronic obstructive pulmonary disease
Bronchial asthma including nocturnal asthma
Peptic ulcer disease
Reflux esophagitis
Rheumatic disorders, including fibromyalgia syndrome
Lyme disease
Acquired immunodeficiency syndrome
Chronic fatigue si ndrome

Neurological disorders causing insomnia are listed in Table 74.15. The pathogenesis of insomnia in neurological disorders may be related to direct or indirect mechanisms. For example, lesions of the hypnogenic neurons in the hypothalamic-preoptic nuclei and the lower brainstem area in the region of the nucleus tractus solitarius can alter the balance between waking and sleeping brain, causing sleeplessness. Other neurological conditions can produce pain, confusional episodes, changes in the sensorimotor system, or movement disorders that interfere with sleep. Insomnia in some neuromuscular diseases may be due to sleep-related hypoventilation with consequent sleep fragmentation. Insomnia may also be due lo medications used to treat neurological illnesses (e.g., anticonvulsants, dopaminergic agents, and anticholinergic drugs).

Insomnia commonly coexists with or precedes the development of a number of psychiatric illnesses. A large epidemiological study found that individuals with insomnia at baseline were about 34 rimes more likely than normal subjects to develop a new psychiatric disorder within a year compared with individuals without insomnia (Chokroverty 2003b). Those with insomnia are also about 40 times more likely than normal subjects to develop a new episode of major depression within 6 months. Individuals with insomnia that resolved within 1 year had a similar incidence of subsequent psychiatric disorders compared with normal individuals. Specific examples of psychiatric disorders that may be associated with insomnia include depression, anxiety disorders, and schizophrenia.

There is a high prevalence of depression among elderly individuals complaining of insomnia. Early morning awakening is considered to be the biological hallmark of depression. Adolescents and young adults with depression, in contrast, may report difficulty in initiating sleep. Characteristic findings in sleep disorders associated with depression are a short REM latency and maldistribution of REM cycle duration, with the longest nocturnal REM cycle occurring in the first one third of the night.

Table 74.15: Neurological disorders causing insomnia

Cerebral hemispheric and brainstem strokes
Neurodegenerative diseases, including Alzheimer's disease and Parkinson's disease
Brain tumors
Traumatic brain injury causing post-trauma tie insomnia
Neuromuscular disorders, including painful peripheral neuropathies
Headache syndromes (migraine, cluster, hypnic headache, and exploding head syndromes)
Fatal familial insomnia, a rare prion disease

Anxiety disorders arc the most common psychiatric disorders and include panic, phobic, obsessive-compulsive, post-traumatic stress, and generalized anxiety disorders. Sleep may be disrupted by panic attacks, nightmares, or flashbacks, depending on the underlying anxiety disorder. Major depression coexists in many patients. In a recent telephone interview of a representative sample of the general population in several European countries Ohayon and Roth (2003) concluded that chronic insomnia can be a residual symptom of a previous mood or anxiety disorder, and subjects with these disorders have a higher risk of relapse.

In schizophrenia, the severity of sleep disturbances is related to the intensity of psychotic symptoms. There is often extremely prolonged sleep-onset latency during the acute illness, with a reduction of total sleep time.

Primary Sleep Disorders Associated with Chronic Insomnia

Some patients with chronic insomnia have either idiopathic or psychophysiological insomnia or insomnia as a symptom of another primary sleep disorder.

Idiopathic Insomnia. Idiopathic or primary insomnia, previously called childhood-onset insomnia, is defined as a life-long difficulty in initiating and maintaining sleep, resulting in poor daytime functioning. The cause of this syndrome is unknown, but a neurochemical imbalance, either in the arousal (hyperactivity) or sleep-promoting neurons (hypoactivity), has been suggested but not proved. Onset occurs in early childhood, and sometimes the syndrome rims in families. This condition should only he diiisMosi'd .ifrer •.•wln-ann of concomitant medical, neurn logical, and psychiatric or other psychological problems.

Psychophysiological Insomnia. Psychophysiological insomnia is defined as chronic insomnia resulting from learned, sleep-pre venting associations and increased tension or agitation. It is estimated that about 15% of all individual with insomnia attending sleep disorder centers have psychophysiological insomnia. Affected individuals are overly concerned and overly focused on the problem of sleep but do not have generalized anxiety, phobic, or other psychiatric disorders. Onset of these syndromes often occurs in young adulthood, and symptoms persist for decades. First-degree relatives may have similar sleep problems, suggesting a possible genetic component.

I be chanickTiNUc tenure i>' psychophysiological IKMIIII nia is development of conditioned responses that are

incompatible with sleep. The disorder begins in some patients during an initial period of stressful events, but the insomnia persists even after the inciting stressors have resolved. The combination of excessive worry, fear, and frustration about being unable to initiate and maintain sleep and the identification of the bedroom as a signal for arousal contribute to negative conditioning and sleeplessness. Affected patients tend to sleep poorly during PSG study, although occasional patients sleep better because they are removed from their usual sleep environment. This condition is distinguishable from generalized anxiety disorder because patients with psychophysiological insomnia have anxiety confined to issues relating to sleep. The condition tends to have a later onset than idiopathic insomnia, which typically begins in childhood.

Sleep-State Misperception. In this disorder, subjects complain of sleeplessness hut without objective evidence (e.g., PSG recording of a sleep disorder). Despite complaints of no sleep or poor sleep over many years, actigraphy (a technique that measures patient activity and permits an objective assessment of sleep time) or PSG recordings document a normal sleep pattern (Saadch et al. 1995).

Inadequate "Sleep Hygiene". Good sleep hygiene measures promote sleep. These include avoidance of caffeinated beverages, alcohol, and tobacco in the evening; avoidance of intense mental activities and vigorous exercise close to bedtime; avoidance of daytime naps and excessive time spent in bed; and adherence to a regular sleep-wake schedule.

Insufficient Sleep Syndrome. Insufficient sleep is probably the most common cause of sleepiness in the general population. The whole society appears to be sleep deprived (bonnet and Arand 1995), which results from various factors, such as lifestyle, competitive drive to perform that sacrifices sleep, and environmental light and sound. Chronic sleep deprivation may lead to daytime sleepiness, irritability, lack of concentration, decreased daytime performance, muscle aches and pains, or depression.

Altitude Insomnia, Altitude insomnia refers to sleeplessness that develops in some individuals on ascent to altitudes higher than 4000 m in conjunction with other features of acute mountain sickness, such as fatigue, headache, and loss of appetite (Coote 1994). The severity of the sleep disturbance is directly proportional to the height of ascent. Those who live at higher altitudes become acclimatized and tend to sleep normally, but in some, chronic mountain sickness may develop, causing sleep disturbance.

Affected patients have periodic breathing (Ghcync-Stokes asthma) due to the stimulation of peripheral chemoreceptors by hypobaric hypoxemia. This causes hyperventilation, hypocapnia, and a respiratory alkalosis that suppresses ventilation. The abnormal breathing pattern causes repeated awakenings and sleep fragmentation, which may be exacerbated by stress, an uncomfortable sleeping environment, and cold temperature. The best treatment for altitude insomnia is aceta/olamidc, which promotes a mild metabolic acidosis that compensates for the hypoxemia-driven respiratory alkalosis.

RLS, periodic limb movement disorder, and circadian rhythm disorders are some of the other causes of persistent insomnia. In some patients, CSA may cause insomnia.

Narcolepsy

In 1880, the French physician Gelineau coined the term *narcolepsy* and gave a classic description of irresistible sleep attacks (Bassetti 2003). He also described "astasia," which had all the clinical features of what was later termed *cataplexy.* Before Gelineau's description, however, there were isolated instances of hypersomnolence, many of which resembled narcolepsy (although some may have been EDS associated with sleep apnea). In the last century, reports of large series of patients brought the entity of narcolepsy to the attention of the medical profession (Bassetti 2003; Overeem et al. 2001). In 1957, Yoss and Daly listed the narcoleptic tetrad of sleep attacks, cataplexy, sleep paralysis, and hypnagogic hallucinations (Bassetti 2003). The modern era of narcolepsy research began in 1960 with Vogel's discovery of sleep-onset REMs (SOREMs) in the narcolepsy syndrome. The observation by Honda and coworkers of the presence of HLA DR2 and DQwl (now called DQwl5) antigens in 100% of Japanese narcoleptic patients brought narcolepsy research to the field of molecular neurobiology (Mignot 1998; Overeem et al. 2001).

Epidemiology, Genetics, and Family Studies in Narcolepsy

There is wide variation in the prevalence of narcolepsy throughout the world, and good epidemiological studies are lacking. In the United States, the prevalence is 3-6 per 10,000; in Japan, it is 1 per 600; and in Israel, it is only 1 per 500,000.

Both genetic and environmental factors contribute to the development of narcolepsy. About 1-2% of first-degree relatives of narcoleptic patients manifest the illness, compared with 0.02-0.18% of the general population (a difference of 10-40 times) (Mignot 1998; Overeem et al. 2001). Several reports of familial narcolepsy have appeared in the literature since the first report in 1877. A positive family history of hypersomnolence and, less commonly, of cataplexy was reported in up to 50% of relatives of narcoleptic patients in the early studies. Early reports were based on symptoms only and not on PSG studies; therefore, cases of sleep apnea causing EDS may have been misdiagnosed as narcolepsy. Reports show that 4.7% of first-degree relatives of people with narcolepsy-cataplexy

complain of F.DS (Billiard et al. 1994). In view of the fact that the prevalence of EDS in the general population may be **abonl 1 1%, M can he** concluded **tliat** IMOSI "slccp>'" **relatives** of patients with narcolepsy do not have narcolepsy.

The mode of inheritance is thought to be autosomal dominant in humans, recessive in Doberman pinschers *{canarc-1)* and Labrador retrievers, and multifactorial in poodles.

Narcolepsy lias been linked io dys:uiiclii'r: ol ;lie hypocretin (orexin) peptide system. Lin and colleagues (1999) found deletions in the transcripts of the hypocretin receptor 2 *{HcrtrZ)* gene in narcoleptic Doberman pinschers and Labrador retrievers. Chemelli and colleagues (1999) created a knockout of the orexin gene in mice, which exhibited a phenotype strikingly similar to that in human narcolepsy patients and *canarc-1* mutant dogs. Orexin-containing neurons are located exclusively in the lateral hypothalamus with projections throughout the CNS, including the major nuclei implicated in sleep regulation. These two studies implicate hypocretins as major sleep-modulating neurotransmitters, which are closelv linked to the pathophysiology of narcolepsy.

Twin studies in narcolepsy do not suggest a strong genetic influence. Approximately 25-31% of monozygotic twins are concordant, but the majority are discordant for narcolepsy, which suggests the influence of environmental factors in the etiology of narcolepsy. Because most monozygotic twin pairs are discordant for narcolepsy-cataplexy and three discordant dizygotic twins were identified in a sample of 11,354 twins in the Finnish study, there may be an interaction of environmental and genetic factors in the development of narcolepsy (Mignot 1998; Overeem et al. 2001).

Honda and co-workers first directed attention to an association between HLAs of the major histocompatibility complex for narcolepsy-cataplexy. The haplotypes DR15 subtype of DR2 and DQ6 subtype of DQ1 are closely associated with narcolepsy in 95-100% of white and Japanese patients (Mignot 1998; Overeem et al. 2001). In blacks with narcolepsy, the DR2 antigen is found in only *65%* of patients, but the DQ1 antigen is present in more than 90%. It has been established that the HLA allele DQB1*0602 is the narcolepsy subtype gene along with the allele DQA1*0102 located nearby on chromosome 6 in all ethnic groups (Mignot 1998; Overeem et al. 2001). However, cases of patients with narcolepsy not carrying HLA DR2 or DQ1 antigens have been reported (Mignot 1998; Overeem et al. 2001}. Also, 12-35% of the general population carry the same HLA alleles, but narcolepsy is present in only 0.02-0.18% of the population. Therefore, the alleles DQB1*0602 and DQAl'0102 are neither necessary nor sufficient for development of narcolepsy.

Clinical Manifestations

The syndrome of narcolepsy is a lifelong neurological condition that generally begins in an adolescent or young adult with EDS and sleep attacks. Peak incidence occurs during the teens and early 20s (mostly at ages 15-20 years); another peak is seen aftct the second decade. Rare occurrences have been described in patients younger than 5 years of age and older than age 50. In modern demographic studies, there is no difference in prevalence between men and women. Many precipitating factors have been described, but most of them are probably incidental. After a variable interval of mouths to years, at least 70% of patients develop the second characteristic feature, cataplexy, which is followed by other symptoms in a certain percentage of patients. Narcolepsy begins before age 10 in about 5-15% of patients and after age 50 in about 5% of patients. In about 10% of patients, cataplexy precedes EDS by a few months and rarely b>T as much as 28 years. Any of the other major symptoms may rarely he the first symptom before narcoleptic sleep attacks and cataplexy (Bassetti 2003; Overeem et al, 2001). Clinical manifestations of narcolepsy syndrome may be described under three headings; major, minor, and miscellaneous.

Major manifestations are narcoleptic sleep attacks and EDS, cataplexy, sleep paralysis, hypnagogic hallucinations, disturbed night sleep, and automatic behavior.

Narcoleptic Sleep Attacks. The patient complains of EDS and characteristic sleep attacks, which are manifested by an irresistible desire to fall asleep. The attacks may come under inappropriate circumstances *Mid* in inappropriate places: during driving, talking, eating, playing, walking, running, working, class time, sexual intercourse, watching television, sitting, and conditions of boredom and monotony. Attacks are generally brief, lasting for a few minutes to 15-30 minutes, and on awakening, the patient usually feels fresh, although occasionally, the patient feels tired and drowsy. The incidence of attacks varies widely from one or more attacks daily to attacks weekly or monthly. Sometimes they occur once every few weeks to months and, occasionally, once every year to every few years. The attacks persist throughout life, although there may be fluctuations and, rarely, temporary remissions. Because of these sleep attacks, EDS, and the common occurrence of microsleep episodes, performance at school and work declines, resulting in a variety of psychosocial and socioeconomic difficulties,

Cataplexy. Lowenfeld coined the term *cataplexy* (Bassetti 2003). Cataplexy is characterized by sudden loss of tone in the voluntary muscles, except for respiratory and ocular muscles. The cataplectic attacks are often *{>95%* of the time) triggered by emotional factors, such as laughter, rage, and anger. The attacks may be complete or partial and, rarely, unilateral (0.5-1.0% of patients). The patient completely loses tone in the limb muscles and falls to the ground. Knees may buckle, there may be head nodding, sagging of the jaw, dysarthria, or loss of voice, and in rare unilateral cases, there may be a loss of power in one arm

or leg. These attacks generally last for a few seconds to a minute and sometimes a few minutes. Consciousness is retained completely during the attacks, and there is never any jerking of the limbs or head. Physical examination during these brief spells reveals flaccidity of the muscles and absent or markedly diminished muscle stretch reflexes. The H-reflcx, which is the electrical counterpart of the muscle stretch reflex, and F responses arc decreased or absent.

Cataplexy is the second most important manifestation of narcolepsy syndrome and is present in 60-100% of patients with narcolepsy. In most patients, cataplexy appears months to years after onset of the sleep attacks, but occasionally, cataplexy may be the initial presentation, which causes diagnostic confusion. At the onset, the patient may have attacks daily or weekly; gradually, they occur less often and may even disappear in old age. Rarely, particularly after withdrawal of tricyclic medications, patients may develop status cataplecticus. The EEG recording shows wakefulness during the brief cataplectic spells, but if these arc prolonged to 1-2 minutes, shows REM sleep and all its manifestations.

Sleep Paralysis, Sleep paralysis is the third major manifestation of narcolepsy. It occurs months to years after onset of narcoleptic sleep attacks and is seen in about 25-50% of patients. There is sudden apparent unilateral or bilateral paralysis or paralysis of one limb, cither during sleep onset at night (hypnagogic) or while awakening (hypnopompic) in the morning. The patient is conscious during these paralytic attacks but is unable to move or speak and is often frightened and fearful. As the patient experiences more and more of these episodes, he or she overcomes the fear and anxiety.

Hypnagogic Hallucination. Hypnagogic hallucination is the fourth major manifestation of narcolepsy syndrome and may occur cither at the onset of sleep or during awakening early in the morning. The hallucination manifests as vivid, often fearful, visual imagery but sometimes has auditory, vestibular, or somesthetic hallucinatory phenomena. These hallucinations may occur years after the onset of sleep attacks in 20-40% of narcoleptic patients. Narcoleptic sleep attacks, cataplexy, and sleep paralysis or hypnagogic hallucination are seen in about 30% of patients; all four major features (narcoleptic tetrad) may occur together in about 10% of patients.

Disturbance of Night Sleep. Disturbance of night sleep, together with the four major manifestations, may be termed the *narcoleptic pentad.* PSG findings showing disturbed night sleep are seen in 72-H0% of patients (see Laboratory Assessment of Sleep Disorders, later in this chapter).

Automatic Behavior. Automatic behavior is included under major manifestation and is found in a large percentage of patients (20^0%). During these episodes, the patient performs the same function repetitively, speaks or writes in a meaningless manner, drives on the wrong side of the toad, or drives to a strange place and then forgets the episodes. The behavior resembles a fuguelikc state and may result from partial sleep episodes, frequent lapses, or microslccp episodes.

Minor Manifestations

In addition to major manifestations, many patients have other minor clinical featutes. These may include psychosocial disturbances, anxiety, depression, morning headache, impotence in men, frigidity and lack of orgasm in women, and recent memory impairment.

Miscellaneous Man ifes tat ions

Patients with narcolepsy syndrome may also have sleep apnea and PLMS, which often aggravate their sleep attacks. The incidence of associated sleep apnea in narcolepsy varies, but about 30% of narcoleptic patients may have sleep apnea, which is most commonly central but it may be obstructive or mixed. It is important to recognize obstructive sleep apnea (OSA) in narcoleptic patients because they may need additional treatment with continuous positive airway pressure (CPAP) for relief of apneas and EDS. The third important miscellaneous manifestation is RBD, which Schenck and Mahowald reported in 17 patients in whom the diagnosis was made by established criteria for narcolepsy and RBD. These patients ranged in age from 8 to 74 years, and 71% were men. Narcolepsy and RBD most commonly emerged in tandem. In three patients, treatment of narcolepsy-cataplexy with stimulants and tricyclic medications either induced or exacerbated RBD.

Differential Diagnosis

Narcoleptic sleep attacks should be differentiated from other causes of EDS. These include sleep deprivation and insufficient sleep syndrome; OSAS; alcohol- and drug-related hypcrsomnolcnce; other medical, neurological, and psychiatric disorders causing hypersomnolence; idiopathic hypersomnia; and circadian rhythm sleep disorders.

OSAS (see Sleep Apnea Syndrome, later in this chapter) is **the** most common cause of EDS in patients referred to a sleep laboratory for evaluation and is characterized by repeated episodes of obstructive and mixed apneas during NREM and REM sleep in overnight PSG recordings. These patients have prolonged daytime sleep episodes, followed by fatigue and drowsiness on awakening, which contrasts with a fresh feeling in narcoleptic patients on awakening from brief sleep attacks. All patients with hypersomnolence can he excluded after careful history and physical elimination and overnight PSG recording.

Idiopathic hypersomnia (see Idiopathic Hypersomnia, later in this chapter) closely resembles narcolepsy syndrome.

In contrast to narcolepsy, the sleep episodes in idiopathic hypersomnia arc prolonged, and the sleep is not refreshing. PSG recordings and MSLT scores do not show SORF.Vts but do show pathological sleepiness. There is no disturbance of REM-NREM organization on PSG recordings. Sun:-: patients with idiopathic hypersomnia ma) have a positive family history.

Cataplexy may be mistaken for partial complex seizure, absence spells, atonic seizures, drop attacks, and syncope. During partial complex seizure, there is an altered state of consciousness, but in cataplexy, patients retain consciousness. Patients with partial complex seizures may have secondary generalized tonic-clonk movements and postictal confusion, and EEG recordings may show characteristic epileptiform discharges in the anterior and midtemporal regions. Absence spells arc characterized by staring and vacant expression lasting for a few seconds to *30* seconds and an altered state of alertness accompanied by characteristic 3-Hz spike-and-wavc discharges on the EEG recording. Atonic seizures are accompanied by transient loss of consciousness, and the EEG findings may show slow spike-and-wavc or polyspike-and-wave discharges. Drop attacks may occur in vertebrobasilar insufficiency {transient ischemic attacks), and the patient may **have other** evidence of brainstem ischemia, such as vertigo, ataxia, or diplopia. Syncope results from Transient loss of consciousness and may have resulted from cardiogenic or other causes, **including** neurogenic orthostatic hypotension.

Sleep paralysis in narcolepsy should be differentiated from isolated and physiological sleep paralysis and familial sleep paralysis. In all these conditions, other manifestations of narcolepsy are absent,

Automatic behavior and fugue states should be differentiated from the automatism seen in partial complex seizure and psychogenic fugue. History, physical exanima tion, and the EEG findings are helpful in the differentiation.

Differential diagnosis should also include neurological conditions that were thought to be associated with secondary or symptomatic narcolepsy. Secondary narcolepsy has been controversial, and many cases of hypcrsom**nolence** resulting from CNS lesions have been described in the past as narcolepsy. Most of these are atypical sleep attacks and did not have the classic features of narcolepsy. Occasional cases of true narcoleptic sleep attacks and cataplexy have been described, however, in association with diencephalic and midbrain tumors. Multiple sclerosis and narcolepsy may occasionally be **seen** in **the** same individual and are associated with a 111.A DR2 antigen positi vity.

Pathophysiological Mechanisms

Physiological, neurochemical, genetic, and environmental factors all play distinct roles in the pathogenesis of narcolepsy syndrome. Physiological abnormalities in narcolepsy suggest a disturbance of REM-NREM sleep-wake state boundaries. The hallmark of physiological testing in narcolepsy is the presence of SOREMs (i.e., the onset of REM sleep at sleep onset or within 15 minutes of sleep onset). In most patients, this sign is found in two of four to five nap recordings in MSLT scores and in approximately 50% of PSG recordings. Other features point to dissociation of REM sleep and intrusion into wakefulness. During cataplexy, there is muscle atonia of REM sleep without other REM features during a wakeful electroencephalogram. If the episode is prolonged, however, the patient develops full REM sleep. Similarly, in sleep paralysis, **muscle** atonia is similar to the REM sleep atonia. **REM** sleep intrusion with dream imagery without other features of REM sleep is noted in hypnagogic hallucinations, In many of these episodes, the sleep state is intermediate between REM and NREM sleep. Many patients also have microsleep episodes during the daytime. The time -is o la tion laboratory experiments conducted by Pollak and coworkers showed strong evidence for circadian disorganization in narcoleptic patients. Although the total 24-hour sleep, as welt as the percentage of REM sleep, is norma! in narcoleptic patients, the intrusion of REM sleep atonia into wakefulness suggests the dissociation of REM sleep regulation. Occasional occurrence of RBD in some narcoleptic patients may be cited as evidence favoring an impairment of state boundary theory in narcolepsy.

Neurochemical Mechanisms

The neurochemical basis of narcolepsy is not well understood. Injection of cholinergic drugs (e.g., physostigmine) in narcoleptic dogs (Doberman pinschers are good models of narcoleptic dogs with an autosomal recessive inheritance) increases the cataplectic episodes, whereas atropine and scopolamine (muscarinic receptor-blocking agents) decrease cataplectic episodes (Guilleminault et al. 1998). M_2 subtypes of muscarinic cholinergic receptors are found to be upregulated in the pontine reticular formation of narcoleptic dogs {Guilleminault et al. 1998). Postmortem studies have also shown increased muscarinic Mj receptor binding in the basal ganglia and the amygdala. These findings, in conjunction with the pharmacological experiments, suggest hypersensitivity of the muscarinic cholinergic system in the cataplectic dog brain. There is also cvilli lice In suggest .1 deU\ I in ir.om >i i;ii[n-r;;ic t i.;;uLiUii!i oi the REM sleep mechanism contributing to narcoleptic symptoms. REM-off cells (serotonergic cells in the raphe and noradrenergic cells in the locus ceruleus) are completely inactive during REM sleep and appear to play a permissive role by modulating cholinergic activity. It has been postulated that an imbalance of the chemical regulation between the cholinergic and monoaminergic neurons may play a role in narcoleptic symptomatology. The stimulants (amphetamine and others) used for effective treatment of sleepiness in narcolepsy increase the synaptic availability of monoamines. Tricyclic antidepressants used in the

treatment of cataplexy decrease the reuptake of norepinephrine; fluoxetine decreases the reuptake of serotonin, thus increasing the availability of both of these monoamines. Modafinil, the wake-promoting agent used in the treatment of narcolepsy, may exert its effect by promoting dopaminergic transmission (Nishino and Mignot 1997; Wisor et al. 2001).

Documentation of an abnormality in the hypocretin (orexin) neurons in the lateral hypothalamus in patients with narcolepsy-cataplcxy is the most exciting recent development in its pathogenesis (Siegel 1999, 2002). This condition can be considered a hypocretin (orexin) deficiency syndrome. Such a hypothesis is supported by the following observations: induction of narcolepsy-like symptoms after preprohypocretin gene knockout in mice and mutation of the hypocretin receptor 2 gene in dogs (Chemelli etal. 1999; Lin etal. 1999); decreased hypocretin 1 levels in the cerebrospinal fluid of patients with narcolepsy-cataplexy (Nishino et al. 2000, 2001; Mignot et al. 2002); postmortem documentation of decreased numbers of hypocretin neurons in brains from narcoleptic individuals (Thannickal ct al. 2000); and identification of a prep ro hypocretin gene mutation in a child with severe narcolepsy and a generalized absence <t hypocretin peptides in the brain (Peyron et al. 2000).

Genetic and Environmental factors

Genetic and environmental factors in narcolepsy are described briefly under Epidemiology. Genetics, and family Studies in Narcolepsy, earlier in this chapter. The exact environmental factors in narcolepsy are unknown. The question of autoimmunity in narcolepsy is the subject of speculation, but no definite evidence has been uncovered (Overeem etal, 2001).

Idiopathic Hypersomnia

ICSD (1997) defines idiopathic hypersomnia as a disorder of excessive sleepiness of presumed (but not proved) CNS cause that is associated with normal or prolonged (1-2 hours) NREM sleep episodes. The syndrome has been described under a variety of labels, including NREM narcolepsy, idiopathic CNS hypersomnia, and functional, mixed, or harmonious hypersomnia. Idiopathic hypersomnia (Billiard and Dauvillicrs 2001) occurs insidiously, generally between the ages of 15 and 30 years. It closely resembles narcolepsy and sleep apnea. Although sometimes it is very difficult to distinguish from narcolepsy syndrome, the sleep pattern is different from that in narcolepsy or sleep apnea (Bassetti and Aldrich 1997). A patient with idiopathic hypersomnia generally sleeps for hours, and the sleep is not refreshing. The patient does not give a history of cataplexy, snoring, or repeated awakenings throughout the night. Sleep drunkenness (i.e., confusional arousal) is often seen in these patients, and they may have automatic behavior with amnesia tor the events. Physical examination uncovers no abnormal neurological or other findings. This is a very disabling and lifelong condition. The MSLT shows evidence of pathological sleepiness without SOREMs.

The differential diagnosis of idiopathic hypersomnia should include other causes of EDS, such as classic narcolepsy-cataplexy, upper airway OSAS, CSA syndrome, upper airway resistance syndrome (UARS), insufficient sleep, drug-induced hypersomnia, and other medical or psychiatric disorders, particularly mood disorders. Post-traumatic hypersomnia, chronic fatigue syndrome, delayed sleep-phase syndrome (DSPS), and long sleeper syndrome should also be included in the differential diagnosis. Based on a retrospective review of clinical and PSG features as well as questionnaire results derived from a database of 3618 patients evaluated between 1985 and 1993 at a sleep disorder center, Aldrich (1996) suggested that idiopathic hypersomnia is a heterogeneous syndrome. I le contradicted some of the previously reported findings, and in his analysis, these patients did not exhibit prolonged night sleep or sleep drunkenness. Aldrich also questioned the validity of using prolonged or "deep" sleep as a diagnostic criterion for idiopathic hypersomnia. He suggested that clinical heterogeneity may reflect differences in etiologies, such as reports of preceding Epstein-Barr viral infection, infectious mononucleosis, Guillain-Barre syndrome, or human immunodeficiency virus (HIV) infection. The author argued for revaluation of the diagnostic criteria for idiopathic disorders of sleepiness not associated with cataplexy. Some of these patients may have a positive family history, but the mode of inheritance is unknown. Unlike narcolepsy, there is no clear association between idiopathic hypersomnia and HLA antigens.

Sleep Apnea Syndrome

Sleep apnea syndrome encompasses both obstructive and central apneas as well as hypopnca. OSAS is very common but remains underdiagnosed, whereas CSA syndrome is uncommon in the general population. OSAS is the most common sleep disorder studied in the sleep laboratory by overnight PSG recording done to assess EDS, In the general population, however, sleep deprivation or insufficient sleep syndrome is the most common cause of EDS today. The reason for underdiagnosis of OSAS is inadequate awareness and insufficient knowledge about the serious consequences of this disorder among physicians and the public. OSAS causes significant morbidity and mortality, and it is important to diagnose the condition because effective treatment is available for most individuals who have it. To understand the condiiiuii, definition ol sever.:.! terms related to sleep disordered breathing (SDB) is necessary.

Sleep-Disordered Breathing: Terminology

Apnea (obstructive, central, or mixed), hypopnea, hypoventilation, paradoxical breathing, periodic breathing, increased upper airway resistance, dysrhyrhmic breathing, apneustic breathing, inspiratory gasps, and nocturnal stridor may all be grouped under SDB. Figure 74,5 shows some patterns of SDB. The term *sleep apnea* refers to temporary cessation or absence of breathing during sleep. Analysis of the breathing pattern has revealed the presence of three types of sleep apnea: upper airway obstructive, central, and mixed. Normal individuals may experience a few episodes of sleep apnea, particularly central apnea at the onset of NREM sleep and during REM sleep. To be of pathological significance, the sleep apnea should last at least 10 seconds, the apnea index (number of episodes of apnea per hour of sleep) should be at least 5, and the patient should have at least 30 episodes during 7 hours of all-night sleep,

Cessation of aitflow with no respiratory effort constitutes central apnea; diaphragmatic and intercostal muscle activities arc absent, as is air exchange through the nose or mouth. Upper airway OSA is characterized by cessation of airflow through the nose or mouth with persistence of diaphragmatic and intercostal muscle activities. Mixed apnea is manifested as an initial cessation of airflow with no respiratory effort {central apnea) followed by a period of upper airway OSA.

Sleep-related hypopnea is defined by the American Academy of Sleep Medicine Task Force (1999) as a reduction in the breathing signal to less than one half the volume measured during the preceding or following respiratory cycle with 3% or more oxygen desatitration or EEG arousal. The Sleep Heart Health Study reported by Shahar et al. (2001) defines hypopnea as a 30% or greater reduction in thoracoabdominal exertion or flow limitation associated with 4% or greater oxygen desaturation.

The respiratory disturbance index (RDI) or apnea-hypopnea index (AHI} is defined as the number of apneas and hypopneas per hour of sleep. A normal index is less than 5, but most investigators consider AHI or RDI of 10 or more significant.

Apneas and hypopneas are accompanied by oxygen desaturation and are terminated by an arousal, which is defined as transient (lasting 3-14 seconds) return of alpha activities in the EEG recording. Repeated arousals causing sleep fragmentation may be the main contributing cause to EDS. Arousals along with repeated hypoxemias are also the most important factors for long-term cardiovascular consequences of OSAS.

During paradoxical breathing, the thorax and abdomen move in opposite directions, thereby indicating increased upper airway resistance. This type of breathing may be noted in patients with OSAS as well as in some patients with UARS.

Periodic breathing includes Cheync-Stokes breathing and the Cheyne-Stokes variant pattern of breathing. Cheyne-Stokes breathing is a special type of central apnea manifested as cyclic changes in breathing, with a crescendo-dccrescendo sequence separated by central apneas. The Cheyne-Stokes variant pattern of breathing is distinguished by the substitution of hypopneas for apneas. Cheyne-Stokes breathing and the variant pattern arc most commonly noted in CHF and neurological disorders.

Dysrhythmic breathing is characterized by nonrhythmic respiration of irregular rate, rhythm, and amplitude that becomes worse during sleep. This type of breathing may

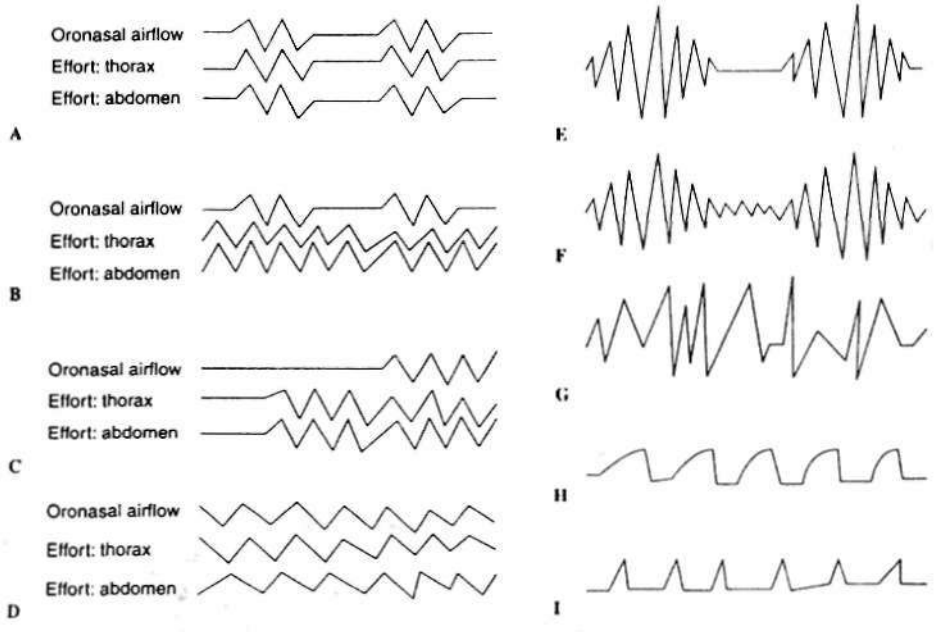

FIGURE 74.5 Patterns of sleep-disordered breathing: (A) central apnea; (B) upper airway obstructive apnea; (C) mixed apnea (initial central apnea followed by obstructive apnea); (D) paradoxical breathing; (E) Cheyne-Stokes bn.[1]:!tiling; (f) ('heytie-Stokes variant pattern; (G) dysrhythmic breathing; (H) apneustic breathing; (1) inspiratory gasp, (Reproduced with permission from Chokroverty, S. 1999, "Sleep, breathing, and neurological problems," in *Sleep Disorders Medicine: Basic Science, Technical Considerations, and Clinical Aspects,* ed S. Chokroverty, Bu rter worth-I leinvituiiiri, Huston,)

result from an abnormality in the automatic respiratory pattern generator in the brainstem.

Apneustic breathing is characterized by prolonged inspiration with an increase in the ratio of inspiratory to expiratory time. This type of breathing may result from a neurological lesion in the caudal pons disconnecting the apneustic center in the lower pons from the pneumotaxic center in the upper pons.

Inspiratory gasp is characterized by short inspiratory time and a relatively prolonged expiration and has been noted after a lesion in the medulla.

Hypoventilation refers to a reduction of alveolar ventilation accompanied by hypoxemia and hypercapnia without any apnea or hypopnea; it may be noted in patients with neuromuscular disorders and kyphoscoliosis and those with underlying lung or chest wall abnormalities that impair gas exchange during wakefulness.

Upper Airway Resistance Syndrome

There is a general gradation from increasing upper airway resistance, which is found in normal individuals during sleep, to the limitation of airflow in subjects with loud snoring to a stage of UARS followed by the next stage of complete airway occlusion, seen in patients with OSAS. Patients with UARS show subtle airflow limitations due to increased upper airway resistance followed by repeated arousals during sleep at night. This subtle aitflow limitation cannot be identified by the usual recording of respiration using an oronasal thermistor or inductance plethysmography to register chest and abdominal wall motions. Nasal pressure monitoring with a nasal cannula is more sensitive than use of a thermocouple or thermistor in detecting airflow limitation and increased upper airway resistance (Ayappa et al. 2000), Intraesophageal balloon manometry, however, is the gold standard for detecting upper airway **resistance, and** this reveals increasing efforts, with increasing intraesophageal pressure, leading to arousal but without any apneas or hypopneas (Figure 74.6). These patients may or may not snore; they do have EDS and all its consequences, as seen in OSAS.

Epidemiology of Obstructive Sleep Apnea Syndrome

No study has been specifically designed to determine the incidence of OSAS in a previously healthy population. Based on a definition of at least five apneas or hypopneas per hour of sleep accompanied by EDS {Young et al. 1993), however, the prevalence of OSAS is 4% in men and 2% in women between 30 and 60 years of age. There is a strong

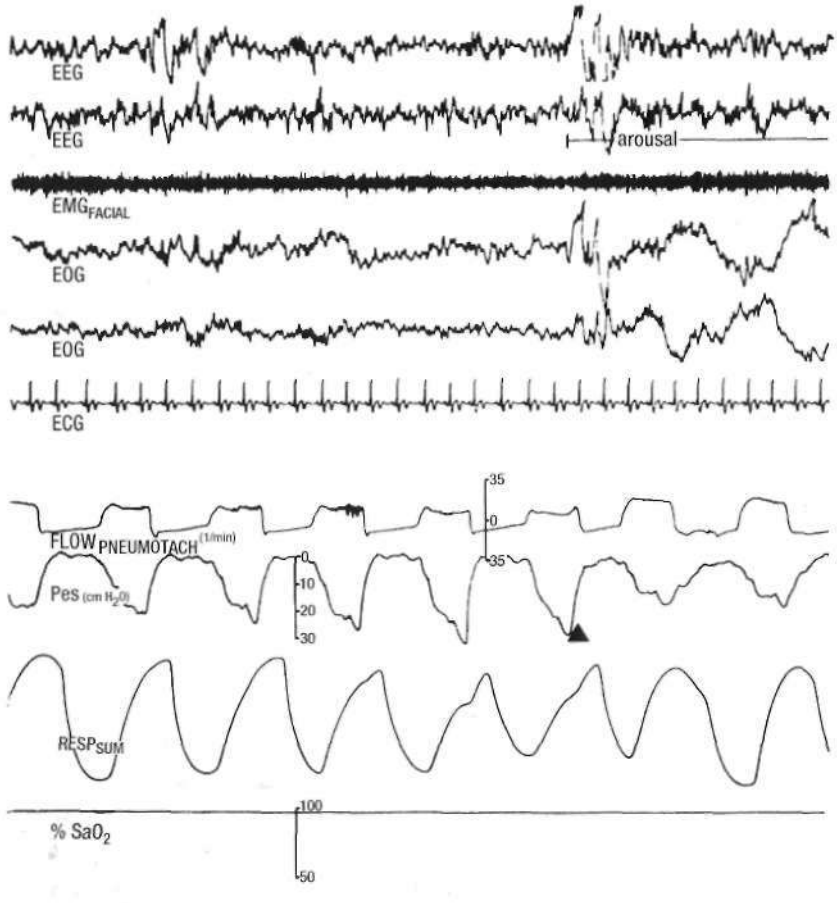

FIGURE 74.6 Polysomnography recording of a patient with upper airway resistance syndrome. Note that peak increase in effort *(solid arrow)* is associated with a small drop in peak flow and tidal volume causing a transient arousal on the electroencephalogram. ECG = electrocardiogram; EMGIJCJ;,] = facial muscle electromyogram; EOG = electrooculogram (right and left); FLOW = pneumotac ho meter to quantity airtli >>>; Pes = esophageal manometry to record esophageal pressure; $RESP_{mm}$=respiratory effort; Sao_2 = oxygen saturation. (Reproduced with permission from Robinson, A. & Guilleminault, C, 1999, in *Sleep Disorders Medicine: Basic Science, Technical Considerations, and Clinical Aspects,* ed S. Chokroverty, Butte i worth-Hcinemann, Boston.)

association between OSAS and male gender, increasing age, and obesity. The condition is common in men older than 40 years of age, and among women the incidence of OSAS is greater after menopause. About 85% of patients with OSAS are men, and obesity is present in about 70% of OSAS patients. There is an increased prevalence of OSAS in those with a thick neck and large abdomen. Men with a neck circumference measuring more than 17 inches and women with a neck measuring more than 16 inches are at risk for OSAS.

Race may be a factor, given that a high ptevalence of SD13 is noted in Pacific Islanders, Mexican-Americans, and African-Americans. There are also family aggregates of OSAS. Other factors with a high association are alcohol, smoking, and drug use.

Consequences of Obstructive Sleep Apnea Syndrome

Short-term consequences of OSAS include impairment of the quality of life and increasing traffic accidents; long-term consequences include cardiovascular and neurological dysfunction. OSAS is associated with increased morbidity and mortality (Robinson and Guilleminault 1999; Flemons 2002).

Prevalence of hypertension in untreated OSAS exceeds 40%, whereas 30% of patients with idiopathic hypertension have OSA (Fletcher 2000; Robinson and Guilleminault 1999). Recent prospective and community-based studies have confirmed the previous suggestion of a clear relationship between hypertension and OSAS including mild OSAS (Peppatd et al. 2000; Nieto et al. 2000). Improvement of hypertension after treatment of OSA (Peppetell et al. 2002; Faceenda et al. 2001; Hla et al. 2002) further supports a causal relationship between OSAS and hypertension. A significant relationship between hypertension and the RD1 exists even after obesity and other confounding factors are eliminated. Factors responsible for hypertension in OSAS include repeated hypoxemia during sleep at night and increased sympathetic activity. Cardiac arrhythmias, pulmonary hypertension, and cor pulmonale, which are noted in patients with severe OSAS, may be related to severe hypoxemia during sleep. There is also a strong relationship between snoring, myocardial infarction, and stroke. The association of supratentorial infarction, mfratentonal infarction, and transient ischemic attacks with snoring and sleep apnea has been clearly documented (Basserti and Chervin 2000). Neuropsychological measurements document that cognitive dysfunction in patients with OSAS improves after treatment (Fugleman et al. 2000; Kim et al. 1997).

Pathogenesis of Obstructive Sleep Apnea Syndrome

The pathogenesis of OSAS includes local anatomical factors as well as neurological factors (Douglas and Polo 1994; Robinson and Guilleminault 1999). Collapse of the pharyngeal airway is the fundamental factor in OSA. During sleep, muscle tone decreases, including that of the upper airway dilator muscles, which maintain upper airway patency. As a result of this decreased tone, these muscles relax, causing increased upper airway resistance and narrowing of the upper airway space. This effect becomes more marked during REM sleep because of marked muscle hypotonia or atonia of muscles at this stage. This generates turbulent flow and vibration, causing snoring; in some individuals, there may be significant narrowing or occlusion, causing apnea. Episodes of upper airway narrowing causing apneas, hypopneas, or increased upper airway resistance that are terminated by arousals and sleep fragmentation, with repetition of the cycles numerous times throughout the night, are responsible for the daytime symptoms in OSAS. The site of narrowing in most individuals is at the level of the soft palate. Therefore, decreased tone in the palatal, genioglossal, and other upper airway muscles, causing increased upper airway resistance and decreased airway space, plays an important role in upper airway obstruction in OSAS. Obesity associated with increased fat deposition in the region of the pharynx and soft palate, abnormal facial features (e.g., rctrognathia or micrognathia), and other conditions (e.g., myxedema or acromegaly) that cause fatty tissue deposit in the pharyngeal region predispose individuals to upper airway narrowing and OSA. Imaging studies of the upper airway region have shown that in OSA, upper airway space is narrower than in those who do not have apnea or hypopnea.)n addition to the smaller airway space in OSAS, the activity of the genioglossus muscle is found to be higher than normal during wakefulness in these patients; this may be considered a compensatory mechanism to keep the upper airway patent. Other anatomical abnormalities include adenotonsillar enlargement in children and craniofacial dysostosis. Defective upper airway reflexes may also play a role in upper airway occlusion. In some family members, abnormal facial structures, a narrow upper airway, and long uvula have been found.

Neural factors responsible for OSAS include abnormalities of respiratory control in the medullary respiratory neurons. The output of sleep-related medullary respiratory neurons is thought to decrease in normal individuals during sleep. This reduction of the medullary respiratory neuronal activity in sleep causes a loss of tonic and phasic motor output to the upper airway dilator muscles, resulting in an increase in airway resistance. 1 [ypoxic and hypercapnic ventilatory responses, however, are found to be normal in OSAS, but in obesity-hypoventilation syndtomc (pickwickian syndrome), which may be considered a very advanced stage of OSAS in obese patients, these responses are depressed, causing hypercapnia and hypoxemia even during wakefulness. Thus a complex intetaction of peripheral upper airway and central neural factors combine to produce the full-blown syndrome of OSAS.

Symptoms

Symptoms of OSAS (Flemons 2002; Robinson and Guilleminault 1999) can be divided into two groups (Table 74.16): those occurring during sleep (nocturnal events) and those occurring during the daytime (diurnal events). Nocturnal sleep symptoms of OSAS include loud snoring (often with a long history), choking, cessation of breathing (apneas witnessed by the bed partner), sitting up fighting for breath, abnormal motor activities with thrashing about in bed, severe sleep disruption, gastroesophageal reflux, nocturia and nocturnal enuresis (seen mostly in children), and occasionally hyperhidrosis,

The major daytime symptom of OSAS is F.DS. Patients fall asleep during the day at inappropriate times and in inappropriate places and may be involved in driving accidents. They cannot function adequately during the day, and some patients may complain of morning headaches and forgetfulncss; men may report impotence. The prolonged duration and the unrefreshing nature of the EDS attacks differentiate them from narcoleptic sleep attacks.

Table 74.16: Symptoms and signs in obstructive sleep apnea syndrome

- Nocturnal symptoms during sleep
  - Loud snoring (often with a long history)
  - Choking during sleep
  - Cessation of breathing (apneas witnessed by bed partner)
  - Sitting up or fighting for breath
  - Abnormal motor activities (e.g., thrashing about in bed)
  - Severe sleep disruption
  - Gastroesophageal reflux causing heartburn
  - Nocturia and nocturnal enuresis (mostly in children)
  - Insomnia (in some patients}
  - Excessive nocturnal sweating (in some patients)
- Daytime symptoms
  - Excessive daytime somnolence
  - Forget fulness
  - Personality changes
  - Decreased libido and impotence in men
  - Dryness of mouth on awakening
  - Morning headache (in some patients)
  - Automatic behavior with retrograde amnesia
  - Hyperactivity in children
  - Hearing impairment (in some patients)
- Physical findings
  - Obesity in the majority of patients
  - Increased body mass index (body weight in kg/height in m^2) >25
  - Increased neck circumference (>17 in. in men and >16 in. in women)
  - In some patients:
    - Large edematous uvula
    - Low-hanging soft palate
    - Large tonsils and adenoids (especially in children)
    - Retrognathia
    - Micrognathia
    - Hypertension
    - Cardiac arrhythmias
    - Evidence of congestive heart failure

Snoring is present in most patients, and there is often a gradation from mild snoring for many years to very loud snoring for a period and then to the development of daytime symptoms. A histoty of apneas witnessed by a bed partner is a strong indicator of the presence of sleep apnea. Occasionally, patients may complain of difficulty falling asleep and numerous awakenings during the night. Excessive sweating in some patients may be related to the increased muscle activity related to abnormal motor activities during sleep at night. Increased release of atrial natriuretic peptide during sleep may be responsible for natriuresis, diuresis, and nocturnal enutcsis. Some patients may complain of hearing impairment related to a history of loud snoring for many years. Other complaints include memory impairment, automatic behavior with retrograde amnesia, dryness of mouth on awakening in the morning, decreased libido, personality changes, and hyperactivity in children. Factors that may aggravate symptoms of OSA include alcohol intake, CNS depressants, sleep deprivation, respiratory allergies, and .smoking.

Signs

Physical examination should include assessment of respiratory, oropharyngeal, neurological, hematological, and cardiovascular funcrions. Examination of the oropharyngeal region may detect redundant oropharyngeal tissues, such as large edematous uvula, redundant mucosal folds of the pharyngeal walls, low-hanging long soft palate, or large tonsils and adenoids, especially in children. Other findings may include microglossia, micrognathia, and rerrognarhin. Body weight and height measurements are important. Neck circumference correlates with SDB. Physical examination reveals obesity in about 70% of patients. Physical examination may also uncover the risk factors associated with repeated hypoxemia and apnea during sleep, such as hypertension, cardiac arrhythmias, and evidence of CHF,

Evaluation and Assessment

Evaluation and assessment are the same as those for other sleep disorders. Particular attention should be paid to the detailed sleep history as well as the daytime history, and careful physical examination should be focused on specific associated and risk factors. The laboratory assessment and management are described later in this chapter, under Laboratory Assessment of Sleep Disorders.

Restless Legs Syndrome

Clinical Manifestations

Thomas Willis gave a graphic clinical description of RLS more than 300 years ago. More than 50 years ago, Ekbom brought the entity to the attention of the medical

community (Chokroverty et al. 2003). RLS remains largely underdiagnosed or undiagnosed. The exact prevalence of RLS is not known because definitive population-based study has been inadequate. Ekbom gave a prevalence rate of 5%, but in several contemporary population surveys using the International Restless Legs Syndrome Study Group (IRLSSG) criteria (Walters et al. 1995; International Restless Legs Syndrome Study Group 2003) the prevalence of RLS has been estimated to be about 10% for all adult populations, particularly those of European descent (Chokroverty et al. 2003). In some surveys from \w„. • w i • • i -..i U: i. .• i-, < urciucb lew . suggesting .i possible ethnic and racial difference in prevalence of RLS. RLS is a lifelong condition that may begin at any age but is most severe in middle-aged and elderly persons, in whom it has a chronic progressive course. The fundamental problem in RLS is a complex sensorimotor disorder involving the legs predominantly (Allen ct al. 2001, 2003). The essential clinical diagnostic features as revised (Allen et al. 2003) from the previous IRLSSG criteria (Walters et al. 1995) are listed in Table 74.17. RLS is idiopathic in most patients, but it also may result from conditions such as iron deficiency, uremia, or polyneuropathy (Chokroverty and Jankovie 1999).

The hallmarks of idiopathic or primary RLS are intense, disagreeable, creeping sensations (paresthesia or dysesthesia) in the lower extremities that arc relieved by moving the legs (Allen et al. 2003). The symptoms are worse when the patient is lying down in bed in the evening and occur most commonly at sleep onset. The sensory manifestations include intense, disagreeable feelings that are generally different from the usual paresthesias or dysesthesias encountered in common polyneuropathies or radiculopathies. These creeping sensations occur mostly between the knees and the ankles, causing an intense urge to move the limbs, which relieves the feelings. Occasionally, patients complain of pain. Affected patients generally have severe difficulty in initiating sleep due to paresthesias and restlessness of the legs. Severely affected individuals may also have paresthesias during the day when resting or sitting quietly,

Motor manifestations of RLS can be divided into three groups: voluntary urge to move the legs causing restlessness, involuntary movements in wakefulness, and PLMS. The restlessness is seen mostly in the legs but occasionally also in the arms. The movements arc usually symmetrical but sometimes may be seen asymmetrically and asynchronously. Motor restlessness generally comprises tossing and turning in bed, floor pacing, leg stretching, leg flexion, foot rubbing, and occasionally marching in place and body rocking. The involuntary movements during relaxed wakefulness include myoclonic jerks and dystonic movements. These movements may be periodic, and these are called periodic limb movements in wakefulness (PLMW). The myoclonic jerks can also be aperiodic or may occur in clusters. The dystonic movements are more sustained and prolonged in duration than the myoclonic jerks. The salient features of PLMS (Table 74.18) are seen in at least 80% of patients with RLS. PLMS are mostly dystonic and rarely myoclonic, based on the EMG criteria of duration of the muscle bursts.

Neurological examination in the idiopathic form of RLS is generally normal because movements arc usually noted in the evening, when the patients are resting in bed. In sevctc cases, however, the movements may be noted during the day while subjects are sitting or lying down, and both voluntary and involuntary movements may be seen during neurological examination. In secondary forms of RLS, clinical signs of associated abnormality may be present. The course is gcnetally chronic and progressive, but remissions sometimes occur. The condition may be exacerbated during pregnancy or by caffeine or iron deficiency. Family history may be positive in 40-50% of the patients, which suggests a dominant mode of inheritance.

Table 74.17: Clinical diagnostic criteria for idiopathic restless legs syndrome

Essential criteria
An urge to move the legs usually accompanied or caused by uncomfortable sensations in the legs
The urge to move or unpleasant sensations beginning or worsening during periods of rest or inactivity such as lying or sitting
The urge to move or unpleasant sensations are partially or totally relieved by movements, MI eh as walking or stretching, at least as long as the activity continues
The urge to move or unpleasant sensations arc worse in the evening or night than during the day or only occur in the evening or night
Supportive features
Dopaminergic responsiveness
Presence of periodic limb movements in sleep or in wakefulness
Positive family histoty
Associated features
Usually progressive clinical course
Normal neurological examination in the idiopathic fotm
Sleep disturbance

['able 4, IK: Features of pcriodie limb movements in sleep

Repetitive, often stereotyped movements during NREM sleep
