Volume I

Neurology in Clinical Practice

Principles of Diagnosis and Management

Fourth Edition-

Edited by **Walter G. Bradley, D.M., F.R.C.P**
Professor and Chairman, Department of Neurology, University of Miami School of Medicine; Chief Neurology Service, University of Miami-Jackson Memorial Medical Center, Miami, Florida
Robert B. Daroff, M.D,
Chief of Staff and Senior Vice President for Academic Affairs, University Hospitals of Cleveland; Professor of Neurology and Associate Dean, Case Western University School of Medicine, Cleveland, Ohio
Gerald M. Fenichel, M.D.
Professor of Neurology and Pediatrics, Vanderbilt University School of Medicine; Director, Division of Pediatric Neurology; Neurologist-in-Chief, Vanderbilt Children's Hospital, Nashville, Tennessee
Joseph Jankovic, M.D.
Professor of Neurology; Director, Parkinson's Disease Center and Movement Disorders Clinic, Baylor College of Medicine, Houston, Texas

NEUROLOGY IN CLINICAL PRACTICE 9997625889

International Standard Book Number: 0-7506-7469-5

Notice

Medicine is an ever-changing field. Standard safety precautions must be followed, but as new research and clinical experience broaden our knowledge, changes in treatment and drug therapy may become necessary or appropriate. Readers are advised to check the most current product information provided by the manufacturer of each drug to be administrated to verify the recommended dose, the method and duration of administration, and contraindications. It is the responsibility of the treating physician, relying on experience and knowledge of the patient, to determine dosages and the best treatment for each individual patient. Neither the Publisher nor the author assumes any liability for any injury and/or damage to persons or property arising from this publication.

Neurology in Clinical Practice

Neurology in Clinical Practice

Contents

Volume II The Neurological Disorders

Contributing Authors

Jeffrey C. Allen, M.D.
Chief, Division of Pediatric Neurology, Hyman-Newman Institute for Neurology and Neurosurgery, Beth Israel Medical Center, New York; Professor of Neurology, Albert Einstein College of Medicine, Bronx, New York

58F. Cancer and the Nervous System: Management of Primary Nervous System Tumors in Infants and Children

Anthony A. Amato, M.D.
Associate Professor of Neurology, Harvard Medical School, Boston, Massachusetts; Vice Chairman, Department of Neurology, and Chief, Neuromuscular Division, Brigham and Women's Hospital, Boston, Massachusetts

85. Disorders of Skeletal Muscle

Michael J. Aminoff, M.D., D.Sc, F.R.C.P.
Professor of Neurology, University of California, School of Medicine, San Francisco, California; Attending Physician, Department of Neurology, Medical Center at the University of California, San Francisco

55A. Neurological Complications of Systemic Disease: In Adults; 64A. Effects of Toxins and Physical Agents on the Nervous System: Effects of Occupational Toxins on the Nervous System; 64E. Effects of Toxins and Physical Agents on the Nervous System: Effects of Physical Agents on the Nervous System

Lisa C. Argueilo, M.Ed., C.C.C.-A.
Clinical Audiologist, Wake Forest University Baptist Medical Center, Winston-Salem, North Carolina

19, *Hearing Loss and Tinnitus without Dizziness or Vertigo; 41, Neuro-Otology*

Stephen Ashwal, M.D.
Professor of Pediatric Neurology, Department of Pediatrics, Loma Linda University School of Medicine, Loma Linda, California

7. *Global Developmental Delay and Developmental Regression*

Vikcn L. Babikian, M.D.
Professor of Neurology, Boston University School of Medicine; Director and Co-Director, Stroke Service, Boston Medical Center, Boston, Massachusetts

37D. Neuroimaging: Ultrasound Imaging of the Cerebral Vasculature

Joachim M. Baehring, M.D.
Assistant Professor of Neurology and Neurosurgery, Yale University School of Medicine, New Haven, Connecticut

58E. Cancer and the Nervous System: Management of Primary Nervous System Tumors in Adults

Laura J. Baker, M.D., M.S.C.E.
Associate Professor, Department of Neurology, University of Pennsylvania School of Medicine, Philadelphia

15. Abnormalities of the Optic Nerve and Retina

J. D. Bartleson, M.D.
Associate Professor of Neurology, Mayo Graduate School of Medicine, Rochester, Minnesota; Consultant, Department of Neurology, Mayo Clinic, Rochester, Minnesota

21. Cranial and Facial Pain

Tracy T. Batchelor, M.D., M.P.H.
Assistant Professor of Neurology, Harvard Medical School, Boston, Massachusetts; Executive Director, Brain Tumor Center, and Director of Neuromedical Oncology, Massachusetts General Hospital, Boston

58. Cancer and the Nervous System; 58A, Cancer and the Nervous System: Epidemiology of Primary Brain Tumors; 58F. Cancer and the Nervous System: Management of Primary Nervous System Tumors in Infants and Children

Roy W. Beck, M.D., Ph.D.
Executive Director, Jaeb Center for Health Research, Tampa, Honda

15. Abnormalities of the Optic Nerve and Retina

Madhuri Behari, M.D., D.M.
Professor and Head, All India Institute of Medical Sciences, New Delhi

59C Infections of the Nervous System: Fungal Infections; 59D. Infections of the Nervous System: Parasitic Infections

Anita L. Bclman, M.D.
Professor of Neurology and Pediatrics, State University of New York Health Sciences Center at Stony Brook School of Medicine, New York; Attending Neurologist, University Hospital, Stony Brook, New York

59F. Infections of the Nervous System: Neurological Manifestations of Human Immunodeficiency Virus Infection in Children

Bruce O. Berg, M.D.
Professor of Neurology and Pediatrics Emeritus, University of California Medical Center, San Francisco

55B. Neurological Complications of Systemic Disease: In Children

Joseph R. Berger, M.D.
Chairman, Department of Neurology, University of Kentucky, Professor or Internal Medicine, Lmversitv of Kentucky Medical School, Lexington

5. Clinical Approach to Stupor and (loma

John A. Bcrtetson, M.D.
Instructor, Department of Psychiatry, Harvard Medical School, Boston; Ronald F, Coles Fellow, Behavioral Neurology and Neuropsychiatry, McLean Hospital, Belmont, Massachusetts
9. Depression and Psychosis in Neurological Practice

Jose Biller, M.D,
Professor and Chairman, Department of Neurology, Indiana University School of Medicine; Chief, Neurology Services, Department of Neurology, Indiana University Medical Center, Indianapolis
57 A. Vascular Diseases of the Nervous System: Ischemic Cerebrovascular Disease; 57E. Vascular Diseases of the Nervous System: Stroke in Children

Thomas D. Bird, M.D.
Professor of Neurology and Medicine, and Head, Division of Neurogenetics, University of Washington School of Medicine; Research Neurologist, Geriatrics Research Education and Clinical Center, Veterans Administration Medical Center, Seattle, Washington
44. Clinical Neurogenetics

David F. Black, M.D.
Instructor of Neurology, Mayo Medical School; Senior Associate Consultant, Department of Neurology, Mayo Clinic, Rochester, Minnesota
21. Cranial and Facial Pain

Christopher J. Boes, M.D.
Assistant Ptofessor of Neurology, Mayo Medical School; Consultant, Department of Neurology, Mayo Clinic, Rochester, Minnesota
75. Headache and Other Craniofacial Pain

E. Peter Bosch, M.D.
Professor of Neurology, Mayo Medical School, Rochester, Minnesota; Consultant in Neurology, Mayo Clinic, Scottsdale, Arizona
82. Disorders of the Peripheral Nerves

Brian C. Bowen, M.D., Ph.D.
Professor of Radiology, Neurology, and Neurological Surgery, and Director, Clinical MR Research, Department of Radiology, University of Miami School of Medicine, Florida
.J7B. *Neuroimaging: Computed Tomographic and Magnetic Resonance Vascular Imaging; 57F. Vascular Diseases of the Nervous System: Spinal Cord Vascular Disease*

Helen M. Bramlett, Ph.D.
Assistant Professor, Department of Neurological Surgery, University of Miami School of Medicine, Miami, Florida
56A. Trauma of the Nervous System: Basic Neuroscience of Neurotrauma

Michael H. Brooke, M.B., B.Ch., F.R.C.P.C.
Professor Emeritus, University of Alberta; Clinical Professor, University of Calgary, Edmonton, Canada
28. Proximal, Distal, and Generalized Weakness; 85. Disorders of Skeletal Muscle

Joseph Bruni, M.D., F.R.C.P.C
Associate Professor of Medicine, University of Toronto Faculty of Medicine; Consultant Neurologist, St. Michael's Hospital, Toronto, Canada
2. *Episodic Impairment of Consciousness*

Thomas N. Byrne, M.D,
Clinical Professor of Neurology, Neurosurgery, and Internal Medicine, Yale University School of Medicine, New Haven, Connecticut
27. *Paraplegia and Spinal Cord Syndromes*

David J. Capobianco, M.D.
Assistant Professor of Neurology, Mayo Medical School, Rochester, Minnesota; Consultant, Department of Neurology, Mayo Clinic, Jacksonville, Florida
75. Headache and Other Craniofacial Pain

David A. Chad, M.D.
Professor of Neurology and Pathology, University of Massachusetts Medical School, Worcester; Attending Neurologist, and Director, MDA Clinic, University of Massachusetts Memorial Health Care, Worcester
81. Disorders of Nerve Roots and Plexuses

Tanuja Chitnis, M.D,
Instructor in Neurology, Center for Neurologic Diseases, Harvard Medical School; Associate Neurologist, Department of Neurology, Brigham and Women's Hospital, Boston, Massachusetts
45. Neuroimmunology

Sudhansu Chokroverty, M.D.
Professor of Neurology, New York Medical College, Valhalla; Associate Chairman of Neurology, Chairman, Division of Neurophysiology, and Director, Center for Sleep Medicine, Saint Vincent's Hospital and Medical Center, New York
74. Sleep and Its Disorders

David P. Ciavcrella, D.O.
Radiology Division, The Oregon Clinic, Portland
79. *Disorders of Bones, Joints, Ligaments, and Meninges*

Paul E. Cooper, M.D., F.R.C.P.C.
Associate Professor of Neurology, University of Western Ontario Faculty of Medicine; Chief of Clinical Neurological Sciences, St. Joseph's Health Centre, London, Ontario, Canada
47. Neuroendocrinology

John R. Corboy, M.D.
Assistant Professor of Neurology, University of Colorado School of Medicine; Staff Neurologist, University of Colorado Health Sciences Center, and Denver V.A. Medical Center, Denver, Colorado
46. Neurovirology

Terry A. Cox, M.D., Ph.D.
Division of Epidemiology and Clinical Research, National Eye Institute, National Institutes of Health, Bethesda, Maryland
17. Pupillary and Eyelid Abnormalities

Thomas O. Crawford, M.D.
Associate Professor of Neurology and Pediatrics, Johns Hopkins University School of Medicine; Child Neurologist, Johns Hopkins Hospital, Baltimore, Maryland
30. The Floppy Infant

F, Michael Cutrer, M.D.
Assistant Professor of Neurology, Mayo Medical School; Consultant, Department of Neurology, Mayo Clinic, Rochester, Minnesota
75. Headache and Other Craniofacial Pain

Josep Dalmau, M.D., Ph.D.
Associate Professor, Department of Neurology, University of Pennsylvania School of Medicine, Philadelphia
58H. Cancer and the Nervous System: Paraneoplastic Disorders of the Nervous System

Ranan DasGupta, M.R.C.S.
Specialist Registrar in Urology, Department of Uro-Neurology, National Hospital for Neurology and Neurosurgery, Queen Square, London, United Kingdom
42. Neurourology

David M. Dawson, M.D.
Professor of Neurology, Harvard Medical School and Brigham and Women's Hospital, Boston, Massachusetts
60. Multiple Sclerosis and Other Inflammatory Demyelinating Diseases of the Central Nervous System

Roberta L. DcBiasi, M.D.
Assistant Professor of Pediatrics and Neurology, University of Colorado Health Sciences Center/The Children's Hospital, Denver
59B. Infections of the Nervous System: Viral Infections

Steven T. DcKosky, M.D.
Professor and Chair, Department of Neurology; Directot, Alzheimer's Disease Research Center, University of Pittsburgh, Pennsylvania
72. The Dementias

W. Dalton Dietrich, M.D.
Kinetic Concepts Distinguished Chair in Neurosurgery and Professor of Neurological Surgery, Neurology, and Cell Biology and Anatomy, University of Miami School of Medicine; Scientific Director, The Miami Project to Cure Paralysis, University of Miami School of Medicine, Miami, Florida
S6A. Trauma of the Nervous System: Basic Neuroscience of Neurotrauma

Bruce H. Dobkin, M.D.
Professor of Neurology, Neurologic Rehabilitation and Research Program, University of California, Los Angeles School of Medicine, Los Angeles
54. Principles and Practices of Neurological Rehabilitation

David W. Dodick, M.D.
Associate Professor of Neurology, Mayo Medical School, Rochester, Minnesota; Consultant, Department of Neurology, Mayo Clinic, Scottsdale, Arizona
75. Headache and Other Craniofacial Pain

Sean P. Donahue, M.D., Ph.D.
Associate Professor of Ophthalmology, Neurology, and Pediatrics, Vanderbilt University School of Medicine, Nashville, Tennessee
39. Neuro-Opbtbalmology: Ocular Motor System

Molly V. Dorfman, B.A.
Clinical Research Associate, Brain Tumor Center, Massachusetts General Hospital, Boston
58A. Cancer and the Nervous System: Epidemiology of Primary Brain Tumors

Darin D. Dougherty, M.D,
Assistant Professor of Psychiatry, Harvard Medical School; Assistant Director, Psychiatric Neuroimaging Research, Massachusetts General Hospital, Boston
37E. Neuroimaging: Functional Neuroimaging

Ronald G. Emerson, M.D.
Professor of Clinical Neurology, Columbia University College of Physicians and Surgeons, New York
36A. Clinical Neurophysiology: Electroencephalography and Evoked Potentials

Eric J. Eross, D.O.
Instructor of Neurology, and Associate Consultant, Department of Neurology, Mayo Clinic, Scottsdale, Arizona
75. Headache and Other Craniofacial Pain

Steven F. Falcone, M.D.
Assistant Professor of Radiology and Neurological Surgery, University of Miami School of Medicine/Jackson Memorial Medical Center, Miami, Florida
37A. Neuroimaging: Structural Neuroimaging

Martha J. Farah, Ph.D.
Professor of Psychology, University of Pennsylvania, Philadelphia
11. The Agnosias

Eliahn S. Fcen, M.D.
Neurology Resident, University Hospitals of Cleveland, Cleveland, Ohio
51. Principles ofNeurointenstve Care

Todd E. Fcinberg, M.D.
Neurobehavior Center, Beth Israel Medical Center, New York
11. The Agnosias

Karin Ferneyhough Hoth, M.A.
Graduate Research Assistant, University of Iowa, Iowa City
38. Neuropsychology

Richard G. Fessler, M.D.
Professor of Surgery, Section of Neurological Surgery, University of Chicago, Chicago, Illinois
56C. *Trauma of the Nervous System: Spinal Cord Trauma*

Pasquale F. Finelli, M.D.
Professor of Neurology, University of Connecticut School of Medicine, Farmington; Associate Director of Neurology, Hartford Hospital, Hartford, Connecticut
20. Disturbances of Taste and Smell

Alan J. Fischman, M.D., Ph.D.
Professor, Harvard Medical School; Director of Nuclear Medicine, Massachusetts General Hospital, Boston
37E. Neuroimaging: Functional Neuroimaging

Laura Flore s-S a mat, M.D.
Postdoctoral Research Fellow in Neuropathology, Cedars-Sinai Medical Center, Los Angeles, California
66. Developmental Disorders of the Nervous System

Clare J. Fowler, F.R.C.P.
Professor of Uro-Neurology, Institute of Neurology, Institute of Urology, University College London; Consultant in Uro-Neurology, The National Hospital for Neurology and Neurosurgery, London, United Kingdom
32. Neurological Causes of Bladder, Bowel, and Sexual Dysfunction; 42. Neurourology

David S. Geldtnacher, M.D.
Associate Professor, Department of Neurology, University of Virginia, Charlottesville
S7F. Vascular Diseases of the Nervous System: Spinal Cord Vascular Disease

David N. Gershfield, M.D.
Fellow in Neuromuscular Disorders and Clinical Neurophysiology, Department of Neurology and Neurological Sciences, Stanford University School of Medicine, Stanford, California
4. Delirium

Pierre Giglio, M.D.
Department of Neuro-Oncology, The University of Texas MD Anderson Cancer Center, Houston
58C. Cancer and the Nervous System: Clinical Features and Complications

Mark R. Gilbert, M.D.
Associate Professor, Department of Neuro-Oncology, The University of Texas MD Anderson Cancer Center, Houston
5&C. *Cancer and the Nervous System: Clinical Features and Complications*

Meredith R. Golomb, M.D., M.Sc.
Department of Neurology, Indiana University Medical Center, Indianapolis
57E. Vascular Diseases of the Nervous System: Stroke in Children

R. Gilberto Gonzalez, M.D., Ph.D.
Associate Professor of Radiology, Harvard Medical School; Director of Neuroradiology, Massachusetts General Hospital, Boston
58D. Cancer and the Nervous System: Neuroimaging

Maurice R. Hanson, M.D.
Physician, Clinical Neurology and Neurophysiology, Cleveland Clinic Florida, Fort Lauderdale
76. Cranial Neuropathies

Kenneth M. Heilman, M.D.
James D. Rooks, Jr. Distinguished Professor, Department of Neurology, University of Florida College of Medicine; Program Director and Chief of Neurology, Veterans Administration Medical Center, Gainesville, Florida
10. Intentional Motor Disorders and the Apraxias

Reid R. Heffner, Jr., M.D.
Professor and Chair, Department of Anatomical Sciences, School of Medicine and Biomedical Sciences, University at Buffalo, New York
S8R. Cancer and the Nervous System: Pathology and Molecular Genetics of Nervous System Tumors

John W. Henson, M.D.
Associate Professor of Neurology, Harvard Medical School; Associate Neurologist, Massachusetts General Hospital, Boston
58D. Cancer and the Nervous System: Neuroimaging

Deborah O. Heros, M.D.
Director of Neuro-Oncology, Mt. Sinai Comprehensive Cancer Cenrer, Miami Beach, Florida
52. Principles of Neurosurgery

Roberto C. Heros, M.D., F.A.C.S.
Professor, Co-Chairman, and Program Director, Department of Neurological Surgery, University of Miami School of Medicine, Miami, Florida
52. Principles of Neurosurgery

Alan Hill, M.D., Ph.D.
Professor and Head, Division of Neurology, British Columbia's Children's Hospital, Vancouver, Canada
86. Neurological Problems of the Newborn

Fred H. Hochberg, M.D.
Attending Neuro-Oncologist, Brain Tumor Center, Massachusetts General Hospital, Boston
SHE. Cancer and the Nervous System: Management of Primary Nervous System Tumors in Adults

James F. Howard, Jr., M.D.
Chief, Neuromuscular Disorders Section, Department of Neurology, The University of North Carolina at Chapel Hill School of Medicine, Chapel Hill
84. Disorders of Neuromuscular Transmission

David J. Hunter, M.D., Sc.D.
Professor of Epidemiology, Harvard School of Public Health, Boston, Massachusetts
58A. Cancer and the Nervous System: Epidemiology of Primary Brain Tumors

Padmaja Kandula, M.D.
Department of Neurology, Vanderbilt University Medical Center, Nashville, Tennessee
SO. Principles of Pain Management

Carlos S. Kase, M.D.
Professor of Neurology, Boston University School of Medicine; Attending Neurologist, Boston University Medical Center, Boston, Massachusetts
S7B. Vascular Diseases of the Nervous System: Intracerebral Hemorrhage

Bashar Katirji, M.D., F.A.C.P.
Professor of Neurology, Case Western Reserve University School of Medicine; Director, Electromyography Laboratory, and Chief, Neuromuscular Division, University Hospitals of Cleveland, Cleveland, Ohio
36B. Clinical Neurophysiology: Clinical Electromyography

Daniel I. Kaufer, M.D.
Associate Professor, Department of Neurology, and Director, Memory and Cognitive Disorders Program, The University of North Carolina Medical School, Chapel Hill
72, *The Dementias*

Samia J. Khoury, M.D.
Associate Professor of Neurology, Harvard Medical School; Director, Partners MS Center, Brigham and Women's Hospital, Boston, Massachusetts
45. Neuro immunology

Howard S. Kirshner, M.D.
Professor and Vice Chair, Department of Neurology, Vanderbilt University School of Medicine; Director, Stroke Service, Vanderbilt University Hospital, and Program Director, Stroke Service, Vanderbilt Stallworth Rehabilitation Hospital; Consultant in Neurology, Nashville VA Medical Center, St. Thomas Hospital, Nashville, Tennessee
6. Approaches to Intellectual and Memory Impairments; 12A. Language and Speech Disorders: Aphasia; 12B. Language and Speech Disorders: Dysarthria and Apraxia of Speech

Edwin H. Kolodny, M.D.
Neurogenetics Unit, Department of Neurology and Pediatrics, New York University School of Medicine, New York
68. Inborn Errors of Metabolism of the Nervous System

John F. Kurtzke, M.D.
Professor Emeritus of Neurology, Georgetown University School of Medicine, Washington, D.C.; Distinguished Professor of Neurology, Uniformed Services University of the Health Sciences, Bethesda, Maryland; Consultant in Neurology and Neuroepidemiology, Neurology Service, Veterans Affairs Medical Center, Washington, D.C.
43. Neuroepidemiology

Anthony E. Lang, M.D., F.R.C.P.C.
Professor of Neurology, University of Toronto Faculty of Medicine; Director of Movement Disorders, The Toronto Western Hospital, Division of the University Health Network, Toroto, Canada
24. Movement Disorders: Diagnosis and Assessment

Patrick J. M. Lavin, M.B., B.Ch., B.A.O., M.R.C.P.I.
Professor of Neurology and Ophthalmology, Vanderbilt University Medical School, Nashville, Tennessee
16. Eye Movement Disorders: Diplopia, Nystagmus, and Other Ocular Oscillations; 39, Neuro-Ophthalmology: Ocular Motor System

Ronald P. Lesser, M.D.
Professor of Neurology, Johns Hopkins University School of Medicine, Baltimore, Maryland
73. The Epilepsies

Alan H. Lockwood, MD
Professor of Neurology and Nuclear Medicine, State University of New York at Buffalo School of Medicine

and Biomedical Sciences; Director of Operations, Center for Positron Emission Tomography, Veterans Administration Western New York Health Care System, Buffalo

62. Toxic and Metabolic Encephalopathies

Oscar L. Lopez, M.D.
Associate Professor of Neurology and Psychiatry, University of Pittsburgh

72. The Dementias

David N. Louis, M.D.
Professor of Pathology, Molecular Pathology Unit, Harvard Medical School; Associate Chief of Pathology, Massachusetts General Hospital, Boston

S8B. Cancer and the Nervous System: Pathology and Molecular Genetics of Nervous System Tumors

Betsy B. Love, M.D.
Clinical Assistant Professor of Neurology, Indiana University School of Medicine, Indianapolis

S7A. Vascular Diseases of the Nervous System: Ischemic Cerebrovascular Disease

Robert G. Mair, Ph.D.
Professor of Psychology, University of New Hampshire, Durham

20. Disturbances of Taste and Smell

Donald W. Marion, M.D.
Professor and Chairman, Department of Neurological Surgery, Boston University School of Medicine; Neurosurgeon-in-Chief, Boston Medical Center, Boston, Massachusets

56B. Trauma of the Nervous System: Craniocerebral Trauma

Christopher J. Mathias, M.B.B.S., D.Phil., F.R.C.P.
Professor of Neurovascular Medicine, Imperial College School of Medicine and University Department of Clinical Neurology, Institute of Neurology, University College London; Consultant Physician, Neurovascular Medicine Unit, St. Mary's Hospital; Consultant Physician, Autonomic Unit, The National Hospital for Neurology and Neurosurgery, London, United Kingdom

83. Disorders of the Autonomic Nervous System

Michael J. McLean, M.D., Ph.D.
Associate Professor, Department of Neurology, Vanderbilt University Medical Center, Nashville, Tennessee

49. Principles of Neuropharmacology and Therapeutics

Mario F. Mendez, M.D., Ph.D.
Director, Neurobehavior Unit, VA Greater Los Angeles Healthcare System; Professor of Neurology and Pyschiatry and Biobehavioral Sciences, David Geffcn School of Medicine at the University of California at Los Angeles

4. Delirium

David J. Michelson, M.D.
Fellow in Child Neurology, Department of Pediatrics, Loma Linda University School of Medicine, Loma Linda, California

7. *Global Developmental Delay and Developmental Regression*

Van S. **Miller, M.D.**
Texas Child Neurology, LLP, Piano, Texas

71. Neurocutaneous Syndromes

Karl E. Misulis, M.D., **Ph.D.**
Clinical Professor of Neurology, Vanderbilt University School of Medicine, Nashville; Neurologist, Semmes-Murphey Clinic, Jackson, Tennessee

26. Hemiplegia and Monoplegia; 31. Sensory Abnormalities of the Limbs, Trunk, and Tace; 34. Lower Back and Lower Limb Pain

Hiroshi Mitsumoto, M.D., D.Sc.
Wesley J. Howe Professor, Department of Neurology, Columbia University College of Physicians and Surgeons; Director, The Eleanor and Lou Gehrig MNA/ALS Research Center; Head, Neuromuscular Diseases Division, Columbia-Presbyterian Hospitals, New York

80. Disorders of Upper and Lower Motor Neurons

Paul L. Moots, M.D,
Associate Professor of Neurology, Vanderbilt University Medical Center, Nashville, Tennessee

SO. Principles of Pain Management

Carlos T. Moracs, M.D.
Associate Professor of Neurology and Cell Biology and Anatomy, University of Miami School of Medicine, Miami, Florida

69. Mitochondrial Disorders

Brian Murray, M.B., B.Ch., B.A.O., M.Sc.
Consultant Neurologist, Department of Neurology, Mater Misericordiac and University Hospital, Dublin, Ireland

S6D. Trauma of the Nervous System: Peripheral Nerve Trauma; 80. Disorders of Upper and Lower Motor Neurons

Ruth Nass, M.D.
Professor of Clinical Neurology, New York University School of Medicine; Attending Pediatric Neurologist, New York University Medical Center, New York

67. Developmental Disabilities

Carissa Nehl, B.S.
Graduate Research Assistant, Universiry of Iowa Hospitals and Clinics, Iowa City
S. *Behavior and Personality Disturbances*

Michael J. Olek, D.O.
Assistant Professor of Neurology; Director, Multiple Sclerosis Center, University of California at Irvine, Irvine
60. Multiple Sclerosis and Other Inflammatory Demyelinating Diseases of the Central Nervous System

Gregory M. Pastores, M.D.
Assistant Professor, Neurology and Pediatrics, New York University School of Medicine, New York
68. Inborn Errors of Metabolism of the Nervous System

Jane S. Paulsen, Ph.D.
Professor, Departments of Psychiatry, Neurology, Psychology, and Neuroscicnces, Roy and Lucille Carver College of Medicine, The University of Iowa, Iowa City; Director, Psychology Division in Psychiatry, The University of Iowa Hospitals and Clinics, Iowa City
S. Behavior and Personality Disturbances; 38. Neuropsychology

Timothy A. Pedley, M.D.
Henry and Lucy Moses Professor of Neurology and Chairman, Department of Neurology, Columbia University College of Physicians and Surgeons; Neurologist-in-Chief, The Neurological Institute of New York, Columbia-Presbyterian Medical Center, New York
36A. Clinical Neurophysiology: Electroencephalography and Evoked Potentials

Arie Perry, M.D.
Associate Professor, Department of Pathology and Immunology, Division of Neuropathology, Washington University School of Medicine; Associate Professor of Pathology, Barnes-Jewish and St. Louis Children's Hospital, St. Louis, Missouri
58B. Cancer and the Nervous System: Pathology and Molecular Genetics of Nervous System Tumors

Alan Pestronk, M.D.
Professor of Neurology and Pathology, and Director, Neuromuscular Clinical Laboratory, Washington University School of Medicine, St. Louis, Missouri
29. Muscle Pain and Cramps

Ronald F. Pfeiffer, M.D.
Professor and Vice Chairman, Department of Neurology, Universiry of Tennessee Health Science Center, Memphis
13. Neurogenic Dysphagia

David C. Preston, M.D.
Professor of Neurology, Case Western Reserve University School of Medicine; Director of the Neuromuscular Service, University Hospitals of Cleveland, Cleveland, Ohio
28. Proximal, Distal, and Generalized Weakness

Bruce H. Price, M.D.
Assistant Professor in Neurology, Harvard Medical School, Boston; Assistant in Neurology, Massachusetts General Hospital, Boston; Chief, Department of Neurology, McLean Hospital, Belmont, Massachusetts
9. Depression and Psychosis in Neurological Practice

Louis J. Ptacek, M.D.
Investigator, Howard Hughes Medical Institute, and Professor, Department of Neurology, University of California at San Francisco, San Francisco
70. Channelopathies: V.pisodic and Electrical Disorders of the Nervous System

Robert M. Quencer, M.D.
Professor and Chairman of Radiology, Neurological Surgery and Ophthalmology, University of Miami School of Medicine/Jackson Memorial Medical Center, Miami, Florida
37A. Neuroimaging: Structural Neuroimaging

Robert A. Ratcheson, M.D.
Harvey Huntington Brown, Jr., Professor and Chairman of Neurological Surgery, Case Western Reserve University-School of Medicine; Director of Neurological Surgery, University Hospitals of Cleveland, Cleveland, Ohio
57C. Vascular Diseases of the Nervous System: Intracranial Aneurysms and Subarachnoid Hemorrhage; 57D. Vascular Diseases of the Nervous System: Arteriovenous Malformations

Scott L. Rauch, M.D.
Associate Chief of Psychiatry, Harvard Medical School; Director, Psychiatric Neuroimaging Research, and Associate Chief of Psychiatry for Neuroscience Research, Massachusetts General Hospital, Boston
37E. Neuroimaging: Functional Neuroimaging

Michael **Ronthal, M.B.B.Ch., F.R.C.P.**
Associate Professor of Neurology, Harvard Medical School; Deputy Chief of Neurology, Beth Isreal Deaconess Medical Center, Boston, Massachusetts
33. Arm and Neck Pain

Richard B. Rosenbaum, M.D.
Clinical Professor of Neurology, Oregon Health and Sciences University and Neurology Division, The Oregon Clinic, Portland
79. *Disorders of Bones, Joints, Ligaments, and Meninges*

Bernd F. Remler, M.D.
Professor of Neurology and Ophthalmology, Medical College of Wisconsin; Staff Physician, Department of Neurology, Froedtert Memorial Lutheran Hospital, Milwaukee, Wisconsin
3. Falls and Drop Attacks

E. Steve Roach, M.D.
Professor of Neurology, Wake Forest University School of Medicine; Director, Comprehensive Epilepsy Program, Wake Forest University Baptist Medical Center, Winston-Salem, North Carolina
71. Neurocutaneous Syndromes

Gary A. Rosenberg, M.D.
Professor and Chairman of Neurology, Departments of Neurology, Neurosciences, Cell Biology and Physiology, University of New Mexico Health Sciences Center; Chief of Neurology Service, University of New Mexico Hospital, Albuquerque
65. *Brain Edema and Disorders of Cerebrospinal Fluid Circulation*

Myrna R. Rosenfeld, M.D., Ph.D.
Associate Professor of Neurology; Division Chief, Neuro-Oncology, University of Pennsylvania School of Medicine, Philadelphia
58H. Cancer and the Nervous System: Paraneoplastic Disorders of the Nervous System

Leslie J. Gonzalez Rothi, Ph.D.
Professor of Neurology, University of Florida, Gainesville; Research Career Scientist and Director, Brain Rehabilitation Research Center, VA Medical Center, Gainesville, Florida
10. Intentional Motor Disorders and the Apraxias

Armando Ruiz, M.D.
Voluntary Assistant Professor of Radiology, University of Miami School of Medicine, Miami, Florida
37A. Neuroimaging: Structural Neuroimaging; 37B. Neuroimaging: Computed Tomographic and Magnetic Resonance Vascular Imaging

Marcin Sadowski, M.D., Ph.D.
Assistant Professor of Neurology, New York University School of Medicine; Attending Physician, New York University Medical Center and Bellevue Hospital, New York
59G. Infections of the Nervous System: Prion Diseases

Gaurav Saigal, M.B.B.S.
Neuroradiology Fellow, University of Miami School of Medicine, Miami, Florida
37 B. Neuroimaging: Computed Tomographic and Magnetic Resonance Vascular Imaging

Donald B. Sanders, M.D.
Professor of Medicine, Division of Neurology, Duke University Medical Center, Durham, North Carolina
84. Disorders of Neuromuscular Transmission

Johnny S, Sandhu, M.D.
Department of Radiology, University of Miami School of Medicine, Miami, Florida
37C. Neuroimaging; Neuroangiographic Anatomy and Common Cerebrovascular Diseases; 53. Principles of Endovascular Surgery

Paul Santiago, M.D.
Spine Fellow, Section of Neurological Surgery, University of Chicago, Chicago, Illinois
56C. Trauma of the Nervous System; Spinal Cord Trauma

Cesar C. Santos, M.D.
Associate Professor of Neurology and Pediatric Neurology; Section 1 lead, Pediatric Neurology, Wake Forest University School of Medicine; Chief, Section of Pediatric Neurology and Director, Neurology Training Program, Wake Forest University Baptist Medical Center, Winston-Salem, North Carolina
71. Neurocutaneous Syndromes

Harvey **B. Sarnat, M.D.,** F.R.C.P.C.
Professor of Pediatrics (Neurology) and Pathology (Neuropathology), David Geffen School of Medicine at UCLA; Director, Division of Pediatric Neurology and Neuropathologist, Cedars-Sinai Medical Center, Los Angeles, California
66. Developmental Disorders of the Nervous System

David Schiff, M.D.
Associate Professor of Neurology, Neurological Surgery, and Medicine; Co-director, Ncuro-Oncology Center, University of Virginia Medical Center, Charlottesville
S8G. Cancer and the Nervous System: Nervous System Metastases

James W. Schmidley, M.D.
Professor of Neurology, University of Arkansas for the Medical Sciences, Little Rock
S7G. Vascular Diseases of the Nervous System: Central Nervous System Vasculitis

James M. Schumacher, M.D.
Neurological Associates, P.A., Sarasota, Florida
52. *Principles of Neurosurgery*

Neil E. Schwartz, M.D.
Chief Resident, Department of Neurology, Stanford University Medical Center, Palo Alta, California

Preface to the Fourth Edition

When preparing the preface to the first edition of *Neurology in Clinical Practice* in 1990, we highlighted the principles upon which the new textbook was based. We wrote that we had long felt the need for a practical textbook of neurology that covered all the clinical neuroscienccs and provided not only a description of neurological diseases and their pathophysiology but also a practical approach to their diagnosis and management. We emphasized that neurology is intellectually challenging because of the complexity of the nervous system, and fascinating because of the insight that neurological disease provides into the workings of the brain and mind. We recognized the major technological and research advances that were coming, and looked with excitement to the not-too-distant future when more of the neurological diseases would be completely understood, when many of the biochemical defects would be correctible, and when effective regeneration of the central and peripheral nervous systems might be possible. Nevertheless, we believed then, as we do now, that technology must remain the servant of the clinician and never become the master.

Now, thirteen years later, those words are yet more relevant, the hopes are nearer to achievement, and we believe that the book remains true to the original principles.

The first edition of *Neurology in Clinical Practice* won the Most Outstanding Book Award of the Association of American Publishers (Professional and Scholarly-Publication Division). At the time of publication of the third edition in 2000, we sadly lost David Marsden, a founder and co-editor of the first three editions. This fourth edition welcomes Joseph Jankovic as co-editor.

This fourth edition has been completely rewritten, and almost half of the chapters were prepared by new authors. In addition, new chaprers are provided on cndovascular surgery and mitochondrial and ion channel disorders.

This book is the amalgam of the scholarly contributions of all our colleagues who wrote the chapters and provided the illustrations and website material. We are deeply grateful to them for their selfless devotion to neurological education. A project of this magnitude would not have been possible without the encouragement and wisdom of Susan Pioli, Executive Publisher for Global Medicine at Elsevier. She was an active participant at every stage of the development of this book. Mary Beth Murphy, Senior Development Editor at Elsevier, was the key person drawing this, product together. Additionally, we thank Joan Sinclair, Production Manager, and Kelly Mabie, Production Editor, without whose energy and efficiency this book would not have seen the light of day. Finally, we acknowledge the contributions of our readers, whose feedback on the *NICP* family of books and website has been invaluable in assisting us to improve this scries of educational instruments,

Over these thirteen years, the *Neurology in Clinical Practice* family of publications has expanded to include the Pocket Companion, the Review Manual, several translations into other languages, and, most important, the website, www.nicp.com. Starting with the third edition of Neurology in Clinical Practice, we developed and launched this innovative and unique website. With this fourth edition, we will continue to expand this dynamic electronic edition of the book. The website publication provides what the print cannot: regularly posted updates on recent advances in clinical neurology; videos showing eye movements, movement disorders, EMG waveforms, and other material; expanded references to the literature; and additional depth of clinical material from other leading Elsevier neurology texts with e-commerce availability.

The *Pocket Companion to NICP*, which is a true synopsis of the two volumes, will be published shortly after the fourth edition of *Neurology in Clinical Practice.* It continues to be a rewritten, condensed, and accessible version ol the most clinically needed material derived from the "parent" two volumes. This companion is a portable quick reference that will lead the reader back to the two volumes for more in-depth coverage.

The *Review Manual for Neurology in Clinical Practice*, written by Karl Misulis and edited by the four Editors, will also be published shortly after the fourth edition of *Neurology in Cltntcal Practice.* This question-and-answer workbook is organized according to the chapters of the fourth edition of *Neurology in Clinical Practice.* The questions are useful in preparing for the Resident In-Service and Board examinations, and the answers provide explanations and referrals to the main two volumes for more complete consideration of the subject matter.

Approach to Common Neurological Problems

Parti

Approach to Common Neurological Problems

Chapter 1
Diagnosis of Neurological Disease

Walter G. Bradley, Robert B. Daroff, Gerald M. Fenichel, and Joseph Jankovic

The neurological diagnosis in a patient is sometimes easy, but at other times it may be quite challenging, requiring specialized skills. If a patient shuffles into the doctor's office and has a pill-rolling tremor of the hands and loss of facial expression, it is not difficult to come to a diagnosis of Parkinson's disease. However, it is important to remember that while it is very satisfying to make such a spot diagnosis, the patient may actually he coming for help with a totally different neurological problem, and therefore an evaluation of the whole problem is necessary.

In all branches of medicine, the history of the symptoms and the clinical examination of the patient are the keys to achieving a diagnosis. This is particularly true in neurology. The standard practice in neurology is to record the patient's chief complaint and take a history of the development of the symptoms, followed by the history of illnesses and surgeries, the family history, the personal and social history, and a review of any symptoms involving the main body systems. The neurologist then performs a neurological examination, and constructs a differential diagnosis of the possible causes of the patient's symptoms. Although this process is also used in making general medical and surgical diagnoses, whar is unique to neurology is the extreme attention to "localization." When a patient presents to an internist or surgeon with abdominal or chest symptoms, the localization is practically established by the symptoms, and the etiology then becomes the primary concern. However, a neurological patient with a weak hand may have a lesion localized to the muscles, the neuromuscular junction, nerve or nerves in the upper limb, brachial plexus, spinal cord, or brain. The neurological examination is essential in determining the site (localization) of the offending lesion. In general, the history provides the best clues fot etiology and the examination is essential for localization.

This diagnostic process consists of a series of steps (Figure 1.1). Although the standard teaching is that the patient should be allowed to provide the history in his or her own words, each step of the process involves active questioning of the patient by the neurologist. At each step, the neurologist should consider rhe possible anatomical localizations, and particularly the etiology of the symptoms (see Figure 1.1). From rhe patient's chief complaint and a detailed history, an astute neurologist can derive clues that lead first to a hypothesis about the location, and then to a hypothesis about the etiology of the neurological lesion. From these hypotheses, the experienced neurologist can predicr what abnormal neurological signs should he present and what should be absent, thereby allowing confirmation of the site of the dysfunction. Alternatively, analysis of the history may suggest two or more possible anatomical locations and diseases, each with a different predicted consrellation of abnormal neurological signs. The findings on neurological examination can be used to determine which of these various possibilities is the most likely. To achieve a diagnosis, the neurologist needs not only to have a good knowledge of the anatomy, physiology, and biochemistry of the nervous system, but also of the clinical features and pathology of the neurological diseases.

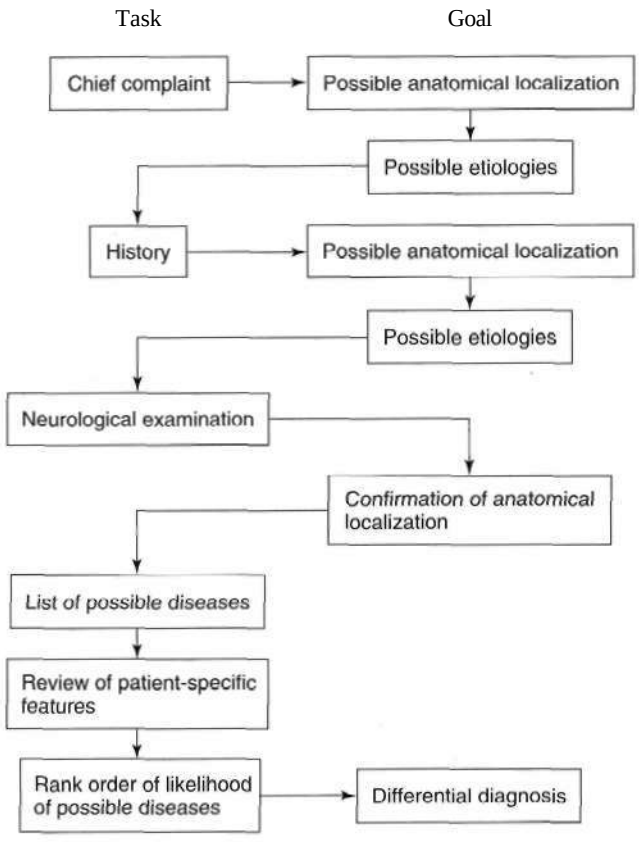

FIGURE 1.1 The diagnostic path is illustrated as a series of steps in which the neurologist collects data (the Task) with the object of providing information on the anatomical localization and nature of the disease process (the Goal).

THE NEUROLOGICAL INTERVIEW

The neurologist is often an intimidating figure for many patients. To add to the stress of the neurological interview and examination, the patient may already have a preconceived notion that the disease causing the symptoms is horrible and life threatening. Because of this background, the neurologist should do everything possible to put the patient at case, and to be empathetic. It is important to introduce oneself to the patient and exchange social pleasantries before leaping into the interview. A few opening questions can break the ice. "How old are you?" "What type of work have you done most of life?" "Who is your doctor, and who would you like me to write to?" "Are you right- or left-handed?" After this, it is easier to ask the first important question: "What brings you to see me? What is your main problem?"

Another technique is to begin by asking the patient, "How can I help you?" This establishes that the doctor is there to ptovide a service and allows patients to express their expectations for the consultation. It is important for the physician to get a sense of patient's expectations from the visit. Usually they want the doctor to find or confirm the diagnosis, and to cure the disease. Sometimes the patient comes hoping that something is *not* present ("Please tell me that my headaches are *not* caused by a brain tumor!"). Sometimes the patient says that other doctors "never told me anything" (which may be true, although in many cases the patient cither did not hear or did not like what was said).

CHIEF COMPLAINT

The chief complaint (or the several main complaints) is the usual starting point of the diagnostic process. An example might be a patient presenting with the triad of complaints of headache, clumsiness, and double vision. The complaints serve to focus attention on the questions to be addressed while taking the history and provide the first clue to the anatomy and etiology of the disease underlying the complaints. In this case, the neurologist would be concerned that the patient might have a tumor in the posterior fossa affecting the cerebellum and brainstem. The mode of onset is critically important in determining the etiology. For example, a sudden onset usually indicates a vascular etiology such as a cerebral infarction or hemorrhage. A course characterized by exacerbations and remissions may suggest multiple sclerosis, whereas a slowly progressive course indicates a neoplasm. Paroxysmal episodes suggest the possibility of seizures; migraines; or some paroxysmal dyskinesias, ataxias, or periodic paralyses.

HISTORY OF PRESENT ILLNESS

Often the patient will give a very clear history of the temporal development of the complaints, the location and severity of the symptoms, and the current level of disability. However, some patients, particularly the elderly, are tangential and insist on telling what other doctors did or said, rather than relating their own symptoms. Direct questioning is often needed to clarify the symptoms, but it is important not to lead the patient. Patients are all too ready to give a positive response to an authority figure, even if it is patently incorrect. It is important to consider whether the patient is reliable. Reliability depends on the patient's intelligence, memory, language function, educational and social status, and whether there are secondary gain issues, such as a disability claim or pending lawsuit.

One should suspect a somatofotm disorder in any patient who claims to have symptoms involving multiple organ systems. Getting information from an observer other than the patient is important for characterizing many neurological conditions, such as seizures and dementia. Taking a history from a child is complicated by shyness with strangers, a different sense of time, and a limited vocabulary. In children, the history is always the composite perceptions of the child and the parent.

Patients and physicians may use the same word to mean very different things. If the physician accepts the word at face value, without ensuring that the patient uses the word in the same way as the doctor, misinterpretation may lead to misdiagnosis. For instance, patients often describe a limb as being "numb" when it is actually paralyzed. Patients often use the term "dizziness" to refer to confusion or weakness and not vertigo. A patient may describe vision as being "blurred" when further questioning reveals diplopia. "Blackouts" may be loss of consciousness, loss of vision, or simply confusion. "Pounding" or "throbbing" headaches are not necessarily pulsating.

The neurologist must understand fully the nature, onset, duration, and progression of each symptom and the temporal relationship of one symptom to another. Are the symptoms getting better, staying the same, or getting worse? What relieves them and what makes them worse? In infants and young children, temporal sequence also includes the timing of developmental milestones; failure to achieve a milestone is as important as loss of achievement.

An example may clarify how the history leads to diagnosis. A 28-year-old woman presents with a 10-year history of recurrent headaches associated with her menses. The unilateral quality of pain in some attacks and the association of flashing lights, nausea, and vomiting points to the diagnosis of migraine. On the other hand, if the same patient has a progressively worsening headache upon wakening, has new onset seizures, and is developing a hemiparesis, this suggests an intracranial space-occupying lesion. Both the absence of expected features and the presence of unexpected features may assist in the diagnosis. A patient with numbness of the feet might have a peripheral neuropathy, but the presence of backache and loss of sphincter control suggests that a spinal cord or cauda equina lesion is more likely.

Patients may arrive for a neurological consultation with a folder of previous laboratory tests and neuroimaging studies. They often dwell on these tests and their interpretation by other physicians. Be wary of accepting the opinions of other doctors; they may have been wrong! The careful neurologist takes a new history and makes a new assessment of the prohlem.

The history of how the patient or the caregiver responded to the symptoms may be important. A pattern of overreaction may be of help in evaluating the significance of the complaints. However, a night visit to the emergency department for a new-onset headache should not be dismissed without investigation. Conversely, the child who was *not* brought to the hospital despite hours of seizures is likely to be the victim of child abuse, or at least of neglect.

REVIEW OF PATIENT SPECIFIC INFORMATION

Information about the patient's background often greatly helps the neurologist make a diagnosis of the cause of the symptoms. This information includes the history of medical and surgical illnesses; current medications and allergies; a review of symptoms in non-neurological systems of the body; the personal history in terms of occupation, marital status, and alcohol, tobacco, and illicit drug use; and the medical history of the parents, siblings, and children, looking for evidence of familial diseases. The order in which these items are considered is not important but consistency avoids something being forgotten.

In the outpatient office, the patient can be asked to complete a form with a series of questions on all of these matters before starting the consultation with the physician. This expedites the interview, although more details are often needed. What chemicals is the patient exposed to at home and at work? Did the patient *ever* use alcohol, tobacco, or prescription or illegal drugs? *h* thete excessive stress at home, in school, or in the workplace, such as divorce, death of a loved one, or loss of employment? Are there hints of abuse or neglect of children or spouse? Sexual preference is important information in this era of human immunodeficiency virus infection. The doctor should question children and adolescents away from their parents if there is a need to obtain mote accurate information about sexual activity and substance abuse.

Review of Systems

The review of systems should include the elements of nervous system function that did not surface in taking the history. The neurologist should have covered the following: cognition, personality and mood change; hallucinations; seizures and other impairments of consciousness; ortho static faintness; headaches; special senses; speech and language function; swallowing; limb coordination; slowness of movement; involuntary movements; strength and sensation; pain; gait and balance; and sphincter, bowel, and sexual function. A positive response m.iy help clarih a diagnosis. For instance, if a patient complaining of ataxia and hemiparesis admits to unilateral deafness, this may suggest an acoustic neuroma. Headaches in a patient with pataparesis suggest a parasagittal meningioma rather than a spinal cord lesion. The developmental history must be assessed in children and may also be of value in adults whose illness started during childhood. The review must include all the organ sysrems. Neurological function is adversely affected by dysfunction of many systems, including the liver, kidney, gastrointestinal tract, heart, and blood vessels. Several neurological diseases are characterized by multi-organ involvement, such as vasculitis, sarcoidosis, mitochondrial disorders, and storage diseases.

History of Previous Illnesses

Items in the patient's medical and surgical history may help explain the present complaint. For instance, seizures and

worsening headaches in a patient who previously had surgery for lung cancer suggest a brain metastasis. Chronic low-back pain in a patient complaining of numbness and weakness in the legs on walking half a mile suggests neurogenic claudication from lumbar canal stenosis. The record of the history should include dates and details of all surgical procedures; significant injuries, including head trauma and fractures; hospitalizations; and conditions requiring medical consultation and medications. For pediatric patients, information on the pregnancy and state of the infant at birth should be recorded.

Certain features in the patient's history should always alert the physician to the possibility that they may be responsible for the neurological complaints. Gastric surgery may lead to vitamin B12 deficiency. Sarcoidosis may cause Bell's palsy, diabetes insipidus, ophthalmoplegia, and peripheral neuropathy. Disorders of the liver, kidney, and small bowel can be associated with a wide variety of neurological disorders. Systemic malignancy can cause direct and indirect (paraneoplastic) neurological problems.

Do not be surprised if the patient fails to remember previous medical or surgical problems. It is common to find abdominal scars on a patient who described no surgical procedures until questioned about the scars.

Medications are often the cause of neurological disturbances, particularly chemotherapy drugs. Isoniazid may cause a peripheral neuropathy. Lithium carbonate may produce tremor and ataxia. Neuroleptic agents can produce a parkinsonian syndrome or dyskinesias. Most patients do not think of vitamins, oral contraceptives, non-prescription analgesics, and herbal compounds as medications, and specific questions about these agents are necessary.

Family History

Many neurological disorders are hereditary. Hence a history of similar disease in family members or of consanguinity may be of diagnostic importance. However, the expression of a gene mutation may be quite different from one family member to another with respect not only to the severity of neurological dysfunction but also to the organ systems involved. For instance, the mutations of the gene for Mach ado-Joseph disease (SCA 3) can cause several phenotypes. A patient with Charcot-Marie-Tooth disease (hereditary motor-sensory neuropathy) may have a severe peripheral neuropathy, whereas relatives may have only pes cavus.

Reported diagnoses may be inaccurate. In families with dominant muscular dystrophy, affected individuals in earlier generations are often said to have had "arthritis" that put them into a wheelchair. Some conditions, such as epilepsy, may be "family secrets." Therefore, one should be cautious in accepting a patient's assertion that there is no family history of a similar disorder. If there is a possibility that the disease is inherited it is helpful to obtain information from parents and grandparents and to examine relatives at risk. Minimum data for all first- and second-degree relatives should include age (currently or at death), cause of death, and any significant neurological or systemic diseases.

THE EXAMINATION

Neurological Examination

A description of the neurological examination may be found in several excellent textbooks (see References), Trainees must be able to perform and understand the complete neurological examination, in which every central nervous system region, peripheral nerve, muscle, sensory modality, and reflex is tested. However, the full neurological examination is too lengthy to perform in practice. Instead, the experienced neurologist uses the *focused neurological examination* to examine in detail the neurological functions that are relevant to the history, and performs a *screening neurological examination* to check the remaining parts of the nervous system. This approach should confirm, refute, or modify the initial hypotheses of disease location and causation derived from the history (see Figure 1.1). Both the presence and absence of abnormalities may be of diagnostic importance. For instance, if a patient's symptoms suggest a left hemiparesis, the neurologist searches carefully for a left homonymous hemianopia; evidence that the blink or smile is slowed on the left side of the face; that rapid, repetitive movements are impaired in the left limbs; that the tendon reflexes are more brisk on the left than the right; that the left abdominal reflexes are absent; and that the left plantar response is extensor. Along with testing the primary modalities of sensation on the left side, the neurologist may examine the higher integrative aspects of sensation, including graphesthesia, stereognosis, and sensory extinction with double simultaneous stimuli, The presence or absence of some of these features can separate a left hemiparesis arising from a lesion in the right cerebral cortex or from one in the left cervical spinal cord.

The screening neurological examination {Table 1.1) is designed for quick evaluation of the mental status, cranial nerves, motor system (strength, muscle tone, presence of involuntary movements and postures), coordination, gait and balance, tendon reflexes, and sensation. More complex functions are tested first; if these are performed well, then it may not be necessary to test the component functions. The patient who can walk hccl-to-toe (tandem gait) does not have a significant disturbance of the cerebellum or of joint position sensation. Similarly, the patient who can do a pushup, rise from the floor without using the hands, and walk on toes and heels will have normal limb strength when each muscle group is individually tested. Asking the patient to hold the arms extended in supination in front of the body with the eyes open allows evaluation of strength and posture. It may also reveal involuntary movements such as tremor, dystonia,

Table 1.1: Outline of the screening neurological examination

Mental status: Assess while recording the history.
Cranial nerves:
I: Not tested
II: Gross visual acuity each eye:
Visual fields by confrontation, including double simultaneous stimuli
Rmduscopy
III, IV, VI; Horizontal and vertical eye movements
Pupillary response to light
Presence of nystagmus
V: Pinprick and touch sensation on face, corneal reflex
VII: Close eyes, show teeth
VIII: Perception of whispered voice in each car or rubbing of fingers. If impaired, look in external auditory canals, and use tuning fork for lateralization and hone versus air sound conduction.
IX, X: Palate lifts in midline, gag reflex present
XI: Shrug shoulders
XI!: Protrude tongue
Limbs: Each limb tested separately:
Presence of involuntary movements
Muscle mass (atrophy, hypertrophy) and look for fascidilations
Muscle tone in response to passive flexion and extension
Power of main muscle groups
Coordination; finger-to-nose and hccl-to-shin testing, performance of rapid alternating movements
Tendon reflexes
Plantar responses
Pinprick and light touch on hands and feet
Double simultaneous stimuli on hands and feet
Joint position sense in hallux and index finger
Vibration sense at ankle and index finger
Gait and balance
Romberg test

myoclonus, or chorea. A downward or pronator drift of a weak arm is expected. Repeating the maneuver with the eyes closed allows assessment of joint position sensation.

The screening neurological examination may miss important neurological abnormalities. For instance, a bitemporal visual field defect may not be detected when the fields of both eyes are tested simultaneously. It is necessary to test each eye separately. Similarly, a parietal lobe syndrome may go undiscovered unless visuospatial function is assessed.

It is sometimes difficult to decide whether a physical finding is normal or abnormal, and only experience prevents the neurologist from misinterpreting as a sign of disease something that is the result of normal variation. Every person has some degree of asymmetry. Moreover, what is abnormal in young adults may be normal in the eldetly. Loss of the ankle reflex and loss of vibration sense at the big toes are common findings in patients older than 60 years. Conversely, children cannot detect the distal stimuli when the hand and face are simultaneously touched on the same side of the body until they are 7 years old.

The experienced neurologist understands the normal range of neurological variation, while the beginner frequently records mild impairment of a number of different functions. These include isolated deviation of the tongue or uvula to one side and minor asymmetries of reflexes or sensation. Such *soft signs* may be incorporated into the overall synthesis of the disorder if they are consistent with other parts of the history and examination; otherwise, they should be disregarded. If an abnormality is identified, all features that are usually associated should be sought. For instance, ataxia of a limb may result from a corticospinal tract lesion, sensory defect, or cerebellar lesion. If the limb incoordination is due to a cerebellar lesion, there will be ataxia on finger-to-nose and hccl-to-shin testing, abnormal rapid alternating movements of the hands (dysdiadochokinesia), and often nystagmus and ocular dysmetria. If some of these signs of cerebellar dysfunction are missing, examination of joint position sense, limb strength, and reflexes may demonstrate that this incoordination is due to something other than a cerebellar lesion.

At the end of the neurological examination, the abnormal physical signs should be classified as definitely abnormal *(bard signs)* or equivocally abnormal *(soft signs).* The hard signs, when combined with symptoms from the history, allow the neurologist to develop a hypothesis about the anatomical site of the lesion or at least about the neurological pathways involved. The soft signs can then be reviewed to determine if they conflict with or support the initial conclusion. Remember that the primary purpose of the neurological examination is to reveal functional disturbances that localize abnormalities. The standard neurological examination is less effective when used to monitor the course of a disease or its temporal response to treatment. Special quantitative functional tests and rating scales are needed to measure change in neurological function over time.

General Physical Examination

The nervous system is damaged in so many general medical diseases that a general physical examination is an integral pan ol the examination ol patients with neurological disorders. For instance, atrial fibrillation, valvular heart disease, or an atrial septal defect may cause embolic strokes in the central nervous system. Hypertension increases the risk for all types of stroke. Signs of malignancy raise the possibility of metastatic lesions of the nervous system or paraneoplastic neurological syndromes, such as a subacute cerebellar degeneration or progressive multifocal leukocnccphalopathy. In addition, some diseases such as vasculitis and sarcoidosis affect both the brain and other organs.

ASSESSMENT OF THE CAUSE OF THE PATIENT'S SYMPTOMS

Anatomical Localization

At the completion of the history, the experienced neurologist should attempt the first assessment of the anatomical

location of the lesion or the neurological systems involved, and of the pathophysiology of the disorder (see Figure 1.1). The experienced neurologist then uses the examination to localize the lesion before trying to determine its cause. The initial question is whether the disease is in the brain, spinal cord, peripheral nerves, neuromuscular junctions, or muscles. Then it must be established whether the disorder is focal, multifocal, or a system disorder. A system disorder is a disease that causes degeneration of one part of the nervous system, while it spares other adjacent ncutological systems. For instance, degeneration of the corticospinal tracts and spinal motor neurons with sparing of the sensory pathways of the central and peripheral nervous systems is the hallmark of the system degeneration termed *motor neuron disease* or *amyotrophic lateral sclerosis.* Another example of a system degeneration is multiple system atrophy, manifested by slowness of movement (parkinsonism), ataxia, and dysautonomia.

The first step in localization is to translate the patient's symptoms and signs into abnormalities of a nucleus, tract, ot system. For instance, loss of pain and temperature sensation on one-half of the body, excluding the face, indicates a lesion of the contralateral spinothalamic tract in the high cervical spinal cord. A left sixth nerve palsy, with weakness of left face and right limbs, points to a left pontine lesion, A left homonymous hemianopia indicates a lesion in the right optic tract, optic radiations, or occipital cortex. The neurological examination plays a crucial role in localizing the lesion. A patient complaining of tingling and numbness in the feet might initially be thought to have a peripheral neuropathy. If examination shows hyperreflcxia in the arms and legs, and no vibration sensation below the clavicles, the lesion is likely to be in the spinal cord, and the many causes of peripheral neuropathy can be dropped from consideration. A patient with a history of weakness of the left arm and leg who is found on examination to have a left homonymous hemianopia has a right cerebral lesion, not a cervical cord problem.

The neurologist must decide if the symptoms and signs could all arise from one focal lesion or whether several anatomical sites must be involved. The *principle of parsimony,* or *Occam's razor,* requires that we strive to hypothesize only one lesion. The differential diagnosis for a single focal lesion is significantly differenr from that for multiple lesions. Thus a patient complaining of loss of left-sided vision and left-sided weakness is likely to have a lesion in the right cerebral hemisphere, possibly caused by stroke or rumor. On the other hand, if the visual difficulty is due to a central scotoma in the left eye, and if the upper motor neuron weakness affects the left limbs but spates the lower cranial nerves, there must be two lesions: one in the left optic nerve and one in the left corticospinal tract below the medulla, as seen, for example, in multiple sclerosis. If a patient with symptoms of slowly progressive slurring of speech and difficulty walking is found to have ataxia of the arms and legs, bilateral extensor plantar responses, and optic atrophy, the lesions must either be multifocal (affecting brainstem and optic nerves, and hence probably multiple sclerosis) or a system disorder, such as a spinocerebellar degeneration. The complex vascular anatomy of the brain can sometimes cause multifocal neurological deficits to tesult from only one vascular abnormality. For instance, a patient with occlusion of one vertebral artery may suffer a srroke producing a midbrain lesion, a hemianopia, and an amnestic syndtome.

Synthesis of symptoms and signs into the anatomical localization of a lesion requires a good knowledge of neuroanatomy, including the location of all major pathways in the nervous system and their inter-relationships at different levels. In making this synthesis, the ttainee will find it helpful to refer to diagrams that show transverse sections of the spinal cord, medulla, pons, and midbrain; the brachial and lumbosacral plexuses; and the dermaromes and myotomes. Knowledge of the functional anatomy of the cerebral cortex and the blood supply of the brain and spinal cord is also essential.

Symptoms and signs may arise not only from disturbances caused at the focus of an abnormality *(focal localizing signs)* but also at a distance. One example is the damage that results from the shift of intracranial contents produced by an expanding supra tentorial tumor. This may cause a palsy of the third or sixth cranial nerve, even though the tumor is far from the cranial nerves. Clinical features caused by damage far from the primary site of abnormality are called *false localizing signs.* The term derives from the era before neuroimaging studies when clinical examination was the major means of lesion localization. In fact, these are not false signs but rarher rhe signs that the inttacranial shifts arc marked, alerting the clinician to the latge size of the tumor.

DIFFERENTIAL DIAGNOSIS

Once the likely site of the lesion is identified, the next step is to generate the differential diagnosis, that is, the list of diseases that may be responsible for a parienr's symptoms and signs (see Figure 1.1). The experienced neurologist automatically first considers the most likely cause of the symptoms, followed by less common causes. The beginner is happy to generate a list of the main causes of the symptoms in whatever order comes to mind. Experience indicates the most likely causes, based on the specific features of rhe patient, the parts of the nervous system affected, and the relative frequency of each disease. Remember that *rare presentations of common diseases are more common than common presentations of rare diseases.*

Sometimes only a single disease can be incriminated, but usually there are several candidate diseases. The list of possibilities should take into account both the temporal features of the patient's symptoms and the pathological

processes known to affect the relevant area of the nervous system. For example, in a patient with signs indicating a lesion of the internal capsule, the cause is likely to be stroke if the hemiplegia had a sudden onset. If there was progression over weeks or months, the cause is likely an expanding tumor. Another example is a patient with signs of multifocal lesions. If symptoms have relapsed and remitted over several years, the diagnosis is likely to be multiple sclerosis or multiple strokes (depending on the patient's age, sex, and risk factors). If symptoms appeared only recently and progressed, multiple metastases should be considered.

Again, the principle of parsimony or Occam's razor should be applied when constructing the differential diagnostic list. Consider a patient with a 3-week history of a progressive spinal cord lesion who suddenly experiences aphasia. Perhaps he or she had a tumor compressing the spinal cord and has incidentally developed a small stroke. However, parsimony would suggest a single disease, probably cancer with multiple metastases. Another example is a patient with progressive atrophy of the small muscles of the hands for 6 months before the appearance of a pseudobulbar palsy. She or he could have bilateral ulnar nerve lesions and recent bilateral strokes, but amyotrophic lateral sclerosis is more likely. However, remember that nature does not always obey the rules of parsimony.

The differential diagnosis generally starts with pathological processes, such as a stroke, a tumor, or an abscess. H;ich pathological process may result from several different diseases. Thus a clinical diagnosis of an intracranial neoplasm generates a list of the different types of tumors thar arc likely to be responsible for the clinical manifestations in this particular patient. Similarly, in a patient with a stroke the clinical history may help separate hemorrhage, embolism, thrombosis, vascular spasm, or vasculitis. The skilled diagnostician is justly proud of placing the correct diagnosis at the top of the list, but it is more important to ensure that all possible diseases are considered. If a disease is not considered, it is unlikely to be diagnosed. Treatable disorders should always be considered, even when there is a very low probability. This is especially true if they may mimic more common incurable neurological disorders, such as Alzheimer's disease or amyotrophic lateral sclerosis.

LABORATORY INVESTIGATIONS

Sometimes the neurological diagnosis can be made without any laboratory investigations. This is true for a clear-cut case of Parkinson's disease, myasthenia gravis, or multiple sclerosis. Nevertheless, even in these situations, appropriate laboratory documentation is important for other physicians who will see the patient in the future. In other cases the cause of the disease will only be elucidated by the use of laboratory tests. These tests may in individual cases include hematological and biochemical blood studies; neurophysiological testing (Chapter 36); neuroimaging (Chapter 37); organ biopsy; and bacteriological and virological studies. The use of laboratory tests in the diagnosis of neurological diseases is considered more fully in Chapter 35.

MANAGEMENT OF NEUROLOGICAL DISORDERS

Not all diseases arc curable. However, even if a disease is incurable the physician will be able to reduce the patient's discomfort and assist the patient and the family in managing the disease. The understanding of neurological diseases is a science. The diagnosis of neurological disease is a combination of science and experience. The management of neurological disease is an art, an introduction to which is provided in Chapter 48.

THE EXPERIENCED NEUROLOGIST'S APPROACH TO THE DIAGNOSIS OF COMMON NEUROLOGICAL PROBLEMS

The skills of a neurologist are learned. Seeing many cases of a disease teaches the neurologist which symptoms and signs *should he present,* and, just as important, which *should not be present.* Although there is no substitute for experience and pattern recognition, the trainee can learn the clues used by the seasoned practitioner to achieve a diagnosis. Part I of this book covers the main symptoms and signs of neurological disease. These chapters describe how an experienced neurologist approaches common presenting problems, such as a movement disorder, a speech disturbance, or diplopia, to arrive at the correct diagnosis. Part II of this book comprises rhe major fields of investigation and management of neurological disease. Part III provides a compendium of the neurological diseases themselves.

Chapter 2
Episodic Impairment of Consciousness

Joseph Bruni

Temporary loss of consciousness may be caused by impaired cerebral perfusion (syncope, fainting), cerebral ischemia, migraine, epileptic seizures, metabolic disturbances, sudden increases in intracranial pressure, or sleep disorders. Anxiety attacks, psychogenic seizutes, panic disorder, and malingering may be difficult to distinguish from these conditions. At times, the diagnosis may not be clatified without detailed laboratory examinations and prolonged periods of observation.

Syncope may result from decreased cardiac output secondary to cardiac arrhythmias, outflow obstruction, hypovolemia, orthostatic hypotension, or decreased venous return. Cerebrovascular disturbances from transient ischemic attacks of the posterior or anterior cerebral circulations or cerebral vasospasm from migraine, subarachnoid hemorrhage, or hypertensive encephalopathy may tesult in temporary loss of consciousness. Metabolic disturbances caused by hypoxia, drugs, anemia, and hypoglycemia may result in frank syncope or, more frequently, may present with the sensation of an impending faint (ptesyncope).

Absence seizures, generalized tonic-clonic seizures, and complex partial seizures are associated with alterations of consciousness and, in most cases, can be easily distinguished from syncope. Epileptic seizutes may be difficult to distinguish from pseudoseizures (psychogenic seizures), panic attacks, and malingering. In children, breath-holding spells, a form of syncope that is discussed latet in the chapter, can cause a transitory alteration of consciousness that may mimic epileptic seizures.

Although sudden increases of intracranial pressure (which may result from intermittent hydrocephalus, severe head trauma, brain tumors, inttacerebral hemorrhage, or Reye's syndrome) may produce sudden loss of consciousness, these patients frequently have other neurological manifestations that lead to this diagnosis.

In patients with episodic impaitment of consciousness, a diagnosis relies heavily on the clinical history described by the patient and observers. Laboratory investigations, however, may provide useful information. In a small number of patients, a cause for the loss of consciousness may not be established, and these patients may require longer periods of observation. Tabic 2.1 compares the clinical features of syncope and seizures.

SYNCOPE

The pathophysiologic basis of syncope is the gradual failure of cerebral perfusion with a reduction in cerebral oxygen availability. *Syncope* is often preceded by a symptom complex (presyncopc) characterized by lightheadedness, generalized muscle weakness, giddiness, visual blurring, tinnitus, and gastrointestinal symptoms. The patient may appear pale and feel cold and sweaty. The onset of loss of consciousness is generally gradual but may be rapid, without prcsyncopal symptoms, if related to certain conditions, such as a cardiac arrhythmia. The gradual onset may allow patients to protect themselves from falling and injury. A simple faint is usually precipitated by emotional stress, unpleasant visual stimuli, prolonged standing, or pain. Although the duration of unconsciousness is brief, it may vary from seconds to minutes. During the faint, the patient may be motionless or display myoclonic jerks. Urinary incontinence is uncommon but not rare. The pulse is weak and often slow. Urea thing may be shallow and the blood pressure barely obtainable. As the fainting episode cotrects itself (e.g., by the patient becoming horizontal), the color returns, breathing becomes more regular, and the pulse and blood pressure return to normal. After the faint, there is some residual weakness, hut unlike

Table 2.1: Comparison of clinical features of syncope and seizures

Features	*Syncope*	*Seizure*
Relation to posture	Common	No
Time of day	Diurnal	Diurnal or nocturnal
Precipitating factors	Emotion, injury, pain, crowc s, heat	Sleep loss, drug/alcoliol withdrawal
Skin color	Pallor	Cyanosis or normal
Aura or premonitory symptoms	Long	Brief
Convulsion	Rare	Common
injury	Rare	Common (with convulsive seizures)
Urinary incontinence	Rare	Common
Postictal confusion	Rare	Common
Postictal headache	No	Common
Focal neurological signs	No	Occasional
Cardiovascular signs	Common (;ardiac syncope)	No
Abnormal electroencephalogram recording	Rare (may show generalized slowing during the event)	Common

Table 2.2: Classification of syncope

Cardiac arrhythmias
  Bradyarrhythmias
  Tachyarrhythmias
  Reflex arrhythmias
Decreased cardiac output
Cardiac outflow obstruction
Inflow obstruction
Cardiomyopathy
Hypovolemia
Hypotension
Drug use
Dysautonomia
Carotid sinus
Vertebrobasilar disease
Vasospasm
Takayasu's arteritis
Metabolic
Hypoglycemia
Anemia
Anoxia

Hyperventilation
Vasovagal (vasodepressor; neurocardiogenic; neural mediated)
Cardiac syncope
Cough, micturition
Multifactorial

with seizures, confusion, headaches, and drowsiness are uncommon sequelae. Nausea may be noted when the patient regains consciousness. The causes of syncope are generally classified according to the pathophysiological mechanism involved (Table 2.2), but the final common pathway is cerebral hypoperfusion.

History and Physical Examination

The history and physical examination are the most important parts of the initial evaluation of syncope. There are sitmificant age and sex differences in the frcq the various types of syncope. Syncope occurring in children and young adults is most commonly due to hyperventilation or vasovagal (vasodepressor) attacks and less commonly due to congenital heart disease (Lewis and Dhala 1999). Fainting associated with benign tachycardias without underlying organic heart disease may also appear in the younger age-groups. Syncope caused by basilar migraine is more common in young females. When repeated syncope begins in later life, organic disease of the cerebral circulation or cardiovascular system is usually responsible.

In establishing the cause of syncope, the most important step is a careful history. The diagnosis often can be made from the patient's description. The previously described presyncopal symptoms and certain clues in the history may help establish the cause. The neurologist should always obtain a full description of the first faint. The clinical features should be established, with emphasis on precipitating factors, posture, type of onset of the faint and whether it was abrupt or gradual, position of head and neck, the presence and duration of preceding and associated symptoms, duration of loss of consciousness, rate of recovery, and sequelae. If possible, an observer should be questioned about clonic movements, color changes, diaphoresis, pulse, respiration, urinary incontinence, and the nature of recovery.

Clues in the history that suggest cardiac syncope include a history of palpitations or a fluttering sensation in the chest before losing consciousness. These symptoms are common in arrhythmias. In vasodepressor syncope and orthostatic hypotension, preceding symptoms of lightheadedness may be common. Episodes of cardiac syncope are generally briefer than vasodepressor syncope, and the onset is usually rapid. Episodes caused by cardiac arrhythmias occur independent of position, whereas in vasodepressor syncope and syncope caused by orthostatic hypotension, the patient is usually standing.

Attacks of syncope precipitated by exertion suggest a cardiac etiology. Exercise may induce arrhythmic syncope or syncope caused by decreased cardiac output secondary to blood flow obstruction, such as may occur with aortic or subaortic stenosis. Exercise-induced syncope may also be caused by cerebrovascular disease, aortic arch disease, congenital heart disease, pulseless disease (Takayasu's disease), pulmonary hypertension, anemia, hypoxia, and hypoglycemia, but often no cardiac disease is uncovered (Colivicchi et al. 2002). A family history of sudden cardiac death, especially in females, might suggest the long QT syndrome. Because many drugs can induce orthostatic hypotension or produce cardiac arrhythmias, a careful and complete medical and medication history is mandatory (Goldschlager et al. 2003).

The neurologist should inquire about the frequency of attacks of loss of consciousness and the presence of cerebrovascular or cardiovascular symptoms between episodes. The patient should be questioned about whether all the episodes are similar, because some parienrs experience more than one type of attack.

With an accurate description of the attacks and familiarity with clinical features of various types of syncope, the physician should be able to correctly diagnose most patients. Some seizure types that have to be distinguished from syncope include orbitofronral complex partial seizures, which can be associated with autonomic changes, and complex partial seizures that are associated with sudden falls and altered awareness followed by confusion and gradual recovery (temporal lobe syncope). Features that distinguish syncope from seizures and other alterations of consciousness are discussed later in this chapter.

After a complete history, the physical examination is of next importance. Examination during the episode is very informative but frequently impossible unless presyncopal symptoms can be reproduced by a Valsalva maneuver or by recrearing the circumstances of the attack, such as by position change. In the patient with suspected cardiac syncope, particular attention should be paid to the vital signs and determination of supine and erect blood pressure. Normally, upon standing the systolic blood pressure *rises* and the pulse rate may *increase.* An orthostatic drop in blood pressure greater than 15 mm Hg may suggest autonomic dysfunction. Blood pressure should be assessed in both arms if cerebrovascular disease, subclavian steal, or Takayasu's arteritis is suspected.

During syncope caused by a cardiac arrhythmia, a heart rate faster than 140 beats per minute usually indicates an ectopic cardiac rhythm, whereas a bradycardia with a heart rate of less than 40 beats per minute suggests complete atrioventricular (AV) block. Supraventricular tachycardias can be terminated abruptly by carotid sinus massage, whereas a ventricular tachycardia shows no response. However, this technique is no longer advised because of the risk of cerebral embolism from atheroma in the carotid artery wall. Stokes-Adams attacks may be of longer duration and may be associated with audible atrial contraction and a variable first heart sound. Heart disease as a cause of syncope is more common in the elderly patient (Brady and Shen 2002).

The patient should undergo cardiac auscultation for the presence of cardiac murmurs and abnormalities of the heart sounds. There may be the murmur of aortic stenosis, subaortic stenosis, or mitral valve disease. An intermittent posture-related murmur may be heard with an atrial myxoma. A systolic click in a young person suggests mitral valve prolapse. A pericardial rub suggests pericarditis.

All patients should undergo observation of the carotid pulse and auscultation of the neck. The degree of aortic-stenosis may at times be reflected in a delayed carotid upstroke. Carotid, ophthalmical, and supraclavicular bruits suggest underlying cerebrovascular disease. Carotid sinus massage may be useful in older patients suspected of having carotid sinus syncope, but it is important to keep in mind that up to 25% of asymptomatic subjects may have some degree of carotid sinus hypersensitivity. Carotid sinus massage should be avoided in patients with suspected cerebrovascular disease, and when performed, it should be done in properly controlled conditions with electrocardiogram (ECG) and blood pressure monitoring.

Causes of Syncope

Cardiac Arrhythmias

Both bradyarrhythmias and tachyarrhythmias may result in syncope, and abnormalities of cardiac rhythm resulting from dysfunction from the sinoatrial (SA) node to the Purkinje network may be involved. Arrhythmias are a common cause of syncope and must be considered in all cases in which an obvious mechanism is not known. Syncope caused by cardiac arrhythmias generally occurs more quickly than syncope from other causes and may be more prolonged. Cardiac syncope may occur in any position, may occasionally be induced by exercise, and may occur in both congenital and acquired heart disease.

Although some patients experience palpitations during some arrhythmias, others are not aware of any cardiac-symptoms, The most common arrhythmias causing syncope are AV block, SA block, and paroxysmal supraventricular and ventricular tachyarrhythmias. *AV block* describes disturbances of conduction occurring in the AV conducting system, which include the AV node to the bundle of His and the Purkinje network. *SA block* describes a failure of consistent pacemaker function of the SA node. *Paroxysmal tachycardia* refers to a rapid heart rate secondary to an ectopic focus outside the SA node; this may be supraventricular or intraventricular,

Atrioventricular Block

AV block is probably the most common cause of arrhythmic cardiac syncope. The term *Stokes-Adams attack* describes disturbances of consciousness occurring in association with a complete AV block, which occurs primarily in elderly patients. The onset of a Stokes-Adams attack is generally sudden, although a number of visual, sensory, and perceptual premonitory symptoms may be experienced. During the syncopal attack, the pulse disappears and no heart sounds are audible. The patient is pale and, if standing, falls down, often with resultant injury. If the attack is sufficiently prolonged, respiration may be labored and urinary incontinence and clonic muscle jerks may occur. Prolonged confusion and neurological signs of cerebral ischemia may be present. Regain of consciousness is generally rapid.

The clinical features of complete AV block include a slow-collapsing pulse and elevation of the jugular venous pressure, sometimes with cannon waves. The firsr heart sound is of variable intensity, and heart sounds related to atrial contractions may be audible. The diagnosis is confirmed by ECG, which demonstrates the independence of atrial P waves and ventricular QRS complexes. During Stokes-Adams attacks, ECG recordings generally show ventricular standstill, but ventricular fibrillation or tachycardia may also occur.

Sinoatrial Block

SA block may result in dizziness, lightheadedness, and syncope. It is most frequent in rhe elderly. Palpitations are common, and the patient appears pale. Patients with SA node dysfunction frequently have other conduction disturbances, and certain drugs, such as verapamil, digoxin, and beta blockers, may further impair SA node function, On examination, the patient's pulse may be regular between attacks. During an attack, the pulse may be slow or irregular, and a number of rhythm disturbances may be present.

Paroxysmal Tachycardia

Supraventricular tachycardias include atrial fibrillation with a rapid ventricular response, atrial flutter, and Wo Iff-Park in son-White syndrome. These arrhythmias may suddenly reduce cardiac output enough to cause syncope.

Ventricular tachycardia or ventricular fibrillation may result in syncope if the heart rate is sufficiently fast and if the arrhythmia lasts longer than a few seconds. Patients are generally elderly and usually have evidence of underlying cardiac disease. Ventricular fibrillation may be part of long QT syndrome in association with congenital deafness in children. In most patients with long QT syndrome, episodes begin in the first decade of life, but onset may be much later. Exercise may precipitate an episode of cardiac syncope. Long QT syndrome may be acquired and may present in adults as epilepsy. Acquired causes include cardiac ischemia, mitral valve prolapse, myocarditis, and electrolyte disturbances (Ackerman 1998), as well as many drugs (Goldschlager et al. 2002). Brugada's syndrome may produce syncope as a result of ventricular tachycardia or ventricular fibrillation. The ECG demonstrates an incomplete right bundle branch block in leads V, and V_2 with ST-segment elevation in the right precordial leads (Goldschlager et al, 2003).

Reflex Cardiac Arrhythmias

A hypersensitive carotid sinus may be a cause of syncope in the elderly, mosr commonly in men. Syncope may result from a reflex sinus bradycardia, sinus arrest, or AV block; peripheral vasodilation with a decrease in arterial pressure; or from a combination of both. Although 10% of the population older than 60 years may have a hypersensitive carotid sinus, not all such patients experience syncope. Accordingly, this diagnosis should be considered only when the clinical history is compatible. Carotid sinus syncope may be initiated by a tight collar or by carotid sinus massage on clinical examination. When syncope occurs, the patient is usually upright and the duration of the loss of consciousness is generally a few minutes. When consciousness is regained, the patient is mentally clear. Unfortunately, there are no accepted diagnostic criteria for carotid sinus syncope, and the condition is overdiagnosed.

Syncope induced by unilateral carotid massage or compression may also be caused by partial occlusion, usually atherosclerotic, of the contralateral carotid or a vertebral artery, or it may be due to the release of atheromatous emboli. Because of these risks, carotid artery massage is no longer recommended. The rare syndrome of glossopharyngeal neuralgia is characterized by intense paroxysmal pain in the throat and neck and is accompanied by bradycardia or asystole, severe hypotension, and, if prolonged, seizures. Episodes of pain may be initiated by swallowing but also by chewing, speaking, laughing, coughing, shouting, sneezing, yawning, or talking. The episodes of pain always precede the loss of consciousness (see Chapter 75), Rarely, cardiac syncope may be due to bradyarrhythmias consequent to vagus nerve irritation caused by esophageal diverticula, tumors and aneurysms in the region of the carotid sinus, mediastinal masses, or gallbladder disease.

Decreased Cardiac Output

Syncope may occur as a result of a sudden and marked decrease in cardiac output. Both congenital and acquired conditions may be causal. Tetralogy of Fallot, the most common congenital malformation causing syncope, does so by producing hypoxia caused by right-to-left shunting.

Other congenital conditions associated with cyanotic heart disease may also cause syncope. Ischemic heart disease and myocardial infarction, aortic stenosis, idiopathic hypertrophic subaortic stenosis, pulmonary hypertension, and other causes of obstruction of pulmonary outflow, atrial myxoma, and cardiac tamponade may sufficiently impair cardiac output to cause syncope. Exercise-induced or effort syncope may occur in aortic or subaortic stenosis and other states in which there is reduced cardiac output and associated peripheral vasodilation induced by the exercise. Exercise-induced cardiac syncope may also be related to exercise-induced cardiac arrhythmias.

In patients with valvular heart disease, syncope may be related to arrhythmias. Syncope may also be due to reduced cardiac output secondary to myocardial failure, to mechanical prosthetic valve malfunction, or to thrombus formation. Mitral valve prolapse is generally a benign condition, but rarely cardiac arrhythmias can occur. The most significant arrhythmias are ventricular.

In atrial myxoma or with massive pulmonary embolism, a sudden decrease in left ventricular output may occur. In atrial myxoma, syncope is often positional and occurs when the tumor falls into the AV valve opening during a change in position of the patient, thereby causing obstruction of the left ventricular inflow.

Decreased cardiac output may also be secondary to conditions that result in inflow obstruction or reduced venous return. These include superior and inferior vena cava obstruction, tension pneumothorax, constrictive cardiomyopathies, constrictive pericarditis, and cardiac tamponade. Syncope associated with aottic dissection may he due to cardiac tamponade but may also be secondary to hypotension, obstruction of cerebral circulation, or a cardiac arrhythmia.

Hypovolemia

Acute blood loss, usually due to gastrointestinal tract bleeding, may cause weakness, faintness, and syncope if sufficient blood is lost. Blood volume depletion by dehydration may cause faintness and weakness, but true syncope is uncommon, unless the dehydration is combined with exercise.

Hypotension

A number of conditions cause syncope by producing a decrease in arterial pressure. The cardiac causes were already discussed. The common faint (designated variously as *vasovagal, vasodepressor, neurocardiogenic,* or *neuraliy mediated syncope)* is rhe most common cause of a transient decrease in blood pressure resulting in syncope (Grubb and Kanjwal 2003). It is often recurrent, tends to occur in relation to emotional stimuli, and may affect 20-25% of young people. Less commonly, it occurs in older patients with cardiovascular disease (Fenton et al. 2000).

The common faint may or may not be associated with bradycardia. The patient experiences impairment of consciousness, with loss of postural tone. Signs of autonomic hyperactivity are common, including pallor, diaphoresis, nausea, and dilated pupils. After recovery, patients may have persistent pallor, sweating, and nausea; if they get up too quickly, they may black out again. The common faint may he preceded by presyncopal symptoms of lethargy and fatigue, nausea, weakness, a sensation of an impending faint, and yawning. It is more likely to occur in certain circumstances, such as a hot crowded room, especially if the person is tired or hungry and upright or sitting. The episode of fainting may be brought on by venipuncture, the sight of blood, or a sudden painful or traumatic experience. When the patient regains consciousness, there usually is no confusion or headache, although weakness is commonly described. As in other causes of syncope, if the period of cerebral hypoperfusion is long enough, urinary incontinence and a few clonic movements may be observed (convulsive syncope).

Orthostatic syncope occurs when autonomic factors that compensate for the upright posture are inadequate. This can result from a variety of clinical disorders. Blood volume depletion or venous pooling may result in syncope when the individual assumes an upright posture. Orthostatic hypotension resulting in syncope may also occur with drugs that impair sympathetic nervous system function. Diuretics, antihypertensive medications, nitrates, arterial vasodilators, calcium-channel blockers, phenothiazincs, L-dopa, alcohol, and tricyclic antidepressants may all result in orthostatic hypotension.

Autonomic nervous sysrem dysfunction resulting in syncope caused by orthostatic hypotension may be a result of primary autonomic failute caused by Shy-Drager syndrome or Riley-Day syndrome. Neuropathies that affect the autonomic nervous system include those of diabetes mellitus, amyloidosis, Guillain-Barre syndrome, acquired immunodeficiency syndrome, chronic alcoholism, hepatic porphyria, and beriberi. Rarely, subacute combined degeneration, syringomyelia, and other spinal cord lesions may damage the descending sympathetic pathways, producing orthostatic hypotension.

Cerebrovascular Ischemia

Syncope may occasionally result from reduction of cerebral blood flow in either the carotid or the vertebrobasilar system. Most commonly, the underlying condition is atherosclerosis of the cerebral vessels, but reduction of cerebral blood flow resulting from cerebral embolism, mechanical factors in the neck (e.g., severe osteoarthritis), and arteritis (e.g., Takayasu's or cranial arteritis) may be responsible. In the subclavian steal syndrome, a very rare impairment of consciousness is associated with upper extremity exercise and resultant diversion of cerebral blood flow to the peripheral circulation. Occasionally,

cerebral vasospasm secondary to basilar migraine or subarachnoid hemorrhage may be responsible. Insufficiency of the cerebral circulation often causes other neurological symptoms, depending on the circulation involved.

Reduction in blood flow in the carotid circulation may lead to loss of consciousness, lightheadedness, giddiness, and a sensation of an impending faint. Reduction in blood flow in the vertebrobasilar system may also lead to loss of consciousness, but dizziness, lightheadedness, drop attacks without loss of consciousness, and bilateral motor and sensory symptoms are more common. Dizziness and lightheadedness alone, however, should not be considered symptoms of vertebrobasilar insufficiency. Syncope resulting from compression of the vertebral artery during certain head and neck movements may be associated with episodes of vertigo, disequilibrium, or drop attacks. Patients may describe blackouts when looking upward suddenly or when turning their heads quickly to one side. Generally, symptoms persist for several seconds after the movement stops.

In Takayasu's arteritis, there may be major occlusion of blood flow in the carotid and vertebrobasilar systems; in addition to fainting, other neurological symptoms are common. Pulsations in the neck and arm vessels are usually absent, and blood pressure in the arms is unobtainable. The syncopal episodes characteristically occur with mild or moderate exercise and with certain head movements.

Cerebtal vasospasm may result in syncope, particularly if the postetior circulation is involved. In basilar artery migraine, usually seen in young women and children, a variety of brainstem symptoms may also be experienced, and a pulsating headache is associated. The loss of consciousness is usually gradual, but a confusional state may last for hours (see Chapter 75).

Metabolic Disorders

A number of metabolic disturbances, including hypoglycemia, anoxia, and hyperventilation-induced alkalosis, may predispose to syncope, but usually only lightheadedness and dizziness ate experienced. The abruptness of onset of loss of consciousness depends on the acuteness and reversibility of the metabolic disturbances. Syncope caused by hypoglycemia generally develops gradually, The patient has a sensation of hunger; there may be a relationship to fasting, a history of diabetes mellitus, and a prompt response to ingestion of food. Symptoms are unrelated to posture but may be aggravated by exercise. During the syncopal attack, there is no significant change in blood pressure or pulse.

Anoxia may produce syncope because of the lack of oxygen or through the production of a vasodepressor type of syncope. Symptoms of lightheadedness are common, but true syncope is less common. Patients with underlying cardiac or pulmonary disease are susceptible. In patients with chronic anemia or certain hemoglobinopathies that impair oxygen transport, similar symptoms may occur. Syncopal symptoms may be more prominent with exercise or physical activity.

Hyperventilation-induced syncope usually has a psychogenic origin. During hyperventilation, the patient may experience paresthesia of the face, hands, and feet; a buzzing sensation in the head; lightheadedness; giddiness; blurring of vision; mouth dryness; and occasionally tetany. Patients often complain of tightness in the chest and a sense of panic. Symptoms can occur in the supine or erect positions and are gradual in onset. The symptoms of hyperventilation may be helped by having the patient rebreathc into a paper bag. During hyperventilation, a tachycardia may be present, but blood pressure generally remains normal.

Miscellaneous Causes of Syncope

In certain types of syncope, more than one mechanism may be responsible for the loss of consciousness. In the common faint, both vasodepressor and cardioinhibitory factors may be operational. In cardiac syncope, a reduction of cardiac output may be due to a single cause, such as obstruction to inflow or outflow or a cardiac arrhythmia, but multiple factors are common.

Cough or tussive syncope and micturition syncope are special cases of reflex syncope for which the mechanisms are poorly understood and probably multifactorial. In cough syncope, loss of consciousness occurs after a paroxysm of severe coughing. This is most likely to occur in obese men, usually smokers or patients with chronic bronchitis. The syncopal episodes occur suddenly, generally after repeated coughing but occasionally after a single cough. Before losing consciousness, the patient may feel lightheaded. The individual's face often becomes congested and then pale. Diaphoresis may be present, and there may be loss of muscle tone. Syncope is generally brief, lasting only seconds, and recovery is rapid. Several factors are probably operational in causing cough syncope. The most significant is blockage of venous return by raised intrathoracic pressure. In weight-lifting syncope, a similar mechanism is operational.

Micturition syncope most commonly occurs in men during or after micturition, usually after arising from bed to urinate in the erect position in the middle of the night. There may be a history of drinking alcohol before going to bed. The syncope may result from sudden reflex peripheral vasodilation caused by the release of intravesicular pressure and bradycardia. The relative peripheral vasodilation from recent alcohol use and a supine sleeping position arc contributory because blood pressure is lowest in the middle of the night. The syncopal propensity may increase with fever. Rarely, micturition syncope with headache may result from a pheochromocytoma in the bladder wall.

Defecation syncope is uncommon, hut it probably shares the underlying pathophysiological mechanisms responsible for micturition syncope. Convulsive syncope is an episode of syncope of any etiology, sufficiently prolonged to result in a few clonic jerks; the other features arc typically syncopal and should not be confused with epileptic seizures.

Investigations of Patients **with** Syncope

In the investigation of the patient with episodic impairment of consciousness, the diagnostic tests performed depend on the initial differential diagnosis (Kapoor 2002). Investigations should be individualized, but some, such as measurement of the hematocrit and blood glucose levels, as well as ECG recordings, are indicated in most patients. A resting ECG recording may reveal an abnormality of cardiac rhythm or the presence of underlying ischemic or congenital heart disease. In the patient suspected of cardiac syncope, a chest x-ray film may show evidence of cardiac hypertrophy, valvular heart disease, or pulmonary hypertension. Other noninvasive investigations include radionuclcotide catdiac scanning, echocardiography, and prolonged I lolrer monitoring for the detection of cardiac arrhythmias. Echocardiography is useful in the diagnosis of valvular heart disease, cardiomyopathy, atrial myxoma, prosthetic valve dysfunction, pericardial effusion, aortic dissection, and congenital heart disease. Holter monitoring detects twice as many ECG abnormalities as a routine ECG and may detect an arrhythmia at the time of a syncopal episode, 1 lolrer monimi'ing is commonly performed for 24 hours, although longer periods of recording may be required. Continuous loop recordings may be used in long-term monitoring and may be useful in a small number of patients (Krahn et al. 1999).

Exercise testing and electrophysiological studies are carried out in a select group of patients. Exercise testing may be useful in detecting coronary artery disease, and exercise-related syncopal recordings may help localize the site of conduction disturbances. Tilt testing may be useful in the evaluation of patients with syncope of unknown origin, although false-positive results occur. Tilt testing commonly employs pharmacological agents such as nitroglycerin or isoproterenol. The specificity of tilt-table testing is approximately 90%.

In patients suspected of syncope from cerebrovascular causes, noninvasive diagnostic studies, including Doppler flow studies of the cerebral vessels and magnetic resonance imaging (MRI) or magnetic resonance angiography, may provide useful information. Occasionally, cerebral angiography may be indicated. Electroencephalography (EEG) is useful in differentiating syncope from epileptic seizure disorders. An EEG should be obtained only when a seizure disorder is suspected.

Despite multiple investigations, in approximately 37% of patients, the cause is unknown (Soteriades ct al. 2002),

SEIZURES

Sudden, unexplained loss of consciousness in a child or adult may be caused by an epileptic seizure, which must be distinguished from syncope. An epileptic seizure is defined as a transient neurological dysfunction resulting from an excessive abnormal electrical discharge of cerebral neurons. The clinical manifestations are numerous, including disturbances of consciousness, changes in emotions, changes in sensation, abnormal movements, and changes in visceral functions or behavior. Epileptic seizures may be classified according to clinical manifestations and EEG findings (Chaptet 73). This section discusses only seizures associated with an alteration of consciousness. Both generalized seizures (absence and tonic-clonic) and complex partial seizures have alteration of consciousness as part of their clinical manifestations. Atonic seizures usually present as drop attacks and loss of consciousness is extremely brief. In most patients, a correct diagnosis can be made on the basis of the history, physical examination, and EEG findings.

History and Physical Examination

The most definitive way to diagnose epilepsy and the type of seizure is clinical observation of the seizure, although this is often not possible, except when seizures are frequent. The history of an episode, as obtained from the patient and an observer, is of paramount importance. The neurologist should obtain a family history and should inquire about birth complications, central nervous system infection, head trauma, and previous febrile seizures, because they may all have relevance.

The neurologist should obtain a complete description of the episode and should inquire about any warning before the event, possible precipitating factors, and other neurological symptoms that may suggest an underlying structutal cause. Important considerations are the age at onset, frequency, and diurnal variation of the events. Seizures are generally brief and have stereotyped patterns, as desctibed previously. With complex partial seizures and tonic-clonic seizures, a period of postictal confusion is highly characteristic. Unlike some types of syncope, seizures are unrelated to posture and generally last longer. In a tonic-clonic seizure, cyanosis is often present, pallor is uncommon, and breathing may be stertorous.

Absence seizures have onset between ages 5 and 15 years in most patients, and a family history of seizures is present in 20-40% of patients. Tonic-clonic and complex partial seizures may begin at any age from infancy to late adulthood, although infants may not demonstrate the typical features because of incomplete development of the nervous system.

The neurological examination may reveal an underlying structural disturbance responsible for the seizure disorder. Birth-related trauma may result in asymmetries of physical

development; cranial bruits may indicate an arteriovenous malformation; and space-occupying lesions may result in papilledema or in focal motor, sensory, or reflex signs. In the pediatric age-group, mental retardation may be found in association with birth injury or metabolic defects. The skin should be examined for abnormal pigment changes and other dysmorphic features characteristic of some of the neurodegenerative disorders.

If absence seizures are suspected, the diagnosis can often be made in the office by having the patient hyperventilate for *$-4* minutes, which often induces an absence seizure. If the patient is examined immediately after a suspected tonic-clonic seizure, the neurologist should search for abnormal signs, such as focal motor weakness and reflex asymmetry, and for pathological reflexes, such as Babinski's sign. These may help to confirm that the attack was a seizure and suggest a possible lateralization or location of the seizure focus.

Absence Seizures

The absence seizure is a well-defined clinical and EEG event. The essential feature is an abrupt, brief episode of decreased awareness without any warning, aura, or postictal symptoms. At the onset of the absence seizure, there is an interruption of activity. A simple absence seizure is characterized only by an alteration of consciousness. A complex absence seizure is characterized by an alteration of consciousness and other signs, such as minor motor automatisms. During a simple absence seizure, the patient remains immobile, breathing is normal, no color changes are observed, there is no loss of postural tone, and there are no motor manifestations. After the seizure, the patient immediately resumes the previous activities and may be unaware of the attack. An absence seizure generally lasts 10-15 seconds, but it may be shorter or as long as 40 seconds.

Complex absence seizures have additional manifestations, such as diminution of postural tone, which may cause the patient to fall; an increase in postural tone; minor clonic movements of the face or extremities; minor face or extremity automatisms; or autonomic phenomena, such as pallor, flushing, tachycardia, piloerection, mydriasis, or urinary incontinence.

Tonic-CIonic Seizures

The tonic-clonic seizure is the most dramatic manifestation of epilepsy and is characterized by motor activity and loss of consciousness. Tonic-clonic seizures may be the only manifestation of epilepsy or may be associated with other seizure types. In a primary generalized tonic-clonic seizure, the patient generally has no warning or aura, although some patients may experience a few myoclonic jerks. The seizure begins with a tonic phase, during which there is sustained muscle contraction lasting 10-20 seconds. This phase is followed by a clonic phase that lasts approximately 30 seconds and is characterized by recurrent muscle contractions. During a tonic-clonic seizure, a number of autonomic changes may be present, including an increase in blood pressure and heart rate, apnea, mydriasis, urinary or fecal incontinence, piloerection, cyanosis, and diaphoresis. Injury may result from a fall or tongue biting. In the postictal period, consciousness is regained slowly. The patient may remain lethargic and confused for a variable period. Pathological reflexes may be elicited.

Some generalized motor seizures with transient alteration of consciousness may have only tonic or only clonic components. Tonic seizures consist of an increase in muscle tone, and the alteration of consciousness is generally brief. Clonic seizures are characterized by a brief impairment of consciousness and bilateral clonic movements. Recovery may be rapid, but if the seizure is more prolonged, a postictal period of confusion may be noted.

Complex Partial Seizures

In a complex partial seizure, the first seizure manifestation may be an alteration of consciousness, but the patient commonly experiences an aura or warning. The seizure may have a simple partial onset, which may include motor, sensory, visceral, or psychic symptoms. The patient may initially experience hallucinations or illusions; affective symptoms, such as fear or depression; cognitive symptoms, such as a sense of depersonalization or unreality; or aphasia.

The complex partial seizure generally lasts 1-3 minutes but may be shorter or longer. A complex partial seizure may become generalized and evolve into a tonic-clonic convulsion. During a complex partial seizure, automatisms, generally more complex than those in absence seizures, may be noted. The automatisms could involve continuation of the patient's activity before the onset of the seizure, or they may be new motor acts. The automatisms are varied but frequently consist of chewing or swallowing movements, lip smacking, grimacing, or automatisms of the extremities, including fumbling with objects, walking, or trying to stand up. Rarely, patients with complex partial seizures have drop attacks and the term *temporal lobe syncope* is often used. The duration of the postictal period after a complex partial seizure is variable, with a gradual return to normal consciousness and normal response to external stimuli. Table 2,3 provides a comparison of absence seizures and complex partial seizures.

Investigations of Seizures

In the initial investigations of the patient with tonic-clonic seizures or complex partial seizures, a complete blood cell count, urinalysis, biochemical screening, blood glucose

Tabic 2.3: Comparison of absence and complex partial seizures

Feature	*Absence seizure*	*Complex partial seizure*
Age at onset	Childhood or adolescence	Any age
Aura or warning	No	Common
Onset	Abrupt	Gradual
Duration	Seconds	Up to minutes
Automatisms	Simple	Mure complex
Provocation by hyperventilation	Common	Uncommon
Termination	Abrupt	Gradual
Frequency	Possibly multiple seizures per day	Occasional
Postictal phase	No	Confusion, fatigue
KkvtrovncephalogtMm	Generalized spike and wave	Focal epileptic discharges or nonspecific lesions
Ncuroimaging	Usually normal	May demonstrate focal lesions

level, serum calcium concentration, and serological test fot syphilis should be obtained. Laboratory investigations generally are not helpful in establishing a diagnosis of absence seizures. In infants and children, biochemical screening for amino acid disorders should be considered.

MRI is the imaging modality of choice for the investigation of patients with suspected seizures. It is superior to computed tomographic scanning and increases the yield of focal structural disturbances. MRI can reveal tumors, cerebral atrophy, hydrocephalus, cerebral hemorrhage, infarction, subdural hematoma, cystic lesions, and vascular malformations. Although childten with absence seizures may have some abnormalities on MRI, this procedure is generally not required for diagnosis or management.

Cerebrospinal fluid (CSF) examination is not necessary in every patient with a seizure disotder and should be reserved for the patient whose recent seizure may be related to an acute central nervous system infection.

The role of the EFLG is to provide laboratory support for a clinical impression and to help classify the type of seizure. Epilepsy is a clinical diagnosis; therefore, EEG cannot produce a diagnosis with certainty unless the patient has a clinical event during the recording. A normal EEG does not exclude epilepsy, and minot nonspecific abnormalities do not confirm epilepsy. Some patients with clinically documented seizures show no abnormality even after serial EF.G recordings, sleep recordings, and special activation techniques. The EEG is most often helpful in the diagnosis of absence seizures. EEG evaluation can be supplemented with simultaneous video monitoring for the documentation of ictal events, allowing for a strict correlation between EEG changes and clinical manifestations. Simultaneous EEG and video monitoring is also useful in distinguishing epileptic seizures from noncpileptic phenomena.

Although an accurate diagnosis can be made in most patients on the basis of the clinical history and the foregoing investigations, some patients ptesent a diagnostic dilemma. A 24-hour ambulatory EEG recording can make more definite a diagnosis of an epileptic seizure rather than nonepileptic phenomena or a clearer classification of the specific type of seizure.

Psychogenic Seizures or Pseudoseizures (Noncpileptic Seizures)

Pscudoepileptic seizutes are paroxysmal episodes of altered behavior that superficially resemble epileptic seizures but lack the expected EEG epileptic changes (Ettinger et al. 1999). However, approximately 40% of patients with pscudoepileptic or nonepileptic seizures also experience true epileptic seizures.

A diagnosis is often difficult to establish based on initial history alone (Devinsky 1998). Often, a correct diagnosis can be made only after witnessing the patient's clinical episodes. Noncpileptic seizures occur in children and adults and are more common in females. Most commonly, they superficially resemble tonic-clonic seizures. They generally are abrupt in onset, occur in the presence of othct people, and do not occur during sleep. Motor activity is uncoordinated, but urinary incontinence is rare, and physical injury is uncommon. They tend to be more prolonged than true tonic-clonic seizures. Pelvic thrusting is often a manifestation of pseudoseizures. During and immediately after the seizure, the patient may not respond to verbal or painful stimuli. Cyanosis is not observed. Postictally, there are no focal neurological signs or pathological reflexes.

In the patient with known epilepsy, the diagnosis of nonepileptic seizures should be considered when previously controlled seizures become medically refractory. For the diagnosis of nonepileptic seizures, the patient should have a psychological assessment because the majority of such patients have other psychiatric disturbances. In this patient group, there is a high frequency of hysteria, depression, and personality disturbances. At times, a sccondaty gain can be identified. In some patients with psychogenic seizures, the clinical episodes can frequently be precipitated by suggestion and by certain clinical tests, such as hyperventilation, photic stimulation, intravenous saline infusion or tactile (vibration) stimulation, or pinching the nose to induce apnea. It is important to keep in mind that hyperventilation and photic stimulation may also induce true epileptic seizures, but their clinical features arc usually distinctive. Some physicians avoid the use of placebo

Table 2.4: Comparison of psychogenic and epileptic seizures

Feature	*Psychogenic seizure*	*Epileptic seizure*
Stereotypy of attack	May be variable	Usually stereotyped
Duration	May be prolonged	Brief
Diurnal variation	Daytime	Nocturnal or daytime
Injury	Rare	Can occur with tonic-clonic seizures
Tongue biting	Rare	Can occur with tonic-clonic seizures
Urinary incontinence	Rare	Common
Motor activity	Prolonged, uncoordinated; pelvic thrusting	Automatisms or coordinated tonic-clonic seizures
Postictal confusion	Rare	Common
Relation to medication changes	Unrelated	Usually related
Interictal KEG	Normal	Frequently abnormal
Ictal EEG	Normal	Abnormal
Presence of secondary gain	Common	Uncommon
Psychiatric disturbances	Common	Uncommon

EEG = electroencephalogram,

procedures because of the possibility that the patient may feel tricked and this could have an adverse effect on the doc tor-patient relationship (Parra et al. 1998).

The interictal EEG in patients with pseu do seizures is normal and remains normal during the clinical episode, demonstrating no evidence of a cerebral dysrhythmia. With the introduction of long-term ambulatory KEG monitoring, the episodic behavior of a patient can be correlated with EEG recordings; thus psychogenic seizures can be distinguished from true epileptic seizures. Table 2.4 compares the features of psychogenic seizures wirh those of epileptic seizures.

As an auxiliary investigation of suspected psychogenic seizures, plasma prolactin concentrations may provide additional supportive data. Plasma prolactin concentrations are commonly elevated after tonic-clonic seizures and less frequently after complex partial seizures. Serum prolactin levels are almost invatiably normal after psychogenic seizures, although such a finding does not exclude the diagnosis of true epileptic seizures. Elevated prolactin levels, however, may also be present after syncope and with the use of drugs such as antidepressants, estrogens, bromocriptine, ergots, phenothiazines, antiepileptic drugs, and others.

Miscellaneous Causes of Altered Consciousness

In children, alteration of consciousness may accompany breath-holding spells (see Chapter 55B) and metabolic disturbances (see Chapter 68), Breath-holding spells must be distinguished from epilepsy. Most spells start at 6-28 months of age, but they may occur as early as the first month of life; they usually disappear by 5 or 6 years of age. Breath-holding spells may occur several times per day and may manifest cither cyanosis or pallor. In cyanotic breath-holding spells, loss of consciousness is triggered by a sudden injury or fright, anger, or frustration. The child is initially provoked, cries vigorously for a few breaths, and then holds his or her breath in expiration, whereon cyanosis develops. Consciousness is lost because of hypoxia. Although stiffening, a few clonic movements, and urinary incontinence are occasionally observed, these episodes can be clearly distinguished from epileptic seizures on the basis of the history of provocation and by noting that the apnea and cyanosis occur before any alteration of consciousness. In these children, the neurological examination and EEG recordings are normal. Pallid breath-holding episodes are generally provoked by a mild painful injury or a startle. The infant cries initially, then becomes pale and loses consciousness. As in the cyanotic type, stiffening, clonic movements, and urinary incontinence may occur. In the pallid infant syndrome, loss of consciousness is secondary to excessive vagal tone, resulting in bradycardia and subsequent cerebral ischemia, similar to a vasovagal attack.

A number of pediatric metabolic disorders may have clinical manifestations of alterations of consciousness, lethargy, or seizures (see Chapter 68), These include disorders of amino acid metabolism, such as phenylketonuria, Hartnup disease, and maple syrup urine disease; the various disorders of the urea cycle; and miscellaneous metabolic disorders, such as hyperglycinemia and disorders of pyruvate metabolism. Neurological abnormalities in these patients may be seen at birth or later in infancy and childhood. Metabolic screening of urine and blood should be considered in an infant who presents with neurological disorders early in life; these include examination of the urine for the detection of aminoaciduria, excess urinary ketones, and urea excretion. Biochemical screening of the serum should also be considered for the infant or child who presents with transienr lethargy, apneic episodes, syncope, or seizures.

Increased intracranial pressure may result from a number of causes, including periodic obsttuction of the circulation of CSF, as in aqueductal stenosis or colloid cyst of the third ventricle. These patients are subject to paroxysmal increases of intracranial pressure rhat may last up to

20 minutes. These episodes may occur spontaneously or may be related to postural changes or Valsalva's maneuver. If sufficient to impair cerebral perfusion, the plateau waves of Lundberg may result in sudden, severe headaches, which may be followed by loss of consciousness. Occasionally, this is accompanied by opisthotonos and clonic movements. In intermittent obstruction of CSF circulation, leg buckling and atonic episodes may occur with changes in head position. Tinnitus is a common accompanying symptom.

Syringomyelia of the cervical spine, often associated with a Chiari malformation (see Chapter 79), is occasionally associated with repeated episodes of syncope in children and adults {Woelfle et al. 1998).

In the patient who presents with an apparent loss of consciousness, the neurologist must also consider the possibility of malingering or some other underlying psychogenic cause. However, it is always important to exclude organic causes first. The neurologist should also distinguish sleep disorders, such as cataplexy and other causes of drop attacks, from alterations of consciousness. These nonsyncopal spells include drop attacks of the elderly, narcolepsy, systemic mastocytosis, carcinoid syndrome, and pheochromocytoma. Systemic mastocytosis, carcinoid syndrome, and pheochromocytoma may also cause true syncope secondary to rapid changes in blood pressure.

Chapter 3
Falls and Drop Attacks

Bernd F. Remler and Robert B. Daroff

Everyone occasionally loses balance and, infrequently, falls. When falls occur repeatedly or without a prior sense of imbalance, the patient may have a neurological problem. Various disease states and neurological impairments cause falls and drop attacks. Associated loss of consciousness implies syncope or seizures (see Chapter 2). Transient ischemic attacks (TIAs) in the posterior circulation or the anterior cerebral artery distribution can cause monosymptomatic drops. Third-ventricular or posterior fossa tumors may also be associated with abrupt drops. Patients with lower-extremity weakness, spasticity, rigidity, sensory loss, or ataxia frequently fall. Narcoleptics experience cataplexy, and patients with Meniere's disease occasionally fall as a result of otolithic dysfunction. Middle-aged women may fall with no discernible cause. Finally, the elderly, with their inevitable infirmities, fall frequently. These associations permit a classification of falls and drop attacks, as presented in Table 3.1, We use the words *falls* and *drops* interchangeably. The term *drop attacks,* on the other hand, describes sudden falls occurring without warning, that are primarily due to intracranial causes, such as midline tumors and transient ischemic attacks. Seizures and vestibular disorders arc much less common causes of drop attacks.

The medical history is essential in evaluating patients with falls and drop attacks. The situational and environmental circumstances of the event must be ascertained. On the basis of the causes listed in Table 3.1, basic questions must be asked of the patient or witnesses. Did the patient lose consciousness? If so, for how long? Did lightheadedness or palpitations precede the event? Is there a history of a seizure disorder? Were there previous symptoms suggestive of TIAs? Does the patient have headaches? Are there symptoms of distal sensory loss, limb weakness, or stiffness? Has the patient had excessive daytime sleepiness, and are the falls precipitated by strong emotions, such as elation or laughter? Is there a history of visual impairment, hearing loss, vertigo, or tinnitus? Given the tendency for middle-aged women and the elderly to fall, the patient's age and gender are imporranr to the evaluation.

The neurological examination is particularly relevant in ascertaining that falling might be related to disorders of the central or peripheral nervous system. Does the patient have motor or sensory deficits in the lower limbs; the rigidity and tremor of Parkinson's disease (PD); the ophthalmoparesis of progressive supranuclear palsy (PSP); ataxia, spasticity, or other signs compatible with multiple sclerosis? Patients with normal neurological examinations and no history of associated neurological or cardiac symptoms present a special challenge. If the falling is recurrent, magnetic resonance imaging (MRI) should be considered to rule out an otherwise silent midline cerebral neoplasm or malformation. Patients who frequently experience near-falls without injuries may have a psychogenic disorder of station and gait.

LOSS OF CONSCIOUSNESS

Syncope

The manifestations and causes of syncope are described in Chapter *2,* Severe ventricular arrhythmias and hypotension lead to cephalic ischemia, loss of consciousness, and falling. If there is a sudden third-degree heart block (Stokes-Adams attack), the patient loses consciousness and falls without warning. Less severe causes of decreased cardiac output, such as bradyarrhythmias or tachyarrhythmias, are associated with a prodromal sensation of faintness before the

loss of consciousness. Elderly patients with cardioinhibitory ("sick") sinus syndrome, however, often describe dizziness and falling, rather than faintness (Kapoor 2000). Orthostatic hypotension conveys a markedly increased risk of falling in the elderly and confounds other factors contributing to falls. Hypotension is almost always associated with a presyncopal syndrome of progressive lightheadedness, faintness, dimming of vision, and rubbery legs before consciousness is lost. Orthostatic hypotension is particularly problematic in the frail elderly, who have many other risk factors for falling (Heitterachi et al. 2002) (see The Aged State, later in this chapter).

Seizures

Epileptic drop attacks are caused by asymmetrical tonic contractions of limb and axial muscles, loss of tone of postural muscles (Tinuper et al. 1998), and seizure-related cardiac arrhythmias. The arrhythmias mimic cardiogenic syncope and, like temporal lobe drop attacks, are typically associated with a period of altered consciousness after the drop. Video-EEG monitoring of epileptic patients with a history of falls permits the characterization of the various motor phenomena that cause loss of posture. For the clinician, however, the precise nature of these events is less important than establishing a diagnosis of seizures. This is often simple in patients with long-standing epilepsy, but falls in patients with poststroke hemiparesis may be falsely attributed to motor weakness rather than to new-onset seizures. Further confusion may result from the difficulties involved in differentiating the destabilizing extensor spasms of spasticity from focal seizures. Epileptic drop attacks in young patients with severe childhood epilepsies may respond favorably to callosotomy (Maehare and Shimizu 2001). Falling as a consequence of the tonic axial component of startle-induced seizures may be controllable with lamotriginc (Faught 1999). Paradoxically, some antiseizure drugs can precipitate drop attacks, such as carbamazepine in Rolandic epilepsy (Genton 2000).

Transient Ischemic Attacks

Drop attacks secondary to TIAs arc sudden falls occurring without warning or obvious explanation (e.g., tripping). There is no, or only momentary, loss of consciousness; the sensorium and lower-limb strength arc intact immediately or shortly after the patient hits the ground. The neurological examination should not reveal lower-limb motor or sensory dysfunction between episodes. If such abnormalities are present, it can be impossible to distinguish drop attacks from the falls associated with sensorimotor impairment of the lower limbs. The vascular distributions of drop attacks from TIAs are the posterior circulation and the anterior cerebral arteries.

Vertebrobasilar Insufficiency

Drop attacks caused by posterior circulation insufficiency result from transient ischemia to the corticospinal tracts or the paramedian reticular formation. They are rarely an isolated symptom of vertebrobasilar insufficiency because most patients have a history of TIAs, including the more common symptoms of vertigo, diplopia, ataxia, weakness, and hemisensory loss. Occasionally, a drop attack may herald progressive thrombosis of the basilar artery, hours before major and permanent neurological signs evolve.

Anterior Cerebral Artery Ischemia

Anterior cerebral artery ischemia causes drop attacks by impairing perfusion of the parasagittal prcmotor and motor cortex controlling the lower extremities. Derivation of both anterior cerebral arteries from the same internal carotid artery—a common vascular variant, with an approximate frequency of 20%—anatomically predisposes to this syndrome. In such patients, an embolus may lodge in the single anterior cerebral artery root and produce bilateral parasagittal ischemia with a consequent drop attack.

Third Ventricular and Posterior Fossa Tumors

Drop attacks can be manifestations of colloid cysts of the third ventricle or mass lesions within the posterior fossa. With colloid cysts, unprovoked falling is the second most common symptom, after position-induced headaches. This history may be the only clinical clue to the diagnosis because the neurological examination may be entirely normal. Abrupt neck flexion may precipitate drop attacks in

otherwise asymptomatic patients who are harboring posterior fossa tumors. Drop attacks occur in 2-3% of patients with Chiari malformations (Ziegler and Mallonce 1999). Drops induced by rapid head turning were considered pathognomonic of cysticercosis of the fourth ventricle in the early 20th century (Brun's sign). Other intracranial mass lesions, such as parasagittal meningiomas, foramen magnum tumors, or subdural hematomas, are usually associated with baseline abnormalities of gait and motor functions, and falling occurs consequent to these impairments (see Table 3.1) tather than to true drop attacks.

MOTOR AND SENSORY IMPAIRMENT OF THE LOWER LIMBS

A wide variety of neurological disorders impair motor functions, coordination, and balance. Such conditions are frequent causes of falls.

Disorders of the Basal Ganglia

Parkinson's Disease

Patients with PD frequently fall. Aggravating risk factors include previous falls, demenria, disease duration, benzodiazepine use, and poor performance on the Romberg test (Wood et al. 2002). Although many patients with PD have postural instability and often fall backward, the office testing of retropulsion is not reliable in predicting falls (Bloem et al. 2001), Patients with PD may also, without warning, drop directly to the ground. This is most commonly related to dopamine-induced motor fluctuations, particularly peak-dose dyskinesias and off periods (see Chapter 77). PD is also associated with a forward-flexed posture that diminishes the ability of patients to compensate for further shifts of the center of gravity. In particular, muscular rigidity and bradykinesia prevent rapid muscle activation and weight shifts when balance is offset,

Progressive Supranuclear Palsy

Patients with PSP (see Chapter 77) are characterized by parkinsonian features, axial rigidity, nuchal dystonia, spasticity, and ophthalmoparesis. They are more likely to fall backward than PD patients, even with equivalent functional impairment. Furthermore, loss of downgaze impairs their ability to avoid obstacles during ambulation. Idiopathic rapid eye movement sleep behavior disorder (sec Chapter 74) is a precursor of PSP as well as a cause of nocturnal falls in the elderly (Morfis er al. 1997). Clonazepam is usually effective in the treatment of this parasomnia and provides reliable prophylaxis for the associated falls.

Similar mechanisms to those described with PD and PSP contribute to falls in patients with related neurodegenerative disorders causing parkinsonism. Recurrent falls are a prominent feature of diffuse Lewy body disease (Imamura et al. 1999), multiple system atrophy, the pure akinesia syndrome, and cortical-basal ganglionic degeneration (sec Chapter 77).

NEUROMUSCULAR DISORDERS (MYOPATHY AND NEUROPATHY)

Myopathies characteristically involve proximal muscles and increase the tendency to fall. The multiple causes of myopathy and neuropathy (genetically determined or acquired) arc discussed in Chapters 82 and 85. Most neuropathies arc mixed (i.e., motor and sensory) in type, Regatdless of cause, neuropathies predispose the patient to falling because of lower-limb weakness and impaired afferent sensations from feet, joints, and muscles. Sensory neuropathies delay or reduce the relay of sensory signals from the lower limbs and promote falling when postural imbalance occurs. Falling may herald the onset of acute polyneuropathies, such as Guillain-Barre syndrome. Polio survivors, who are now reaching middle age and older, have a high annual frequency of falling that may exceed 60% (Silver and Aiello 2002!.

Myelopathy

Patients with spinal cord disease (see Chapter 27) are at *a* particularly high risk of falling because all descending motor and ascending sensory tracts traverse the cord. Aside from weakness, spasticity, and impaired sensory input from the lower limbs, there is disruption of vestibulospinal and cerebellar pathways. This precludes adequate corrections for sudden shifts in the center of gravity,

CEREBRAL OR CEREBELLAR DISORDERS

Motor, sensory, vestibular, and cerebellar dysfunction occur in isolation, or in any combination, in patients with central nervous system disease. Patients with acute basal ganglia lesions may show a slow, contralateral, tilting movement, causing falls. Strokes, as would be expected, increase the subsequent fall risk at least twofold. Right hemispheric stroke location, depression, and reduced arm function put these patients at particularly high risk (Jorgensen et al. 2002; Ugur et al. 2000). Metabolic encephalopathies cause characteristic transienr loss of the postural tone (asterixis). If this is extensive and involves the axial musculature, episodic loss of the uptight posture can mimic drop attacks in chronic uremic patients. Cerebellar disease causes gait ataxia, a prime cause of postural instability and falling. Moreover, patients with degenerative (see Chapter 78) or demyelinating (see Chapter 60)

cerebellar disease often have coexisting brainstem, spinal cord, or cerebral involvement.

Cataplexy

Cataplexy, the sudden loss of lower-limb tone, is a part of the tetrad of narcolepsy that also includes excessive daytime sleepiness, hypnagogic hallucinations, and sleep paralysis (see Chapter 74). Consciousness is preserved during a cataplectic attack, which varies from slight lower-limb weakness to complete flaccid paralysis and abrupt falling. Once on the ground, the patient is unable to move but continues breathing. The attacks usually last less than 1 minute and only rarely exceed several minutes. Cataplectic attacks are provoked by laughter, anger, surprise, and startle. Occasionally, they interrupt or follow sexual orgasm. During the attack, there is electromyographic silence in antigravity muscles, and deep tendon reflexes and the H-reflex (see Chapter 36B) cannot be elicited. Cataplexy occurs in the absence of narcolepsy when associated with cerebral disease (symptomatic cataplexy), as in Nicmann-Pick disease, Nome's disease, or brainstem lesions. It may occur rarely as an isolated problem in normal individuals, which may be familial (Aldrich 1998). A liquid formulation of gamma hydroxybutyrate (sodium oxybatc), an agent infamous for **its** use in date rape, is available for the treatment of cataplexy.

Vestibular Disorders (Otolithic Crisis)

During attacks of vertigo, patients often lose balance and fall. In contrast, Meniere's disease (see Chapter 18) may be complicated by drop attacks unassodated with preceding or accompanying vertigo (Tumarkm's otolithic crisis) (Kentala et al. 2001; Ishiyama et al. 2001). Presumably, stimulation of otolithic receptors in the saccule triggers inappropriate reflex postural adjustments, via vestibulospinal pathways, leading to the falls. The patients, without warning, feel as if they are being thrown to the ground. They may fall straight down or be propelled in any direction. Indeed, one of the authors (RBD) had a patient who suddenly saw and felt her legs moving forward in front of her as she did a spontaneous back-flip secondary to an otolithic crisis. This condition occurs only in patients with Meniere's disease.

CRYPTOGENIC FALLS IN MIDDLE-AGED WOMEN

Enigmatically, women older than 40 years of age have a tendency to fall. The fall is usually forward and occurs, without warning, while walking. There is no loss of consciousness, dizziness, or even a sense of imbalance. The patients are convinced that they have not tripped but that their legs suddenly gave way. As soon as they get to their feet, walking continues normally. It occurs in more than 3% of women; the disorder develops in 75% of these women after the age of 40. Twenty percent have at least one close relative (mother, aunt, or sister) with the condition. The falling frequency is quite variable. Most patients fall between 2 and 12 times per year. Only one fourth fall more than once per month or have clusters of frequent falls with prolonged asymptomatic intervals. Rarely, head trauma and significant intracranial injury results. Causal factors for this strictly female condition have been elusive. Footwear, specifically high heels, is not the cause. Occasional patients date the onset of the disorder to early in a pregnancy, before abdominal distention would be expected to **alter** postural stability. When falls begin during pregnancy, the women invariably continue falling even after delivery. The perimenstrual period makes some women with this condition more vulnerable. There is no relationship between falling and body weight. The most reasonable explanatory postulate is a prolonged long-loop (transcortical) reflex in women that delays the generation of sufficient quadriceps tension to decelerate a falling trunk.

The diagnosis is made in a middle-aged woman with inexplicable falls, a normal neurological examination, and no evidence of any other known cause of falling (see Table 3.1). There is no available pharmacological therapy. All that can be done is to reassure the patient and prevent injury by using protective knee and elbow padding. Some women, fearing falls, can become agoraphobic and should be treated with behavioral intervention,

THE AGED STATE

Most patients presenting to neurologists with a chief complaint of falling are elderly and chronically impaired. As the chance of falling increases with age, so does the severity of injury and the number of chronic disabilities predisposing to falls (Tideiksaar and **Fillit** 1997). Next to fractures, falls are the single most disabling condition leading to nursing home admission. As would be expected, elderly in sheltered accommodations have the highest frequency of falls; this may affect up to 50%. Many of these patients fall repeatedly, with elderly women bearing the highest risk. In the very old, falls constitute the leading source of injury-related deaths. This, and estimated annual health care expenditures of $20 billion for the consequences of falls, underscores their significance as a major health problem (KannuS et al. 1999).

The normal aging process is associated with a decline in multiple physiological functions that diminish the ability to compensate for external stressors that challenge the upright posture. Decreased proprioception, loss of muscle bulk (Pavol et al. 2002), arthritis of the knee and ankle joints, cardiovascular disturbances (Kario et al. 2001), deteriorating vision and ocular motor functions (Di **Fabio** et al,

2002), cognitive impairment, and failing postural reflexes (prcsbyastasis) summate and increase the risk of falling. Even the healthy elderly have a pronounced age-related decline in the ability to compensate for simulated forward falling. White matter abnormalities on brain MRIs correlate with postural instability and mobility impairment in the elderly (Kwa et al. 1998; Benson et al. 2002).

Some elderly individuals without a discernible neurological disorder lose their ability to restitute when their center of gravity is displaced backward. They retropulsc when gently pushed in the chest, and sometimes fall back when simply asked to stand up straight. They may adapt a compensatory tendency to stoop forward when upright, and walk cautiously, with a wide base and short steps.

Most of the falling elderly have one or, more commonly, several pathological predisposing conditions, and the chance of falling increases markedly with the number of identified risk factors (Tinctti 2003). In predisposed patients, a large proportion of these falls is accidental, reflecting an interaction between a debilitated patient and potential environmental hazards. This is in contrast to endogenous falls related to loss of consciousness, which are less frequent. Among tin[1] important conditions associated with tails arc dementia, metaholic and toxic encephalopathies, depression, arthritis (Tinetti 2003), cerebral infarcts, parkinsonism, neuropathy, and gait disorders (see Chapter 25).

Walking and postural recovery require more extensive attentional resources in the elderly (Brown et al. 1999). Accordingly, patients with Alzheimer's disease, when compared with healthy elderly, have slower walking speed, more difficulty clearing obstacles, and further deterioration of gait properties when asked to perform a simultaneous cognitive task, such as talking. Applying this paradigm to elderly patients in general, the observation of gait interruptions while speaking ("stops walking when talking," I.undin-Olsson et al. 1997) has a high predictive value for falling.

The clinical evaluation should aim at identifying predisposing medical conditions and differentiating accidental from endogenous falls. A detailed medication history is essential. Antidepressants, anticonvulsants, antihypertensives, antiarrhythmics, benzodiazepines and other tranquilizers, and neuroleptics increase the risk of falls (Tinetti 2003). Finally, a description of contributing environmental factors should be obtained, either from the patients or from others rami liar with their living circumstances.

Therapeutic ami risk reduction intervention for the falling elderly patient requires (1) treatment of correctable conditions, (2) provision of rehabilitative services and assistive devices, and (3) prevention by controlling environmental hazards. Pacemakers, supportive stockings, and medications may be helpful for patients experiencing autonomic dysfunction, cardiac dysrhythmias, and pharmacologically treatable movement disorders, but all unnecessary medications that increase the risk of falling (see the previous discussion) should be discontinued. Proper spectacle lenses and orthotic and other assistive devices, such as walkers, canes, and crutches, can return a progressively immobilized falling patient to a safer and more independent lifestyle. Women should be encouraged to wear sturdy low-heeled shoes. The risk of fall-related fractures may further be reduced by using specifically designed joint protectors (Kannus et al. 2000). A variety of exercise programs, particularly rhose stressing muscle strengthening and balance, reduce the risk of falls (Campbell et al. 1997; Gillespie et al. 2000). Rehabilitative efforts are indicated for those patients in whom, after a few falls, a postfall syndrome develops consisting of phobic avoidance and restrictive behavior (Friedman et al. 2002).

Controlling environmental hazards include lighting hallways, stairs, and entrances; anchoring rugs and using non-skid mats; and installing handrails in bathrooms, halls, and stairways. In addition, climbing ladders, or even stepladders, should be avoided.

SUMMARY

A careful history and physical examination should, in most cases, uncover the cause of falls and drop attacks. Unfortunately, with middle-aged women and the elderly, the cause may be merely a function of gender or age. Patients with fixed motor or sensory impairments must be advised honestly about their almost unavoidable tendency to fall. Nevertheless, environmental adjustments and use of protective devices can reduce the frequency of falls and related injuries.

Chapter 4
Delirium

Mario F. Mendez and David N. Gershfield

Delirium is a ncurobehavioral disorder characterized by an acute mental status change, fluctuating course, and abnormal attention. Delirium is a common disorder among hospitalized patients, occurring in 10-30% of medically ill patients and among 14-56% of patients 65 years of age and older (Brown and Boyle 2002; Elie et al. 2000; Inouye et al. 1998). Delirium may be the most common presentation of disease in the elderly (Bucht, Gustafson, and Sandberg 1999). The consequences of delirium are serious: They include longer hospitalizations, increased mortality, high rates of discharge to institutions, and more than $4 billion of annual Medicare expenditures in the United States (Inouye et al. 1999).

Physicians have known about this disorder since antiquity. Hippocrates referred to it as *pbrenitis,* the origin of our word *frenzy.* In the first century AD, Celsus introduced the term *delirium* from the Latin for "out of furrow," meaning derailment of the mind, and Galen observed that delirium was often due to physical diseases that affected the mind "sympathetically." In the nineteenth century, Gowers recognized that these patients could he either lethargic or hyperactive. Bonhoeffer, in his classification of organic behavioral disorders, established that delirium is associated with clouding of consciousness. Finally, Kngel and Romano described alpha slowing and delta and thcta intrusions on electroencephalograms (LLCs) and correlated these changes with clinical severity. They noted that treating the medical cause resulted in reversal of both the clinical and the EEG changes of delirium.

Despite this long history, clinicians often fail to diagnose delirium. They often miss this syndrome more from lack of recognition than from misdiagnosis as something else. The elderly, in particular, may have a "quieter," more subtle presentation of delirium. Adding to the confusion about delirium are the many terms used to describe this disorder: acute brain failure, acute brain syndrome, acute cerebral insufficiency, acute confusional state, acute organic syndrome, delirium, exogenous psychosis, metabolic encephalopathy, organic psychosis, toxic encephalopathy, toxic psychosis, and others.

One of the problems in recognizing delirium is defining the disorder. Delirium often reflects a global failure of brain metabolism from a large variety of medical etiologies, yet it is difficult to judge the impact of medical conditions on the brain. Most delirium in the elderly is superimposed on dementia, yet several investigators question the reversibility of delirium and its distinction from dementia. In sum, the definition of delirium must emphasize an acute behavioral decompensation with fluctuating attention, regardless of etiology or the presence of baseline cognitive impairments. In addition, we must carefully define the terms used with these disorders. *Attention* is the ability to focus on specific stimuli to the exclusion of others. *Arousal,* a basic prerequisite for attention, indicates responsiveness or excitability into action. *Coma, stupor, wakefulness,* and *alertness* arc states of arousal. *Consciousness,* a product of arousal, means clarity of awareness of the environment.

CLINICAL CHARACTERISTICS

The essential elements of delirium are summarized in Tables 4.1 and 4.2. Among the American Psychiatric Association's criteria (American Psychiatric Association 2000) for these disorders are an acute onset **with** fluctuations over the course of a day, reduced ability to focus and sustain attention, disorganized thinking, and evidence of a neurological or medical cause. Furthermore,

Table 4,1: Clinical characteristics of delirium

Acute onset of mental status change with fluctuating course
Attentional deficits
Disorganized thinking
Altered level of consciousness
Perceptual disturbances
Disturbed sleep-wake cycle
Altered psychomotor activity
Disorientation and memory impairment
Other cognitive deficits
behavioral and emotional abnormalities

Table 4.2: *Diagnostic and Statistical Manual of Mental Disorders,* fourth edition, Revised, criteria for delirium

A. Disturbance of consciousness (i.e., reduced clarity of awareness of the environment) with reduced ability to focus, sustain, or shift attention.
B. A change in cognition (such as memory deficit, disorientation, language disturbance) or the development of a perceptual dis turbance that is not better accounted for by pre-existing, established, or evolving demenria.
C. The disturbance develops over a short period (usually hours to days) and tends to fluctuate during the course of the day.
D. There is evidence from the history, physical examination, or laboratory findings rhat the disturbance is caused by rhe direct physiological consequences of a general medical condition.

Source: Modified with permission from American Psychiatric Association. 2000, *Diagnostic and Statistical Manual of Me/ital Disorders,* 4th ed, revised text, American Psychiatric Associatioti, Washington, DC.

delirious patients have disorganized thinking and altered level of consciousness, perceptual disturbances, disturbance of the sleep-wake cycle, increased or decreased psychomotor activity, disorientation, and memoty impairment. Other cognitive, behavioral, and emotional disturbances may also occur as part of the spectrum of delirium.

Acute Onset with Fluctuating Course

Delirium develops rapidly over hours or days but tarely over more than a week, and fluctuations in the course occur throughout the day. There are lucid intervals interspersed with the daily fluctuations. Gross swings in attention, arousal, or both occur unpredictably and irregularly and become worse at night. Because of potential lucid intervals, medical personnel may be misled by patients who exhibit improved attention and awareness unless the patients are evaluated over time,

Attentional Deficits

A disturbance of attention is the cardinal symptom of delirium. Patients are distractible, and stimuli may gain attention indiscriminately, trivial ones often getting mote attention than important ones. All components of attention ate disturbed, including selectivity, sustainability, processing capacity, case of mobilization, monitoring of the environment, and the ability to shift attention when necessary. Although many of the same illnesses result in a spectrum of disturbances from mild inattention to coma, delirium is not the same as disturbance of arousal.

Disorganized Thinking

The stream of thought is disturbed in delirium. There are multiple intrusions of competing thoughts and sensations, and patients are unable to order symbols, carry out sequenced activity, and organize goal-directed behavior, *Confusion* refers to this inability to maintain the stream of thought with accustomed clarity, coherence, and speed.

The patient's speech reflects this jumbled thinking. Speech shifts from subject to subject and is rambling, tangential, and circumlocutory, with hesitations, repetitions, and perseverations. Decreased relevance of the speech content and decreased tcading comprehension are characteristic of delirium. Confused speech is further characterized by an abnormal rate, frequent dysarthria, and nonaphasic misnaming, particularly of words related to stress or illness, such as those referable to hospitalization.

Altered Level of Consciousness

Consciousness, or clarity of awareness, may be disturbed. Most patients have lethargy and decreased arousal. Others, such as [IIDM- with delirium tremens, arc hypcralerl and easily aroused. In hyperalert patients, the extreme arousal does not preclude attentional deficits because patients are indiscriminate in their alertness, are easily distracted by irrelevant stimuli, and cannot sustain attention. The two exttemes of consciousness may overlap or alternate in the same patient or may occur from the same causative factor.

Perceptual Disturbances

The most common perceptual disturbance is decreased perceptions pet unit of time; patients miss things that are going on around them. Illusions and other misperceptions result from abnormal sensory discrimination. Perceptions may be multiple, changing, or abnormal in size or location. Hallucinations also occur, particularly in younger patienrs and in those in the hyperactive subtype. They ate most common in the visual sphere and arc often vivid, three-dimensional, and in full color. Patients may see lilliputian animals or people that appear to move about. Hallucinations are generally unpleasant, and some patients attempt to fight them or run away with fear. Some

hallucinatory experiences may be release phenomena, with intrusions into wakefulness of dreams or of visual imagery. Psychotic auditory hallucinations, with voices commenting on the patient's behavior, are unusual.

Disturbed Sleep-Wake Cycle

Disruption of the day-night cycle causes excessive daytime drowsiness and reversal of the normal diurnal rhythm. "Sundowning"—with restlessness and confusion during the night—is common, and delirium may be manifest only at mght. Nocturnal peregrinations can result in a serious problem when the delirious patient, partially clothed in a hospital gown, has to be retrieved from the hospital lobby or from the street in the middle of the night. This is one of the least specific symptoms and also occurs in dementia, depression, and other behavioral conditions. In delirium, however, disruption of circadian sleep cycles may result in rapid eye movement or dream-state overflow into wakin».

Altered Psychomotor Activity

There are two subtypes of delirium, based on changes in psychomotor activity. The hypoactive-hypoalert subtype is characterized by psychomotor retardation. These are the patients with lethargy and decreased arousal. The hyperactive-hyperalert subtype is usually hyperalert and agitated and has prominent overactivity of the autonomic nervous system. Moreover, the hyperactive type is more likely to have delusions and perceptual disorders, such as ha 11 Lie illations. About half of patients with delirium manifest elements of both subtypes or fluctuate between the two. Only about 15% are strictly hyperactive. In addition to the patients being younger, the hyperactive subtype has more drug-related causes, a shorter hospital stay, and a better prognosis.

Disorientation and Memory Impairment

Disturbances in orientation and memory are related. Patients are disoriented first to time of day, followed by other aspects of time, and then to place. They may perceive abnormal juxtapositions of events or places. Disorientation to person—in the sense of loss of personal identity—is rare. Disorientation is one of the most common findings in delirium. Disorientation is not specific for delirium, however, and it occurs in dementia and amnesia as well. Among patients with delirium, recent memory is disrupted in large part by the decreased registration caused by attentional problems.

In delirium, reduplicative paramnesia, a specific memory-related disorder, results from decreased integration of recent observations with past memories. Persons or places are "replaced" in this condition. In general, delirious patients tend to mistake the unfamiliar for the familiar. For example, they tend to relocate the hospital closer to their homes. In a form of reduplicative paramnesia known as *Capgras' syndrome,* however, a familiar person is mistakenly thought to be an unfamiliar impostor.

Other Cognitive Deficits

Disturbances occur in visuospatial abilities and in writing. Higher visual-processing deficits include difficulties in visual object recognition, environmental orientation, and organization of drawings and other constructions.

Writing disturbance is the most sensitive language abnormality in delirium. The most salient characteristics are abnormalities in the mechanics of writing: The formation of letters and words is indistinct, and words and sentences sprawl in different directions (Figure 4.1). There is a reluctance to write, and there are motor impairments, such as tremors or micrographia, and spatial disorders (e.g., misalignment or leaving insufficient space for the writing sample). Sometimes the writing shows perseverations of loops or aspects of the writing. Spelling

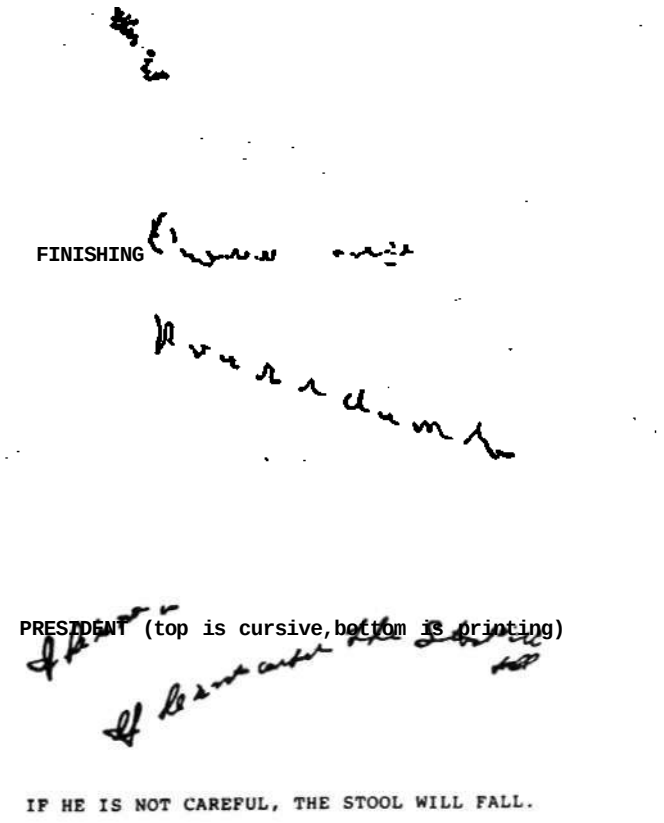

FIGURE 4.1 Writing disturbances in delirium. The patients were asked to write indicated words to dictation. (Reprinted with permission from Chédru, J. & Geschwind, N. 1972, "Writing disturbances in acute confusional states," *Neuropsychologia* vol. 10, pp. 343-353.)

and syntax are also disturbed, with spelling errors particularly involving consonants, small grammatical words (prepositions and conjunctions), and the last letters of words. Writing is easily disrupted in these disorders, possibly because it depends on multiple components and is the least-used language function.

Behavioral and Emotional Abnormalities

Behavioral changes include poorly systematized delusions, often with persecutory and other paranoid ideation and personality alterations. Delusions, like hallucinations, are probably release phenomena and are generally fleeting, changing, and readily affected by sensory input. These delusions are most often persecutory. Some patients exhibit facetious humor and playful behavior, lack of concern about their illness, poor insight, impaired judgment, and confabulation.

There can be marked emotional lability. Sometimes patients are agitated and fearful, or depressed, or quite apathetic. Dysphoric (unpleasant) emotional states arc the more common, and emotions are not sustained. Up to one half of elderly delirious patients display symptoms of depression with low mood, loss of interests, fatigue, decreased appetite and sleep, and other feelings related to depression, Thete may be mood-congruent delusions and hallucinations. The mood changes of delirium are probably due to direct effects of the confusional state on the limbic system and its regulation of emotions,

Finally, more elementary behavioral changes may be the principal symptoms of delirium. This is especially the case in the elderly, in whom decreased activities of daily living, urinary incontinence, and frequent falls are among the major manifestations of this disorder,

PATHOPHYSIOLOGY

The pathophysiology of delirium is not entirely understood, but it depends on a widely distributed neurological substrate. Normal attention requires both the ascending reticular activating system (ARAS) in the upper brainstem and polymodal association areas of the cortex. Stimulation of the ARAS elicits arousal, and lesions of the ARAS may result in sleep, coma, or akinetic mutism rather than attentional problems or delirium (see Chapters 5 and 74). The ARAS primes the cortex for stimulus reception, whereas the polymodal association cortex controls and focuses this arousal energy for attention.

Certain brain areas may be particularly involved in attention: bilateral or right prefrontal cortex in attcntional maintenance and executive control, the temporoparietal junction region in disengaging and shifting attention, the thalamus in engaging attention, and the upper brainstem structures in moving the focus of attention. Cortical blood flow studies suggest that the polymodal cortical areas and their limhic connections arc the "attentional gate" for sensory input through feedback to the reticular nucleus of the thalamus (Figure 4.2). The thalamic nuclei are uniquely positioned to further screen sensory information from the ARAS, and small lesions in the thalamus may cause delirium. As part of thalamofrontal circuits, the thalamic nuclei influence and regularc the activity of cerebral and limbic cortices. In addition, there is evidence that the right hemisphere is dominant for attention, although split-brain studies clearly point out the need for bihemispheric cooperation in maintaining attention.

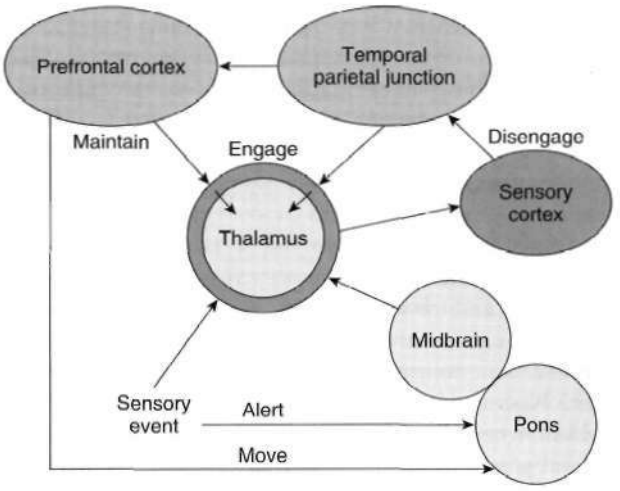

FIGURE 4.2 A proposed schema for the attention system. The important polymodal areas arc the prefrontal cortex and the temporal-parietal junction, particularly in the right hemisphere. A sensory signal leads to alerting and localization as it is relayed from the thalamus to the primary sensory cortex. Upon transmission to the temporal-parietal cortex, attention is disengaged from its current focus and moved to engage the sensory event. Environmental monitoring and the "'gate" function of attention may occur through feedback from the polymodal cortical areas to the nucleus reticularis of the thalamus (external thalamic ring), a modulator of sensory input.

A second explanation for delirium is alterations in neurotransmitters, particularly a cholinergic-dopaminergic imbalance. Anticholinergic agents can induce the clinical and EEC changes of delirium, which are reversible with the administration of cholinergic medications, such as physostigmine. The beneficial effects of tacrine and donepezil, acetylcholinesterase inhibitor medications used for Alzheimer's disease, may be partly due to an activating or attention-enhancing role, Moreover, cholinergic neurons project from the pons and the basal forebrain to the cortex and make cortical neurons more responsive to other inputs, A decrease in acetylcholine results in decreased perfusion in the frontal cortex. Hypoglycemia, hypoxia, and other metabolic-changes may differentially affect acetylcholinc-mediated functions. Other neurotransmitters may be involved in delirium, including dopamine, serotonin, norepinephrine, y-aminobutyric acid, glutamine, opiates, and histamine.

Dopamine appears to function in a reciprocal fashion to acetylcholine, hence the delirium-producing effects of i.-dopa and other antiparkinsonism medications. Opiates may induce the effects by increasing dopamine and glutamate activity. Future studies may show a role for inflammatory cytokines in the pathogenesis of delirium.

Any explanation of delirium must take into account not only specific structural lesions and neurotransmitter changes but also the diffuse metabolic causes that can result in the same disturbances of attention. The diffuse causes, the universal susceptibility to developing delirium, **and** the minimal or nonspecific pathologic changes suggest an impairment of some common metabolic pathways in nerve cells. Metabolic pathways involving the ARAS and i he poly modal cortex may he vulnerable because these lira areas have the most polysynaptic chains.

DIAGNOSIS OF DELIRIUM

Diagnosis is a two-step process. The first step is the recognition of delirium, which requires a thorough history, a bedside mental status examination focusing on attention, and a review of established diagnostic scales or criteria for delirium. The second step is to identify the cause from a large number of potential diagnoses. Because the clinical manifestations offer few clues to the cause, crucial to the differential diagnosis are the general history, the physical examination, and the laboratory assessment. In addition, the clinician should thoroughly review the patient's medication list.

History

An abrupt decline in mentation, particularly in the hospital, should be presumed to be delirium. Although patients may state that they cannot think straight or concentrate, family members or other good historians should be available to describe the patient's behavior and medical history. The observer may have noted early symptoms of delirium, such as inability to perform at a usual level, decreased awareness of complex details, insomnia, and frightening or vivid dreams. Furrhermore, it is crucial to obtain accurate information about systemic illnesses, drug use, recent trauma, occupational and environmental exposures, malnutrition, allergies, and any preceding symptoms leading to a confusional state.

The patient's risk factors for delirium should be carefully assessed (Table 4.3). Of the risk factors that predispose to incident delirium in the hospital, the most important are advanced age, pre-existing cognitive dysfunction or dementia, and chronic medical illnesses (Johnson 2001). Advanced age itself seems to be an independent risk factor, especially for those older than 80 years. Many of these elderly parients predisposed to delirium have cerebral atrophy or white matter and basal ganglia ischemic changes on neuroimaging. Among the elderly, those with dementia are five times more likely to develop delirium than those without dementia (Elie et al. 1998). As many as one half of hospitalized patients with delirium have an underlying dementia, and many of the remainder have mild cognitive impairment, A third factor is the severity of the illness and the degree of physical impairment. Additional risk factors include vision impairment (<20/70 binocular); hip and other bone fractures; dehydration, serum sodium changes, and azotemia; infections and fevers; and the use of multiple drugs, particularly those with narcotic, anticholinergic, or psychoactive properties. The risk factors are additive, each new factor increasing the risk considerably. Precipitating factors for incident delirium after hospitalization include the use of physical restraints, malnutrition defined as albumin levels less than 30 g/L, the addition of more than three new medications, the use of a bladder catheter, and any iatrogenic medical complications (lnouye and Charpentier 1996). Ultimately, delirium occurs in patients from a synergistic interaction of predisposing factors with precipitating factors.

Sensory overstimulation or undersrimulation facilitates confusional behavior, probably because optimal attention requires an optimal amount of sensory input. Novel situations and unfamiliar surroundings contribute to

Table 4.3: Risk factors for delirium

Elderly, especially SO years or older
Dementia, cognitive impairment, or other brain disorder
Fluid and electrolyte disturbances and dehydration
Other metabolic disturbance, especially elevated blood urea nitrogen level, or hepatic insufficiency
Number and severity of medical illnesses including cancer
Infections, especially urinary tract, pulmonary, and acquired immunodeficiency syndrome
Malnutrition, low serum albumin level
Cardiorespiratory failure or hypoxemia
Prior stroke or other nondementia brain disorder
Polypharmacy and use of analgesics, psychoactive drugs, or anticholinergics
Drug abuse, alcohol or sedative dependency
Sensory impairment, especially visual
Sensory overstimulation and "intensive care unit psychosis"
Sensory deprivation
Sleep disturbance
Functional impairment
Fever, hypothermia
Physical trauma or severe burns
Fractures
Male gendef
Depression
Specific operations
Cardiac, especially open heart surgery
Orthopedic, especially femoral neck and hip fractures, bilateral knee replacements
Ophthalmologics], especially cataract surgery
Noneardiac thoracic surgery and aortic aneurysmal repairs
Transurethral resection of the prostate

sensory overstimulation in the elderly, and sensory overload may be a factor in producing "intensive care unit (ICU) psychosis." Immobilization, with decreased kinesthetic inputs, contributes to sensory deprivation. Sleeplessness may cause confusion; however, it is not the decreased total amount of sleep that predisposes to delirium but the resulting disruption of circadian sleep cycles.

Mental Status Examination

Initial general behavioral observations are an important part of the neurological mental status examination. The most important arc observations of attentiveness and arousability. Attention may wander so much that it must constantly be brought back to the subject at hand. General behavior may range from falling asleep during the interview to agitation and combativeness. Slow and loosely connected thinking and speech may be present, with irrelevancies, perseverations, repetitions, and intrusions. Patients may propagate their errors in thinking and perception by elaboration and by bringing other observations into agreement with them. Finally, the examiner should evaluate the patient's general appearance and grooming; motor activity and spontaneity; mood and affect, propriety, and witticisms; and the presence of any special preoccupations or inaccurate perceptions.

Bedside tests of attention can be divided into serial recitation tasks, continuous performance tasks, and alternate response tasks. The digit span test is a serial recitation task in which a series of digits is presented, one digit per second, and the patient is asked to repeat the entire sequence immediately after presentation. Perceptual clumping is avoided by the use of random digits and a regular rhythm of presentation. Correct recitation of seven (plus or minus two) digits is considered normal. The serial reversal test is a form of recitation task in which the patient recites backward a digit span, the spelling of a word such as *world*, or the results of counting by ones, threes, or sevens from a predetermined number. Continuous performance tasks include the *A* vigilance test, in which the patient must indicate whenever she hears the letter *A* among random letters presented one per second. This can also be done visually by asking the patient to cross out every instance of a particular letter in a magazine or newspaper paragraph. Alternate response tasks are exemplified by the repetition of a three-step motor sequence (palm-side-fist), which is also a test of frontal functions. These attentional tests are not overly sensitive or specific, and they can be affected by the patient's educational background, the degree of effort, or the presence of other cognitive deficits. In sum, the best assessment of attention may be general behavioral observations and an appraisal of how "interviewablc" the patient is.

Attentional or arousal deficits may preclude the opportunity to pursue the mental status examination much further, but the examiner should attempt to assess orientation and other areas of cognition. Patients who are off 3 days on the date, 2 days on the day of the week, or 4 hours on the time of day may be significantly disoriented to time. The examiner should inquire whether the patient knows where he or she is, what kind of a place it is, and under what circumstances he or she is there. Disturbed recenr memory is demonstrated by asking the patient to retain the examiner's name or three words for 5 minutes. A language examination should distinguish between the language of confusion and that of a primary aphasia (sec Special Problems in Differential Diagnosis, later in this chapter). Attempts at simple constructions, such as copying a cube, may be unsuccessful. Hallucinations can somerimes be brought out by holding a white piece of paper or an imaginary string between the fingers and asking the patient to describe what he or she sees.

Diagnostic Scales and Criteria

The usual mental status scales and tests may not help in differentiating delirium from dementia and other cognitive disturbances. Specific criteria and scales are available for the diagnosis of delirium. Foremost among these are the *Diagnostic and Statistical Manual of Mental Disorders*, fourth edition *(DSM-1V)*, criteria for delirium (see Table 4,2). Investigators have criticized these criteria because of the required "disturbance of consciousness" and the broadness of "a change in cognition." The Confusion Assessment Method (CAM) is a widely used instrument for diagnosing delirium (Ely et al. 2001), It is a structured interview with nine ope rationalized questions from the *DSM-IV*. The CAM can be simplified to a diagnostic algorithm of four items: an acute onset with fluctuating course, inattention, and either disorganized thinking or an altered level of consciousness. A version of the CAM for ICU patients (CAMTCU) is a 2-minute assessment instrument that has been shown to be valid and reliable in detecting delirium in mechanically ventilated ICU patients (Ely et al. 2001). The Delirium Rating Scale-Revised-98 (DRS-R-98), a revision of the earlier Delirium Rating Scale (DRS), is a 16-item scale with 13 severity items and three diagnosric items that reliably distinguish delirium from dementia, depression, and schizophrenia (Trzepacz et al. 2001). The Memorial Delirium Assessment Scale (MDAS) is a 10-item scale designed to quantify the severity of delirium in medically ill patients that may also be useful as a diagnosric tool (Breirbart er al. 1997). The Delirium Symptom Interview is also a valuable instrument but may not distinguish delirium from dementia. The diagnosis of delirium is facilitated by the use of the CAM/CAM-ICU, DRS-R-98, MDAS, or the Delirium Symptom Interview along with the history from collareral sources, such as family and nursing notes; a mental status examination focusing on attention; and specific tests, such as a writing sample.

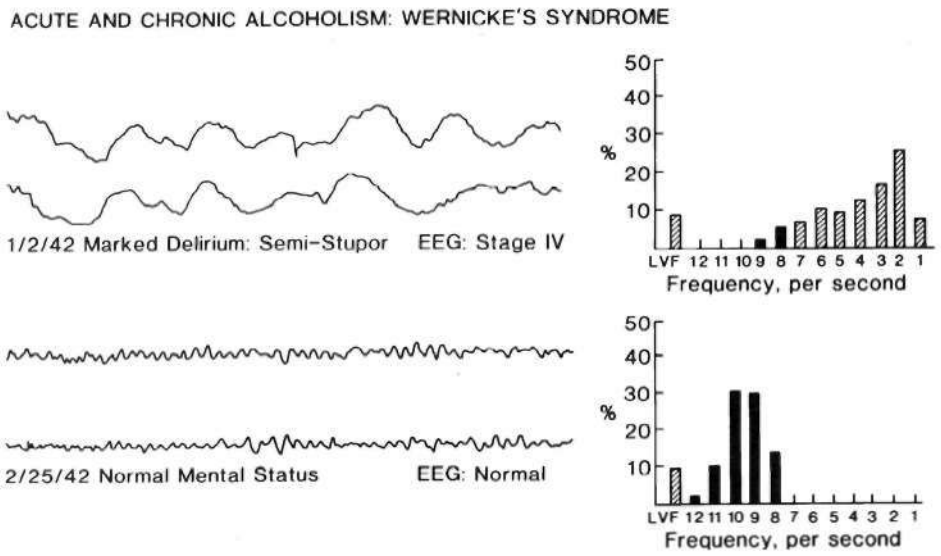

FIGURE 4.3 Electroencephalogram (EEG) showing changes caused by delirium. LVF = low-voltage filter. (Reprinted with permission from Romano, J. & Engel, G. L. 1944, "Delirium, 1: EEG data," *Arch Neurol Psychiatry*, vol. 51, p. 356.)

Physical Examination

The physical examination should elicit any signs of systemic illness, focal neurological abnormalities, meningism, increased intracranial pressure, extracranial cerebrovascular disease, or head trauma. In delirium, less specific findings include an action or postural tremor of high frequency (8-10 Hz), asterixis or brief lapses in tonic posture, especially at the wrist; multifocal myoclonus or shocklikc jerks from diverse sites; choreiform movements; dysarthria; and gait instability. Patients may manifest agitation or psychomotor retardation, apathy, waxy flexibility, catatonia, or carphologia ("lint-picking" behavior). The presence of hyperactivity of the autonomic nervous system may be life threatening because of possible dehydration, electrolyte disturbances, or tachyarrhythmias.

Laboratory Tests

EEG changes virtually always accompany delirium when the EEGs arc followed serially over time (see Chapter 36A). Disorganization of the usual cerebral rhythms and generalized slowing are the most common changes. The mean EEG trvqiiency or degree of slowing correlates with the degree of delirium. Both hypoactive and hyperactive subtypes of delirium have similar EEG slowing; however, predominant low-voltage fast activity is also present on withdrawal from sedative drugs or alcohol. Additional EEG patterns from intracranial causes of delirium include focal slowing, asymmetric delta activity, and paroxysmal discharges (spikes, sharp waves, and spike-wave complexes). Periodic complexes, such as triphasic waves, and periodic latcralizing epileptiform discharges may help in the differential diagnosis (see Chapter 36A). EEGs arc of value in deciding whether confusional behavior may be due to an intracranial cause, in making the diagnosis of delirium in patients with unclear behavior, in evaluating demented patients who might have a superimposed delirium, in differentiating delirium from schizophrenia and other primary psychiatric states, and in following the course of delirium over time. Romano and Engel (1944) demonstrated the presence of background slowing in all subtypes of delirium in their now classic paper (Figure 4.3).

Other essential laboratory tests include a complete blood cell count; measurements of glucose, electrolytes, blood urea nitrogen, creatinine, transaminase, and ammonia levels; thyroid function tests; arterial blood gas studies; chest x-ray films; electrocardiogram; urinalysis; and urine drug screening. Although they arc nonspecific, evoked potential studies often show prolonged latencies. The need for a lumbar puncture deserves special comment. This valuable test, which is often neglected in the evaluation of delirious patients, should be performed as part of the workup when the cause is uncertain. The lumbar puncture should be preceded by a computed tomographic or magnetic resonance imaging scan of the brain, especially if there are focal neurological findings or suspicions of increased intracranial pressure, a space-occupying lesion, or head trauma. The yield of functional imaging is variable, showing global increased metabolism in patients with delirium tremens and global decreased metabolism or focal frontal hypoactivity in many other delirious patients.

Differential Diagnosis

The following discussion is a selective commentary that illustrates some basic principles and helps organize the approach to working through the large differential diagnosis. Almost any sufficiently severe medical or surgical illness can cause delirium, and the best advice is to follow

Table 4.4: Major causes of delirium

Metabolic disorders	Hepatic encephalopathy, uremia, hypoglycemia, hypoxia, hyponatremia, hypocalcemia/ hypercalcemia, Hypomagnesemia/ hypermagnesemia, other electrolyte disturbances, acidosis, hyperosmolar coma, endocrinopathies (thyroid, parathyroid, pituitary), porphyria, vitamin deficiencies (thiamine, vitamin R|$_2$, nicotinic acid, folic acid), toxic and industrial exposures (carbon monoxide, organic solvent, lead, manganese, mercury, carbon disulfide, heavy metals)
Drug related	Withdrawal syndromes (alcohol, benzodiazepines, barbiturates, other), amphetamines, cocaine, coffee, phencyclidine, hallucinogens, inhalants, meperidine and other narcotics, antiparkinsonism drugs, sedative-hypnotics, corticosteroids, anticholinergic and antihistaminic drugs, cardiovascular agents (beta blockers, clonidinc, digoxin), psychotropics (phenothiazines, clozapine, lithium, tricyclic antidepressants, trazodone), 5-fluorouracil and cytotoxic antineoplastics, anticonvulsants (phenobarbital, phenytoin, valproate), cimetidine, disulfirarn, ergot alkaloids, salicylates, methyldopa, and selected anti-infectious agents (acyclovir, amphotericin B, cephalexin, chloroquine, isoniazid, rifampin)
Infections	Meningitis, encephalitis, brain abscess, neurosyphilis, Lyme neuroborreliosis, cerebritis, systemic infections with septicemia
Neurological	Strokes, epilepsy, head injury, hypertensive encephalopathy, brain tumors, migraine, other neurovascular disorders
Perioperative	Specific surgeries (cardiac, orthopedic, ophthalmologics!), anesthetic and drug effects, hypoxia and anemia, hyperventilation, fluid and electrolyte disturbances, hypotension, embolism, infection or sepsis, pain, fragmented sleep, sensory deprivation or overload
Miscellaneous	Cerebral vasculitidcs, paraneoplastic and limbic encephalitis, hyperviscosity syndromes, trauma, cardiovascular, dehydration, sensory deprivation

all available diagnostic leads (Table 4.4). (For further discussion of individual entities, the reader should refer to corresponding chapters in this book.) The confusion-inducing effects of these disturbances arc additive, and there may be more than one causal factor, the individual contribution of which cannot be elucidated. Nearly one half of elderly patients with delirium have mote than one cause of their disorder. Of the causes for delirium, the most common among the elderly are metabolic disturbances, infection, stroke, and drugs, particularly anticholinergic and narcotic medications. The most common causes among the young are drug abuse and alcohol withdrawal.

Metabolic Disturbances

Metabolic disturbances are the most common causes of delirium (see Chapters 55A and 5.SB, 61, 62, and *63).* Fortunately, the examination and routine laboratory tests screen for most acquired metabolic disturbances that might be encountered. Because of tlie potential lor life-threatening or permanent damage, some of these conditions—particularly hypoxia and hypoglycemia—must be considered immediately. Also consider dehydration, fluid and electrolyte disorders, and disturbances of calcium and magnesium. The rapidity of change in an electrolyte level may be as important a factor as its absolute value for the development of delirium. For example, some people tolerate chronic sodium levels of 115 mEq/L or less, but a rapid fall to this level can precipitate delirium, seizures, or even central pontine myelinolysis, particularly if the correction of hyponatremia is too rapid. Hypoxia from low cardiac output, rcspiratoty insufficiency, or other causes is another common source of delirium. Also consider other major organ failures, such as liver and kidney failure, including the possibility of unusual causes, such as undetected portocaval shunting or acute pancreatitis with the release of lipases. Delirium caused by endocrine dysfunction often has prominent affective symptoms, such as hyperthyroidism and Cushing's syndrome. Delirium occasionally results from roxins, including industrial agents, pollutants, and heavy metals, such as arsenic, bismuth, gold, lead, mercury, thallium, and zinc. Other considerations are inborn errors of metabolism, such as acute intermittent porphyria. Finally, it is particularly important to consider thiamine deficiency. In alcoholics and others at risk, thiamine must be given immediately to avoid precipitating Wernicke's encephalopathy with the administration of glucose.

Drugs

Drug intoxication and drug withdrawal are among the most common causes of delirium. In the elderly, medications contribute to delirium in up to 39% of patients (Inouye and Charpcnticr 1996). Drug effects are additive, and drugs that are especially likely to cause delirium arc those with anticholinergic properties, including many over-the-counter cold preparations, antihistamines, antidepressants, and neuroleptics. Patients with anticholinergic intoxication ptcscnt "hot as a hare, blind as a bat, dry as a bone, red as a beet, and mad as a hatter," reflecting fever, dilated pupils, dry mouth, flushing, and delirium. Other important groups of drugs associated with delirium, especially in the elderly, are sedative-hypnotics, narcotic analgesics, and I ^-receptor blockers. Antiparkinsonism drugs result in confusion, with prominent hallucinations and delusions in patients with Parkinson's disease, who are particularly susceptible. Corticosteroid psychosis may develop in patients taking the equivalent of 40 mg per day or more of prednisone. The behavioral effects of corticosteroids often begin with euphoria and hypomania and proceed to a hyperactive delirium. Any drug administered intra thee ally, such as metrizamide, is prone to induce confusional behavior. Drug withdrawal syndromes can be

caused by many agents, including barbiturates and other minor tranquilizers, sedative-hypnotics, amphetamines, cocaine or "crack," and alcohol. Delirium tremens begins 72-96 hours after alcohol withdrawal, with profound agitation, tremulousncss, diaphoresis, tachycardia, fever, and frightening visual hallucinations.

Infections

Infections and fevers often produce delirium. The main offenders are urinary tract infections, pneumonia, and sepricemia. In a sporadic encephalitis or meningoencephalitis, important causal considerations are herpes simplex virus, Lyme disease, and acquired immunodeficiency syndrome (AIDS) (see Chapter 59E). Patients with AIDS may be delirious because of the human immunodeficiency virus (HIV) itself or because of an opportunistic infection. Immunocompromised patients are at greater risk of infection, and any suspicion of infection should prompt culture of urine, sputum, blood, and cerebrospinal fluid.

Strokes

Delirium can be the nonspecific consequence of any acute stroke, but posrinfarct confusion usually resolves in 24-48 hours (see Chapter 57A). Sustained delirium can result from specific strokes, including right middle cerebral artery infarcts affecting prefrontal and posterior parietal areas, and posterior cerebral artery infarcts resulting in cither bilateral or left-sided occipitotemporal lesions (fusiform gyrus). The latter lesions usually involve the left hemisphere and can lead to agitation, visual field changes, and even Anton's syndrome (see Chapter 14), Delirium may also follow occlusion of the anterior cerebral artery or rupture of an anrerior communicating artery aneurysm with involvement of the anterior cingulate gyrus and septal region. Thalamic or posterior parietal cortex strokes may present with severe delirium, even with small lesions.

Other cerebrovascular conditions that can produce delirium include high-grade bilateral carotid stenosis, hypertensive encephalopathy, subarachnoid hemorrhage, and central nervous system (CNS) vasculitides, such as systemic lupus erythematosus, temporal arteritis, and Behcet's syndrome. Migraine can present with delirium, particularly in children. It must be emphasized that the frequency of delirium in transient ischemic attacks, even in vertebrobasilar insufficiency, is low. Transient ischemic attacks should not be consideted the cause of delirium unless there are other neurological signs and an appropriate time course.

Epilepsy

Abnormal brain electrical activity is associated with delirium in four conditions: (1) ictally, with absence status, complex partial srarus, tonic status without convulsions, or periodic lateralizing epileptiform discharges; (2) postictally, after complex partial or generalized tonic-clonic seizures; (3) interictally manifested as increasing irritability, agitation, and affective symptoms associated with the prodrome of impending seizures; and (4) from the cognitive effects of anticonvulsant medications.

Postoperative Causes

The cause of delirium in postoperative patients is often multifactorial (Winawer 2001). Predisposing factors to postoperative delirium include age older than 70 years, preexisting CNS disorders such as dementia and Parkinson's disease, severe underlying medical conditions, and a history of alcohol abuse. Precipitating factors include residual anesthetic and drug effects, especially after premedication with anticholinergic drugs; postoperative hypoxia; perioperative hypotension; electrolyte imbalances; infections; psychologic stress; and multiple awakenings with fragmented sleep. There is no clear correlation of delirium with specific anesthetic route. Postoperative delirium may start at any time but often becomes evident about the third day and abates by the seventh, although it may last considerably longer.

A number of surgeries are associated with a high rate of postoperative delirium. Between 30% and 40% of patients experience delirium after open heart or coronary artery bypass surgery. Patients older than 60 years are at special risk for postoperarive delirium after cardiac surgery. Additional factors are decreased postoperative cardiac output and length of time on cardiopulmonary bypass machine, with its added risk for microemboli. In addition to an alteady high rate of delirium following fractures, orthopedic surgeries, particularly femoral neck fractures and bilateral knee replacements, further increase the frequency of delirium by about 18%. Elective noncardiac thoracic surgery is also associated with a 9-14% frequency of delirium in the elderly. Cataract surgery is associated with a 7% frequency of delirium, possibly because of sensory deprivation. Patients who have undergone prostate surgery may develop water intoxication as a result of absorption of irrigation water from the bladder.

Other Neurological Causes

Other CNS disturbances predispose to delirium. In general, patients with dementia, Lewy body disease, Parkinson's disease, and atrophy or subcortical ischemic changes on neuroimaging are particularly susceptible. Electroconvulsive rherapy in these patients often produces a delirium of a week or more. Head trauma can result in delirium as a consequence of brain concussion, brain contusion, intracranial hematoma, or subarachnoid hemorrhage (see Chapter 56B). Moreover, subdural hematomas can occur in the elderly with little or no history of head injury. Rapidly growing tumors in the supratcntorial region are especially

likely to cause delirium with increased intracranial pressure. Paraneoplastic processes produce limbic encephalitis and multifocal leukoencephalitis. Delirium can result from acute demyelinating diseases and other diffuse multifocal lesions, and from communicating or noncommunicating hydrocephalus. In transient global amnesia, there is initial delirium, disproportionate anterograde amnesia, some retrograde amnesia for the preceding hours, and improvement within 24 hours. In Wernicke's encephalopathy, delirium accompanies oculomotor paresis, nystagmus, ataxia, and frequently residual amnesia (Korsakoff's psychosis).

Miscellaneous Causes

Various other disturbances can produce delirium. Bone fractures are associated with delirium in the elderly, and about 50% of those admitted with a hip fracture have delirium. In orthopedic cases, the possibility of fat emboli requires evaluation of urine, sputum, or cerebrospinal fluid for fat. ICU psychosis is associated with sleep deprivation, immobilization, unfamiliarity, fear, and frightening sensory overstimulation or sensory deprivation. Delirium results from blood dyscrasias, including anemia, thrombocytopenia, and disseminated intravascular coagulopathy. Finally, physical factors, such as heatstroke, electrocution, and hypothermia may be causal.

Special Problems in Differential Diagnosis

Delirium must be distinguished from dementia, Wernicke's aphasia, and psychiatric conditions (see Chapters 6, 8, 12, and 72). The main differentiating features of dementia are the longer time course and the absence of prominent fluctuating attentional and perceptual deficits. Chronic confusional states lasting 6 months or more are a form of dementia. Patients with delirium that becomes chronic tend to settle into a lethargic state without inattention or fluctuations throughout the day, and they have fewer perceptual problems and less disruption of the day-night cycle. In addition, delirium and dementia often overlap because demented patients have increased susceptibility for developing a superimposed delirium. Demented patients who suddenly get worse should always be evaluated for delirium. Moreover, distinguishing delirium from certain forms of dementia, such as vascular dementia and dementia with Lewy bodies, may be particularly difficult. Patients with vascular dementia may have an acute onset or sharp decline in cognition similar to delirium. Patients with dementia with Lewy bodies have fluctuations in attention and alertness and visual hallucinations that can look identical to delirium. Most of these patients, however, have parkinsonism, repeated falls, or other supportive features. Nevertheless, the differential diagnosis of delirium and dementia with Lewy bodies may not be possible until after a diagnostic workup is completed.

The language examination should distinguish Wernicke's aphasia from the language of delirium. Aphasics have prominent paraphasias of all types, including neologisms, and they have relatively preserved response to axial or whole-body commands. Their agraphia is also empty of content and is paragraphic compared with the mechanical and other writing disturbances previously described in patients with delirium.

Psychiatric conditions that may be mistaken for delirium include schizophrenia, depression, mania, attention-deficit disorder, autism, dissociative states, and Ganser's syndrome, which is characterized by ludicrous or approximate responses (see Chapter 8). In general, patients with psychiatric conditions lack the fluctuating attentional and related deficits associated with delirium. Schizophrenic patients may have a very disturbed verbal output, but their speech often has an underlying bizarre theme. Schizophrenic hallucinations are more often consistent persecutory voices rather than fleeting visual images, and their delusions arc more systematized and have personal reference. Conversely, delirious hallucinations are usually visual, and their delusions are more transitory and fragmented. Mood disorders may also be mistaken for delirium, particularly if there is an acute, agitated depression or a predominantly irritable mania. A general rule is that psychiatric behaviors may be due to delirium, especially if they occur in someone who is 40 years or older without a prior psychiatric history.

Table 4.5 outlines the special problems that must be considered in the differential diagnosis of acute confusional states.

MANAGEMENT

There are several steps in the management of delirium. First, attention is aimed at finding the cause and eliminating it. Second, the delirium is managed with symptomatic measures involving attention to fluid and electrolyte balance, nutritional status, and early treatment of infections. Third, management focuses on environmental interventions. Reduce unfamihanty by providing a calendar, a clock, family pictures, and personal objects. One should maintain a moderate sensory balance in the patient by avoiding sensory overstimulation or deprivation. Minimize staff changes, limit ambient noise and the number of visits from strangers, and provide a radio or a television set, a night light, and where necessary eyeglasses and hearing aids. Other environmental measures include providing soft music and warm baths and allowing the patient to take walks when possible. Fourth, proper communication and support are critical with these patients. As much as possible, everything should be explained. Delusions and

Table 4.5: Special problems in the differential diagnosis of delirium*

Clinical feature	*Delirium*	*Dementias*	*Stroke with Wernicke's aphasia*	*Schizophr*
Course	Acute onset; hours, days, or more	Insidious onset ; months or years; progressive	Sudden onset; chronic, stable deficit	Insidious more; acu
Attention	Markedly impaired attention and arousal	Normal early; impairment later	Normal	Normal t
Fluctuation	Prominent in attention arousal; disturbed day-night cycle	Prominent fluctuations absent; lesser disturbances in day-night cycle	Absent	Absent
Perception	Misperceptions; hallucinations, usually visual, fleeting; paramnesia	Perceptual abnormalities much less prominent*; paramnesia	Normal	Hallucin with pers
Speech and language	Abnormal clarity, speed, and coherence; disjointed and dysarthric; misnaming; characteristic dysgraphia	Early anornia; empty speech; abnormal comprehension	Prominent paraphasias and neologisms; empty speech; abnormal comprehension	Disorgan theme
Other cognition	Disorientation to time, place; recent memory and visuQspatial abnormalities	Disorientation to time, place; multiple other higher cognitive deficits	No other necessary deficits	
Behavior	Lethargy or delirium; nonsystematized delusions; emotional lability	Disinterested; disengaged; disinhibitcd; delusions and other psychiatric symptoms	Paranoia possibly ensuing	
Electroencephalogram	Diffuse slowing; low-voltage fast activity; specific patterns	Normal early; mild slowing later	Normal	

The characteristics listed are the relative and usual ones and arc not exclusive.
Vatients with vascular dementia may have an abrupt decline in cognition.
•Patients with dementia with diffuse cortical Lewy bodies often have a fluctuating mental status and hallucinations.

hallucinations should be neither endorsed nor challenged. Patients should receive emotional support including frequent family visits. They also benefit from frequent reorientation to place, time, and situation. Finally, the management of delirium includes attention to risk factors. A risk factor intervention strategy aimed at managing six key risk factors for delirium—cognitive impairment, sleep deprivation, immobility, visual impairment, hearing impairment, and dehydration—can produce significant reductions in the number and duration of episodes of delirium in hospitalized older patients (Inouye et al. 1999}.

In general, it is best to avoid the use of drugs in confused patients because they further cloud the picture and may worsen the delirium. All the patient's medications should be reviewed, and any unnecessary drugs should be discontinued. When medication is needed, these patients should receive the lowest possible dose and should not get drugs such as phenobarbital, which can cause a paradoxical reaction. Many patients benefit from regulation of the sleep-wake cycle and from a good night's sleep, provided by hypnotics, such as chloral hydrate or temazepam. Medication may be necessary if the patient's behavior is potentially dangerous, interferes with medical care, or causes the patient profound distress. Drug rrcarment can be directed at anxiety, fear, paranoia, hallucinations, delusions, agitation, and aggression. Clinicians have used the older antipsychotic drugs, such as haloperidol (starting at 0.25 mg daily) for these symptoms; however, the arypical antipsychotics at low doses, such as risperidone (starting at 0.2.5-0.5 mg twice daily, which may be increased up to .3^ mg per day), olanzapine (2.5-5.0 mg at bedtime, increased if needed to up to 20 mg daily), and quetiapine (starting at 25-50 mg twice a day and increasing to 200 mg per day if necessary), may be better alternatives (Schwartz and Masand 2002). Ondansetron may be effective and safe in the treatment of delirium occurring after coronary artery surgery (Bayindir et al. 2001). Benzodiazepines and anticholinergic medications should be avoided, if possible. Whether these chemical restraints are better than physical restraint is controversial. One form of restraint may work better than another docs in individual patients; however, physical rcsrraints should be avoided if possible and a sirtcr used instead.

PROGNOSIS

If the causative factor is rapidly corrected, the prognosis is good in most cases. The average duration of delirium is a few days to 2 weeks, but it may extend to 12 weeks in the elderly. After hospital discharge, older patients who were delirious may not recover back to baseline (McCusker et a). 2001). A partial delirium, which meets some but not all criteria, occurs in about one third of postdelirium elderly, and less rhan 20% have returned to their baseline by *6* months. Moreover, after delirium, elderly patients often have a decline in activities of daily living and increased likelihood of nursing home placement. Delirium itself is an independent predictor of adverse outcomes in older hospitalized patients, including increased mortality (McCusker et al. 2002; O'Keeffe and Lavan 1997), and contributes to falls, pressure sores, and other adverse events. In general, an improved prognosis relates to an increased awareness of delirium, with more rapid diagnosis of the causative factor and better overall management One final reason for the vigorous management of delirium is that delirium itself is a stressor that may lead to depression or post-trail ma tic stress disorder.

Chapter 5
Clinical Approach to Stupor and Coma

Joseph R. Berger

DEFINITIONS

Consciousness may be defined as a state of awareness of self and surroundings. Alterations in consciousness are conceptualized into two types. One, which affects arousal, is the subject of this chapter. The other involves cognitive and affective mental function, sometimes referred to as the *content* of mental function. Examples of the latter type of alteration in consciousness include dementia (see Chapter 6), delusions, confusion, and inattention (see Chapter 8). These altered states of consciousness, with the exception of advanced dementia, do not affect the level of arousal. Sleep, the only normal form of altered consciousness, is discussed in Chapter 74.

The term *delirium* describes a clouding of consciousness with reduced ability to sustain attention to environmental stimuli (Taylor and Lewis 1993). Diagnostic criteria for delirium from the *DSM-SV-R* include at least two of the following: (1) perceptual disturbance (misinterpretations, illusions, ot hallucinations), (2) incoherent speech at times, (3) disturbance of sleep-wake cycle, and (4) increased or decreased psychomotor activity *(DSM-IV-R* 2000). Delirium is a good example of a confusional state in which a mild decline in arousal may be clinically difficult to separate from a change in cognitive or affective mental function. In clinical practice, the exact boundary between different forms of altered consciousness may be vague.

Alterations in arousal, although often referred to as levels of consciousness, do not actually form discrete levels but rather are made up of a continuum of subtly changing behavioral states that range from alert to comatose. It is clinically important to note that these states are dynamic and thus may change with time. Four points on the continuum of arousal are often used in describing the clinical state of a patient: alert, lethargic, stuporous, and comatose. *Alert* refers to a perfectly normal state of arousal. *Stupor* is defined as unresponsiveness from which the subject can be aroused only by vigorous and repeated stimuli. *"Coma* is unarousable unresponsiveness," in which the patient lies with the eyes closed (Plum and Posner 1980). *Lethargy* lies between alertness and stupor. The terms *lethargy* and *stupor* cover a broad area on the continuum of behavioral states and thus are subject to misinterpretation by subsequent observers of a patient when used without further qualification. In clinical

practice, where relatively slight changes in arousal may be significant, only the terms *alert* and *comatose* (the endpoints of the continuum) have enough precision to be used without further qualification.

BEHAVIORAL STATES CONFUSED WITH COMA

Several different behavioral states may appear similar to coma or may be confused with it (Table 5.1). Moreover, patients who survive initial coma may progress to certain of these syndromes after various lengths of time. Once sleep-wake cycles occur, true coma is no longer present. Differentiation of these states from true coma is important to administer appropriate therapy and to help determine prognosis.

In the *locked-in syndrome (de-efferented state),* patients are alert and aware of their environment but are quadriplegic, with lower cranial nerve palsies because of bilateral ventral pontine lesions that involve the corticospinal, corticopontine, and corticobulbar tracts. The patients are awake and alert but voluntarily able only to move their eyes vertically, to blink, or both. The locked-in syndrome is most often observed as a consequence of pontine infarction accompanying basilar attery thrombosis. Other causes include central pontine myelinolysis and brainstem mass lesions. A state similar to the locked-in syndrome may also be seen with severe polyneuropathy—in particular, acute inflammatory demyelinating polyradiculoneuropathy, myasthenia gravis, and neuromuscular blocking agents.

In the *persistent vegetative state,* patients have lost cognitive neurological function but retain vegetative or noncognitive neurological function such as cardiac action, respiration, and maintenance of blood pressure (ANA Committee on Ethical Affairs 1993). This state follows coma and is characterized by the absence of cognitive function or awareness of the environment, despite a preserved sleep-wake cycle. Spontaneous movements may occur and the eyes may open in response to external stimuli, but the patient does not speak or obey commands. A number of poorly defined syndromes have been used synonymously with persistent vegetative state, including *apallic syndrome* or *state, akinetic mutism, coma vigil, alpha coma, neocortical death,* and *permanent unconsciousness.* These terms, used variously by different authors, are probably best avoided because of their lack of precision (ANA Committee on Ethical Affairs 1993). The diagnosis of persistent vegetative state should be made cautiously and only after extended periods of observation (Childs et al. 1993).

The term *minimally conscious state* is distinguished from coma and persistent vegetative state by the preservation of discernible behavioral evidence of consciousness (Giancino et al. 2002). Patients in coma or persistent vegetative state may evolve into a minimally conscious state after acute brain injury. The diagnosis is established by the presence of one or more of the following behaviors: (1) ability to follow simple commands, (2) gestural or verbal yes/no responses, (3) intelligible verbalization, or (4) purposeful behaviors that are contingent upon and relevant to the external environment. It is important to differentiate this condition from coma and the persistent vegetative state for prognostic purposes.

Abulia is a severe apathy in which patients have blunting of feeling, drive, mentation, and behavior so that they neither speak nor move spontaneously (Mesulam 1986). Severe cast's resemble akinetic mutism, except that the patients remain alert and aware of their environment.

Catatonia may result in a state of muteness, with dramatically decreased motor activity. The maintenance of body posture, with preserved ability to sit or stand, distinguishes it from organic pathologic stupor. It is generally a psychiatric manifestation but may be mimicked by frontal lobe dysfunction or drug effect.

Pseudocoma is the term for patients who appear comatose (that is, unresponsive, unarousable, or both)

Tabic 5.1: Behavioral states confused with coma

Behavioral $tate	*Definition*	*Lesion*	*Comments*
Locked-in syndrome	Alert and aware, quadriplegic with lower cranial nerve palsy	Bilateral anterior pontine	A similar state may be seen with severe polyneuropathies, myasthenia gravis, and neuromuscular blocking agents
Persistent vegetative state	Absent cognitive function but retained "vegetative" components	Extensive cortical gray or subcortical white matter with relative preservation of brainstem	Synonyms include apallic syndrome, coma vigil, cerebral cortical death
Abuli;	Severe apathy, patient neither speaks nor moves spontaneously	Bilateral frontal medial	Severe cases resemble akinetic mutism, but patient is alert and aware
Catatonia	Mute, with marked decrease in motor activity	Usually psychiatric	May be mimicked by frontal lobe dysfunction or drugs
Pseudocoma	Feigned coma		

but have no structural, metabolic, toxic, or psychiatric disorder.

APPROACH TO COMA

The initial clinical approach to stupor and coma is based on the principle that *alt* alterations in arousal are acute, life-threatening emergencies until vital functions such as blood pressure and oxygenation are stabilized, potentially reversible causes of coma are treated, and the underlying cause of the alteration in arousal is understood. Urgent steps may be necessary to avoid or minimize permanent brain damage from reversible causes. In view of the urgency of this situation, every physician should develop a diagnostic and therapeutic routine to use with a patient with an altetation in consciousness. A basic understanding of the mechanisms that lead to impairment in arousal is necessary to develop this routine. The anatomic and physiologic bases for alterations in arousal are discussed in Chapter 74.

Although one should keep in mind the concept of a spectrum of arousal, for the sake of simplicity and brevity we use only the term *coma* in the rest of this chaptet. Table 5.2 lists many of the common causes of coma. More than half of all cases of coma are due to diffuse and metabolic brain dysfunction. In Plum and Posner's study (1995) of 500 patients initially diagnosed as having coma of unknown cause (in whom the diagnosis was ultimately established), "526 patients had diffuse and metabolic brain dysfunction. Almost half of these patients had dtug poisonings. Of the remaining patients, 101 had supra tentorial mass lesions, including 77 hemorrhagic lesions and nine infarctions; 65 had subtentorial lesions, mainly brainstem infarctions; and eight had psychiatric coma.

A logical decision tree often used in searching for the cause of coma divides the categories of diseases that cause coma into three groups: structural lesions, which may be above or below the tentorium; metabolic and toxic causes; and psychiatric causes. The history and physical examination determine the presence or absence of a structural lesion and quickly differentiate the general categories to decide what further diagnostic tests arc needed or to allow for immediate intervention if necessary.

Serial examinations are needed, with precise description of the behavioral state at different times, to determine if the patient is improving or, more ominously, worsening, and to decide if a change in therapy ot further diagnostic tests are necessary. Subtle declines in the intermediate states of arousal may herald precipitous changes in brainstem function, which may affect regulation of vital functions such as respiration or blood pressure. The dynamic quality of alterations of consciousness and the need for accurate documentation at different times cannot be overemphasized.

RAPID INITIAL EXAMINATION AND EMERGENCY THERAPY

A relatively quick initial assessment of the comatose patient is important to make sure the patient is medically and neurologically stable before a more detailed assessment is made. One must be sure that the patient is not in immediate need of medical or surgical intervention.

Urgent and sometimes empirical therapy is given to prevent further brain damage. Potential immediate metabolic needs of the brain are supplied by empirical use of supplemental oxygen, thiamine (at least 100 mg), and inttavenous 50% dextrose in water (25 g). A baseline serum glucose level should be obtained before glucose administration.

The use of intravenous glucose in patients with ischemic or anoxic brain damage is controversial. Fxtra glucose may augment local lactic acid production by anaerobic glycolysis and may worsen ischemic or anoxic damage. Clinically, however, we currently recommend empirical glucose administration when the cause of coma is unknown. There are two reasons for our approach: the frequent occurrence of alterations in arousal due to hypoglycemia, and the telativcly good prognosis for coma due to hypoglycemia when it is treated expeditiously and the potentially permanent consequences if it is not treated. In comparison, the prognosis for anoxic or ischemic coma is generally poor and probably will remain poor regardless of glucose supplementation.

Thiamine must always be given in conjunction with glucose to prevent precipitation of polioencephalitis hemorrhagica superioris (Wernicke's encephalopathy). Naloxone hydrochloride may be given parentcrally, preferably intravenously, in doses of 0.4 to 2.0 mg if opiate overdose is the suspected cause of coma. An abrupt and complete reversal of narcotic effect may precipitate an acute abstinence syndrome in individuals who are physically dependent on opiates.

An initial examination should include a check of general appearance, blood pressure, pulse, temperature, respiratory rate and breath sounds, best response ro stimulation, pupil size and responsiveness, and posturing or adventitious movements.

The neck should be stabilized in all instances of trauma until cervical spine fracture or subluxation can be ruled out. The airway is protected in all comatose patients and an intravenous line is placed.

Abdominal rigidity is a feature of peritonitis or perforated viscus. In coma, however, the classic signs of an acute condition in the abdomen may be subtle or nonexistent. In addition, the diagnosis of blunt abdominal trauma is difficult in patients with a change in mental status. Therefore, in unconscious patients with a history of trauma, peritoneal lavage by an experienced surgeon may be warranted.

Hypotension, marked hypertension, bradycardia, arrhythmias causing depression of blood pressure, marked

Table 5.2: Causes of coma

I. Symmetrical, Nonstructural

Toxins
- 1 tad
- Thallium
- Mushrooms
- Cyanide
- Methanol
- Ethylene glycol
- Carbon monoxide

Drills
- Sedatives
- Barbiturates*
- Other hypnotics
- Tranquilizers

- Postinfectious encephalomyelitis
- Syphilis
- Sepsis
- Typhoid fever
- Malaria
- Waterhouse-Friderichsen syndrome

Psychiatric
- Catatonia

Other
- Postictal*
- Diffuse ischemia (myocardial infarction, congestive heart failure, arrhythmia)
- Hypotension
- Fat embolism*
- Hypertensive encephalopathy
- Hypothyroidism

II. Symmetrical, Structural

Supra tentorial
- Bilateral internal carotid occlusion
- Bilateral anterior cerebral artery occlusion
- Subarachnoid hemorrhage
- Thalamic hemorrhage*
- Trauma—contusion, concussion[1]
- Hydrocephalus

Infratentorial
- Basilar occlusion*
- Midline brainstem tumor
- Pontine hemorrhage*

III. Asymmetrical, Structural

Supra tentorial
- Thrombotic thrombocytopenic purpura!
- Disseminared intravascular coagulation
- Nonbacterial thrombotic endocarditis (marantic endocarditis)
- Subacute bacterial endocarditis
- Fat emboli
- Unilateral hemispheric mass (tumor, bleed) with herniation
- Subdural hemorrhage bilateral
- Intracerebral bleed
- Pituitary apoplexyf
- Massive or bilateral supratentorial infarction
- Multifocallcukoenccphalopathy
- Creutzfeldt-Jakob disease
- Adrenal leukodystrophy
- Cerebral vasculitis
- Cerebral abscess
- Subdural empyema
- Thrombophlebitis!
- Multiple sclerosis
- Leukoencenhalopathy associated with chemotherapy
- Acute disseminated encephalomyelitis
- Infratentorial
- Brainstem infarction
- Brainstem hemorrhage

* Relatively common asymmetrical presentation.
f Relatively symmetrical presentation.

hyperthermia, and signs of herniation mandate immediate therapeutic intervention.

Hyperthermia or meningismus leads to consideration of urgent lumbar puncture. *A computed tomography (CT) scan of the brain should he performed before lumbar puncture in any comatose patient.* Although the only absolute contraindication to lumbar puncture is the presence of an infection over the site of puncture, medicolegal considerations make a CT scan mandatory before lumbar puncture. To avoid a delay in therapy required to perform a CT scan, some authorities recommend initiating antibiotics immediately when acute bactetial meningitis is strongly suspected. If there is an inordinate delay in obtaining an emergency CT scan, lumbar puncture may have to be performed before the CT to allow the administration of antibiotics.

The risk of herniation from a lumbar puncture in patients with evidence of increased intracerebral pressure is difficult to ascertain from the literature; estimates range from 1% to 12%, depending on the series (Plum and Posner 1995). One must always keep in mind that both central and tonsillar herniation may increase neck tone.

Despite an elevated intracranial pressure, sufficient cerebrospinal fluid should always be obtained to perform the necessary studies. The performance of bacterial culture and cell count, essential in cases of suspected bacterial meningitis, requires but a few milliliters of fluid. Intravenous access and intravenous mannitol should be ready in case unexpected herniation begins after the lumbar puncture. When the cerebrospinal fluid pressure is greater rhan 500 mm H2O, some authorities recommend leaving the needle in place to monitor the pressure and administering intravenous mannitol to lower the pressure. If focal signs develop during or after the lumbar puncture, immediate intubation and hyperventilation may also be necessary to reduce intracerebral pressure urgently until more definitive therapy is available.

Ecchymosis, pctcchiae, or evidence of easy bleeding on general examination may indicate coagulation abnormality or thrombocytopenia. This increases the risk of epidural hematoma, which may cause devastating spinal cord compression. Measurements of prothrombin time, partial thromboplastin time, and platelet count should precede lumbar puncture in these cases, and the coagulation abnormality or thrombocytopenia should be corrected before lumbar puncture.

COMMON PRESENTATIONS

Coma usually presents in one of three ways. Most commonly, it occurs as an expected or predictable progression of an underlying illness. Examples of this are focal brainstem infarction with extension; the patient with chronic obstructive pulmonary disease who is given too high a concentration of oxygen, decreasing the patient's respiratory drive and resulting in carbon dioxide narcosis; and the patient with known barbiturate overdose when the ingested drug cannot be fully removed and begins to cause unresponsiveness. Second, coma occurs as an unpredictable event in a patient whose previous medical conditions are known to the physician. The coma may be a complication of an underlying medical illness, such as in a patient with arrhythmia who suffers anoxia after a cardiac arrest, or an unrelated event may occur, such as sepsis from an intravenous line in a cardiac patient or a stroke in a hypothyroid patient. Finally, coma can occur in a patient who is totally unknown to the physician. Sometimes this type of presentation is associated with a known probable cause, such as head trauma following a motor vehicle accident, but often the unknown comatose patient presents to the physician without an obvious associated cause. Although the patient without an obvious cause of coma may seem most challenging, thorough objective systematic assessment must be applied to every comatose patient. Special care must be taken not to be lulled or misled by an apparently predictable progression of an underlying illness or other obvious cause of coma.

HISTORY

Once the patient is relatively stable, clues to the cause of the coma should be sought by briefly interviewing relatives, friends, bystanders, or medical personnel who may have observed the patient before or during the decrease in consciousness. Telephone calls to family members may be helpful. The patient's wallet or purse should be examined for lists of medications, a physician's card, or other information.

Attempts should be made to ascertain the patient's social background and medical history and the circumstances in which the patient was found. The presence of drug paraphernalia or empty medicine bottles suggests a drug overdose. Newer recreational drugs, such as gamma hydroxybutyrate, must be considered in the differential diagnosis (Ryan and Stell 1997). Oral hypoglycemic agents or insulin in the medicine cabinet or refrigerator imply possible hypoglycemia. Antiarrhythmic agents such as procainamide or quinidine suggest existing coronary artery disease wirh possible myocardial infarction or warn that an unwitnessed arrhythmia may have caused cerebral hypoperfusion, with resulting anoxic encephalopathy. Warfarin is given to patients with deep venous thrombosis or pulmonary embolism, those at risk of cerebral emboli, and those with a history of brainstem or cerebral ischemia. Its use may be complicated by massive intracerebral bleeding. Patients found to be unresponsive at the scene of an accident, such as a motor vehicle accident, may be unresponsive because of trauma that occurred in the accident; alternatively, sudden loss of consciousness may have precipitated the accident.

The neurologist is often called when patients do not awaken following surgery or when coma supervenes following a surgical procedure. Postoperative causes of coma include many of those mentioned in Table 5.2. In addition, the physician must also have a high index of suspicion for certain neurological conditions that occur in this setting, including fat embolism, addisonian crisis, or hypothyroid coma (precipitated by acute illness or surgical stress); Wernicke's encephalopathy from carbohydrate loading without adequate thiamine stores; and iatrogenic overdose of a narcotic analgesic.

Attempts should be made to ascertain if the patient complained of symptoms before coma. Common symptoms include headache before subarachnoid hemorrhage, chest pain with aortic dissection or myocardial infarction, shortness of breath from hypoxia, stiff neck in meningoencephalitis, or vertigo in brainstem cerebrovascular accident. Nausea and vomiting are common in poisonings. Coma may also be due to increased intracranial pressure. Observers may have noted head trauma, drug abuse, seizures, or hemiparesis. Descriptions of falling to one side, dysarthria or aphasia, ptosis, pupillary dilation, or disconjugate gaze may help localize strucrural lesions. The time course of the disease as noted by family or friends may

help differentiate the often relatively slow, progressive course of toxic-metabolic or infectious causes from abrupt, catastrophic changes that are seen most commonly with vascular events.

Finally, family members or friends may be invaluable in identifying psychiatric causes of unresponsiveness. The family may describe a long history of psychiatric disease, previous similar episodes from which the patient recovered, current social stresses on the patient, or the patient's unusual, idiosyncratic response to stress. Special care must be taken with psychiatric patients because of the often biased approach to these patients, which may lead to incomplete evaluation. Psychiatric patients ate subject to all the causes of coma listed in Table 5.2.

GENERAL EXAMINATION

A systematic, detailed gcnctal examination is especially helpful in the approach to the comatose patient who is unable to describe his or her prior or current medical problems. This examination was begun in the initial rapid examination, with evaluation of blood pressure, pulse, respiratory rate, and temperature.

Blood Pressure Evaluation

Hypotension

Cerebral hypoperfusion secondary to hypotension may result in coma if the mean arterial pressure falls below the value for which the brain is able to autoregulate (normally 60 mm Hg). This value is substantially higher in chronically hypertensive individuals, as the cerebral blood flow-mean arterial pressure curve is shifted to the right. Among the causes of hypotension are hypovolemia, massive external or internal hemorrhage, myocardial infarction, cardiac tamponade, dissecting aottic aneurysm, intoxication with alcohol ot othet drugs (especially barbiturates), toxins, Wernicke's encephalopathy, Addison's disease, and sepsis. Although most patients with hypotension are cold because of peripheral vasoconstriction, patients with Addison's disease ot sepsis may have warm shock caused by peripheral vasodilation. Medullary damage may also result in hypotension because of damage to the pressor center.

Hypertension

Hypertension is the cause of alterations in arousal in hypertensive crisis and is seen secondarily as a response to cerebral infarction, in subarachnoid hemorrhage, with certain brainstem infarctions, and with increased intracerebral pressure. The Kocher-Cushing (or Claude Bernard) reflex is hypertension associated with bradycardia and respiratory irregularity caused by increased intracranial pressure- This response occurs more commonly in the setting of a posterior fossa lesion and in children. It results from compression or ischemia of the pressor area lying beneath the flour of the fourth ventricle. I lypertension is a common condition and thus may be present but unrelated to the cause of coma.

Heart Rate

In addition to the Kochet-Cushing reflex, bradycardia can result from myocardial conduction blocks, certain poison ings, and drugs, such as the beta blockers. Tachycardia is a result of hypovolemia, hyperthyroidism, fever, anemia, and certain toxins and drugs, including cocaine, atropine, and other anticholinergic medications.

Respiration

The most common causes of decreased respiratory rate are metabolic or toxic, such as carbon dioxide narcosis or drug overdose with central nervous system (CNS) depressants. Increased respiratory tate can result from hypoxia, hypercapnia, acidosis, hyperthermia, hepatic disease, toxins or drugs (especially those that produce a metabolic acidosis, such as methanol, ethylene glycol, paraldehyde, and salicylates), sepsis, pulmonary emboli (including fat emboli), and sometimes psychogenic unresponsiveness. Brainstem lesions causing hypopnea or hyperpnea are discussed below. Changes in respiratory rate or rhythm in a comatose patient may be deceiving, because a metabolic disorder may coexist with a CNS lesion.

Temperature

Core temperature must be measured with a rectal probe in a comatose patient, because oral or axillary temperatures are unreliable. Pyrexia is most often a sign of infection. Thus any evidence of fever in a comatose patient warrants strong consideration of lumbar puncture. Absence of an increased temperature does not rule out infection. Immunosuppresscd patients, elderly patients, and patients with metabolic or endocrine abnormalities such as uremia or hypothyroidism may not have increased temperature in response to overwhelming infection. Pure neurogenic hyperthermia is rare and is usually due to subarachnoid hemorrhage or diencephalic (hypothalamus) lesions. A clue to brainstem origin is shivering without sweating. Shivering in the absence of sweating, particularly when unilateral in nature, may also be observed with a deep intracerebral hemorrhage. Other causes of increased temperature associated with coma are heatstroke, thyrotoxic crisis, and drug toxicity. (Atropine and other anticholinergic agents elevate

core temperature but decrease diaphoresis, resulting in a warm, dry patient with dilated pupils and diminished bowel sounds.)

Except in heatstroke and malignant hyperthermia, fever does nor result in stupor or coma by itself. Conversely, hypothermia, regardless of cause, is anticipated to lead to altered consciousness. Hypothermia causes diminished cerebral merabolism and, if the temperature is sufficiently low, may result in an isoelectric electroencephalogram. Hypothermia is usually metabolic or environmental in cause; however, it is also seen with hypotension accompanied by vasoconstriction and may Occur with sepsis. Other causes of hypothermia associated with coma are hypothyroid coma, hypopituitarism, Wernicke's encephalopathy, cold exposure, drugs (barbiturates), and other poisonings. Central lesions causing hypothermia are found in the posterior hypothalamus. The absence of shivering or vasoconstriction or the presence of sweating is a clue to the central origin of these lesions.

General Appearance

The general appearance of the parient may provide further clues to the diagnosis. Torn or disheveled clothing may indicate prior assault. Vomitus may be a sign of increased intracranial pressure, drug overdose, or metabolic or other toxic cause. Urinary or fecal incontinence indicates an epileptic seizute or may result from a generalized autonomic discharge resulting from the same cause as the coma. Examination of body habitus may reveal a cushingoid patient at risk for an acute addisonian crisis with abrupt withdrawal of his or her medications or additional stress from intercurrent illness. Cachexia suggests cancer, chronic inflammatory disorders, Addison's disease, hypothyroid coma, or hyperthyroid crisis. The cachectic patient is also subject to Wernicke's encephalopathy in association with carbohydrate loading. Gynecomastia, spider nevi, testicular atrophy, and decreased axillary and pubic hair are common in the alcoholic with cirrhosis.

Head and Neck Examination

The head and neck must be carefully examined for signs of trauma. Palpation for depressed skull fractures and edema should be attempted, although it is not very sensitive. Laceration or edema of the scalp is indicative of head trauma. The term *raccoon eyes* refers to orbital ecchymosis resulting from anterior basal skull fracture. *Battle sign* is a hematoma overlying the mastoid, originating from basilar skull fracture extending into the mastoid portion of the temporal bone. The ecchymotic lesions are typically not apparent until 2 to 3 days after the traumatic event.

Meningismus

The slightest degree of neck stiffness may be a sign of infectious or carcinomarous meningitis, subarachnoid hemorrhage, or central or tonsillar herniation. Neck stiffness is absent in coma from any cause but may be present in less severe alterations in arousal. Scars on the neck may be from endarterectomy, implying vascular disease, or from thyroidectomy or parathyroidectomy, suggesting concomitant hypothyroidism, hypoparathyroidism, or both. Goiter may be found with hypothyroidism or hyperthyroidism.

Eye Examination

Examination of the eyes includes observation of the cornea, conjunctiva, sclera, iris, lens, and eyelids. Edema of the conjunctiva and eyelids may occur in congestive heart failure and nephrotic syndrome. Congestion and inflammation of the conjunctiva often occur in the comatose patient as a result of exposure. Enophthalmos indicates dehydration. Scleralicterus is seen with liver disease, and yellowish discoloration of the skin without scleral involvement may be due to drugs such as rifampin. Band keratopathy is caused by hypercalcemia, whereas hypocalcemia is associated with cataracts. Kayser-Fleischer rings are seen in progressive lenticular degeneration (Wilson's disease). Arcus senilis is seen in normal aging but also in hyperlipidemia. Fat embolism may cause petechiae in conjunctiva and eye grounds.

Funduscoptc Examination

Funduscopic examination demonstrates evidence of hypertension or diabetes. Grayish deposits surrounding the disc have been reported in lead poisoning. The retina is congested and edematous in methyl alcohol poisoning, and the disc margin may be blurred. Subhyloid hemorrhage appears occasionally as a consequence of a rapid increase in intracranial pressure resulting from subarachnoid hemorrhage. Papilledema results from increased intracranial pressure and may be indicative of an intracranial mass lesion or hypertensive encephalopathy.

Otoscopic Examination

Otoscopic examination should rule out hemotympanum or otorrhea from a basilar skull fracture involving the petrous ridge as well as infection of the middle ear. Infections of the middle ear, mastoid, and paranasal sinuses are the most common sources of underlying infection in brain abscess (Osenbach and Loftus 1992). Rhinorrhea, which appears as clear fluid from the nose, may depend on head position. The presence of glucose in this watery discharge is virtually diagnostic, though false-positive results may be observed.

Oral Examination

Alcohol intoxication, diabetic ketoacidosis (acetone odor), uremia, and hepatic encephalopathy (musty odor of cholemia or fetor hepatis) may be suspected from the odor of the breath. Arsenic poisoning produces the odor of garlic. Poor oral hygiene or oral abscesses may be a source of sepsis or severe pulmonary infection with associated hypoxemia. Pustules on the nose or upper lip may seed the cavernous sinus with bacteria by way of the angular vein. Lacerations on the tongue, whether old or new, suggest seizure disorder. Thin, blue-black pigmentation along the gingival margin may be seen in certain heavy-metal poisonings (bismuth, mercury, and lead).

Integument Examination

Systematic examination of the integument includes inspection of the skin, nails, and mucous membranes. A great deal of information can be gained by a brief examination of the skin (Table *53).* Hot, dry skin is a feature of heatstroke. Sweaty skin is seen with hypotension or hypoglycemia, Drugs may cause macular-papular, vesicular, or petechial-purpuric rashes or bullous skin lesions. Bullous skin lesions are most often a result of barbirurates but also may be caused by imipramine, meprobamate, glutcthimide, phcnothiazine, and carbon monoxide. Kaposi's sarcoma, anogenital herpetic lesions, or oral candidiasis should suggest the acquired immunodeficiency syndrome (AIDS), with its plethora of CNS abnormalities.

Examination of Lymph Nodes

Generalized lymphadenoparhy is nonspecific; it may be seen with neoplasm, infection (including AIDS), collagen vascular disease, sarcoid, hyperthyroidism, Addison's disease, and drug reaction (especially due to phenytoin). Local lymph node enlargement or inflammation, however, may provide clues to a primary tumor site or source of infection.

Cardiac Examination

Cardiac auscultation will confirm the presence of arrhythmias such as atrial fibrillation, with its inherent increased risk of emboli. Changing mitral murmurs are heard wirh atrial myxomas and papillary muscle ischemia, which is seen with current or impending myocardial infarction. Constant murmurs indicate valvular heart disease and may be heard with the valvular vegetation of bacterial endocarditis.

Abdominal Examination

Possibly helpful findings on abdominal examination include abnormal bowel sounds, organomegaly, masses, or ascites. Bowel sounds are absent in an acute abdominal condition as well as with anticholinergic poisoning. Hyperactive bowel sounds may be a consequence of increased gastrointestinal motility from exposure to acetylcholinesterase inhibitor (a common pesticide ingredient). The liver may be enlarged as a result of right heart failure or tumor infiltration. Nodules or a rock-hard liver may be caused by hepatoma or metastatic disease. The liver may be small and hard in cirrhosis.

Splenomegaly is caused by porral hypertension, hematologic malignancies, infection, and collagen vascular diseases. Intra-abdominal masses may indicate carcinoma. Ascites occurs with liver disease, right heart failure, neoplasms with metastasis to liver, or ovarian cancer.

Miscellaneous Examinations

Examination of the breasts in the female and the testicles in the male and rectal examination may reveal common primary tumors. Stool from a rectal examination that tests positive for blood is consistent with gastrointestinal bleeding and, possibly, bowel carcinoma. Blood in the gastrointestinal tract may be sufficient to incite hepatic encephalopathy in the patient with cirrhosis.

NEUROLOGICAL EXAMINATION

Neurological signs may show every degree of change along a continuum, and they may be partial or incomplete. For example, the patient may have a partial third nerve palsy with pupillary dilation rather than a complete absence of all third nerve funcrion, or muscle rone may be decreased but not absent. This concept is especially important in the examination of the stuporous or comatose patient because the level of arousal may also influence the expression of neurological signs. In the stuporous or comatose patient, findings that are not completely normal should not be dismissed as unimportant. These findings should be carefully considered until their pattern or meaning is understood.

The neurological examination of a comatose patient serves three purposes: (1) to aid in determining the cause of coma, (2) to provide a baseline, and (3) to help determine the prognosis of coma. For prognosis and localization of a structural lesion, certain parts of the examination have been found to be most helpful: (I) state of consciousness, (2) respiratory pattern, (3) pupillary size and response to light, (4) spontaneous and reflex eye movements, and (5) skeletal muscle motor response.

Tabic '5..1: Skin lesions and rashes in coma

Lesion or rash	*Possible cause*
Antecubital needle marks	Opiate drug abuse
Pale skin	Anemia or hemorrhage
Sallow, puffy appearance	Hypopituitarism
Hype melanosis (increased pigment)	Porphyria, Addison's disease, chronic nutritional deficiency, disseminated malignant melanoma, chemotherapy
Generalized cyanosis	Hypoxemia or carbon dioxide poisoning
Grayish-blue cyanosis	Methemoglobin (aniline or nitrobenzene) intoxication
Localized cyanosis	Arterial emboli or vasculitis
Cherry-red skirl	Carbon monoxide poisoning
Icterus	Hepatic dysfunction or hemolytic anemia
Perec hi ae	Disseminated intravascular coagulation, thrombotic thrombocytopenic purpura, drugs
Ecchymosis	Trauma, corticosteroid use, abnormal coagulation from liver disease or anticoagulants
Telangiectasia	Chronic alcoholism, occasionally vascular malformations of the brain
Vesicular rash	Herpes simplex Varicella Behcet's disease Drugs
Petechial-purpuric rash	Meningococcemia Other bacterial sepsis (rarely) Gonococcemia Staphylococcemia *Pseudomonas* Subacute bacterial endocarditis Allergic vasculitis Purpura fulminans Rocky Mountain spotted fever Typhus Fat emboli
Macular-papular rash	Typhus *Candida* *Cryptococcus* Toxoplasmosis Subacute bacterial endocarditis Staphylococcal toxic shock Typhoid Leptospirosis *Pseudomonas* sepsis Immunological disorders Systemic lupus erythematosus Dcrmatomyositis Scrum sickness
Other skin lesions	
Ecthyma gangrenosum	Necrotic eschar often seen in the anogenital or axillary area in *Pseudomonas* sepsis
Splinter hemorrhages	Linear hemorrhages under the nail, seen in subacute bacterial endocarditis, anemia, leukemia, and sepsis
Osier's nodes	Purplish or erythematous painful, tender nodules on palms and soles, seen in subacute bacterial endocarditis
Gangrene of digits' extremities	Emboli to larger peripheral ur arteries

State of Consciousness

The importance of a detailed description of the state of consciousness has been stressed previously. It is imperative that the exact stimulus and the patient's specific response be recorded. Several modes of stimulation should be used, including auditory, visual, and noxious. Stimuli of progressively increasing intensity should be applied to the patient, with the maximal state of arousal noted and the stimuli, site of stimulation, and patient's exact response described. One should start with verbal stimuli, softly and then more loudly calling the patient's name or giving simple instructions to open his or her eyes. If there is no significant response, more threatening stimuli, such as taking the patient's hand and advancing it toward the patient's face, are applied. Finally, painful stimuli may be needed

to arouse the patient. All patients in apparent coma should be asked to open their eyes and look up and down, thus avoiding the possibility of mistaking the locked-in syndrome, in which these voluntary movements are preserved, for coma.

Supraorbital pressure evokes a response in patients who may have lost afferent pain pathways as a result of peripheral neuropathy or spinal cord or some brainstem lesions. Pinching the chest or extremities may help localize a lesion. Care must be taken to avoid soft-tissue damage. Purposeful movements indicate a milder alteration in consciousness. Vocalization to pain in the early hours of a coma, even if only a grunt, indicates relatively light alteration in consciousness. Later, primitive vocalization may be a feature of the vegetative state. Asymmetry in response from either side of the face or body may localize structural lesions.

The Glasgow Coma Scale (Table 5.4) is used widely ro assess rhe initial sevcriry of traumatic brain injury. This battery assesses three separate aspects of a patient's behavior: the stimulus required to induce eye opening, rhe best motor response, and the host verbal response. Degrees of increasing dysfunction are scored. Its reproducibility and simplicity make the Glasgow Coma Scale an ideal method of assessment for non-neurologists involved in the care of comatose patients, such as neurological inrensive care nurses. However, its failure to assess other essential neurological parameters limits its utility. Additionally, in patients who arc intubated or who have suffered facial trauma, it may be difficult to assess certain components of the Glasgow Coma Scale, such as eye opening and speech. Wijdicks and colleagues (1998) have suggested two new tools that may serve as substitutes for the Glasgow Coma Scale in these patients as well as those with fluctuating levels of consciousness. One test referred to as the "continuous performance test" monitors level of alertness and requires the patient to raise his hand every time he hears a certain letter in a standardized sentence. Another, the "hand position test,[11] is a test of praxis in which the patient must mimic three different hand positions that are demonstrated to him.

Respiration

Normal breathing is quiet and unlabored. The presence of any respiratory noise implies airway obstruction, which must be dealt with immediately to prevent hypoxia. Normal respiration depends on two components: a brainstem mechanism, located between the mid pons and cervical medullary junction, that regulates metabolic needs, and forebrain influences that subserve behavioral needs such as speech production. The organization and function of brainstem mechanisms responsible for respiratory rhyrhm generation as well as forebrain influences are complex and beyond the scope of this chapter. For an excellent review of this subject, the reader is referred to Long and Duffin (J986). Neuropathologies correlates of respiration are presented in Figure 5.1

Respiratory patterns that arc helpful in localizing level of involvement include Cheyne-Stokes respiration, central neurogenic hyperventilation, apneustic breathing, cluster brearbing, and ataxic respiration. *Cheyne-Stokes respiration* is a respiratory pattern that slowly oscillates between hyperventilation and hypoventilation. In 1818 Cheyne described his patient in rhe following manner: "For several days his breathing was irregular; it would entirely cease for a quarter of a minute, then it would become perceptible, though very low, then by degrees it became heaving and quick and then it would gradually cease again. This revolution in the state of his breathing occupied about a minute during which there were about 30 acts of respiration," Cheyne-Stokes respiration is associated with bilateral hemispheric or diencephalic insults, but it may occur as a result of bilateral damage anywhere along rhe descending pathway between the forebrain and upper pons. It also is seen with cardiac disorders that prolong circulation time. Alertness, pupillary size, and heart rhythm may vary during Cheyne-Stokes respiration (Plum and Posner 1995). Patients are more alert during the waxing portion of breathing.

A stable pattern of Cheyne-Stokes respiration is a relatively good prognostic sign, usually implying that pcrmanenr brainstem damage has not occurred. However, the emergence of Cheyne-Stokes respiration in a patient with a unilateral mass lesion may be an early sign of herniarion. A change in pattern from Cheyne-Stokes respiration to the respiratory patterns described in the following is ominous.

Two breathing patterns similar to Cheyne-Stokes respiration should not be confused with it. *Short-cycle periodic breathing* is a respiratory pattern with a shorter cycle {faster rhythm) than Cheyne-Stokes respiration, with one

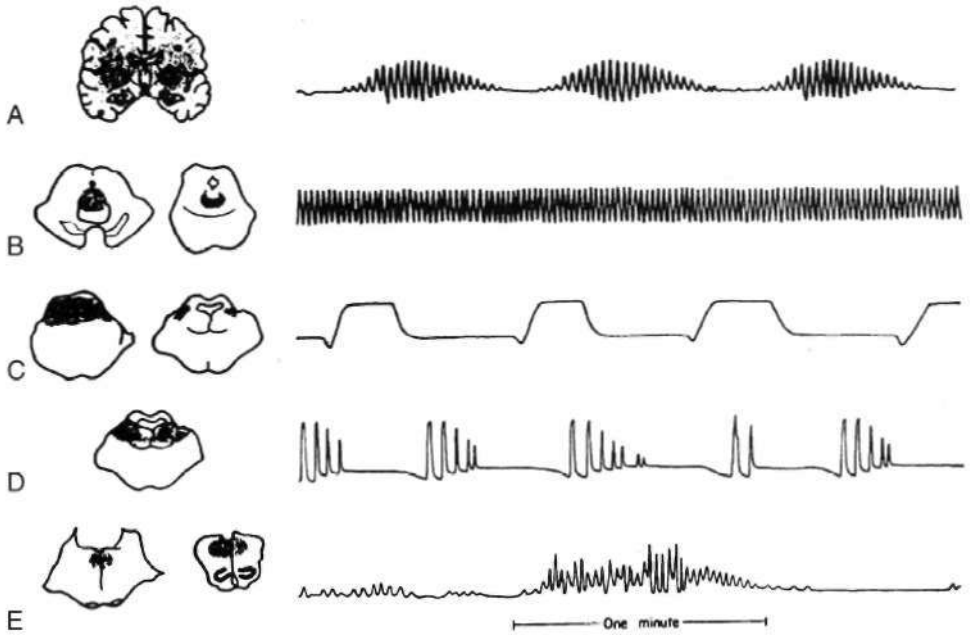

FIGURE 5.1 Abnormal respiratory patterns associated with pathologic lesions (shaded areas) at various levels of the brain. Tracings by chest-abdomen pneumograph; inspiration reads up. (A) Chcync-Stokes respiration—diffuse forebrain damage. (B) Central neurogenic hyperventilation—lesions of low midbrain ventral to aqueduct of Sylvius and of upper pons ventral to the fourth ventricle. (Q Apneusis—dorsolateral tegmental lesion of middle and caudal pons. (D) Cluster breathing—lower pontine tegmental lesion. (E) Ataxic breathing—lesion of the reticular formation of the dorsomedial part of the medulla. (Reprinted from Plum, K, &; Posner, J. B. 1995, *The Diagnosis of Stupor and Coma,* 3rd ed, Oxford University Press, New York. Copyright 1966, 1972, 1980, 1996, Oxford University Press, Inc. Used by permission of Oxford University Press, Inc.)

or two waxing breaths, followed by two to four rapid breaths, then one or two waning breaths. It is seen with increased intracranial pressure, lower pontine lesions, or expanding lesions in the posterior fossa (Plum and Posner 1995). A similar type of respiration, in which there are short bursts of seven to ten rapid breaths, then apnea without a waning and waxing prodrome, has been erroneously referred to as *Biot's breathing.* Biot, in fact, described an ataxic respiratory pattern.

Central neurogenic respiration refers to rapid breathing, from 40 to 70 breaths per minute, usually caused by central tegmental pontine lesions just ventral to the aqueduct or fourth ventricle (Plum and Posner 1995). This type of breathing is rare and must be differentiated from reactive hyperventilation resulting from metabolic abnormalities of hypoxemia secondary to pulmonary involvement. Large CNS lesions may cause neurogenic pulmonary edema, with associated hypoxemia and increased respiratory rate. Increased intracerebral pressure causes spontaneous hyperpnea. Hyperpnea cannot be ascribed to a CNS lesion when arterial oxygen pressure is less than 70 to 80 mm Hg or carbon dioxide pressure is greater than 40 mm Hg.

Kussmaui breathing is a deep, regular respiration observed with metabolic acidosis. *Apneustic breathing* is a prolonged inspiratory gasp with a pause at full inspiration. It is caused by lesions of the dorsolateral lower half of the pons (Plum and Posner 1995). *Cluster breathing,* which results from high medullary damage, involves periodic respirations that are irregular in frequency and amplitude, with variable pauses between clusters of breaths.

Ataxic breathing is irregular in rate and rhythm and is usually due to medullary lesions. Ataxic respiration and bilateral sixth nerve palsy may be a warning sign of brainstem compression from an expanding lesion in the posterior fossa. This is an important sign, because brainstem compression resulting from tonsillar herniation (or other causes) may result in abrupt loss of respiration or blood pressure. Ataxic and gasping respiration are signs of lower brainstem damage and are often preterminal respiratory patterns.

Pupil Size and Reactivity

Normal pupil size in the comatose patient depends on the level of illumination and the state of autonomic innervation. The sympathetic efferent innervation consists of a three-neuron arc. The first-order neuron arises in the hypothalamus and travels ipsilaterally through the posterolateral tegmentum to the ciliospinal center of Budge at the level of Tl spinal cord. The second-order neuron leaves this center and synapses in the superior cervical sympathetic ganglion. The third-order neuron travels along the internal carotid artery and then through the ciliary ganglion to the puptllodtlator muscles. The parasympathetic efferent

innervation of the pupil arises in the Edinger-Westphal nucleus and travels in the oculomotor nerve to the ciliary ganglion, from which it innervates the pupillosphinctcr muscle (Figure 5.2).

Afferent input depends on the integrity of the optic nerve, optic chiasm, optic tract, and projections into the midbrain tectum and efferent fibers through the Edinger-Westphal nucleus and oculomotor nerve. Abnormalities in pupil size and reactivity help delineate structural damage between the thalamus and pons (Figure 5.3), act as a warning sign heralding brainstem herniation, and help differentiate structural causes of coma from metabolic causes.

Thalamic lesions cause small, reactive pupils, which are often referred to as *diencephalic pupils.* Similar pupillary findings arc noted in many toxic-metaholic conditions resulting in coma. Hypothalamic lesions or lesions elsewhere along the sympathetic pathway result in *Horner's syndrome.* Midbrain lesions produce three types of pupillary abnormality, depending on where the lesion occurs. Dorsal tcctal lesions interrupt the pupillary light reflex, resulting in *midposition eyes,* which arc fixed to light but react to accommodation, though the reaction is impossible to test in the comatose patient. Spontaneous fluctuations in size occur, and the ciliospinal reflex is preserved. Nuclear midbrain lesions usually affect both sympathetic and parasympathetic pathways, resulting in *fixed, irregular midposition pupils,* which may be unequal. Lesions of the third nerve in the brainstem or after the nerve has left the brainstem parenchyma cause *wide pupillary dilation,* unresponsive to light. Pontine lesions interrupt sympathetic pathways only to cause small, so-called *pinpoint pupils,* which remain reactive, although magnification may be needed to observe this. Lesions above the thalamus and below the pons should leave pupillary function intact, except for Horner's syndrome in medullary or cervical spinal cord lesions. The pathophysiology of pupillary response is discussed further in Chapter 17.

Asymmetry in pupillary size or reactivity, even of minor degree, is important. Asymmetry of pupil size may be due to dilation (mydriasis) of one pupil, such as with third nerve palsy, or contraction (miosis) of the other, as in Horner's syndrome. These may be differentiated by associated neurological deficits. A dilated pupil caused by a partial third nerve palsy is less reactive and may also be associated with extraocular muscle involvement. The pupil in Horner's syndrome is reactive and, if it results from a lesion in the CNS, may be associated with anhidrosis of the entire ipsilateral body. Cervical sympathetic lesions produce anhidrosis only of face, neck, and arm. A partial or complete third nerve palsy causing a dilated pupil may result from an intramedullary lesion, most commonly in the midbrain, such as an intramedullary glioma or infarction; uncal herniation compressing the third nerve; or a posterior communicating artery aneurysm. A sluggishly reactive pupil may be one of the first signs of uncal herniation, soon to be followed by dilation of that pupil and, later, complete third nerve paralysis.

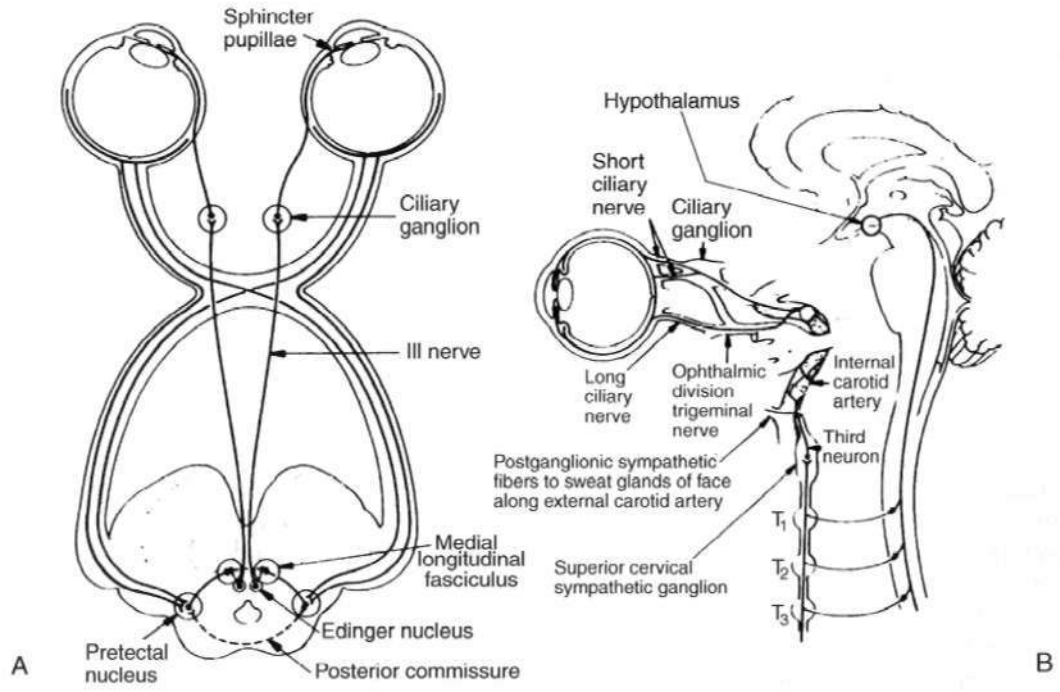

FIGURE 5.2 (A) The parasympathetic pupilloconstrictor pathway. (B) The sympathetic pupillodilator pathway. (Reprinted from Plum, F. & Posner, J. B. 1995, *The Diagnosis of Stupor and Coma*, 3rd ed. Oxford University Press, New York. Copyright 1966, 1972, 1980, 1996, Oxford University Press, Inc. Used by permission of Oxford University Press, Inc.)

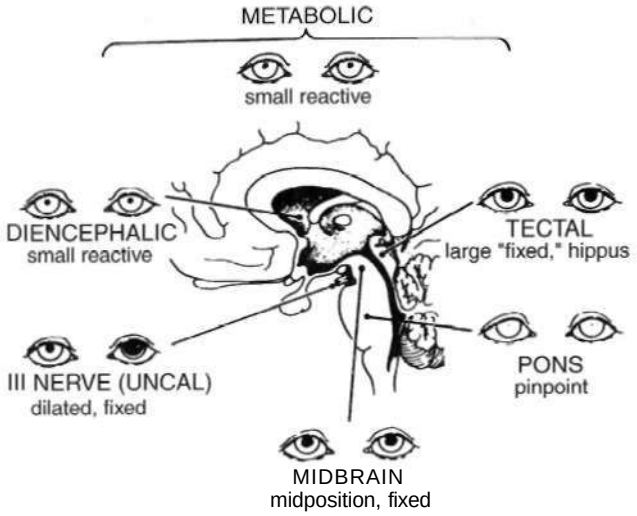

FIGURE 5.3 Pupils in comatose patients. (Reprinted from Plum, F. & Posner, J. B. 1995, *The Diagnosis of Stupor and Coma*, 3rd ed. Oxford University Press, New York. Copyright 1966, 1972, 1980, 1996, Oxford University Press, Inc. Used by permission of Oxford University Press, Inc.)

Several caveats are important when examining the pupil or pupillary reflexes. A common mistake is the use of insufficient illumination. The otoscope may be useful in this regard because it provides both adequate illumination and magnification. Rarely, pre-existing ocular or neurological injury may fix the pupils or result in pupillary asymmetry. Seizures may cause transient anisocoria. Local and systemic medications may affect pupillary function. Topical ophthalmologic preparations containing acetylcholinesterase inhibitor, used in the treatment of glaucoma, result in miosis. The effect of a mydriatic agent placed by the patient or a prior observer may wear off unevenly, resulting in pupillary asymmetry. Some common misleading causes of a unilateral dilated pupil include prior mydriatic administration, old ocular trauma or ophthalmic surgery, and, more rarely, carotid insufficiency.

Ocular Motility

Normal ocular motility depends on the integrity of a large portion of the cerebrum, cerebellum, and brainstem. Preservation of normal ocular motility implies that a large portion of the brainstem from the vestibular nuclei at the pontomedullary junction to the oculomotor nucleus in the midbrain is intact. Voluntary ocular motility cannot be judged in the comatose patient, so one must rely on reflex eye movements that allow for assessment of the oculomotor system. The eyes normally are conjugate and in the midposition in the alert person. Sleep or obtundation alone may unmask a latent vertical or horizontal strabismus, resulting in disc on jugate gaze; therefore, patients must be examined when maximally aroused. The eyes return to the midposition when patients are brain dead.

Evaluation of ocular motility consists of three main elements: (1) observation of the restmi; position of the eyes, including eye deviation; (2) notation of spontaneous eye movements; and (3) testing of reflex ocular movements.

Abnormalities in Resting Position

Careful attention must be paid to the resting position of the eyes. Even a small discrepancy in eye position may represent a partial extraocular nerve palsy. Partial nerve palsies or combined nerve palsies predictably result in a more complex picture on examination. Unilateral third nerve palsy from either an intramedullary midbrain lesion or extra medullary compression causes the affected eye to be displaced downward and laterally. A sixth nerve palsy produces inward deviation. Isolated sixth nerve palsy, however, is a poor localizer because of its extensive course and because nonspecific increases in intracranial pressure may cause a sixth nerve palsy, presumably from stretching of the extramedullary portion of the nerve. A fourth netve palsy is difficult to assess in the comatose patient because of the subtle nature of the deficit in ocular motility. Extraocular nerve palsies often become more apparent with the doll's eye maneuver or cold caloric testing in the comatose patient.

Eye Deviation

Spontaneous eye deviation may be conjugate or dysconjugate. Conjugate lateral eye deviation is usually caused by an ipsilateral lesion in the frontal eye fields but may be due to a lesion anywhere in the pathway from the ipsilateral eye fields to the contralateral parapontine reticular formation (lateral gaze center). Dysconjugate lateral eye movement may result from a sixth nerve palsy in the abducting eye, a third nerve palsy in the adducting eye, or an internuclear ophthalmoplegia. An internuclear ophthalmoplegia may be differentiated from a third nerve palsy by the preservation of vertical eye movements.

Downward deviation of the eyes below the horizontal meridian is usually caused by brainstem lesions (most often from tectal compression); however, it may also be seen in metabolic disorders such as hepatic coma. Thalamic and subthalamic lesions produce downward and inward deviation of the eyes. Patients with these lesions appear to be looking at the tips of their noses. Sleep, seizure, syncope, apnea of Cheync-Stokes respiration, hemorrhage into the vermis, and brainstem ischemia or encephalitis cause upward eye deviation, making it a poor localizing sign. Skew deviation is a maintained deviation of one eye above the other (hypertropia) that is not due to a peripheral neuromuscular lesion or a local extracranial problem in the orbit. It usually indicates a posterior fossa lesion (brainstem or cerebellar) (Leigh and Zee 1991). Dysconjugate vertical

eye position may sometimes occur in the absence of a brainstem lesion in the obtunded patient.

Spontaneous Eye Movements

Spontaneous eye movements are of many types. Purposeful-appearing eye movements in a patient who otherwise **seems unresponsive** lead **to** consideration **ot the locked-in** syndrome, catatonia, pseudocoma, or the persistent vegetative state. *Roving eye movements* are slow, conjugate, lateral to-and-fro movements. For roving eye movements to be present, the oculomotor nuclei and their connections must be intact. Generally, when roving eye movements are present, the brainstem is relatively intact and coma is the result of a metabolic or toxic cause or bilateral lesions above the brainstem. Roving eye movements may be complicated by ocular palsies or internuclear ophthalmoplegia. These superimposed lesions produce relatively predictable patterns but often obscure the essential roving nature of the movement for the inexperienced observer,

Nystagmus occurring in comatose patients suggests an irritative or epileptogenic supratentorial focus. An epileptogenic focus in one frontal eye field causes contralateral conjugate eye deviation. Nystagmus due to an irritative focus may rarely occur alone, without other motor manifestations of seizures. In addition, inconspicuous movements of the eye, eyelid, face, jaw, or tongue may be associated with electroencephalographic status epilepticus. An electroencephalogram may be required to ascertain this condition.

Spontaneous conjugate vertical eye movements are separated into different types according to the relative velocities of their downward and upward phases. In *ocular bobbing,* there are rapid downward jerks of both eyes, followed by a slow return to the midposition (Leigh and Zee 1991). In the typical form, there is associated paralysis of both reflex and spontaneous horizontal eye movements. *Monocular* or *paretic bobbing* occurs when a coexisting ocular motor palsy alters the appearance of typical bobbing. The term *atypical bobbing* refers to all other variations of bobbing that cannot be explained by an ocular palsy superimposed on typical bobbing. Most commonly, the term is used to describe ocular bobbing when lateral eye movemenrs are preserved. *Typical ocular bobbing* is specific but not pathognomonic for acute pontine lesions. Atypical ocular bobbing occurs with anoxia and is nonlocaiizing. *Ocular dipping,* also known as *inverse ocular bobbing,* refers to spontaneous eye movements in which an initial slow downward phase is followed by a relatively rapid return. Reflex horizontal eye movements are preserved. It is usually associated with diffuse cerebral damage. In *reverse ocular bobbing* there is a slow initial downward phase, followed by a rapid return that carries the eyes past the midposition into full upward gaze. Then the eyes slowly return to the midposition. It is n on localizing.

Vertical nystagmus, caused by an abnormal pursuit or vestibular system, is slow deviation of the eyes from the primary position, with a rapid, immediate return to the primary position. It is differentiated from bobbing because there is no latency between the corrective saccade and the next slow deviation. *Ocular-palatal myoclonus* occurs after damage to the lower brainstem involving the Guillain-Mollaret triangle, which extends between the cerebellar dentate nucleus, red nucleus, and inferior olive, Ocular movements, which may be rotatory or circular, move with the same beat as palatal movements. Ocular flutter is back-to-back saccades in the horizontal plane and may be a feature of cerebellar disease.

Reflex Ocular Movements

Examination of ocular movement is not complete in the comatose patient without assessment of reflex ocular movements, including the oculocephalic reflex (doll's eye phenomenon) and, if necessary, the vestibulo-oculogyric reflex, by caloric (thermal) testing. In practice, the terms *doll's eye phenomenon* and *doll's eye maneuver* are used synonymously to refer to the oculocephalic reflex, but rhese terms are often confusing to the non-neurologist. It is better to use the term *oculocephalic reflex,* followed by a description of the response. This reflex is tested by sudden passive rotation of the head in both directions laterally and flexion and extension of the neck wink- observing the motion of the eyes. When supranuclear influences on the oculomotor nerve are removed, the eyes appear to retain their fixation on a point in the distance when the head is turned. *This maneuver should not be performed on any patient until the stability of the neck has been adequately assessed.* If there is any question of neck stability, a neck brace should be applied and caloric testing substituted. In the normal oculocephalic reflex (normal or positive doll's eye phenomenon), the eyes move conjugately in a direction opposite to the direction of movement of the head. Cranial nerve palsies predictably alter the response to this maneuver (Table *5.5).*

Clinical caloric testing (as distinct from quantitative calorics, used to assess vestibular end organ disorders} is commonly done by applying cold water to the tympanic membrane. It is done with the head tilted backward 60 degrees from the horizontal to allow maximal stimulation of the lateral semicircular canal, which is most responsible for reflex lateral eye movements. After carefully checking to make sure that the ear canal is patent and the tympanic membrane is free of defect, 10 mL of ice-cold water are slowly injected into one ear canal. For purposes of the neurological examination, irrigation of each ear with 10 mL of ice water is generally sufficient.

Cold water applied to the tympanic membrane causes currents to be set up in the cndolymph of the semicircular canal. This results in a change in the baseline firing of the vestibular nerve and slow (tonic) conjugate deviation of

Table 5.5: Oculocephalic reflex (to be performed only after neck stability has been ascertained)

Method	*Response*	*Interpretation*
Lateral: rotation of the head	Eyes remain conjugate, move in direction opposite to head movement (appear to maintain fixation)	Notmal
	No movement in either eye on rotating head to left or rijiln	Brainstem lesion
	Eyes move appropriately when head is rotated in one direction but do not move when head is rotated in opposite direction	Bilateral labyrinth dysfunction
	One eye abducts, the other eye docs not adduct	Drugs
	One eye abducts, the othet does not adduct	Anesthesia Unilateral lesion in lateral ga/.c center (PPRF) Third nerve palsy Intranuclear ophthalmoplegia Fourth nerve palsy
Vertical: flexion and extension of the head	Eyes remain conjugate, move in direction opposite ro head movement	Normal
	No movement in either eye	Same as above with no movement on lateral head rotation
	Only one eye moves	Third nerve palsy
	Bilateral symmetrical limitation of upg;ue	Aging

the eyes toward the stimulated ear. In an awake person, the eye deviation is corrected with a resulting nystagmoid jerking of the eye toward the midline (fast phase). Warm-water irrigation produces reversal of flow of the endolymph, which causes conjugate eye deviation with a slow phase away from the stimulated ear and a normal corrective phase toward the ear. By tradition, the nystagmus is named by the direction of the fast phase. The mnemonic COWS (raid opposite, warm same) refers to the fast phases. Simultaneous bilateral cold water application results in slow downward deviation, whereas simultaneous bilateral warm water application causes upward deviation.

Oculocephalic or caloric testing may elicit subtle or unsuspected ocular palsies. Abnormal dysconjugate responses occur with cranial nerve palsies, intranuclear ophthalmoplegia, or restrictive eye disease. Movements may be hyperactive, sluggish, or absent. Sometimes reinforcement of cold caloric testing with superimposed passive head turning after injection of cold water into the ear may reveal eye movement when either test alone shows none.

False-negative or misleading responses on caloric testing occur with pre-existing inner ear disease, vestibulopathy like that caused by ototoxic drugs such as streptomycin, vestibular paresis caused by illnesses such as Wernicke's encephalopathy, and drug effects. There is no response when the labyrinth is destroyed; however, partial lesions of the labyrinth may increase or decrease the response. Lesions of the vestibular nerve cause a decreased or absent response. Drugs that suppress eirher vestibular or oculomotor function, or both, include sedatives, anticholinergics, anticonvulsants, tricyclic antidepressants, and neuromuscular blocking agents. If the response from one ear is indeterminate, both cold- and warm-water stimuli should be applied to the other ear. If the test remains equivocal, superimposition of the doll's eye maneuver is recommended. The interpretation of abnormal cold caloric responses is summarized in Table 5.6.

An unusual ocular reflex that has been observed in the setting of the persistent vegetative state is reflex opening of both eyes triggered by flexion of an arm at the elbow. This reflex is distinct from reflex eye opening in the comatose patient induced by raising the head or turning it from side to side.

MOTOR SYSTEM

Examination of the motor system of a stuporous or comatose patient begins with a description of the resting posture and adventitious movements. Purposeful and nonpurposeful movements are noted and the two sides of the body compared. Head and eye deviation to one side, with contralateral hemiparesis, suggests a supratentorial lesion, whereas ipsilatcral paralysis indicates a probable brainstem lesion. External rotation of the lower limb is a sign of hemiplegia or hip fracture.

Decerebrate posturing is bilateral extensor posture, with extension of the lower extremities and adduction and internal rotation of the shoulders and extension at the elbows and wrist. Bilateral midbrain or pontine lesions are usually responsible for decerebrate posturing. Less commonly, deep metabolic encephalopathies or bilateral supratentorial lesions involving the motor pathways may produce a similar pattern.

Tabic 5.6: Caloric testing

Method	*Response*	*interpretation*
Cold water instilled in right ear	Slow phase to right, fast (corrective) phase to the left	Normal
	No response (make sure canal is patent, apply warm-water stimulus to opposite ear)	Obstructed ear canal, "dead" labyrinth, eighth nerve or nuclear dysfunction, false negative (see text)
	Slow phase to right, no fast phase	Toxic-metabolic disorder, drugs, structural lesion above brainstem
	Down beating nystagmus	1 lori/ontal gaze palsy
Cold water instilled in left ear		Responses should be opposite to above
Warm water instilled in left car after no response from cold water in right ear	Slow phase to right, fast phase to left	Peripheral eighth nerve or labyrinth disorder on right (assuming right canal is patent)

Decorticate posturing is bilateral flexion at **the** elbows and wrists, with shoulder adduction and extension of the lower extremities. It is a much poorer localizing posture, as it may result from lesions in many locations, although usually above the brainstem. Decorticate posture is not as ominous a sign as decetebrate posture because the former occurs with many relatively reversible lesions.

Unilateral decerebrate or decorticate postures are also less ominous. Lesions causing unilateral posturing may be anywhere in the motor system from cortex to brainstem. Unilateral extensor posturing is common immediately after a cerebrovascular accident, followed in time by a flexor response.

Posturing may occur spontaneously or in response to external stimuli such as pain, or may even be set off by minimal events, such as the patient's breathing. These postures, although common, may also be variable in their expression because of other associated brainstem or more rostral brain damage. Special attention should be given to posturing because it often signals a brainstem herniation syndrome. Emergency room personnel and inexperienced physicians may mistake these abnormal postures for convulsions (seizures) and institute anticonvulsant therapy, resulting in an unfortunate delay of apptoptiate thetapy for these patients.

Adventitious movements in the comatose patient may be helpful in sepatating metabolic from structural lesions. Tonic-clonic ot othet steteotyped movements signal seizure as the probable cause of decreased alertness. *Myoclonic jerking,* nonrhythmic jerking movements in single or multiple muscle gtoups, is seen with anoxic encephalopathy ot othet metabolic comas, such as hepatic encephalopathy, *Rhythmic myoclonus,* which must be differentiated from epileptic movements, is usually a sign of brainstem injury, Tetany occurs with hypocalcemia. *Cerebellar fits* result from intermittent tonsillar herniation. They are characterized by a deterioration of level of arousal, opisthotonos, respiratory rate slowing and irregularity, and pupillary dilation.

The motor response to painful stimuli should be tested, although it should be noted that the pattern of tesponse may vary depending on the site stimulated. Purposeful responses may be difficult to discern from more primitive reflexes. Flexion, extension, and adduction may be eithet voluntary or reflex in nature. In general, abduction is most reliably voluntary, with shoulder abduction stated to be the only definite nonreflex reaction. This is tested by pinching the medial aspect of the upper arm.

Reflex flexor response to pain in the upper extremity consists of adduction of the shoulder, flexion of the elbow, and pronation of the arm. The *triple flexion response* in the lower extremities refers to reflex withdrawal, with flexion at the hip and knee and dorsiflcxion at the ankle, in response to painful stimulation on the foot or lower extremity. Such reflexes are seldom helpful in localizing a lesion.

Spinal reflexes are reflexes mediated at the level of the spinal cotd and do not depend on the functional integrity of the brain or brainstem. Most patients with absent cortical or brainstem function have some fotm of spinal reflex.

The *plantar reflex* may be extensor in coma from any cause, including drug overdoses and postictal states. It becomes flexor on recovery of consciousness if there is no underlying structural damage,

Muscle tone and asymmetry in muscle tone are helpful in localizing a focal structural lesion and may help differentiate metabolic from structural coma. Acute structural damage above the btainstem usually results in decreased or flaccid tone. In oldct lesions, tone is usually increased. Metabolic insults generally cause a symmetric decrease in tone. Finally, one must remember **that** generalized flaccidity is ultimately seen after brain death.

BRAIN HERNIATION

Clinical Signs of Herniation

Herniation syndromes are explained in Chapter 56B. However, a knowledge of some of the clinical signs of herniation is especially important in the clinical approach

to coma. Traditional signs of herniation due to supratcntorial masses are usually variations of either an uncal or central pattern. Classically, in the former, there are early signs of third nerve and midbrain compression. The pupil initially dilates as a result of third nerve compression but later returns to the midposition with midbrain compression that involves the sympathetic as well as the parasympathetic tracts. In the central pattern, the earliest signs are mild impairment of consciousness, with poor concentration, drowsiness, or unexpected agitation; small but reactive pupils; loss of the fast component of cold caloric testing; poor or absent reflex vertical gaze; and bilateral corticospinal tract signs, including increased tone of the body ipsilateral to the hemispheric mass lesion responsible for herniation (Plum and Posner 1995}.

Signs of herniation tend to progress generally in a rostrocaudal manner. An exception occurs when intraventricular bleeding extends to the fourth ventricle and produces a pressure wave compressing the area around the fourth ventricle. Also, when a lumbar puncture reduces cerebrospinal fluid pressure suddenly in the face of a mass lesion that produced increased intracranial pressure, sudden herniation of the cerebellar tonsils through the foramen magnum may result (Plum and Posner 1995). In both cases there may be sudden, unexpected failure of medullary functions that support respiration or blood pressure. The clinical examination of patients with herniation syndromes may be confusing because of changing signs or the expression of scattered, isolated signs of dysfunction in separate parts of the brain. In addition, certain signs may be more prominent than others.

Increased intracranial pressure invariably accompanies brainstem herniation and may be associated with increased systolic blood pressure, bradycardia, and sixth nerve palsies. These signs, however, as well as many of the traditional signs of herniation described previously, actually occur relatively late. Earlier signs of potential herniation are decreasing level of arousal, slight change in depth or rate of respiration, or the appearance of a Babinski sign. It is important to suspect herniation early, because once midbrain signs develop, structural injury is likely to have occurred; subsequently there is less chance of reversal.

DIFFERENTIAL DIAGNOSIS

Differentiating Toxic-Metabolic Coma from Structural Coma

Many features of the history and physical examination help differentiate structural from metabolic and toxic causes of coma. Some have already been mentioned above. When the history is available, a patient's underlying illnesses and medications or the setting in which he or she is found often guide the physician to the appropriate cause. The time course of the illness resulting in coma can be helpful. Generally, structural lesions have a more abrupt onset, whereas metabolic or toxic causes are more slowly progressive. Multifocal structural diseases such as vasculitis or leukoencephalopathy arc an exception to this rule, as they may exhibit slow progression, usually in a stepwise manner. Supratentorial or infratentorial tumors characterized by slow growth and surrounding edema may also mimic metabolic processes.

The response to initial emergency therapy may help differentiate metabolic or toxic causes of coma. The hypoglycemic patient usually awakens following administration of glucose, the hypoxic patient responds to oxygen, and the patient experiencing an opiate drug overdose responds to naloxone.

In general, structural lesions have focal features or at least notable asymmetry on neurological examination. Toxic, metabolic, and psychiatric diseases are characterized by their symmetry. Bilateral and often multilevel involvement is frequently seen with metabolic causes. Asymmetries may be observed but are generally of small degree and tend to fluctuate over time.

Many features of the neurological examination differentiate metabolic or toxic causes from structural lesions:

1. *State of consciousness.* Patients with metabolic problems often have milder alterations in arousal and tend to have waxing and waning of the behavioral state. Patients with acute structural lesions tend to stay at the same level of arousal or progressively deteriorate. Toxins may also cause progressive decline in level of arousal.
2. *Respiration.* Deep, frequent respiration is most commonly due to metabolic abnormalities, although rarely it is caused by pontine lesions or by neurogenic pulmonary edema secondary to acute structural lesions.
3. *Funduscopic examination.* Subhyaloid hemorrhage or papilledema are almost pathognomonic of structural lesions. Papilledema caused by increased intracranial pressure may be indicative of an intracranial mass lesion or hypertensive encephalopathy. Papilledema does not occur in metabolic diseases except hypoparathyroidism, lead intoxication, and malignant hypertension.
4. *Pupil size-* The pupils are usually symmetric in coma from toxic-metabolic causes. Patients with metabolic or toxic encephalopathies often have small pupils with preserved reactivity. Exceptions occur with methyl alcohol poisoning, which may produce dilated and unreactive pupils, or late in the course of toxic or metabolic coma if hypoxia or other permanent brain damage has occurred. In terminal asphyxia the pupils dilate initially and then become fixed at midposition within 30 minutes. The initial dilation is attributed to massive sympathetic discharge.
5. *Pupil reactivity.* Assessment of the pupillary reflex is one of the most useful means of differentiating

metabolic from structural causes of coma. Pupillary reactivity is relatively resistant to metabolic insult and is usually spared in coma from drug intoxication or metabolic causes, even when other brainstem reflexes are absent. Hypothermia may fix pupils, as does severe barbiturate intoxication; neuromuscular blocking agents produce midposition or small pupils, and glutethimide and atropine dilate them.

6. *Ocular motility.* Asymmetry in oculomotor function is typically a feature of structural lesions.
7. *Spontaneous eye movements,* Roving eye movements with full excursion most often suggest metabolic or toxic abnormalities.
8. *Reflex eye movements.* Reflex eye movements are normally intact in toxic-metabolic coma, except rarely in phenobarbital or phenytoin intoxication or deep metabolic coma from other causes.
9. *Adventitious movement.* Coma punctuated by periods of motor restlessness, tremors, or spasm is often due to drugs or toxins such as chlorpromazine or lirhium. Brainstem herniation or intermittent CNS ischemia may also produce unusual posturing movements. Myoclonic jerking is generally metabolic and often anoxic in origin.
10. *Muscle tone.* Muscle tone is usually symmetric and normal or decreased in metabolic coma. Structural lesions cause asymmetric muscle tone. Tone may be increased, normal, or decreased by structural lesions.

The examiner should be aware of common structural lesions that mimic toxic-metabolic causes and, conversely, toxic or metabolic causes of coma that may have focal findings on examination. Structural lesions that may mimic toxic-metabolic causes include subarachnoid hemorrhage, sinus vein thrombosis, chronic or bilateral subdural hemorrhage, and other diffuse or multifocal disorders, such as vasculitis, demyelinating diseases, or meningitis. Any toxic-metabolic cause of coma may be associated with focal findings; however, focal features are most often observed with barbiturate or lead poisoning, hypoglycemia, hepatic encephalopathy, and hyponatremia. Old structural lesions such as stroke may leave residual findings on neurological examination in a patient who is comatose from toxic or metabolic causes. Moreover, metabolic abnormalities such as hypoglycemia may unmask relatively silent structural abnormalities. Detailed descriptions of the toxic and metabolic encephalopathies arc provided in Chapter 62,

Differentiating Psychiatric Coma and Pseudocoma from Metabolic or Structural Coma

The patient who appears unarousable as a result of psychiatric disease and the patient who is feigning unconsciousness for other reasons may be difficult to differentiate from a patient with true coma or stupor. In these cases, the history, when available, and the physical examination may seem suspect to the physician, hinting that a nonphysiologic mechanism is at work. Multiple inconsistencies are present on examination, and abnormalities that are found do not fit the pattern of usual neurological syndromes. Examinations of the eyelid, pupil, adventitious eye movements, and vestibulo-oculogyric reflex by cold caloric testing are especially useful to confirm the suspicion of pseudocoma.

Eyelid tone is difficult to alter voluntarily. In the patient with true stupor or coma, passive eyelid opening is easily performed and is followed by slow, gradual eyelid closure. The malingering or hysterical patient often gives active resistance to passive eye opening and may even hold his or her eyes tightly closed. It is nearly impossible for the psychiatric or malingering patient to mimic the slow, gradual eyelid closure. Blinking also increases in hysterical patients but decreases in true stupor.

The pupils normally consrrict in sleep or (eyes-closed) coma but dilate with the eyes closed in the awake state. Passive eye opening in a sleeping person or a truly comatose patient (if pupillary reflexes are spared) results in pupillary dilation. Opening the eyes of an awake person produces constriction. This principle may help to differentiate a comatose patient from a patient with pseudocoma.

Roving eye movements cannot be mimicked and thus arc also a good sign of true coma. Finally, if the fast phase of ocular movement is preserved on cold caloric testing, the diagnosis of coma is suspect. Cold caloric testing often serves as a sufficient stimulus to awaken the patient.

Laboratory Studies

Laboratory tests that are extremely helpful in evaluating the comatose patient are listed in Table 5.7. Arterial blood gas determinations rule out hypoxemia and carbon dioxide narcosis and help differentiate primary CNS problems from secondary respiratory problems. Liver disease, myopathy, or rhabdomyolysis increase alanine aminotransferase and aspartate aminotransferase levels. Liver function tests may be misleading in end-stage liver disease because they may be normal or only mildly elevated with markedly abnormal liver function. Although the blood ammonia level does not correlate well with the level of hepatic encephalopathy, it often may be markedly elevated and thus helpful in cases of suspected liver disease with relatively normal liver function studies. Hepatic encephalopathy may continue for up to 3 weeks after liver function studies return to normal.

Thyroid function studies are necessary to document hypothyroidism or hyperthyroidism. When addisonian crisis is suspected, a serum Cortisol level should be obtained. A low or normal level in the stressful state of coma or illness strongly suggests adrenal insufficiency. Further

testing of adrenal function should be performed as appropriate.

When the cause of coma is not absolutely certain, or in possible medicolegal cases, a blood alcohol level and a drug and toxin screen are mandatory. The results of these tests are not usually available immediately but may be invaluable later. Serum osmolality can usually be measured rapidly by the laboratory and may be used to estimate alcohol level because alcohol is an osmotically active particle and increases the osmolar gap in proportion to its blood level. Serum osmolality can be calculated by the following;

- Serum osmolality = 2 Na^+(mEq/liter)
- + BUN (mg/dI.)/2.8
- + glucose (mg/dL)/18

The osmolar gap, which is the difference between the measured serum osmolality and the calculated serum osmolality, represents unmeasured osmotically active particles.

Creatine kinase levels should routinely be measured in comatose patients initially and then at least daily for the first several days because of the great risk of rhabdomyolysis and subsequent preventable acute tubular necrosis in these patients. Measuring creatine kinase MB isoenzyme levels every 8 hours for the first 24 hours helps rule out a myocardial infarction.

Other Studies

Electroca rdiogtaphy

The electrocardiogram is useful to show myocardial infarction, arrhythmia, conduction blocks, bradycardia, or evidence of underlying hypertension or atherosclerotic coronary vascular disease. Hypocalcemia causes QT prolongation. Hypercalcemia shortens the QT interval. The heart rate is slow in hypothyroid patients with low-voltage QR.S, flat or inverted T waves, and flattened ST segments. Hyperthyroid patients are generally tachycardic.

Neuroradioiogical Imaging

Once the patient is treated and stabilized, the initial examination is complete, and necessary laboratory studies

Table 5.7: Laboratory tests helpful in cuma

Laboratory study	*Result*	*Associated disorders*

are ordered, the next test of choice is a CT scan of the brain, without contrast enhancement, but with 5-mm cuts of the posterior fossa. Alternatively, magnetic resonance imaging (MRI) may be performed, depending on the clinical setting and the stability of the patient's condition. MRI provides superb visualization of the posterior fossa and its contents, an extremely useful feature when structural disease of the brainstem is suspected. However, MRI is not specific for visualizing early intracranial hemorrhage, as the CT scan is, and ii is limited at present by the time required to perform the imaging, image degradation by even a slight movement of the patient, and the relative inaccessibility of the patient during the imaging process. The CT scan, when performed as described, is currently the most expedient imaging technique, giving the physician the most information aboui possible structural lesions with the least risk to the patient. Intravenous dye may later be necessary to better define lesions seen on the initial CT scan.

The value of the CT scan in demonstrating mass lesions and hemorrhage is undeniable. Furthermore, it may demonstrate features of brain herniation. Uncal herniation is characterized on CT scan by (1) displacement of the brainstem toward the contralateral side, with increase in width of subarachnoid space between the mass and ipsilateral free edge; (2) medial stretching of the posterior cerebral and posterior communicating arteries; (3) obliteration of the interpeduncular cistern; (4) occipital lobe infarction; and (5) distortion and elongation of the 1.1-shaped tentorial hid sura. The clinician should be aware that the CT scan may miss early infarction, encephalitis, and isodense subdural hemorrhage. Special caution must be taken in evaluating CT scans in comatose patients, especially before lumbar puncture, to rule out isodense subdural or bilateral subdural hemorrhage. Interpretation of CT scans is discussed in Chapter 37B.

In severe head injury, studies of cerebral metabolism with use of single-photon emission computed tomography (SPECT) may be of prognostic value (Delia Corte et al. 1997). Although cerebral blood flow in the first 48 hours after trauma does not appear to correlate with severity or prognosis, cerebral metabolic rate of oxygen (CMRO2), like the Glasgow Coma Scale, may be useful in predicting prognosis.

Electroencephalography

The electroencephalogram (EEG) is hcipfu! in many situations, including confirming underlying cortical structural damage in patients too unstable to travel to a CT scan; postictal states in patients slow to wake after a presumed seizure; partial complex seizures; electroencephalographic or nonconvulsive status epilepticus, such as that seen in comatose patients following anoxic ischemic damage; and toxic-metabolic disorders. With metabolic disorders, the earliest LEG changes are typically a decrease in the frequency of background rhythms and the appearance of diffuse theta activity that progresses to more advanced slowing in association with a decrease in the level of consciousness. In hepatic encephalopathy, bilaterally synchronous and symmetric, medium- to high-amplitude, broad triphasic waves, often with a frontal predominance, may be observed. Herpes simplex encephalitis may be suggested by the presence of unilateral or bilateral periodic sharp waves with a temporal preponderance. The EEG also helps confirm the clinical impression of catatonia, pseudocoma, the locked-in syndrome, the persistent vegetative state, and brain death. Electroencephalograms arc discussed further in Chapter 36A.

Evoked Potentials

Evoked potentials may help in evaluating brainstem integrity and in assessing prognosis for comatose patients. Brunko and Zegers de Beyl (1987) studied 50 hemodynamically stable patients remaining in coma 4 hours after resuscitation from cardiopulmonary arrest with short latency somatosensory-evoked potentials within 8 hours after arrest. They found that none of the 30 patients without cortical potentials recovered cognition. Five of the 20 patients with cortical potentials recovered. Forty percent of their patients who did not recover had preserved brainstem reflexes, allowing some evaluation of prognosis in a group of patients in whom prognosis is difficult to assess by other means. Event-related potentials may prove particularly useful as an objective assessment of cognitive function in patients with the locked-in syndrome (Onofrj ctal. 1997).

Intracranial Pressure Monitoring

Intracranial pressure (ICP) measurements provide an index of the degree of brain swelling and are particularly useful in the treatment of patients who have suffered severe head injury. Postmortem studies of fatal head injuries demonstrate a direct correlation between very elevated ICP and death due to tentorial herniation. In the absence of intracranial hematomas, however, comatose patients with normal brain imaging studies have a low incidence of increased ICP and almost never develop uncontrolled intracranial hypertension.

CLINICAL APPROACH TO PROGNOSIS

Given our current state of knowledge, one cannot reliably predict outcome in any comatose patient with 100% certainty unless that patient meets the criteria for brain death, as described below. Available studies do not allow us to say definitely that any single non-brain-dead patient will not recover from coma, nor do they allow us to prognosticate on how much recovery may occur in specific

cases. However, general statistics on the outcome of coma based on serial exams at various times after the onset of coma have been compiled (Levy etal. 1981;Torner 1992) and give the examiner a general idea of expected prognosis.

The natural history of coma can be considered in terms of three subcategories: drug-induced, nontraumatic, and traumatic coma. Drug-induced coma is usually reversible unless the patient has nor had appropriate systemic support while comatose and has sustained secondary injury from hypoperfusion, hypoxia, or lack of other necessary metabolic substrates.

Nontraumatic Coma

Only approximately 15% of patients in nontraumatic coma make a satisfactory recovery. Functional recovery is related to the cause of coma. Diseases causing structural damage, such as cerebrovascular disease including subarachnoid hemorrhage, have the worst prognosis; coma from hypoxia-ischemia due to causes such as cardiac arrest has an intermediate prognosis; coma due to hepatic encephalopathy and other metabolic causes has the best ultimate outcome. Age does not appear to be predictive of recovery. The longer a coma lasts, the less likely the patient is to regain independent functioning (Levy et al. 1981).

In the early days after the onset of nontraumatic coma, it is not possible to predict with certainty which patients will ultimately enter or remain in a persistent vegetative state. Although rare cases have been reported of patients awakening after prolonged vegetative states, patients with nontraumatic coma who have not regained awareness by the end of 1 month are unlikely to regain consciousness. Even if they do regain consciousness, they have practically no chance of achieving an independent existence. A large multi-institutional study determined that within 3 days of cardiac arrest, evaluation in the intensive care unit is sufficiently predictive of neurological outcome to allow for informed decisions regarding life support (Edgren et al. 1994), The absence of pupillary light response, motor response to pain, and low Glasgow Coma scores (<5) were predictive of poor neurological outcome.

Clinical experience must be combined with data from studies such as this one to aid the individual physician in prognosticating about each individual patient who is comatose from nontraumatic causes but not clinically btain dead.

Traumatic Coma

The prognosis for traumatic coma differs from that for nontraumatic coma in many ways. First, many patients with head trauma are young. Second, prolonged coma of up to several months does not preclude a satisfactory outcome in traumatic coma. Third, in relationship to their initial degree of neurological abnormality, traumatic coma patients do better than nontraumatic coma patients (Levy et al. 1981).

The prognosis for coma from head trauma may be considered in terms of survival; however, because many more patients survive traumatic coma than nontraumatic coma, it is equally important to consider the ultimate disabilities of the survivors because many who survive are left with profound disabilities.

The Glasgow Outcome Scale is a practical system for describing outcome in traumatic coma. As originally proposed, there arc five categories in this scale: (1) death; (2) persistent vegetative state; (3) severe disability (conscious but disabled and dependent on others for activities of daily living); (4) moderate disability (disabled but independent); and (5) good recovery (resumption of normal life even though there may be minor neurological and psychiatric deficits).

Jennettet al, (1979) studied 1000 patients in coma longer than 6 hours from severe head trauma: 49% of these patients died, 3% remained vegetative, 10% survived with severe disability, 17% survived with moderate disability, and 22% had good recovery. Depth of coma, as evaluated by the Glasgow Coma Scale; pupil reaction; eye movements; and motor response in the first week after injury and the patient's age were found to be the most reliable predictors of outcome 6 months later.

In summary, early predictors of the outcome of posttraumatic coma include the patient's age, motor response, pupillary reactivity, eye movements, and depth and duration of coma. The prognosis worsens with increasing age. The cause of injury, skull fracture, lateralization of damage to one hemisphere, and extracranial injury appear to have little influence on the outcome.

CLINICAL APPROACH TO BRAIN DEATH

A thorough knowledge of the criteria for brain death is essential for the physician whose responsibilities include evaluation of comatose patients. Despite differences in state laws, the criteria for the establishment of brain death are fairly standard within the medical community. These criteria include the following:

1. *Coma.* The patient should exhibit an unarousable unresponsiveness. There should be no meaningful response to noxious, externally applied stimuli. The patient should not obey commands or demonstrate any verbal response, either reflcxivcly or spontaneously. Spinal reflexes, however, may be retained.
2. Wo *spontaneous respirations.* The patient should be removed from ventilatory assistance and carbon dioxide should be allowed to build up because of the respiratory drive that hypercapnia produces. The diagnosis of absolute apnea requires the absence of spontaneous tespiration at a carbon dioxide tension of

at least 60 mm Hg, A safe means of obtaining this degree of carbon dioxide retention involves the technique of apneic oxygenation, in which 100% oxygen is delivered endotracheal!}' through a thin sterile catheter for 10 minutes. Arterial blood gas levels should be obtained to confirm the arterial carbon dioxide pressure.

3. *Absence of brainstem reflexes.* Pupillary, oculocephalic, vestibulo-oeulogyric on cold calorics, corneal, and gag reflexes must all be absent.
4. *Extracerebral silence.* An isoelectric EEG should denote the absence of cerebrocortical function. Some authorities do not regard rhe performance of an EEG as mandatory in assessing brain death, and instances of preserved cortical function, despite irreversible and complete brainstem disruption, have been reported.
5. *Absence of cerebral blood flow.* Cerebral contrast angiography or radionuclide angiography can substantiate the absence of cerebral blood flow, which is expected in brain death. These tests are considered confirmatory rather than mandatory. On rare occasions in the presence of supratentorial lesions with preserved blood flow to the brainstem and cerebellum, cerebral angioscintigraphy may be misleading.
6. *Absence of any potentially reversible causes of marked CNS depression.* This includes hypothermia (temperarure 32°C or less), drug intoxication {particularly barbiturate overdose), and severe metabolic disturbance,

Brain Death Survival

Despite aggressive therapeutic measures, survival of longer than 1 week in "brain-dead" individuals is uncommon. Shewmon found in a meta-analysis of 56 of 175 cases surviving longer than 1 week after diagnosis of "brain death" (Shewmon, 1998) that one half survived longer than 1 month, one third longer than 2 months, and only four longer than 1 year. Survival correlated inversely with age; the longest survivors (2.7, 5.1, and 14.5 years) were all children (Shewmon 1998). Longer survival was more common with primary brain pathology than other etiologies. The tendency to cardiovascular collapse in brain death may be transient and more likely attributable to systemic than brain pathology.

Chapter 6
Approaches to Intellectual and Memory Impairments

Howard S. Kirshner

The term *intellect* designates the totality of the mental or cognitive operations that comprise human thought, the higher cortical functions that make up the human mind. The intellect and its faculties, the subject matter of human psychology, are the qualities that most separate human beings from other animals. Memory is a specific cognitive function: the storage and retrieval of information. As such, it is the prerequisite for learning, the building block of all human knowledge. Other "higher" functions, such as language, calculations, spatial topography and reasoning, music, and creativity, all represent the functions of specific brain systems. The relationship of the mind and brain has long been of philosophical interest. Recent advances in cognitive neuroscicncc have made mind-brain questions the subject of practical scientific and clinical study. It is now possible to study how the metabolic activation of brain regions and firing patterns of neurons give rise to the phenomenon of consciousness, the sense of self, the ability to process information, and develop decisions and attitudes. The pattern of an individual's habitual decisions and attitudes amount to one's personality. Francis Crick (1994), who with James Watson discovered the structure of deoxyribonucleic acid (DNA), expressed the "astonishing hypothesis" that "you, your joys, and your sorrows, your sense of personal identity, and free will, are in fact no more than the behavior of a vast assembly of nerve cells and their associated molecules." This chapter considers our knowledge of intellect and memory, mind and brain, from the perspective of the clinical neurologist who must assess disorders of the higher functions.

This chapter is dedicated to the memory of Dr. D. Frank Benson, author of the chapter in the first and second editions of this book and a friend and mentor to all who study the higher functions in humans.

NEURAL BASIS OF COGNITION

Cerebral Cortex

The cognitive operations discussed in this chapter take place among a large network of cortical cells and connections, the neural switchboard that gives rise to conscious thinking. The cortical mantle of the human brain is very large compared with animal brains, containing more than 14 billion neurons, The information stored in the human cerebral cortex rivals that of large libraries. Within the cortical mantle, the areas that have expanded the most from animal to human are the "association cortices," cortical zones that do not carry out a primary motor or sensory function but inter-relate the functions of the primary motor and sensory areas. According to Nauta and Feirtag's 1986 text, 70% of neurons in the human central nervous system are in the cerebral cortex, and 75% of those are in the association cortex. Higher conical functions, with few exceptions, take place in the association cortex.

The neuroanatomy of the cerebral cortex has been known in considerable detail since the 1800s. Primary cortical sensory areas include the visual cortex in the occipital lobe, the auditory cortex in the temporal lobe, the somatosensory cortex in the parietal lobe, and probably gustatory and olfactory cortices in the fronral and temporal lobes. Each of these primary cortices receives signals in only one modality (vision, hearing, or sensation) and has cortical-cortical connections only to adjacent portions of the association cortex also dedicated to this modality, called *unimodal association cortex.* Sensory information is sequentially processed in increasingly complex fashion, leading from raw sensory data to a unified percept. Within each cortical area are columns of cells with similar function, called *modules.*

The organization of the primary sensory and unimodal association cortex has been especially well worked out in the visual system through the Nobel prize-winning research of Hubcl and Wiesel and others. Retinal ganglion cells are

activated by light within a bright center, with inhibition in the surround. These cells project through the optic nerve to the lateral geniculate body of the thalamus, then via the optic radiations to the primary visual cortex in the occipital lobes. In the primary visual cortex, a vertical band of neurons may be dedicated to the detection of a specific bright area, but in the cortex, this is usually a bar or edge of light rather than a spot. These "simple" cells of the visual cortex respond to bright central bars with dark surrounds. Several such cells project to complex cells, which may detect an edge or line with a specific orientation or a specific direction of movement but with less specificity about the exact location within the visual field. By the operation of these cells, visual shapes are perceived. Complex cells, in turn, project to cells in the visual unimodal association cortex (Brodmann's areas 18 and 19), where cells may detect movement or patterns. Complex cells also respond to movement anywhere in the visual field, an important characteristic because of the organism's need to maintain visual attention for possible hazards in the environment. In the visual association cortex, columns may respond to specific shapes, colors, or qualities, such as novelty. In this fashion, the functions of cell columns or modules become more sophisticated from the primary cortex to the association cortex. In Fodor's model, the modules of primary visual perception project to central systems. Cognitive science has yet to develop a clear understanding of higher perceptual functions, such as the concept of beauty in a starry sky or in a painting, or the cross-modality processes that underlie, for example, the adaptation ot a ballet to a specific musical accompaniment.

Unimodal association cortices communicate with each other via still more complex connections to the hetero-modal association cortex, of which there are two principal sites. The posterior heteromodal association cottex involves the posterior inferior parietal lobe, especially the angular gyrus. The posterior heteromodal cortex makes it possible to perceive an analogy between an association in one modality (e.g., a picture of a boat and the printed word *boat* in the visual modality) with a percept in a different modality (e.g., the sound of the spoken word *boat).* These intermodality associations are difficult for animals, even chimpanzees, but easy for human beings. Cross-sensory associations involve the functioning of *cortical networks* of multitudes of neurons; the analogy drawn by neuroscien-tists is to the vast arrays of circuits active in computer networks. The product of such associations is a concept.

The second heteromodal association cortex involves the lateral prefrontal region (G-oldman-Rakic 1996). This region is thought to be involved with attention or "working memory" and with sequential processes, such as storage of temporally ordered stimuli and the planning of motor activities. This temporal sequencing of information and of motor planning is referred to by neuropsychologists as the *executive function* of the brain: the decisions we make every instant regarding which of the myriad sensory stimuli reaching the sensory cortices merit attention, which require a motor response, and in what sequence and timing these motor responses will occur.

Another frontal cortical area, the orbitofrontal pottion of the prefrontal cortex, is thought to be involved in emotional states, appetites, and drives, or in integration of internal bodily states with sensations with the external world. The orbirofrontal cortex is known as the *supramodal cortex* (Benson 1996) because it relates the functions of the heteromodal cortex, regarding attention and sequencing of responses, with interoceptive inputs from the internal milieu of the body. The orbitofrontal area has close connections with the limbic system and autonomic, visceral, and emotional processes. In studying brain evolution from primitive reptiles to humans, Paul Mac-Lean hypothesized that the internal and emotional parts of the brain, the limbic system, must be tied into the newer neocortical areas responsible for intellectual function and that the linking of these two systems must underlie the phenomenon of consciousness. Benson and Ardila (1996), in reviewing clinical data from individuals with frontal lobe damage, state that the supramodal cortex is the brain system that "anticipates, conjectures, ruminates, plans for the future, and fantasizes." In other words, it is rhis part of the brain that brings specific cognitive processes to conscious awareness and may be responsible for the phenomena of consciousness and self-awareness.

Consciousness

All human beings have a subjective understanding of what it means to be conscious and have a concept of self, yet the neural basis for conscious awareness and the sense of self remain poorly understood. Until recently, many neuro-scientists left consciousness to the realm of religion and philosophy. Even Hippocrates, however, knew that con-sciousness emanated from the brain: "to consciousness the brain is messenger." For Crick (1994), the best model for the study of consciousness is visual awareness, because the anatomy and physiology of the visual system are well understood. Crick argues that neurons in the primary visual cortex likely do nor have access to conscious awareness. Stated another way, we do not pay attention to much of what our eyes see and our visual cortex analyzes. A perceived object, however, excites neurons in several areas of rhe visual association cortex, each with associations that enter consciousness or are stored in short-term memory.

Crick and Koch (1995) argue that activation of the frontal cortex is necessary for visual percepts to enter consciousness, although subconscious awareness in rhe form of "blindsight" may exist at the level of the occipital cortex. Conscious visual perception involves interactions between the visual parts of the brain and the prefrontal systems for attention and working memory (Ungerleider, Courtney, and Haxby 1998). The orbitofrontal cortex

contains neurons that integrate interoceptive stimuli related to changes in the internal milieu with exteroceptive sensory inputs, such as vision. As stated earlier, this interaction between attention to external stimuli and internal stimuli underlies conscious awareness.

There are many clinical examples of "unconscious" mental processing, and a number of these involve vision. Patients with cortical blindness sometimes show knowledge of items they cannot See, a phenomenon called "blindsight." Patients with right hemisphere lesions who extinguish objects in the left visual field when presented with bilateral stimuli nonetheless show activation of the right visual cortex by functional magnetic resonance imaging (fMRI), indicating that the objects are perceived, though not consciously (Rees et al. 2000). Libet (1999) demonstrated experimentally that visual and other sensory stimuli have to persist at least 500 ins to reach conscious awareness, yet stimuli of shorter duration can elicit reactions. An experimental example of unconscious visual processing comes from Gur and Snodderly (1997), who tested color vision in monkeys. When two colors were projected at a frequency of more than 10 Hz, the monkey perceived a fused color, yet cellular recordings clearly demonstrated coding of information about the two separate colors in the monkey's visual cortex. Motor responses to sensory stimuli can occut before conscious awareness, as in the ability to pull one's hand away ftom a hot stove before feeling the heat. Racers begin running before they are aware of having heard the staffing gun (Crick and Koch 1998), A familiar example of unconscious visual processing is the drive home from work; most individuals can remember very little that they saw on the trip, yet they drove without accidents. Crick and Koch (1998) refer to the unconscious visual processing as an "online visual system," They suggest that the "dorsal visual stream," an occipitoparietal system for perception of location and movement direction of objects, is largely conscious, whereas the "ventral visual stream," an occipitotemporal system for identification of objects, is largely unconscious. We shall discuss unconscious or "implicit" memories later in this chapter (see Othet Types of Memory [Nondeclarative or Implicit Memory]). In language syndromes, patients can match spoken to written words without knowledge of their meaning, suggesting that there are unconscious rules of language. Brust (2000) has called all of these unconscious mental processes the "non-freudian unconscious."

Recent research has linked the right frontal cortex to the sense of self. Keenan et al. (2001) studied patients undergoing Wada tests, in which a barbiturate is injected into the carotid artery to determine cortical language dominance, They presented subjects with a self-photograph and a photograph of a famous person, followed by a "morphed" photograph of a famous person and the patient. When the left hemisphere was anesthetized, the subjects said that the morphed photograph represented themselves, whereas with right hemisphere anesthesia, the subjects selected the famous face. Patients with frontotemporal dementia also indicate a relationship between the right frontal lobe and self-concept. In the series of Miller et al. (2001), six of the seven patients who developed a major change in self-concepr during their illness had predominant atrophy in the nondominant frontal lobe.

The frontal lobes, as the executive center of the brain and the determining agent for attention and motor planning, are the origin of several critical networks for cognition and action. Cummings (1993) described five frontal networks for consciousness and behavior. The frontal cortex projects to the basal ganglia, then to thalamic nuclei, and back to the cortex.

Clinical neurology provides important information about how lesions in the brain impair consciousness. The functioning of the awake mind requires the ascending inputs referred ro as the *reticular activating system,* with its way stations in the brainstem and thalamus, as well as an intact cerebral cortex. Bilateral lesions of the brainstem or thalamus produce coma. Very diffuse lesions of the hemisphetes produce an "awake" patient who shows no responsiveness to the environment, a state sometimes called *coma vigil.* Less severe, diffuse abnormalities of the association cortex produce encephalopathy, delirium, or dementia; stupor and coma are discussed in Chapter 5, and encephalopathy, or delirium, is covered in Chapter 4.

Focal lesions of the cerebral cortex generally produce deficits in specific cognitive systems. A detailed listing of such disorders would include the whole subject matter of behavioral neurology. Examples include Broca's aphasia from a left frontal lesion, Wernicke's aphasia from a left temporal lesion, and Gerstmann's syndrome (acalculia, left-right confusion, finger agnosia, and agraphia) from a left parietal lesion, visual agnosia or failure to recognize visual objects (usually from bilateral posterior lesions), apraxia from a left parietal lesion, and constructional impairment from a right parietal lesion. Multiple focal lesions can affect cognitive function in more global fashion, as in the dementias {Chapter 72). Some authorities separate "cortical" dementias, such as Alzheimer's disease, in which combinations of cortical deficits are common, from "subcortical" dementias, in which mental slowing is the most prominent feature.

The frontal lobes are heavily involved in integration of the functions provided by other areas of the cortex, and lesions there may affect personality and behavior in the absence of easily discernible deficits of specific cognitive, language, or memory function. In severe form, extensive lesions of the orbirofrontal cortex may leave the individual awake but staring, unable to respond to the environment, a state called *akinetic mutism.* With lesser lesions, patients with frontal lobe lesions may lose their ability to form mature judgments, reacting impulsively to incoming stimuli in a manner reminiscent of animal behavior. Such patients may be inappropriately ftank or disinhibited. A familiar example is the famous case of Phineas Gage, a worker who

FIGURE 6.1 Luna's test of alternating sequences. (Adapted with permission from Luria, A. R. 1969, "Frontal lohe syndromes," in *Handbook of Clinical Neurology,* vol. 2, eds P. J. Vynken, G. W. Bruyn, Elsevier, New York; and reprinted wirh permission from Kirshner, H. S. 2002, *Behavioral Neurology: Practical Science of Mint! and Brain.* Bntterworth-Heinemann, New York.)

sustained a severe injury to the frontal lobes. Gage became irritable, impulsive, and so changed in personality that co-workers said he was "no longer Gage." Bedside neurological testing and even standard neuropsychological tests of patients with frontal lobe damage may reveal normal intelligence, except for concrete or idiosyncratic interpretation of proverbs and similarities. Experimentally, subjects with frontal lobe lesions can be shown to have difficulty with sequential processes or shifting of cognitive sets, as tested by the Wisconsin Card Sorting Test or the categories rest of the Halstead-Reitan battery. I.uria introduced a simple bedside test of sequential shapes (Figure 6.1). In contrast to the subtlety of these deficits to the examiner, the patient's family may state that there is a dramatic change in the patient's personality.

Another clinical window into the phenomena of consciousness comes from surgery to separate the hemispheres by cutting the corpus callosum. In split-brain or eommissurotomized patients, each hemisphere seems to have a separate consciousness. The left hemisphere, which has the capacity for speech and language, can express this consciousness in words. For example, a split-brain patient can report words or pictures that appear in the right visual field. The right hemisphere cannot produce verbal accounts of items seen in the left visual field, **but** the patient can choose the correct item by pointing with the left hand, at the same time the patient claims to have no conscious knowledge of the item. In terms of the speaking left hemisphere, the right hemisphere has "unconscious" visual knowledge, or Hindsight. At times, the left hand of the patient may seem to operate under a different agenda from the right hand: A split-brain patient may select a dress from a rack with the right hand while the left hand puts it back or selects a more daring fashion. This rivalry of the left hand with the right is called the *alien band syndrome,* a striking example of the separate consciousnesses of the two divided hemispheres (Gazzaniga 1998). Callosal syndromes, including the alien hand syndrome, have also been described in patients with strokes involving the corpus callosum (Chan and Ross 1997).

MEMORY

Memory Stages

Memory refers to the ability of the brain to store and retrieve information. Some memories are so vivid that they seem like a reliving of a prior experience, as in Marcel Proust's sudden recollections of his youth on biting into a madeleine. Other memories are more vague or bring up a scries of facrs rather than a perceptual experience. Memory has been divided into several types and several stages, leading to a confusing set of terms and concepts. Clinical neurologists divide memory into three temporal stages. The first stage, called *immediate memory span,* corresponds to Baddelcy's concept of *working memory. Immediate memory* refers to the amount of information a subject can keep in conscious awareness without active memorization. The normal human being can retain seven digits in active memory span. Perhaps by coincidence, seven digits comprise a local telephone number. Most normal people can hear a telephone number, walk across the room, and dial the number without active memorization. Numbers of more than seven digits, called *supraspan numbers,* do require active memory processing, as do unnatural tasks, such as reverse digit span. Disorders of attention affect digit span, and very focal lesions of the superior frontal neocortex, affecting Brodmanu's areas 8 and 9, may have profound effects on immediate memory (Goldman-Rakic 1996). Many patients with aphasia secondary to left frontal lesions have impaired immediate memory. The items in immediate memory are normally forgotten as soon as the subject's attention switches to another topic (telephone numbers that we look up and call once tend to be completely forgotten quickly unless we actively try to "memorize" them).

The second stage of memory, referred to by clinicians as *short-term* or *recent* memory, involves the ability to register and recall specific items, such as words or events, after a delay of minutes or hours. Some memory researchers refer to immediate memory span as *short term* and recent memory as *long term.* This second stage of memory, which has also been called *declarative* or *episodic* memory (Squire and Zola 1996), requires the function of the hippocampus and parahippocampal areas of the medial temporal lobe for both storage and retrieval. The amygdala, an adjacent structure of the medial temporal cortex, is not essential for episodic memory but seems crucial for recall of emotional contexts of specific events and the reactions of fear or pleasure associated with these events. The familiar bedside test of recalling three unrelated memory items at 5 minutes demonstrates short-term memory, as do questions about this morning's breakfast.

Long-term memory, also called *remote memory,* refers to long-known information, such as where one grew up, who was one's first-grade teacher, or the names of grandparents. Recall of famous figures, such as presidents, is also used as a test of remote memory, but these questions really probe the subject's fund of information, which can be continuously replenished by reading and conversation. Remote memory, as we shall see later, resists the effects of medial temporal damage; once memory is well stored, probably in the neocortex, it can be retrieved without use of the hippocampal system.

Amnestic Syndrome

The *amnestic syndrome* (Table 6.1) refers to profound loss of the second Stage of recent or short-term memory. These patients, most of whom have bilateral hippocampal damage, have normal immediate memory span and largely normal ability to recall remote memories, such as their childhood upbringing and education. Other cognitive or higher cortical functions may be completely intact, which distinguishes these patients from those with dementias, such as Alzheimer's disease. Motor memories (see Other Types of Memory [Nondeclarative or Implicit Memory], later in this chapter) tend to be preserved in patients with amnestic-syndrome. Other more variable features of the amnestic syndrome are disorientation to time and sometimes place and "confabulation," or making up information that the memory system does not supply. Amnestic patients live in an eternal present tense, in which they can interact, speak intelligently, and reason appropriately, but they do not remember anything about the interaction a few minutes after it ends. An amnestic patient may complete an intelligence quotient (IQ) test with high scores but not recall taking the examination minutes later. These patients are condemned to repeat the same experiences without learning from them.

The registration of short-term memory involves a consolidation period, during which a blow to the head, as in a football injury, can prevent memories from being stored or recalled. The recognition or recall of items appears to require the hippocampus. The site of storage of memories is not known but probably involves large areas of the neocortex, specialized for specific cognitive functions, such as auditory or visual analysis. Once processed in the neocortex and stored for a long period, items can be recalled even in the presence of hippocampal damage, as in the case of remote memories. After an injury producing hippocampal damage, a retrograde period of memory loss may extend back from minutes to years, and the subject cannot form new antegrade memories. As the ability to form new memories returns, the period of retrograde amnesia shortens, or shrinks. After a minor head injury, the permanent amnestic period may involve a few minutes of retrograde amnesia and a few hours or days of anterograde amnesia. In experimental studies in which amnestic subjects are shown famous people from past decades, a temporal gradient has been found in which subjects have excellent memory for remote personages but recall progressively less from periods dating up to the recent past.

Tabic 6.1: Amnestic syndrome features

Impaired recent memory (anterograde, retrograde)
Global amnesia
Spared procedural memory
Preserved immediate memory
Preserved remote memory
Intact general cognitive function
Disorientation to time or place
Confabulation

The neuroanatomy of the amnestic syndrome is one of rhe best-studied areas of cognitive neuropsychology. In animal models, bilateral lesions of the hippocampus, parahippocampal gyrus, and entorhinal cortex produce profound amnesia (Squire and Zola 1996). Human patients undergoing temporal lobectomy for epilepsy have shown very similar syndromes. In the early period of this surgery, a few parients were deliberately subjected to bilateral medial temporal ablations, with disastrous results for memory, as seen in the famous patient H, M. (Corkin 2002). In other cases, unilateral temporal lobectomy caused severe amnesia. In one such case, an autopsy many years later showed preexisting damage to the contralateral hippocampus. Patients currently receive extensive evaluation, such as the Wada test of intracarotid barbiturate infusion, to ensure that ablation of one hippocampus will not result in the amnestic syndrome, although partial memory deficits still occur. Other common causes of the amnestic syndrome involving bilateral medial temporal lesions include bilateral strokes in the posterior cerebral artery territory, involving the hippocampus, and herpes simplex encephalitis, which has a predilection for the orbital frontal and medial temporal cortices.

The anatomy of memory storage and retrieval has been known for many years, with numerous recent refinements. Figure 6.2 shows a simplified diagram of the memory system in the human brain. The hippocampus on each side projects via the fornix to the septal areas, then to the mamillary bodies, which project to the anterior nucleus of the thalamus and on to the cingulatc gyrus of the frontal lobe, which projects back to the hippocampus. This circuit (the Papez circuit) is critical for short-term memory registration and retrieval. Disease processes that affect extrahippocampal parrs of this circuit also cause amnesia. One well-studied example is Wernicke-Korsakoff syndrome induced by thiamine deficiency, usually in the setting of alcoholism, with damage to the mamillary bodies and dorsomedial thalamic nuclei. A second clinical example is that of patients with ruptured aneurysms of the anterior communicating artery, which is associated with damage to the deep medial frontal areas, such as the septal nuclei. These two amnestic syndromes arc commonly associared with confabulation. Traumatic brain injuries commonly produce memory loss, probably because the most common sites of damage are in the frontal and temporal lobes, but other deficits in addition to memory frequently occur. Of course, memory loss can be seen in several other neurological conditions, including brain tumors of the thalamus or temporal lobes; white matter diseases, such as multiple sclerosis; and dementing diseases, such as Alzheimer's disease, which has a predilection for the hippocampus, basal frontal nuclei, and neocortex. In these other disorders, memory loss is usually not as isolated a deficit as in the amnestic syndrome.

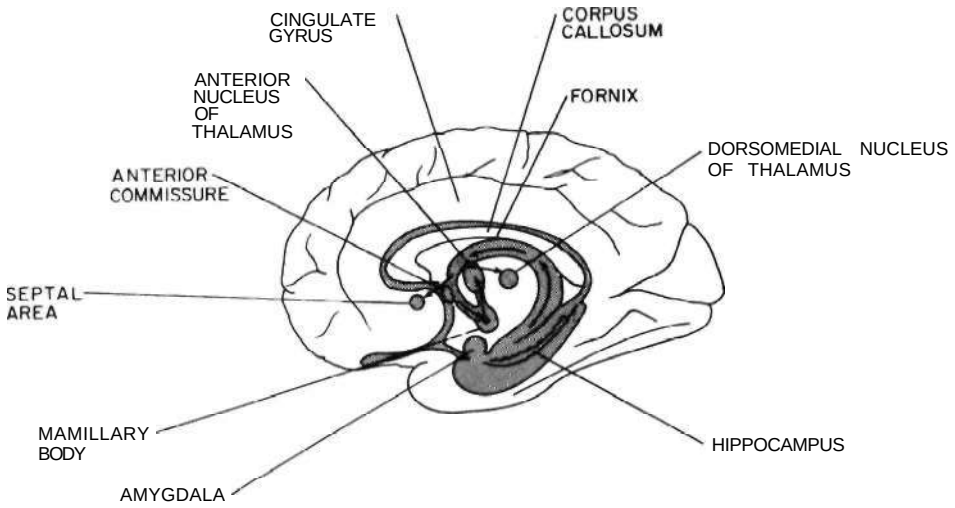

FIGURE 6.2 The Papez circuit and the neuroanatomy of memory. The hippocampus projects, via the fornix, to the septal area and mamillary hodies. The mamillary hodies project to the anterior nucleus of the Thalamus and then to the cingulate gyrus to the frontal lohe. Recurrent pathways (not shown) lead back from the cingulate and frontal cortex to the hippocampus. (Reprinted with permission from Kirshner, H. S. 2002, *Behavioral Neurology: Practical Science of Mind and Brain,* 2nd cd, Butterworth-Hcincmann, Boston.)

Recently, functional brain imaging in awake patients has contributed to knowledge of the anatomy of memory function. According to one positron emission tomography (IT. 1 i study, six brain regions show consistent activation in normal subjects during memory testing. These brain regions are (1) the prefrontal cortex, especially on the right; (2) the hippocampal and adjacent medial temporal regions; (3) the anterior cingulate cortex; (4) the posterior midline regions of the cingulate, prccuneatc, and cuneate gyri; (5) the inferior parietal cortex, especially on the right; and (6) the cerebellum, particularly on the left (Cabeza et al. *1997).* Preliminary analyses of the functions of these areas in memory are as follows: The prefrontal cortex appears to relate to retrieval activation and to attention. The hippocampi relate to conscious recollection, the cingulate cortex to the activation of memory and selection of a specific response, the posterior midline regions to visual imagery, the parietal cortex to spatial awareness, and the cerebellum to voluntary, self-initiated retrieval. In subjects asked to recognize previously presented pairs of associated words, the right prefrontal cortex, anterior cingulate cortex, and inferior parietal region were the most activated. When the subject had to recall the words, the basal ganglia and left cerebellum also became active. In similar studies using functional MRI, Wagner et al. (1998) found that the left prefrontal region was predominantly involved when words were semantically encoded in memory; the right frontal activations seen in the previous study reflected nonverbal memory stimuli. In studies of the recognition of visual designs, Petersson, Elfgren, and Ingvar (1997) found that the medial temporal cortex activates more during new learning tasks than during previously trained and practiced memory tasks. Other areas activated during the new learning task included the prefrontal and anterior cingulate areas, more on the right side, and the parieto-occipital lobes bilaterally. Trained tasks activated the hippocampi much less but did activate the right inferior occipitotemporal region. This finding correlates with human studies indicating that ovcrlcarned memories gradually become less dependent on the hippocampus. Rugg et al. (1997) also found greater activation of the left medial temporal cortex in tasks in which the subject remembered words by "deep encoding" their meaning compared with simpler "shallow" encoding of the specific word. Other studies have shown that the deeper the encoding of a word's meaning, the better the subject remembers it (Schacter 1996). Finally, the amygdala appears necessary for affective aspects of memory items such as recall of fear associated with a specific stimulus.

Basic research on animals has begun to unravel the fundamental biochemical processes involved in memory, Bailey, Bartsch, and Kandel (1996) have studied memory formation in the giant snail, *aplysia.* Development of long-term facilitation, a primitive form of memory, requires activation of a gene called *CREB* (cyclic adenosine monophosphate response element binding protein) in sensory neurons. In this system and in similar studies on the fruit **fly** *Drosophila,* gene activation and protein synthesis are necessary for memory formation. Injection of protein synthesis inhibitors into the hippocampus can prevent the consolidation of memories (McGaugh 2000). Although similar studies have not been performed in humans, it is likely that similar gene activation and protein synthesis, perhaps beginning in the hippocampi bur proceeding through irs ncocortical connections, are necessary for the transition from immediate working memory to longer term storage of memory (Bear 1997). This field of research may hold promise for the development of drugs to enhance memory storage.

Syndromes of Partial Memory Loss

In contrast to the global amnesia seen in amnestic syndrome, patients have been described who have memory loss for selected classes of items. For example, patients with left temporal lobectomy for intractable epilepsy usually have detectable impairment of short-term verbal memory,

whereas those undergoing right temporal lobe resection have impairment only of nonverbal memory. Isolated sensory-specific memory loss syndromes have also been described, such as pure visual or tactile memory loss. Ross (1980) described two patients with bilateral occipital lesions, which disconnected the visual correx from the memory structures. These patients could draw a diagram of their homes but could not learn new spatial layouts. Ross postulated thai diagnosis oi a selective visual recenl memory deficit requires documentation of normal visual perception, absence of aphasia sufficient to impair testing, intact immediate visual memory, intact remote visual memory, and normal recenr memory in other modalities. A similar syndrome of isolated tactile memory loss has also been described.

Transient Amnesia

Transient amnesia is a temporary version of amnestic syndrome. The most striking example of transient amnesia is the syndrome of transient global amnesia (TGA), lasting from several hours to 24 hours. In this syndrome, an otherwise cognitively intact individual suddenly loses memory of recent events, asks repetitive questions about his or her environment, and sometimes confabulates. During the episode, the patient has both anterograde and retrograde amnesia, as in the pcrmanenr amnestic syndrome. As recovery occurs, however, the retrograde portion "shrinks" to a short period, leaving a permanent gap in memory of the brief retrograde amnesia before the episode and the period of no learning during the episode. The syndrome is of unknown cause but can be closely imitated by known disorders, such as complex partial seizures, migraine, and possibly transient ischemia of the hippocampus on one or both sides. Srrupp et al. (1998) reported that 7 of 10 patients imaged during TGA episodes showed an abnormal diffusion-weighted MRI signal in the left hippocampus, 3 of whom had bilateral hippocampal abnormalities. Permanent infarctions were not found. Other investigators have found frontal lobe abnormalities by diffusion-weighted MRI or PET imaging. These studies do not prove an ischemic etiology for TGA; rather, they indicate transient dysfunction in the hippocampus or its connections. The last six patients with TGA observed at our hospital have had normal diffusion-weighted MRI studies. Drug intoxication, alcoholic "blackouts," and minor head injuries can also produce transient amnesia.

OTHER TYPES OF MEMORY (NONDECLARAT1VE OR IMPLICIT MEMORY)

The three-stage model of immediate, short-term, and long-rerm memory has proved inadequate to describe the complexity of human memory. A confusing array of memory classifications and terminology has arisen, as shown in Table 6.2. Several aspects of memory do not involve the conscious recall involved in the three memory stages. A simple example is motor memory, such as the ability to ride a bicycle, which is remarkably resistant to hippocampal damage. Such motor memories probably reside in the basal ganglia and cerebellum. In the classification by Squire and Zola (1996), motor memories of this type are called *procedural* or *nondeclarative* memories.

Table 6.2: Types of memory and their localization

Types of recent memory	*Localization*
Declarative (explicit): facts, events	Medial temporal lobe
Nondeclarative (implicit)	
Procedural skills	Basal ganglia, frontal lobes
Classical conditioning	Cerebellum (plus amygdala)
Probabilistic classification learning	Basal ganglia
Priming	Neocortex

Another term for the whole class of memories for which subjects have no conscious awareness is *implicit* memory (in contrast to the explicit memory of episodic events). Implicit memories have in common storage and retrieval mechanisms that do not involve the hippocampal system; perhaps for this reason, the subject has no conscious knowledge of them. These procedural memories involve "knowing how" rather than "knowing that." Amnestic patients can learn new moror memories, such as mirror drawing, which they can perform once started, although they have no recollection of knowing the task. Motor learning likely involves the motor cortex and basal ganglia. Another type of memory, localized to the cerebellum, is classical conditioning, in which an unconditioned stimulus hecomes associated with a reward or punishment given when the conditioned stimulus is presented (Thompson and Kim 1996). The conditioning itself clearly involves the cerebellum, but the emotional aspect of the reward or punishment stimulus may reside in the amygdala. Classical conditioning can continue to function after bilateral hippocampal damage. Squire and Zola (1996) outlined other types of nondeclarative memory that take place independent of the hippocampal system. Probabilistic classification learning, such as predicting the weather from a combination of cues that are regularly associated with sunny or rainy weather, is unaffected by hippocampal damage but is impaired in diseases of the basal ganglia, such as Huntington's and Parkinson's diseases. Learning artificial grammar can also take place in the presence of amnestic syndrome. In all of these memory experiments, the patient has no awareness of how he or she is able to answer the questions. The last form of nondeclarative memory is called *priming,* the presentation of a stimulus associated with the word or idea to be remembered, which then aids in the retrieval of the item (e.g., recalling the word "doctor"

when "nurse" appears on a priming list). Priming appears to involve the neocortex (Thompson and Kim 1996). Schacter and Buckner (1998) have shown that deliberate use of priming can help amnestic patients compensate for their memory loss in everyday life.

BEDSIDE TESTS OF MEMORY AND COGNITIVE FUNCTION

The most important point to be made about bedside evaluations of cognition and memory is that they are an integral part of the neurological examination and a tool by which the neurologist localizes lesions affecting the higher cortical functions, just as the motor or cerebellar examinations localize neurological deficits. The most common error made by neurologists is to omit a systematic evaluation of mental function in patients who seem "alert and oriented." Deficits of memory, fund of knowledge, or focal deficits, such as apraxia, agnosia, acalculia, or constructional impairment, can be missed. Some patients have a "cocktail party" speech pattern that belies such deficits, whereas others become expert at deferring questions to a spouse or family member. Every neurologist has the task of deciding which patients need formal cognitive testing and whether to make up an individual test routine or to rely on one of the standard tests. Again, it is more important to make the assessment than ro follow a specific format.

Several versions of bedside mental status testing have been published. Perhaps the most widely used is Folstein's Mini-Mental State examination (MMSE). The MMSE consists of 30 points:

- 5 for orientation to time (year, season, month, date, and day)
- 5 for orientation to place (state, county, town, hospital, and floor)
- 5 for attention (either serial 7s with one point for each of the first five subtractions or "spell *world* backward")
- 3 for registration of three items
- 3 for recall of three items after 5 minutes
- 2 for naming a pencil and a watch
- 1 for repeating "no ifs, ands, or buts"
- 3 for following a three-stage command
- 1 for following a printed command "close your eyes"
- 1 for writing a sentence
- 1 for copying a diagram of two intersecting pentagons

The advantages of the MMSE are short time of administration and quantitation, which is useful in documentation for insurance benefits, such as rehabilitative therapies or drug therapy, and for disability assessment.

Several disadvantages of the MMSF have been identified. First, the normal range of scores depends on education. The low-normal curoff is estimated by Crum et al. (1993) to be 19 for uneducated people, 23 for graduates of elementary or junior high school, 27 for high school graduates, and 29 for college graduates. Age is aiso a factor. In addition, the test is weighted toward orientation and language, and it can be normal in patients with right hemisphere or frontal lobe damage. Finally, even an abnormal score does not distinguish a focal lesion from a more diffuse disorder, such as an encephalopathy or dementia.

One answer to the dilemma of mental status testing is to use the MMSE as a screening test and then supplement it with more focused tests. Teng and Chui (1987) suggested adding four items to the test and making it more quantitative, but this test has not gained wide acceptance. Table 6.3 lists the key elements of a mental status examination, whether the examiner chooses to adopt the MMSE or to create an individual test battery. Several texts provide further detail on such a battery. Although the mental status examination is the most neglected area of the neurological examination, it generally requires only a few minutes, and its cost-effectiveness compares well with brain imaging studies, such as MRI or PET.

An experienced examiner can learn much about the subject's mental status by careful observation during the history. Considerable insight can be gained into the subject's recent memory, orientation, language function, affect or mood, insight, and judgment. Affect and mood are best assessed in this fashion; if there is doubt, the examiner should consider how the patient makes the examiner feel: A depressed patient often makes the examiner feel depressed, whereas a manic patient makes the examiner feel happy and amused.

The formal mental status examination should always include explicit testing of orientation, including the date, place, and situation. Memory testing should include an immediate attention test, of which the most popular are forward digit span, serial-7 subtractions from 100, or the MMSE test "spell *world* backward." Short-term memory should include recall of three unrelated words at 5 minutes. The subject should always be asked to say them back after presentation, to make sure that the three items have registered. At times, nonverbal short-term memory, such as recalling the locations of three hidden coins or reproducing drawings, can be useful to test. Remote memory can be tested by having the subject name children or siblings. Fund of information can be tested with recent

Calculations
Visuaa I-construction a I abilities
Abstract reasoning, sequential processes

presidents or other political figures. For patients who do not pay attention to politics, use of athletic stars or television celebrities may be more appropriate. Language testing should include spontaneous speech, naming, repetition, auditory comprehension, reading, and writing (the bedside language test is described in more detail in Chapter 12). Praxis testing should include the use of both imaginary and real objects, such as a saw, hammer, and pencil. Both hands should be tested separately. Calculation tasks include the serial-7 subtraction test and simple change-making problems. Visual-spatial-constructional tasks can include line bisection, copying a cube or other design, and drawing a clock or a house (Figure 6.3). The MMSE contains only one constructional task, the copying of intersecting pentagons. Insight and judgment are probably best tested by assessing the patient's understanding of his or her own illness. Artificial tests include interpretation of proverbs, such as "Those who live in glass houses should not throw stones," or stating why an apple and an orange are similar. An artificial test sometimes used to test frontal lobe processing is the copying and continuation of Luria's test of sequential squares and triangles (see Figure 6.1). With these tests, preliminary localization can be made in the deep memory structures of the medial temporal lobes, the frontal lobes (insight and judgment, proverbs, similarities, Luria's sequence test), the left hemisphere language cortex in the frontal and temporal lobes, the left parietal region (calculations), and the right parietal lobe (visual-constructional tasks).

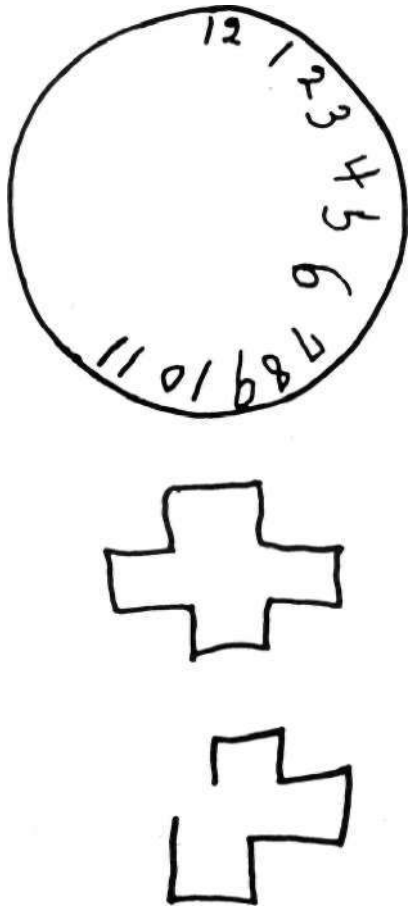

FIGURE 6.3 Luna's test of alternating sequences. Spontaneous clock drawing and copying of a cross by a patient with a right parietal infarction. The patient had only mild hemiparesis but dense left hemianopia and neglect of the left side of the body. The neglect of the left side of space is evident in both drawings. CONCLUSION

This chapter considers the areas of neurology that most physicians find the most abstruse, namely, the higher cortical functions, intellect, and memory. As stated at the outset, this area of neurology can be treated as a series of specific functions to be analyzed at the bedside and localized, just like other functions of the nervous system. In fact, the rapidly increasing knowledge of cognitive neuroscience and our vastly improved ability to image the brain, both at rest and during functional activities, promises a new era of practical diagnosis of higher cognitive disorders.

Chapter 7
Global Developmental Delay and Developmental Regression

David J. Michelson and Stephen Ashwal

Early measurement of a child's intellectual potential is made more difficult by the innate variability of normal maturation, Developmental disability, estimated to affect 5-10% of children, is defined as a disturbance in the acquisition of cognitive, motor, language, or social skills with a significant and continuing impact on developmental progress.

The term *global developmental delay* refers to *significant* delay seen across multiple domains of function and adaptation, whete *significant* is defined as performance that is two standard deviations below the mean for chronological peers. The diagnosis of *mental retardation* is reserved for children older than 5 years, in whom standardized intelligence quotient (1Q) testing can be reliably performed.

A slowed pace of development and a diminished intellectual potential can result from any of several adverse early influences, causing nonprogressive or *static encephalopathy,* or from diseases causing slow neurological deterioration. Most progressive neurological disorders eventually cause *developmental regression,* with loss of previously acquired motor or cognitive skills, as well as signs of nervous and organ system dysfunction. Children demonstrating neurological deterioration, especially when the deterioration is acute, require urgent evaluation.

The many goals of the physician managing a child with suspected developmental disability include (1) evaluating prior and current levels of function to confirm the presence of delay or regression, (2) undertaking a reasonable search for an underlying cause, (3) assessing and managing associated medical, behavioral, and psychosocial needs, and (4) providing appropriate referrals for ongoing rehabilitation and support services.

GLOBAL DEVELOPMENTAL DELAY

Evaluation

Primary care physicians have been encouraged to become familiar with the range of normal age-appropriate development and to monitor their pediatric patients during routine clinical encounters. Children with biological or social risk factors for later developmental disability are often targeted for additional periodic screening.

The Denver Developmental Screening Test II **(DDST-II)** is the tool most often used or referred to for esrimating a child's personal/social, fine motor/adaptive, language, and gross motor skills. Although the DDST-II is insensitive on its own, it remains useful when combined with parental concern to identify children who need further evaluation,

Observant caregivers provide valuable descriptions of a child's past development and possible loss of milestones but may have difficulty reliably recollecting the details of language acquisition. The expected milestones of infants arc shown in Table 7.1.

Once a problem is suspected, a child's motor, cognitive, behavioral, social, and functional abilities should undergo formal assessment. This requires the assistance of other members of a multidisciplinary ream, including psychologists and physiotherapists, who are trained to administer standardized testing. The tests most often used to provide both full-scale and categorical **IQs** are the Bay ley Scales of Infant Development, the Stanford-Binet Intelligence Scale, and the Wcchslcr scales {Wechslcr Preschool and Primary Scale of Intelligence-Revised, Wechslcr Intelligence Scale for Children III, and Wechsler Adult Intelligence Scale}. Test results should be confirmed by repetition and should not be unduly influenced by sensory, language, or attention deficits.

Etiology

The perception among primary care providers and third-party payers of a low diagnostic yield when evaluating global developmental delay or mental retardation is unfortunate and incorrect. The diagnostic yield is now estimated at 60-80% because of improved understanding

Table 7.1: Normal developmental milestones by age (50th to 75th percentile)

Age	*Language*	*Social*	*Motor*
1 111)	Cooing (ooh, ah)	Smiles with social contact	Holds head up 45 degrees
4 nni	Laughs and squeals	Sustained social contact	Grasps objects, hears weight on legs
6 mo	imitates speech sounds, single syllables	Prefers mother, enjoys mirror	Transfers objects between hands, uses a raking grasp, sits with support
8 mo	Jabbering (dadada, bababa)	Plays peekaboo or patty-cake, waves bye-bye	Sits without support, creeps or crawls
12 mo	"Da da/ma ma" specific	Plays simple ball games, adjusts body to dressing	Stands alone, uses a thumb-finger pineer grasp
14 mo	l-2-word vocabulary	Indicates desires by pointing, hugs parents	Walks alone, stoops and recovers
IS mo	6-word vocabulary	Feeds self	Walks up steps with hand held, imitates scribbling
24 mo	Combines words, 250-word vocabulary	Helps to undress, listens to stories with pictures	Runs well, makes circular scribbles, copies a horizontal line
50 mo	Refers to self as "I," knows full name	Pretends in play, helps put things away	Climbs stairs with alternate feet, copies a vertical line
16 mi>	Counts three objects correctly, knows age and sex	Helps in dressing	Rides a tricycle, stands on one foot briefly, copies a circle
4S mo	Tells a story, counts four objects	Plays with other children, uses toilet alone	Hops on one foot, uses scissors to cut out pictures, copies a square and a cross
60 mo	Names 4 colors, counts 10 objects	Asks about word meanings, domestic role playing	Skips, copies a triangle

of developmental pathophysiology, increased imaging resolution, and availability of genetic testing {Shevell ct al. 2000). Establishing the cause of a retardation syndrome may not always alter medical management but does ptovide a family with important information regarding prognosis and recurrence risk for future pregnancies, and it also limits the need for further testing. A child's development depends on the complex interplay of biological, social, and environmental influences. Table 7.2 summarizes the biological conditions associated with developmental disability and organizes examples by presumed time of onset and disease category. (The interested reader is referred to the appropriate chapters of this textbook for detailed descriptions of these conditions.)

History

The caregiver's report of a child's past developmental history is the first step in estimating the degree and scope of developmental delay. Questions should address the child's current level of function and possible associated medical problems, seizures, or difficulties with feeding, sleeping, or behavior. Prior medical records, past and current classroom placements, and reports from teachers provide corroboration.

A family history of similar illness suggests a genetic syndrome and should be pursued in detail, including consanguinity, ethnicity, relatives with neurological impairments, and early postnatal deaths. Although family history is becoming increasingly difficult as families spread geographically, information should be sought from both parents and from both sets of grandparents. An equally detailed prenatal, birth, and postnatal history may reveal those risk factors that arc associated with neurological injury (Table 7.3).

Physical Examination

Observing a child's interactions with parents and with age-appropriate toys allows an initial assessment of motor skill and dexterity; curiosity, impulsivity, and artcntion span; and social skills, eye contact, and communicative intent. The hands-on physical examination should be as complete as a child will allow, focusing on possible etiological clues such as growth parameters; abnormalities of the eyes, skin, and hair; dysmorphic features; abnormal tone, posture, movements, and reflexes; signs of cerebellar or peripheral nerve dysfunction; and organomegaly. Findings that suggest specific syndromes are listed in Tables 7.4 and 7.5.

Diagnostic Testing

An evidence-based and stepwise search for an underlying cause is preferable to the use of a large panel of screening tests. One stepwise approach is presented in Figure 7.1.

Table 7.2: Etiology of developmental delay by time of onset

Prenatal/perinatal	*Examples.*
Congenital malformations of the CNS	Lissencephaly, Chiari malformation
Ch romos om a 1 a bn orma 1 ities	Down syndrome, Turner's syndrome
Endogenous toxins from maternal organs	Maternal hepatic or renal failure
Exogenous toxins from maternal use	Alcohol, anticonvulsants, anticoagulants, drugs of abuse
Fetal infection	Congenital infections (toxoplasmosis, rubella, cytomegalovirus, HIV, and syphilis)
Prematurity and/or fetal malnutrition	Periventricular leukomalacia, intraventricular hemorrhage
Perinatal trauma	Intracranial hemorrhage, spinal cord injury
Perinatal asphyxia	H y pox ic-i sch e mic en c e ph a lo pa thy
Postnatal	*Examples*
Inborn errors of metabolism	Aminoacidopathies, mitochondrial diseases, urea cycle defects
Abnormal storage of metabolites	Lysosomal storage diseases, glycogen storage diseases
Abnormal postnatal nutrition	Vitamin or calorie deficiency
Endogenous toxins from organ failure	1 k-paiic or renal failure, kern icterus
Exogenous toxins	Prescription drugs, illicir substances, lead
Endocrine organ failure	Neonatal or acquired hypothyroidism, hypoadrenocorticism (Addison's disease)
CNS infection	Meningitis, cerebral abscess, viral meningoencephalitis, HIV encephalopathy, subacute sclerosing panencephalitis
CNS trauma	Nonaccidental trauma, traumatic brain injury
Neoplasia	Infiltration, edema, hydrocephalus, radiarion
Neurocutaneous syndromes	Neurofibromatosis, tuberous sclerosis, incontinentia pigmenti, Sturgc-Weber syndrome
Neuromuscular disorders with CNS involvement	Congenital muscular dystrophy, congenital myotonic dystrophy, congenital myopathies
Vascular conditions	Systemic lupus erythematosus, moyamoya disease, stroke, venous sinus thrombosis
Other	Autism, uncontrolled epilepsy, severe mood disorder, schizophrenia

CNS = central nervous system; HIV = human immunodeficiency virus.

Metabolic Testing

Universal newborn screening in the United States, particularly the use of tandem mass spectroscopy, identifies many of the more common metabolic disorders. Metabolic screening of children with unexplained global developmental delay has a less than 1% yield. The yield remains less than 5% even when a metabolic etiology is suggested by history or examination. Screening these children with basic metabolic tests before ordering specific metabolic tests may increase the yield to 14% (Papavasiliou et al. 2000). Thyroid studies are not indicated in children with global developmental delay who have already been screened as newborns unless clinical features are also present.

Table 7.3: Perinatal risk factots for neurological injury

Material Up renatal	*Natal*	*Postnatal*
Age less than 16 or more than 40 yr	Cesarean section after a trial of labor	Abnormal sucking or feeding
Cervical or pelvic abnormalities	Firstborn male	Abnormal crying
Infection	Premature twins	Asymmetrical face or extremities
Diabetes mellitus	Cyanosis	Dysmorphic features
Drug addiction	Need for resuscitation	Hyperbilirubinemia
Malnutrition	Low Apgar score	Hypotonia
I [ypertension or toxemia	Gestational age less than 30 wk	Birth injuries
Thyroid disease	Hypoxic-ischemic encephalopathy	Seizures
Hemorrhagic shock	Midforceps delivery	Fever
Polyhydramnios or oligohydramnios	Breech presentation	Need for an incubator or oxygen
Low socioeconomic status	Placental abruption	Poor weight gain
Prior miscarriages or stillbirths	Umbilical prolapse	Malnutrition
Vaginal bleeding after first trimester		
Prior placental abnormalities

Table 7.4: Ocular findings associated with selected syndromic developmental disorders

Finding	*Examples*
Cataracts	CerebrotendinouS xanthomatosis, galactosemia, Lowe's, LSD, Wilson's
Chorioretinitis	Congenital infections
Corneal opacity	Cockayne's, Lowe's, LSD, xeroderma pigmentosa, Zellweger's
Glaucoma	Lowe's, mucopolysaccharidoses, Sturge-Weber, Zellweger's
Lens dislocation	Homocystinuria, sulfite oxidase deficiency
Macular cherry-red spot	LSD, multiple sulfatase deficiency
Nystagmus	Aminoacidopathies, AT, CDG, Chediak-Higashi, Friedrich's ataxia, Leigh's, Marinesco-Sjogren, metachromatic leukodystrophy, neuroaxonal dystrophy, Pelizaeus-Merzbacher, SCD
Ophthalmoplegia	AT, Basscn-Kornzwcig, LSD, mitochondrial diseases
Optic atrophy	Alpers', Leber's optic atrophy, leukodystrophies, LSD, neuroaxonal dystrophy, Pelizaeus-Merzbacher, SCD
Photophobia	Cockayne's, Hartnup's, homocystinuria
Retinitis pigmentosa or macular degeneration	AT, Bassen-Kornzweig, Cockayne, CDG, Hallervorden-Spatz, Laurence-Moon-Beidl, LSD, mitochondrial diseases, Refsum's, Sjogren-La rsscn, SCD

AT = ataxia-telangiectasia; CDG = congenital disorders of glycosylation; LSD = lysosomal storage diseases; SCD = spino-cerehellar degeneration.

Source: Adapted with permission from Shevell, M. 1. & Swaiman, K. F. 1999, "Global developmental delay and mental retardation," in *Pediatric Neurology, Principles and Practice,* eds K. F. Swaiman & S. Ashwa!, Moshy, St. I.ouis.

Metabolic testing should he considered when the history or physical examination is suggestive of a metabolic disorder or when newborn screening results are not available. Tests to consider include a capillary blood gas, scrum lactate and pyruvate (energy metabolism), serum ammonia (aminoacidopathies and urea cycle defects), serum amino acids (aminoacidopathies), urine organic acids (organic acidopathies), serum creatine kinase (myopathies), serum very-long-chain fatty acids (peroxisomal disorders), urine mucopolysaccharides and oligosaccharides (mucopolysaccharidoses), and thyroid function tests,

Genetic Testing

Cytogenetic study of children with global developmental delay, using karyotyping at the 500-band level of resolution, has a yield of about 3.5%. For children with multiple minor dysmorphic features of the face and limbs, the yield is up to 20% (Graham and Selikowitz 1993). Down syndrome, recognizable by its characteristic dysmorphic features and hypotonia, is the most common chromosomal abnormality found, accounting for 25-50% of severe retardation. The fragile X mutation (FMR-1) is the most common inherited cause of mental retardation. Its prevalence among developmental!;- delayed children is 2.5-5,0%. The yield of FMR-1 testing in postpuhertal males increases to 7.6% when common clinical features are used for selection (DeVries et al. 1999) (Table *7.6).* The X-1inked Rett's syndrome mutation (McCP2) is the most common cause of mental retardation in females after Down syndrome. The features at presentation arc listed in Table 7,7. In one study, the Rett's mutation was found in 2.5% of institutionalized female children (Vorsanova ct al. 2001). The prevalence of the mutation in males and in more mildly affected females is unknown. Using fluorescence in situ hybridization (FISH) and microsatellitc markers to screen for the more subtle subtelomeric chromosomal rearrangements may have a yield as high as 8.5% in moderately to severely affected children (Baker et al. 2002).

Routine cytogenetic testing should be performed on all developmentally delayed children. Testing for the fragile X mutation should also be considered, although clinical preselection can be used to exclude some postpuhertal males. Rett's syndrome testing should be considered for all moderately to severely delayed females, especially those demonstrating typical clinical features. Subtelomeric testing should be considered in children whose moderate to severe delay remains unexplained. FISH testing for other less common single gene mutations and contiguous gene deletions are warranted when clinical features of those syndromes are present (Table 7.8).

Imaging Studies

Routine imaging with computed tomography (CT) yields the etiology in 33% of unselccted populations of children with global developmental delay. This yield increases to 65% when magnetic resonance imaging (MRI) is used because MRI is more sensitive for cerebral dysgenesis and white matter abnormalities, the most common radiological findings (Dcmaerel, Kingsley, and Kendall 1993). Yields are higher still in patients with cerebral palsy, focal neurological deficits, or microcephaly.

Brain imaging with MRI should be routine in children with developmental disability. CT still has a place in the evaluation of children with suspected calcifications (as from congenital infections or tuberous sclerosis) or craniosynostosis.

Table 7.5: Other findings associated with selected syndromic developmental disorders

binding	*Examples*
Cerebellar dysfunction	Aminoacidopathics, AT, Bassen-Kornzwcig, CDG, cercbrotendinous xanthomatosis, Chediak-Higashi, Cockayne's, Friedreich's ataxia, Lafora's disease, LSD, Marim-sco Sjogren's, mitochondrial disease, neuroaxonal dystrophy, Pelizaeus-Merzbacher, Ramsay Hunt syndrome, SCD, Wilson's
Hair abnormalities

Other Tests

Lead exposure is unlikely to cause a significant degree of developmental delay but does correlate with lower IQ scores. Testing in developmentalIy delayed children should be reserved for those who have risk factors for excessive exposure, as established by consensus guidelines. In this group, the yield is about 10% (Lewendon et al. 2001).

Electroencephalography (EEG) is useful in classifying epileptic syndromes in children with clinically apparent seizures but rarely contributes an etiological diagnosis. There is not sufficient evidence to support routinely performing 11 d testing on dcvcloptncnrally delayed children without clinically evident seizures. However, pseudo-retardation can very rarely result from an unrecognized but treatable epileptic syndrome such as electrical

status epilepticus during slow-wave sleep, Landau-Kleffner syndrome, or severe absence epilepsy.

Complete visual and auditory testing, including a full ophthalmological examination, vision screening, and behavioral audiometry or brainstem auditory evoked response testing, is indicated for all children with developmental disability. The prevalence of visual and auditory impairments, including refractive errors, ranges from 25-50%.

More invasive tests, such as cerebrospinal fluid analysis, nerve conduction velocities, nerve or muscle biopsies, or cell cultures for enzyme analyses have utility in specific clinical situations, after screening tests have been done.

DEVELOPMENTAL REGRESSION

A progressive neurological disorder should be suspected when a child loses function or fails to progress beyond a prolonged plateau after a period of relatively normal development. Repeated medical evaluations, prior photographs, and home movies can help support the diagnosis of regression and establish the timing of its onset. Children with a static encephalopathy can experience neurological deterioration with the onset or worsening of a seizure or movement disorder, worsening of spasticity, progression of hydrocephalus, or the influence of sedating medications, or intervening medical illness.

Other elements from the history and examination that should raise suspicion of genetic-metabolic disease are (1) parental consanguinity or close relatives with similar or related neurological disorders, (2) new or worsening neurological deficits including blindness and deafness, (3) recurrent, episodic weakness, hypotonia or spasticity, ataxia, lethargy, or vomiting, and (4) dysfunction of other organ systems, including organomegaly and ocular, hair, or skin abnormalities.

The possible causes of progressive neurological decline include genetic, metabolic, degenerative, infectious, inflammatory, neoplastic, and vascular diseases. Most metabolic disorders are rare and are transmitted in an autosomal or X-linked recessive manner.

It is useful to conceptualize neurological decline as, at least initially, predominantly affecting gray matter or alternatively white matter within the central nervous system. Features suggestive of gray matter involvement include seizures or EEG changes, movement disorders, blindness with retinal changes, personality changes, and dementia. An MRI scan of the brain may not show significant change early on, but generalized atrophy and vcntriculomegaly are seen later. Features of white matter involvement include spasticity, rigidity, visual impairment with optic atrophy but no retinal changes, and demyelination on MRI.

Diagnostic clues from a detailed physical and ophthalmological examination, listed in Tables 7.4 and 7.5, are helpful in suggesting specific syndromes. Table 7.9 lists the usual age at onset of neurological decline for some of the more common diseases.

A stepwise approach to the evaluation of a child with developmental regression is shown in Figure 7.2. If suspicion of a metabolic disease is high despite normal results, tests may need to be repeated during an exacerbation or after a high-protein or high-carbohydrate meal. Determining a definitive diagnosis at times requires more invasive testing, including biopsies of brain, skin, conjunctiva, muscle, nerve, or bone marrow.

Tabic 7.9: Age at onset of selected degenerative and metabolic disorders

Age	*Examples*
Neonatal	Alport's, aminoacidopathies, urea cycle disorders, galactosemia, incontinentia pigmenti, leukodystrophies, Menkes', Pclizaeus Met/bacher, progressive spinal muscular atrophy, sphingolipidoses, Zellweger's
Infancy	leukodystrophies, lysosomal storage diseases, mitochondrial diseases, neuroaxonal dystrophy, Pelizaeus-Merzbacher, Sjdgren-Larsson
Early childhood	Aminoacidopathies, ataxia-telangiectasia, Cheduik-Higashi, Cockayne's, leukodystrophies, lysosomal storage diseases, Marinesco-Sjogren, mitochondrial diseases, neuroaxonal dystrophy, xeroderma pigmentosa
Late childhood to adolescence	Adrenolcukodystrophy, Bassen-Komzweig, cerebrotendinous xanthomatosis, dystonia musculorum deformans, Friedreich's ataxia, Hallervorden-Spatz, homocystinuria, juvenile Huntington's, juvenile Parkinson's, Lafora body, Lesch-Nyhan, lysosomal storage diseases, Ramsay Hunt, spinocerebellar degeneration, subacute sclerosing panencephalitis, Wilson's

Children with Rett's syndrome experience an initial 6-18 months of normal development before undergoing regression, but the MeCP2 gene defect is thought to directly influence postnatal brain development, and thus it was considered in the previous section with global developmental delay. Most children with infantile autism also appear normal during their first year but later show regression and impairment of verbal and nonverbal communication, poor socialization, and the onset of testricted and repetitive patterns of behavior. Although many children with retardation of definable etiology have autistic features, few cases of isolated autism have been associated with a definite genetic disorder or neurological insult. The screening and diagnosis of autism have recently been reviewed (Filipek et al. 2000).

Management

Counseling

Stating the problem as clearly as possible is important in communicating the diagnosis of developmental delay or retardation. Clinicians should be prepared to address a range of emotional reactions, from guilt and sorrow to denial and anger. Once the diagnosis is accepted, families often wish to know the functional level and degree of

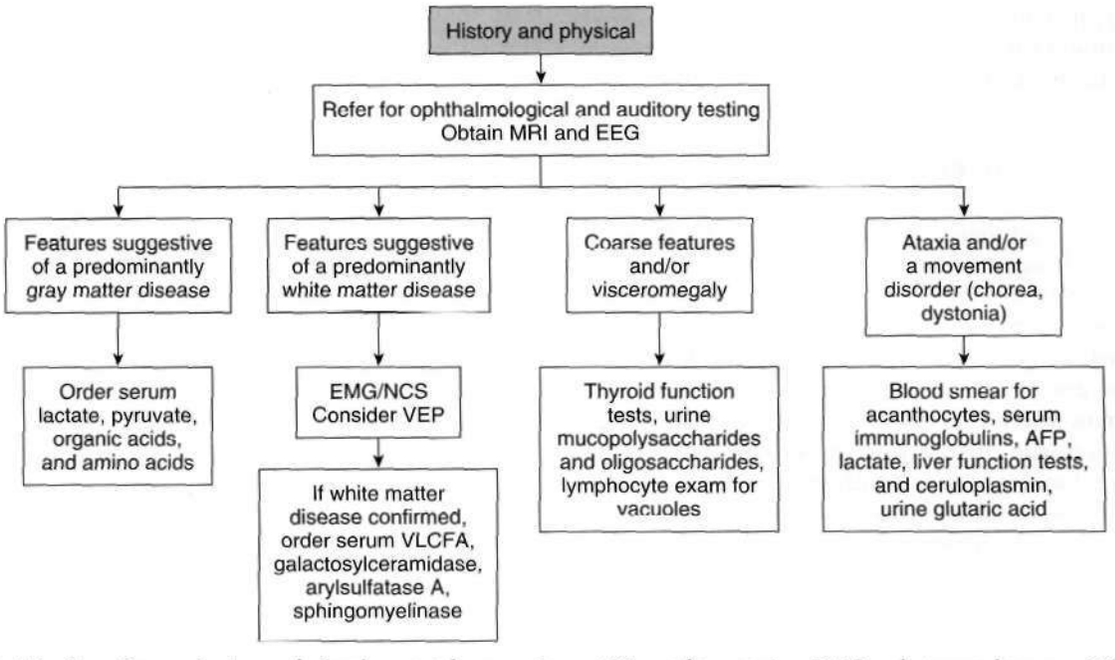

FIGURE 7.2 Stepwise evaluation of developmental regression. AFP = α-fetoprotein; EMG = electromyelogram; NCS = nerve conduction studies; VEP = visual evoked potentials; VLCFA = very-long-chain fatty acids.

independence the child will eventually attain. Because this cannot always be predicted with certainty, a balance should be sought between preparing parents for the worst and allowing room for reasonable hope,

Prognosis

In the absence of cardiorespiratory disease, mildly retarded children have a normal life expectancy. Mortality in more severely affected children is not directly related to the underlying etiology of the retardation but is secondary to immobility, aspiration, and seizures. Many of the progressive neurological diseases have no specific therapy and lead to death relatively soon after diagnosis.

Children with mild to moderate mental tetardation can continue to develop cognitivcly and functionally with appropriate education and should be encouraged to undergo vocational training if possible. Issues of sexuality, living arrangements, employment, and financial support become significant challenges during the transition to adulthood,

Children identified as having developmental delay are not all destined to be mentally retarded adults. Children whose development is affected by significant environmental deprivation or medical illness have the potential for recovery if their circumstances improve. Early development is predominantly that of sensorimotor function and many infants with cerebral palsy or neuromuscular disorders who are identified as delayed eventually demonstrate normal cognition,

Treatment

Psychologists, physical therapists, occupational therapists, and language therapists can provide families with more formal assessments of their child's function, as well as with structured interventions toward rehabilitation. Many of these resources are made available on referral through county-specific programs and schools. In the United States, federal law mandates the provision of early intervention programs for at-risk children aged 3 to 5, and appropriate public school education for children up to age 21.

As there are no specific treatments for most developmental disorders. Treatments focus on the medical, emotional, and behavioral problems that affect up to 30% of children with mental retardation. Feeding difficulties may require supplemental nutrition through a gastrostomy tube. Mood disorders, schizophrenia, aggressive behaviors, hyperactivity, and disrupted sleep may require pharmacological therapy. Seizures affect up to 20% of children with mental retardation and may be difficult to control.

Children in whom the cause of developmental delay remains unclear after the initial evaluation should be followed on a regular basis for possible regression and the need for more extensive testing. Institutionalized care is a consideration for some severely and profoundly retarded

Chapter 8
Behavior and Personality Disturbances

Jane S. Paulsen and Carissa Nehl

Behavioral and personality disturbances are quite common in individuals with neurological disease, traumatic brain injury (TBI), and stroke (Table 8.1). Identification and treatment of behavioral disturbances are critical as they are associated with reduced functional capacity, decreased quality of life, greater economic cost, larger caregiver burden, and increased morbidity.

Historically clear divisions between the fields of psychiatry and neurology have existed. Psychiatry has primarily focused on disruptions of behavior and personality resulting from "nonorganic" or psychological causes, whereas neurology has historically focused on disease and injury with "organic" causes. As research continues to detect neuroanatomical and biochemical correlates of behavior and personality disturbances, the division between psychiatry and neurology becomes less clear. Within the last two decades, increased collaboration and partnership between these two fields have begun. An example of this collaboration is the creation of the American Neuropsychiatric Association (ANPA) established in 1988. ANPA's mission statement notes that it is dedicated to the advancement of clinical, educational, and research activities in the field of clinical neutoscience and that it supports collaboration between professionals in psychiatry, neuropsychiatry, behavioral neurology, neuroradiology, neuropathology, neurosurgery, and researchers in the basic sciences. In addition, journals such as the *Journal of Neuropsychiatry and Clinical Neurosciences*, the official journal of ANPA, present research conducted at the crosstoads of neurology and psychiatry.

The aim of this chapter is twofold. First, theoretical information linking frontal-subcortical circuitry and behavior and personality disturbances is described. Second, information regarding the prevalence, phenomenology, and treatment of behavior and personality disturbances in dementia, movement disorders, epilepsy, stroke, and TBI is presented.

FRONTAL-SUBCORTICAL CIRCUITRY

The frontal-subcortical circuits provide a unifying framework for understanding the behavioral changes that accompany cortical and subcortical brain dysfunction. In the past three decades, a number of significant advances have been made in our understanding of the neuroanatomy, neurophysiology, and ehemoarchitecture of the frontal-subcortical circuits. An increasingly broad spectrum of neuropsychiatric phenomenology is now being interpreted in the context of frontal-subcortical circuit dysfunction. A brief overview of the frontal-subcortical circuits and their signature behavioral syndromes is offered as a strategy to better understand the behavior and personality changes that accompany neurological conditions. Alexander and colleagues (1986) described five discrete parallel circuits linking regions of the frontal cortex to the striatum, the globus pallidus and substantia nigra, and the thalamus. These circuits consist of "direct" and "indirect" pathways. In general, the direct pathway facilitates the flow of information, and the indirect pathway inhibits it. The overall model for the frontal-subcortical circuits can be observed in Figure 8.1.

Five frontal-subcortical circuits were initially described: motor, oculomotor, dorsolateral prefrontal, lateral orbitofrontal, and anterior cingulate. Disruption of the final three of these circuits is associated with behavioral and personality disruptions. Each of these circuits is associated with distinct neurological correlates. See Table 8.2 for descriptions of specific neuroanatomical pathways for these circuits.

Efforts to link functional domains to this brain circuitry have been developed and revised over the past few decades. It has been proposed that the basal ganglia be divided into a neurologist's, psychologist's, and psychiatrist's portion responsible for motor, cognitive, and emotional disorders, respectively. In this schema, the neurologist's circuit is the

Table 8.1: Prevalence of behavioral and psychiatric disturbances in neurological disorders

	Depression	*Apathy*	*Anxiety*	*Euphoria*	*Psychosis*	*Aggression*

AD = Alzheimer's disease; FTD = frontotemporal dementia; HD = Huntington's disease; HlV = human immunodeficiency virus and HIV dementia; MS = multiple sclerosis; PD = Parkinson's disease; TS = Tourette's syndrome; TBI = traumatic brain injury; VaD = vascular dementia.

putamen-based motor circuits (i.e., motor and oculomotor circuits), the psychologist's emphasis is on the caudate-dorsolateral prefrontal circuit, and the psychiatrist's pathway is the anterior cingulate circuit. More recently, specific behavioral syndromes have been attributed to dysfunction in these circuits (Table 8.3). Disruptions at any point in the circuit (e.g., the frontal cortex, striatum, pallidum) may result in behavioral changes.

Disruption of the dorsolateral circuit {Figute 8.2) is associated with executive dysfunction and motor programming abnormalities. Mote specifically, a disruption of this circuit is associated with poor organization skills, memory retrieval deficits, and poor set shifting. See Table 8,4 for examples of neurological disotders associated with disruption of the dorsolateral circuit. The orbitofrontal circuit (see Figure 8.2) is associated with increased irritability', impulsivity, mood lability, tactlessness, and socially inappropriate behavior, whereas disruptions of the latter part of the orbitofrontal circuit may also result in mood disorder and/or obsessive-compulsive disorder (OCD), Table 8.5 provides examples of disorders associated with disruption of the orbitofrontal citcuit. Finally, the anterior cingulate circuit is associated with decreased motivation, apathy, decreased speech, and akinesia. (See Table 8.6 for a list of disorders associated with disruption of the anterior cingulate circuit.) Although these models may be heuristic in developing function-structure hypotheses, it is unlikely that any current model is sufficient to explain the complex interface of behavior and brain circuitry.

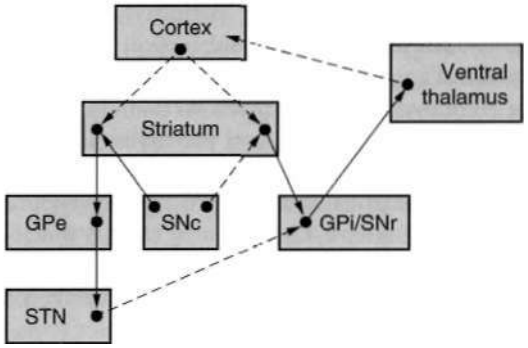

FIGURE 8.1 Fronta(-subcortical circuit general model. Note: Solid line represents inhibitory neurons while dotted lines represent excitatory neurons, GPe = external segment of the globus pallidas; GPi = internal segment of the globus pallidus; SNc = substantia nigra pars compacta; SNr = substantia nigra pars reticulata; STN = subthalamic nucleus.

BEHAVIOR AND PERSONALITY DISTURBANCES ASSOCIATED WITH CEREBRAL DYSFUNCTION

Dementia

Alzheimer's Disease

Patients with Alzheimet's disease (AD) experience a wide range of behavioral disturbances, including affective symptoms, agitation, aggression, and psychosis. Behavioral disturbances in AD are associated with increased caregiver burden, patient and caregiver abuse, greater use of psychotropic medications, more tapid cognitive decline, and earlier institutionalization. Longitudinal research suggests that once psychiattic symptoms are present in patients with AD, they frequently recur. Early identification and intervention may help alleviate the chronicity of psychiattic disturbance in AD and may contribute to improved outcomes fur patients with AD and caregivers. In general, social comportment is relatively spated in AD. Subtle personality changes occur in nearly every person with AD, although profound changes in judgment or behavior are unusual. Often, patients show decreased

Table 8.2: Frontal-subcortical circuitry

Circuit	*Frontal lobe*	*Striatum*	*GPi and SNr*	*Thalamus*
Dorsolateral	Dorsolateral PFC	Dorsolateral CN	Lateral Mediodorsal GPi Rostrolateral SNr	VA nucleus
Orbitofronral	Orbitofrontal PFC	Ventromedial CN	Mediodorsal GPi Rostromedial SNr	VA nucleus
Anterior cingulate	Supracallosal Anterior cingulate	Ventral Striatum	Rostromedial GPi Ventral pallidum Rostrodorsal SNr	Mediodorsal nucleus

CN = caudate nucleus; GPi: internal segment of the globus pallidus; PFC = prefrontal cortex; SNr = substantia nigra pars reticulata; VA = vcntral anterior; ventral striatum = ventromedial caudate nucleus, ventral putamen, nucleus accumbens, and olfactory tubercle.

energy, indifference, egocentncity, impulsivity, or irritability. Social withdrawal and selfishness are seen in some individuals with AD. In contrast to patients with frontotemporal demenria (FTD), many patients with AD show normal social skills.

Depression. The true prevalence of depression in AD is controversial, with estimates ranging from 0-86%. One reason for the mixed findings lies in the inherent difficulty of detecting depression in AD. Some studies use family intetviews, and others emphasize patient evaluation. Recent research has suggested that concordance between patient and caregivers on endorsement of depression is less than 13%. Patients with AD tend to endorse more neurovegetative symptoms, whereas cognitive and mood symptoms are more readily endorsed by caregivers. Some symptoms of depression are confounded with other components of AD (e.g., concentration, energy, and interest), making the detection of depression difficult. The probability of depression in AD appears to be greater if there is a history of depression either in the patient or in the family. Table 8.7 suggests differences between the signs of depression and possibly confounding signs from the AD itself.

Selective serotonin reuptake inhibitors (SSRIs) are the preferred mode of treatment for depression in AD. Tricyclic antidepressants (TCAs) are avoided because of their anticholinergic effects on cognitive performance. Although clinical trials are relatively few, sertraline and citalopram have been shown to be effective (Lyketsos et al. 2000).

Apathy. Apathy, defined as diminished motivation not attributable to decreased level of consciousness, cognitive impairment, or emotional distress, is the most common behavioral change noted in AD and may occur in up to

Table 8.3: Behavioral syndromes associated with dysfunction of the motor circuits

Symptoms associated with disruption of the dorsolateral circuit

92% of patients. The assessment of apathy in AD may be difficult because it may be unclear whether decreased activity is due to apathy or inability to perform activities. In addition, apathy is often confused with depression, although recent research has demonstrated their independence (Figure 8.3). Apathy typically occuts early in AD and is present throughout the course of the disease, although apathy has been associated with seventy of dementia.

Aggression. Aggressive verbalizations and acts are common in AD. Reported prevalence rates range from 25-67%. Studies have indicated that verbal aggression is more common in men and in individuals with delusions or agitation. Verbal aggression and aggressive behavior do not appear to be associated with depression, although sertraline was assoeiared with a 38% response rate for the treatment of aggression and irritability in AD.

Psychosis. Ptcvalcncc rates of psychotic symptoms in AD range from 10-73%, with tates in clinical populations exceeding community-based samples. In a recent study of 329 patients with AD, the cumulative 4-year incidence of new-onset psychosis of AD was computed to be 51%. Once present, delusions tecur or persist for several years in

most patients with AD (Figure 8.4). Psychotic symptoms have implications for the management, treatment, course, prognosis, and pathophysiology of AD. Specifically, psychotic symptoms are chronic and are associated with longer duration of illness, more rapid progression of clinical course, and earlier institutionalization. Predictors of psychosis in AD have included parkinsonian gait, bradyphrenia, exaggerated general cognitive decline, and exaggerated semantic memory decline (Paulsen et al. 2000). Personality and behavioral changes including increased aggression, asocial behavior, and functional impairment are associated with psychotic symptoms in AD. These findings have contributed to diagnostic subtyping of AD based on the presence of delusions,

The most common psychotic symptoms reported in patients with AD are delusions and hallucinations. The delusions are typically paranoid type, nonbizzare, and simple. Complex or bizarre delusions seen in patients with schizophrenia are conspicuously absent in **the** patients with AD. Misidentification phenomena however are common in AD. Whereas hallucinations in AD are more often visual than auditory, the reverse is true for schizophrenia (Table 8,Si, I'syehonc symptoms tend to disappear in advanced stages of dementia; this could reflect an apparent remission, rather than real remission, because the patient with severe dementia may be unable to articulate his or her delusions and hallucinations.

Evidence from neuropsychological investigations suggests relatively mote executive dysfunction, and findings from clinicoanatomic studies implicate increased frontal dysfunction in AD with psychotic symptoms than AD

Table 8.7: Clinical aspects differentiating dementia from depression

FIGURE R.3 Neuropsychiatric inventory subseale scores for apathy and depression. AD = Alzheimer's disease; FTD = frontotemporai dementia; PD = Parkinson's disease; PSP = pr og re ss i vc supranuclear palsy; HD = Huntington's disease. (Reprinted with permission from Levy, M. L., Gummings, J. L., Fairbanks, L. A., et al. *1998,* "Apathy is not depression,"/ *Neuropsychiatry Clin Neurosci,* vol. 10, pp. 314-319.)

without these symptoms (Rao and Lyketsos 1998). For example, compared with patients with AD without psychotic symptoms, neuropsychological studies indicated that patients with AD with delusions were more impaired on an abstraction task and were more perseverative. Using survival analyses, wc recently found that lower scores on measures of fluency, grooved pegboard, trail making, and digit span wete predictors ($p < .05$) of future psychosis in AD. In addition, greater worsening on the Dementia Rating Scale (DRS), attention and construction subscales, total DRS, and fluency scores were associated with a twofold to threefold increase in the risk of developing psychosis. For instance, for every one z-score change in fluency, the risk of psychosis increased threefold.

Atypical antipsychotics are the preferred method of treatment for psychosis in AD because of the lowered anticholinergic and hypotensive effects. Although few treatment studies have been performed, the National Institutes of Health is currently supporting a multisite study of atypical antipsychotics (e.g., quetiapine, olanzapine, risperidone, and citalopram) in AD.

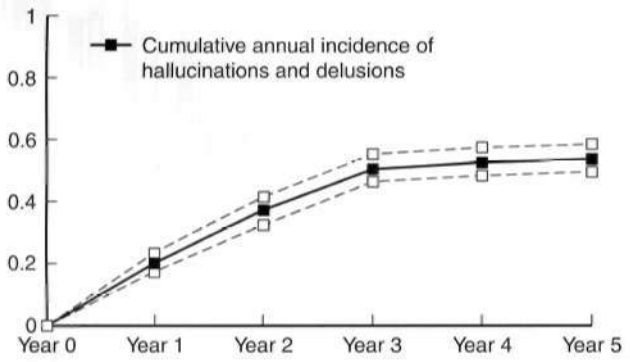

FIGURE 8.4 Incidence of psychosis in patients with Alzheimer's disease. (Reprinted with permission from Paulsen, J. S., Salmon, D. P., et al. 2000, "Incidence of and risk factors for hallucinations and delusions in patients with probable AD," *Neurology*, vol. 54, no. 10, pp. 1965-1971.)

Frontotemporal Dementia

FTD, previously called Pick's disease, is composed of at least three syndromes: semantic dementia, progressive nonfluent aphasia, and frontal lobe degeneration of non-Alzheimer type (FLD). The term FTD therefore describes a heterogeneous group of disorders. Clinical presentation of FTD may vary significantly. A distinct neuropsychological profile of FTD has not yet emerged; as a result, some have described FTD as a ncurobehavioral disorder rather than ;i neuropsychological disorder. Recent consensus criteria for diagnosis of FTD have been reported and primary criteria relate to the presence of behavioral change (Table 8.9).

Behavioral Disruption. As the name suggests, FTD syndromes are marked by progressive atrophy of the frontal and temporal lobes. Atrophy within the frontal lobes leads to disruption of the frontal-subcortical circuits and the associated behavioral syndromes described earlier, Individuals with FTD exhibit symptoms of orbitofrontal syndrome, such as disinhibition, poor impulse control, tactlessness, and poor judgment. In addition, loss of empathy, mental inflexibility, and stereotyped behaviors are common. Individuals with FLD frequently have impaired social relationships and inappropriate social interactions. Symptoms associated with Kliiver-Bucy syndrome, such as byperorality and hypersexuality, may occur in late stages of FTD. Patients may develop a propensity for sweets.

Disruption of the anterior cingulate circuit may also occur, resulting in symptoms of apathy and lack of motivation, which may be the earliest signs of FTD. In addition, these individuals may show little concern for personal hygiene, appearing unkempt. Finally, disruption of the dorsolateral circuit in FTD is associated with impaired planning and organization.

The inability to demonstrate basic and social emotions is also common. Often, the family members and caregivers are the ones who report these behavioral disturbances because many patients with FTD experience a lack of insight into their current difficulties. Although no large-scale clinical trials have been conducted, evidence suggests that behavioral disturbances, such as disinhibition, overeating, and compulsions, may respond to treatment with SSRIs,

Studies have attempted to distinguish FTD from AD based on behavioral symptoms. Disinhibition, apathy, aberrant motor behavior, and euphoria are more common in FTD than AD, as illustrated in Figure 8.5. Others have noted that lack of insight and emotion, food cramming, indifference, and impulsivity are more common in FTD than vascular dementia (VaD).

Psychiatric Disturbances. Although the more classic psychiatric syndromes, such as depression, anxiety, and psychosis, are observed in FTD, symptoms are rarely severe enough to meet criteria for diagnosis. Depression in FTD is associated with irritability, increased appetite with weight

Table 8.8: Psychotic symptoms in Alzheimer's disease vs. schizophrenia in elderly patients

	Psychosis in AD	*Schizophrenia in the elderly*
Incidence	30-50%	<1%
Bizarre or complex delusions	Rare	Common
Misidentification of caregivers	Common	Rare
Common form of hallucinations	Visual	Auditory
Schneiderian first-rank symptoms	Rare	Common
Active suicidal ideation	Rare	Common
History of psychosis	Rare	Very common
Eventual remission of psychosis	Common	Uncommon
Need for many years of maintenance on antipsychotics	Uncommon	Very common
Average optimal daily dose of an antipsychotic	15-25% of that in young adult with schizophrenia	40-60% of that in a young adult with schizophrenia

gain, anhedonia, withdrawal, and alexithymia. In contrast, apathy is reported in nearly all (95%) patients with FTD.

Approximately 20% of patients with FTD exhibit delusions, hut hallucinations are less common (7%). Euphoric symptoms such as elevated mood and exaggerated self-esteem arc reported in up to one third of individuals with FTD. Finally, disinhibition is observed in a high proportion (68%) of individuals with FTD.

Table 8.9: Consensus criteria for the diagnosis of fro n tote in poral dementia

I. Core diagnostic features:
  A. Insidious onset and gradual progression
  li. I'.iiilv decline in social interpersonal conduct
  (.'.. Karly impairment in regulation *at* personal conduct
  D. Early emotional blunting
  E. F.arly loss of insight
II. Supportive diagnostic features
  A. Behavioral disorder
    1. Decline in personal hygiene and grooming
    2. Mental rigidity and inflexibility
    3. Distractibility and impersistence
    4. Hyperorality and dietary changes
    5. Perseveration and stereotyped behavior
    6. Utilization behavior
  B. Speech and language
    I. Altered speech output (aspontaneity and economy of speech, press of speech), stereotypy of speech, echolalia, perseveration, mutism
  C. Physical signs
    1. Primitive reflex, incontinence, akinesia, rigidity, tremor, low/labile blood pressure
  D. Investigations
    1. Neuropsychology: impaired frontal lobe test results; no amnesia or perceptual deficits
    2. Electroencephalogram (EEG): normal on most conventional EEGs despite clinically evident dementia
    3. Brain imaging: predominant frontal and/or anterior temporal abnormality

Relationship to Primary Pathology. Underlying pathology varies widely in individuals with FTD; asymmetrical brain involvement has been linked to distinct behavioral profiles (Mychack etal. 2001). Individuals with primary left frontal involvement typically present with nonfluent aphasia, intact social abilities, depression, and social withdrawal. Left temporal involvement is associated with a diagnosis of semantic dementia, or loss of semantic knowledge. Primary right frontal involvement is usually associated with social dysfunction and presentation. Patients with primary right temporal dysfunction also exhibit significant behavioral dysfunction. In addition, irritability, impulsiviry, lack of

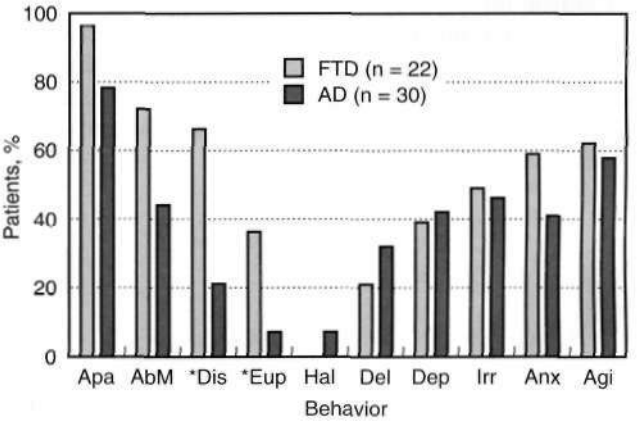

FIGURE 8.5 Psychiatric disturbance in frontotemporal dementia and Alzheimer's disease. Note: The percentage of patients with FTD and AD with non-0 scores on the neuropsychiatric inventory. Behavior distinctions," *Arch Neurol,* vol. 53, pp. 687-690.)

empathy, and changes in self-concept (i.e., patients may drastically alter their religious or political beliefs) are common. Involvement of the right hemisphere is associated with changes in expression of affect; spouses may report that the patient seems like a different person with a blunted affect.

Vascular Dementia

VaD primarily affects subcortical structures; therefore fronral-subcortical circuits are disrupted and behavioral disturbances are common. These disturbances often result in increased challenges to health care providers and caregivers. Apathy, depression, and behavioral changes are common in VaD; however, a clear relationship between these behavioral changes and dementia severity has not been well established.

Depression. The mean reported prevalence of depression in VaD is 32%, although rates vary widely between studies (Ballard and O'Brien 2002). Sample source likely influences the reported prevalence rates, with community samples exhibiting lower rates of depression than clinic samples. Depression in VaD is qualitatively different from typical major depression. Individuals with VaD and depression are less likely to have had a stroke and are more likely to have a history of depression and impairments in memory or attention than patients with VaD without depression. The relationship between age and depression in VaD is unclear; some have noted that depression is more common in younger patients and others have noted increased rates in older patients.

Distinct differences exist in the comparison of depression in VaD and AD. First, depression is both more common and more severe in patients with VaD than AD. Patients with VaD experience more behavioral symptoms of depression, accounting for the increased severity. Few studies have assessed depression through the progression of VaD; however, initial studies indicate depression is more likely to enter remission in VaD than AD. Depression phenomenology differs in VaD and AD patients such that VaD patients report more low affect, withdrawal, and psychomotor slowing than AD patients (Figure 8.6).

Apathy. Apathy in VaD is associated with increased impairment in both basic and instrumental activities oi daily living. This relationship is particularly apparent in patients with VaD who have also experienced a stroke.

Psychosis. Rates of psychotic symptoms are similar in AD and VaD. Delusions (33%) and visual hallucinations (13-25%) are reported in VaD and are associated with impaired cognitive functioning (Ballard and O'Brien 2002). Care must be taken in the assessment of delusions in VaD and in dementia in general. It is important to differentiate delusions from confabulation or thought processes based on impaired cognitive functioning.

Anxiety. Anxiery symptoms are reported in 19% of the population and up to 70% of inpatient samples. Generalized anxiety disorder (GAD) is more common than panic disorder. Anxiety is not associated with severity of cognitive impairment or changes in functional abilities. However, it has been noted that anxiety is more common in individuals with Mini-Mental State examination (MMSE) scores of less than 10.

Dementia with Letvy Bodies

Dementia with Lewy bodies (DUB) has recently received significant attention. Difficulty remains in attaining an accurate diagnosis of DLB before performing a neuropathologic examination. There is significant clinical presentation overlap between the presentation of DLB and both AD and Parkinson's disease (PD).

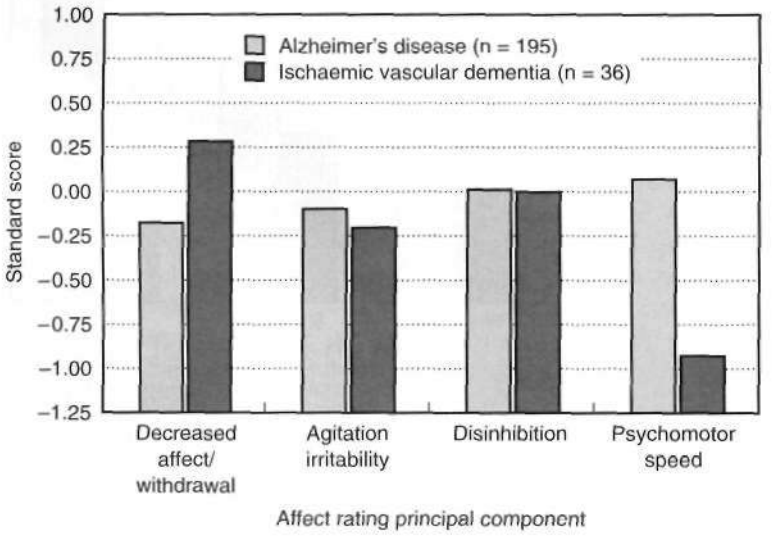

FIGURE 8.6 Depressive symptoms in vascular dementia versus Alzheimer's disease. Note: Values are expressed in standard score units with a mean of 0 and a standard deviation of 1 based on the overall subject sample. (Reprinted with permission from Hargrave, R., Geek, L. C, Reed, B., & Mungas, D. 2000, "Affective behavioral disturbances in Alzheimer's disease and ischaemic vascular disease," / *Neurol Neurosurg Psychiatry*, vol, 68, pp. 41-46.)

Psychotic symptoms, particularly hallucinations, are a hallmark symptom of DLB, with between 48% and 100% of individuals with DLB experiencing visual hallucinations, Insight is usually poor. It has been suggested that psychotic symptoms observed in DLB are similar to symptoms seen in L-dopa-induced psychosis. Disruptions of the nigro-amygdaloid connection and the resultant hypersensitivity of the dopamine receptors in the amygdala is a potential explanation for the cause of hallucinations in DLB. Mania in DLB has been noted in at least one case study.

Management of psychosis in DLB is critical because it is associated with distress in the patient, increased caregiver burden, early entrance in institutional care, and earlier morbidity. Typical neuroleptics are typically avoided in DLB because patients exhibit high sensitivity to these drugs and may experience severe parkinsonian symptoms and other side effects. In contrast, atypical neuroleptics, such as clozapine and quetiapinc, as well as cholinesterasc inhibitors are associated with improved cognition and decreased psychotic symptoms (McKeith 2002).

Human Immunodeficiency Virus and Human Immunodeficiency Virus Dementia

Depression. Psychiatric and behavioral disturbances have been noted in individuals with human immunodeficiency virus (HP/) and with HiV dementia. Depression is common in individuals with HIV and is associated with number of years living with HIV diagnosis, coping style, and low levels of social support. The World Health Organization Neuropsvchiatric AIDS study noted that 3.0-10.9% of individuals with asymptomatic HIV and 4.0-18.4% of individuals with symptomatic HIV meet criteria for major depressive disorder (MDD). Lifetime rates of major depression are particularly high, with 43-55% of individuals meeting criteria for MDD during at least one period in their lifetime. A recent path analysis assessed the relationship between cognition, social support, life events, disability, stress, and depression in men with HIV, They noted that life events and disability were directly related to depression in individuals with HIV. Higher intelligence quotient (IQ) was associated with increased social support, which is associated with lower rates of depression.

Much of the research assessing psychiatric symptoms in HIV has been conducted with homosexual male populations, Reported rates of depression in women with HIV vary from 1.9-35.0% in clinical and 30-60% in community samples. Current diagnosis of major depressive disorder was four times more common in HIV-positive women (19.4% vs. 4,8%). Depression severity was associated with older age, white race, and lower education.

Anxiety. Approximately 17-36% of individuals with HIV meet criteria for an anxiety disorder (Martin ct al. 2002). Although individuals with HIV report more severe anxiety symptoms, diagnoses of anxiety disorders are not any more common in women with HIV than in women without HIV.

Movement Disorders

Parkinson's Disease

Depression. Depression is the most common psychiattic disturbance in persons with PD, with the overall frequency as high as 70%, depending on threshold for diagnosis. Cross-sectional studies have demonstrated that approximately 20% of patients with PD have major depression and another 20% have minor depression. Longitudinal studies show that more than 50% of patients with PD will develop depression at some point in the disease. Nearly 20% of patients with PD without depression will develop depression within a year and depression onset predates the onset of motor symptoms in 12-37% of cases. Risk factors for depression in PD have included greater cognitive impairment, earlier disease onset, and family history of depression.

The typical duration of depression in PD is more than 1 year; however, patients with PD with minor depression experience a briefer duration. Patients with PD with majot depression, but not those with minor depression, exhibit impaired cognitive functioning and more rapid disease progression (Figure 8.7). Given the association between depression severity and course, effective treatment of depression in PD may result in slowed progression of disease.

Some have proposed rhat the degeneration of dopaminergic neurons likely causes dysfunction of orbitofrontal cortex, which secondarily affects serotonergic connections

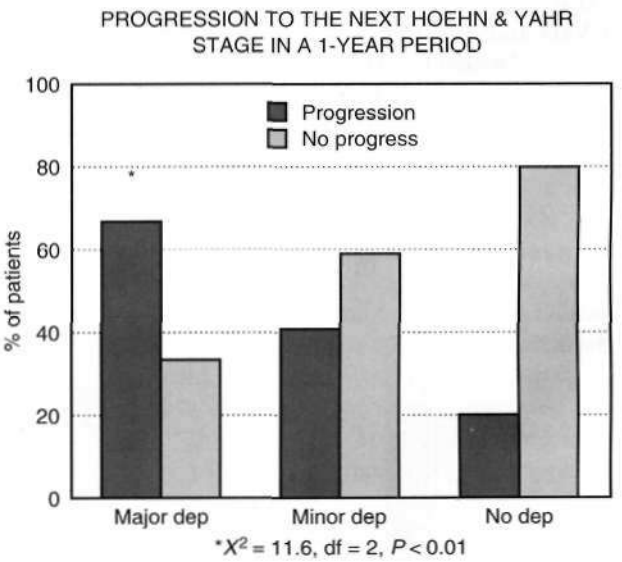

FIGURE 8.7 Faster progression of Parkinson's disease in patients with major depression. (Reprinted with permission from Starkstein, S. E. & Mayberg, H. S. 1993, "Depression in Parkinson disease," in *Depression in Neurologic Disease*, eds S. E. Starkstein & R. G. Robinson, Johns Hopkins University Press, Baltimore.)

of the dorsal raphe nucleus. This dysfunction in the dorsal raphe nucleus affects the serotonergic cell bodies.

There are only four controlled clinical trials of antidepressant therapy in PD. SSRIs are considered first-line therapy for depression in patients with PD, although SSRIs can worsen motor symptoms. In such cases, TCAs may be an effective alternative. A survey of the Parkinson Study Group documented that 26% of patients with PD are prescribed an antidepressant. Double-blind prospective studies are needed to evaluate the safety and efficacy of antidepressants in PD. The largest prospective study of SSRIs in PD suggests that paroxetine is well tolerated over 3 months and effective in decreasing depressive symptoms in PD (Tesei et al. 2000).

Psychosis. Hallucinations occur in up to 40% of patients with PD, and 16% report delusions. Psychotic symptoms are more common in patients with PD with greater cognitive impairment, longer duration of illness, greater daytime somnolence, and older age and in those who are institution;ili/L'd.

Researchers have long suggested a relationship between L-dopa treatment and psychosis in PD (in part because psychosis in untreated PD is rare). Although L-dopa may be responsible for psychosis in a portion (20%) of patients with PD, no relationship between i.-dopa dosage and psychosis is observed in these patients. There are a number of possible explanations for this lack of relationship. It is possible that clinicians regularly reduce L-dopa dosage in individuals who experience hallucinations or delusions in an attempt to reduce these symptoms. It is plausible that individuals diagnosed with PD who experience psychotic symptoms are actually suffering from DI.B. Newer theories regarding psychotic symptoms in PD suggest that cholinergic deficits may be the cause of these symptoms. Cholinergic therapy may reduce psychotic symptoms in PD.

Psychosis is among the most difficult complications of L-dopa treatment. Hallucinations that are nonthreatening often remain untreated. However, paranoid delusions and threatening hallucinations require treatment. Most practitioners recommend a simplification of antiparkinsonian drugs followed by a discontinuation of anticholinergics, selegiline, and amantadine before reducing i.-dopa. Atypical antipsychotics are added only when a reduction of other medications has not resulted in improvement.

Apathy. Individuals with PD often experience increased rates of apathy. Hstimates of apathy in PD have ranged from 16.5^10.0%. Apathy may occur with or without the presence of depression. Apathy is associated with increased dementia and lower rates of disability.

Progressive Supranuclear Palsy

Psychiatric and behavioral symptoms are common in progressive supranuclear palsy (PSP). Nearly all (>90%) patients with PSP show high levels of apathy, whereas about half of patients with PSP exhibit a change in personality and less than half suffer from depression. Disinhibition, or loss of control for emotions, is noted in 30-36% of patients with PSP.

Huntington's Disease

Psychiatric and behavioral symptoms are common in Huntington's disease (HD) and have been reported as the presenting disease manifestations in up to 79% of patients. Research on the incidence of psychiatric symptoms in HD is variable though, encumbered by limitations within and across studies. Some limitations of the available research are as follows: (1) affected people are often medicated to minimize abnormal involuntary movements; such treatment may mask psychiatric and behavioral symptoms; (2) most available tieuropsychiatrie assessment tools use conventional psychiatric terminology based on idiopathic psychiatric illness, which fails to distinctly reflect the symptoms associated with striatal deterioration; and (3) most research has emphasized the motor and cognitive impairments associated with HD, despite family reports that psychiatric disturbances are most strongly associated with stress, disability, and placement decisions. Data from 1857 Huntington Study Group (HSG) subjects with a diagnosis of symptomatic HD arc presented in Table 8.10. Subjects are grouped into disease stages according to ratings obtained on the Total Functional Capacity Scale.

Depression. Depression is one of the most common concerns for individuals and families with HD, occurring in up to €*3>%* of patients. It has been suggested that depression can precede the onset of neurological symptoms in HD by 2 to 20 years, although large-scale empirical research has been minimal. Recent data from the HSG indicate that depression is most common immediately before diagnosis, when neurological soft signs and other subtle abnormalities become evident. Following a definite diagnosis of HD, however, depression is most prevalent in the middle stages of the disease (i.e., Shoulson-Fahn stages 2 and 3) and may diminish in the later stages. Positron emission tomography (PET) studies indicate that patients

Table 8.10: Percentage of patients with Huntington's disease endorsing psychiatric symptoms by TFC stage

Symptom	*(n = 4.U)*	*(n = 660)*	*(n = 520)*	*(n = 221)*	*(n = 84)*
Depression	57.5%	62.9%	59.3%	ill'!-,,	42.2%

Source: Data provided by the Huntington Study Group.

with HD with depression have hypermetabolism in the inferior frontal cortex and thalamus relative to nondepressed patients with HD or normal age-matched controls. Though less well studied, mania episodes occur in 2-12% of patients with HD.

Suicide. Suicide is more common in HD than in other neurological disorders with high rates of depression, such as stroke and I'D. Most studies have found a fourfold to sixfold increase of suicide in HD, and some studies have reported it to be 8-20 times higher than the general population. Suicidal ideation, as measured by the Behavioral Rating Scale on the Unified Huntington's Disease Rating Scale (UHDR.S), is highly prevalent throughout the disease, with 8% of all individuals diagnosed with HD having active ideation. Suicidal ideation was recently examined in 4342 individuals in the HSG database. Two primary "critical periods" were evident, during which suicidal ideation in HD increased dramatically. First, frequency of suicidal ideation doubled from 10.4% in at-risk persons with a normal neurological examination to 20.5% in at-risk persons with soft neurological signs. Second, in persons with a diagnosis of HD, 16% had suicidal ideation in stage 1, whereas nearly 21% had suicidal ideation in stage 2 (Figure 8.8). Although the underlying mechanisms for suicidal risk in HD are poorly understood, it may be beneficial for health care providers to be aware of periods during which patients may be at an increased risk of suicide.

Psychosis. Psychosis occurs with increased frequency in HD, with estimates ranging from 3-12%. Although the majority of the research has been conducted using the Johns Hopkins sample, data are consistent with others' clinical experience, suggesting that psychosis in HD is broad and similar to that seen in other psychiatric disorders. Psychosis is more common among early adulthood-onset cases than among those whose disease begins in middle or late adulthood. Psychosis associated with HD is more resistant to treatment than psychosis in schizophrenia. HSG data suggest that psychosis may increase somewhat as the disease progresses (see Table 8.10), although psychosis can become difficult to measure in the later stages of disease.

Obsessive-Compulsive Traits. Although true OCD is not often reported in HD, obsessive and compulsive behaviors are prevalent (13-30%). Obsessional thinking often increases with pruximin in disease onset and then remains somewhat stable throughout the illness. Obsessional thinking associated with HD is reminiscent of perseveration, such that individuals get "stuck" on a previous occurrence or need and are unable to shift,

Aggression. A spectrum of behaviors ranging from irritability to intermittent explosive disorders occur in 19-59% of patients with HD. Although aggressive outbursts are often the principal reason for admission to a psychiatric facility, research on the prevalence and incidence of irritability and aggressive outbursts in HD is spatse. The primary limitation in summarizing these symptoms in HD is the varied terminology used to describe this continuum of behaviors. A recent survey of several clinicians and HD family members suggested that difficulty with placement, because of aggression, was among the principal obstacles to providing an effective continuum of care for people with HD. Table 8.11 shows that skilled nursing facilities surveyed rated behaviors such as agitation, irritability, disinhibition, and depression as the most common behavior problems in institutionalized patients with HD,

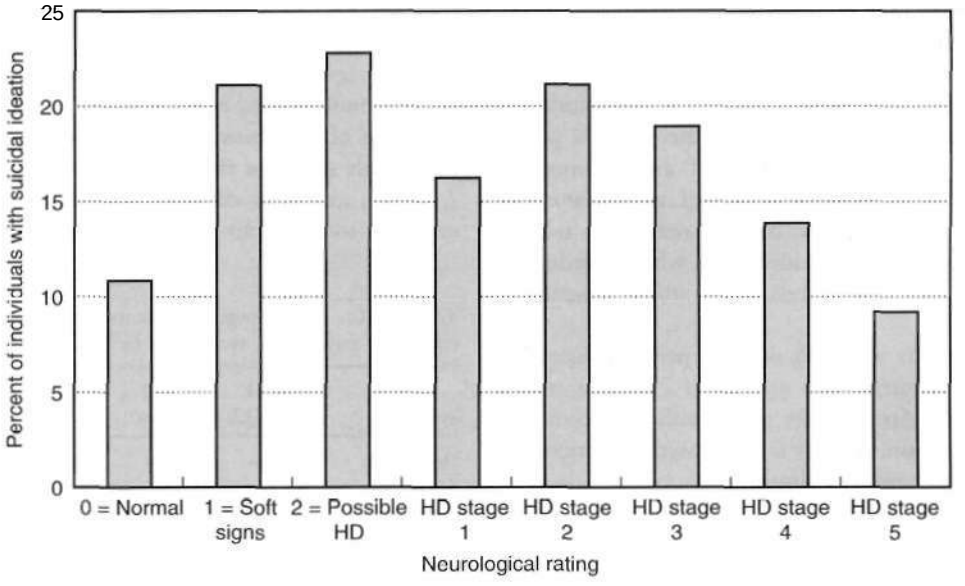

FIGURE 8.8 Suicidal ideation by Huntington's disease stage. (Reprinted with permission from Ferneyhough, K. C., Stierman, L. M., Turner, B. M., et al. 2002, "Critical periods of suicide risk in Huntington's disease," *J Neuropsychiatry Clin Neurosci*, vol. 14, p. 104.)

Table 8.11: Ratings by nursing home staff of problematic behaviors in patients with Huntington's disease

Behavior problem	*Percentage*	*Rank*
Agitation	76	2.0
Irritability	72	2.9
Disinhibition	59	3.3
Depression	51	4.2
Anxiety	50	4.4
Appetite	54	5.1
Delusions	43	5.5
Sleep disorders	50	5.5
Apathy	51	6.8
Euphoria	40	6.9

Source: From Paulsen & Hamilton.

Apathy. Early signs of HD may include withdrawal from activities and friends, decline in personal appearance, lack of behavioral initiation, decreased spontaneous speech, and constriction of emotional expression. However, these symptoms are considered merely reflective of depression, and more conclusive evaluations are precluded. Though difficult to distinguish, apathy is defined as diminished motivation not attributable to cognitive impairment, emotional distress, or decreased level of consciousness. Depression involves considerable emotional distress, evidenced by tearfulness, sadness, anxiety, agitation, insomnia, anorexia, feelings of worthlessness and hopelessness, and recurrent thoughts of death. Both apathy (59%) and depression (70%) are common in HD. However, 5.3% of individuals experienced only one of these symptoms rather than the two combined. Furthermore, depression and apathy were not correlated. Apathy was correlated with lower cognitive function, replicating previous research indicating telationships between apathy and dementia. Although the frequency of complaints from patients and family members about apathy may be low, the prevalence of this behavior is not. The consequences of apathy are rarely problematic (in contrast to temper outbursts, which are less common but highly distressing), but patients and family members typically appreciate effective treatment of apathy.

Tourette's Syndrome

Psychiatric comorbidity is common in individuals with Tourette's syndrome (TS) (Jankovic 2001). Rates of psychiatric disorders vary widely; significantly higher rates of psychiatric disorders are reported when samples are drawn from psychiatric clinics than from movement disorder clinics. Traditionally, clinicians focused on the high rates of attention-deficir/hypcractivity disorder (ADHD), OCD, and oppositional defiant disorder (ODD) in children and adults with TS.

ADHD is estimated to co-occur in 40-70% of individuals with TS. ADHD symptoms may precede the onset of TS by 2-3 years. Approximately 30% of individuals with TS meet criteria for OCD, The rares of oppositional behaviors are somewhat mixed; although earlier reports suggested that children with TS exhibited higher rates of oppositional behavior, some studies suggest that the rate of conduct difficulties is lower than in the general child psychiattic clinic population.

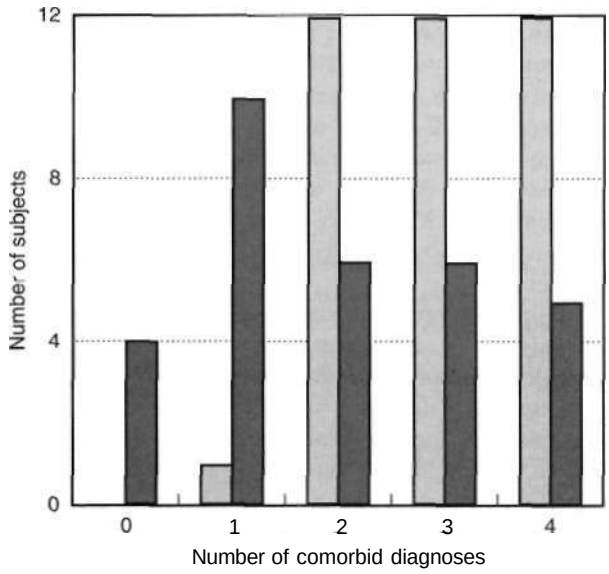

FIGURE 8.9 Comorbid diagnoses in individuals with Tourette's syndrome (TS), Light bars = TS with explosive outbursts; dark bars = TS without explosive outbursts. (Reprinted with permission from Budman, C. L., Bruun, R. D., Park, K. S., et al. 2000, "Explosive outbursts in children with Tourette's disorder,"/ *Am Acad Child Adoiesc Psychiatry,* vol. 39, no. 10, pp. 1270-1276.)

Other behavioral and personality disturbances occur in TS. Individuals with TS are also more likely to meet criteria for a personality disorder. Approximately 64% of individuals with TS meet criteria for one or more personality disorders. Borderline, depressive, obsessive-compulsive, paranoid, and passive-aggressive personality disorders were among the most common diagnoses. In addition, approximately 25% of patients with TS experience explosive outbursts. These outbursts arc more common in children (35%) than in adults (8%) with TS (Budman et al. 2000). Explosive outbursts are associated with increased psychiatric comorbidity in TS (Figure 8.9).

Finally, mood and anxiety symptoms are common in TS. Reports suggest that up to 73% of children with TS experience clinically significant difficulties with depression.

Multiple Sclerosis

The assessment of behavioral symptoms in multiple sclerosis (MS) is particularly difficult because one of the hallmark symptoms of MS is the variability within patients across time. In addition, there is significant variation between patients with MS, Charcot (1877) and Surridge (1969) noted that many patients with MS show dissociation between subjective mood state and outward affect.

Deptession. Depression is the most common behavioral symptom in MS, with rates of 37-54%. Up to one half of patients with MS with depression experienced periods of depression before disease onset. Patients with MS may report symptoms of depression even with outward signs of euphotia. In addition, a large proportion (73%) of individuals with MS report difficulty in controlling their emotions and incteased irritability (57%) (Fcinstein and Feinstein 2001),

Although tesearch has suggested that a family history of deptession of alcoholism is mote common in patients with MS with depression, more recent studies suggest that this relationship does not hold. Depression in MS is *not* associated with increased rates of stressful events, disease duration, type of MS, age, gender, or socioeconomic status.

A psychological cause of deptession in MS has been proposed, which suggests that depression is a result of ftustration with progressive disability and uncertainty regarding the future. Although some studies have noted a relationship between depression and increased disability in MS, others have failed to replicate these findings. Depression in MS is more common in patients experiencing an exacerbation of MS symptoms and increased feelings of uncertainty regarding the future, lending support to the psychosocial models of depression etiology.

Furthermore, patients with MS report highct rates of depression than patients with othet chronic disabling disorders. Imaging studies in MS, howevet, have failed to show clear neuropathological correlates of depression. Results have shown that depression in MS is associated with right parietal, right temporal, or right frontal involvement, implying disruption of ftontal-subcortical circuitry. In addition, diffetences have been noted in regional blood flow asymmetries in the limbic cortex among individuals with both MS and deptession. It is likely that depression in MS results ftom a combination of psychosocial and biological factors.

Some pharmacological interventions used in the treatment of MS may be associated with increased rates of depression. Although research results have been mixed, studies suggest that depression is a side effect for some individuals being treated with interferon-/!-1 b (IFN-/S-lb) (Feinstein 2000). Thus a consensus statement was put forth suggesting that patients with severe depression should be closely monitored while receiving IFN-^-lb, and SSRIs were suggested as the treatment of choice fot depression in MS.

The relationship between depression and other treatments of MS has received less attention. The association between depression and IFN-j8-la and interferon-a is equivocal, as conflicting results have been reported; glatiramer acetate has not been associated with increased depressive symptoms. Research has shown that the increased tates of depression apparent following tteatment with IFN-^-la may represent a return of pretreatment levels of depression. Thus physicians should take care to thoroughly assess patients' history of depression before beginning IFN interventions because patients with recent histotics of depression may be more likely to rc-cxperience symptoms of deptession after IFN treatment.

Anxiety. Anxiety often occurs in individuals with MS. Unfortunately, this symptom is often ovetlookcd because anxiety symptoms may be viewed as being solely associated with poor coping skills. Some strategies to minimize anxiety in individuals with MS ate described in Table 8.12. Clinically significant anxiety has been reported in 25% of individuals with MS recruited ftom a clinic; 9.2% of these individuals were also experiencing clinically significant symptoms of depression. Anxiety symptoms are more common in women with MS than in men with MS. The combination of anxiety and depressive symptoms was more strongly associated with somatic complaints, social difficulties, and suicidal ideation than either anxiety or depression alone.

Euphoria and Pathological Laughing and Crying. In contrast to other neurological disorders, increased rates of cheerfulness, optimism, denial of disability, and pathologic laughing are noted in MS. Early studies suggested that more than 70% of individuals with MS experienced periods of euphoria. However, more recent studies suggest that

Tabic 8.12: Strategies to minimize anxiety in patients with multiple sclerosis

Respect adaptive denial as a useful coping mechanism.
Provide referrals to the National Multiple Sclerosis Society (1-800-Fight-MS) early in disease.
Help patients to live "one day at a time," and restrict predictions regarding the future.
Help patients manage stress with relaxation techniques.
Involve occupational therapists for energy conservation techniques.
Focus on the patient's abilities, not disabilities.
Consider patient's educational and financial background when giving explanations and referrals.
Realize that patients have access to the Internet, self-help groups, and medical journals and may ask "difficult" questions.
Expect grief reactions to losses.
Deal with losses one at a time.
Attend to the mental health needs of the patients' families and caregivers.
Respect the patient's symptoms as real.
Avoid overmedicating.
Focus supportive psychotherapy on concrete, reality-based cognitive and educational issues related to multiple sclerosis.
Provide targeted pharmacotherapy.
Refer appropriate patients for cognitive remediation training.
Ask about sexual problems, as well as bowel and bladder dysfunction.
Keep an open dialogue with the patient about suicidal thoughts.

Source: Modified with permission from Riether. 1999, "Anxiety in patients with multiple sclerosis," *Seniin neuropsychiatry*, vol. 4, pp. 103-113.

prevalence rates for symptoms of euphoria are likely closer to 25%, although those for individuals with sustained petiods of elevated mood are closer to 10%. Individuals with euphoria are more likely to have cerebral involvement, enlarged ventricles, poorer cognitive and neurological function, and increased social disability.

A small (9.9%) but significant proportion of individuals with MS exhibit periods of pathological laughing and crying (PLC), the inability to control outbursts of laughter or crying. PLC is more common in patients with MS who have entered the chronic-progressive disease course and who have high levels of disability and cognitive dysfunction.

Amyotrophic Lateral Sclerosis

Little empirical research has assessed psychiatric or behavioral disturbances in individuals with amyotrophic lateral sclerosis (ALS). Some observations have noted that individuals with ALS exhibit unexpected cheerfulness and stoicism. One study employed a clinical interview to assess the prevalence of psychiatric disorders in individuals with ALS. This study showed that 11% of individuals with ALS met criteria for MDD (Ganzini et al, 1998). In a study assessing 56 patients with ALS, only 2% of their sample met criteria for MDD; however, 28% of their sample endorsed significant depressive symptoms (>13 on the Beck Depression Inventory). Depression in ALS is associated with increased physical impairment, although these results are not always replicated. Individuals with low psychologic well-being were at increased risk of mortality {Figure 8.10). Mortality risk was more strongly associated with psychological distress than age and similar to the association of risk associated with severity of illness.

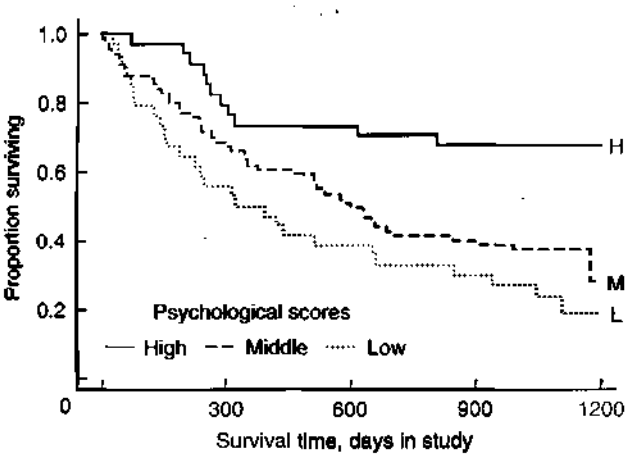

FIGURE 8.10 Psychological well-being and morbidity in amyotrophic lateral sclerosis. Note: High psychological well-being is associated with decreased morbidity. (Reprinted with permission from McDonald, E. R., Wiedenfeld, S., Hillel, A., et al. 1994, "Survival in amyotrophic lateral sclerosis: The role of psychological factors," *Arch Neurol*, vol. 51, pp. 17-23.)

Epilepsy

Behavioral and personality disturbances occur in up to 50% of individuals with epilepsy (Lambert and Robertson 1999; Torta and Keller 1999). Few adequate population-based studies have fully assessed the comorbidity of psychological disorders in individuals with epilepsy, so the prevalence estimates remain relatively crude. One of the largest population-based studies suggests that adults with childhood-onset epilepsy have a fourfold increased risk of having a psychiatric disorder when compared with controls.

Factors related to risk of psychiatric disturbance in patients with epilepsy may he separated into clinical, biological, and social factors. Some specific risk factors have been identified: additional brain injury, type and severity of epilepsy syndrome, and medication effects. Historically, behavioral disturbances were thought to be more severe in patients with temporal lobe epilepsy. Research suggests, however, that patients with any focal epilepsy tend to exhibit increased rates of psychiatric disturbances. In epilepsy, psychiatric disturbances may be associated with ictal, postictal, and/or interictal states (Table 8.13).

To facilitate understanding of the patient and for accurate treatment of symptoms, we must recognize that behavioral and personality disturbances can occur during the ictal state. Individuals in the ictal period may experience episodes of anxiety, depression, psychosis, and aggression. Similarly, patients with epilepsy may report mood disturbances

Table 8.13: Psychiatric disturbances in ictal, postictal, and interictal states

ictal	*Postictal*	*Interictal*
A n \ ion-	Confusion	Major depression
Intense feelings of horror	Depression	Adjustment disorders
Panic attacks	Agitation	Dysthymic disorder
Depressed mood	Paranoia	Atypical depressive syndromes
Tearfulness	Hallucinations	Med ica ti o n - i n d u c ed mood changes
Sexual excitement	Mania	Panic disorder
Paranoia	Aggression/ violence	Generalized anxiety disorder
Hallucinations		Obsessive-compulsive disorder
Illusions		l'hobias
Laughter		Conversion disorder
Forced thoughts resembling obsessions		Medication-induced conditions
Obsessions		Psychotic syndromes
Deja vu and other memory experiences		Aggress ion/violence
Confusion		
Aggression/violence

immediately before or after an ictal period. Much of the discussion regarding psychiatric disturbances in epilepsy focused on interictal behavioral and personality disturbances; thus these disturbances arc the focus of this section.

Depression

Depression is the most common psychiatric disorder in epilepsy. Prevalence rates are widely varying with reports of 8-63% of individuals with epilepsy experiencing depression. Rates of depression vary as a function of the sample assessed (clinical samples report higher rates of depression than population samples) and measures used to diagnosis depression.

Deptcssion often goes undiagnosed in patients with epilepsy because symptoms of depression may be viewed as a normal reaction to illness. However, accurate diagnosis of depression is critical because depression is associated with decreased quality of life. Depression in patients with epilepsy typically presents differently than in individuals with MDD alone. Depression in epilepsy is associated with fewer "neurotic" traits such as anxiety, rumination, low self-esteem, and somatization than typically observed in MDD. In conttast, depression in epilepsy is associated with more "psychotic" traits, such as paranoia, delusions, and hallucinations, than in MDD. Depression in epilepsy typically runs a chronic course, with periods of major depression separated by periods of dysthymic mood.

Attempted and completed suicides are common in epilepsy. The suicide rate in epilepsy is four times that of the general population. Rates of suicide are even higher in temporal lobe epilepsy (25 times that of the general population). Risk factors include history of self-harm, family history of suicide, stressful life situations, poot morale, stigma, and psychiatric disorders.

The cause of depression in epilepsy is unclear. Psychosocial stressors, genetic disposition, and neuropathology all likely play a contributing role. Although psychosocial stressors have been suggested as important in the cause of depression in epilepsy, observed rates of depression in epilepsy are higher than those in other chronically ill patient populations, lending support to theories of biologic etiology. Although few studies have assessed the relationship between depression and gender, most of these studies suggest that men with epilepsy ate at a higher risk of developing depression than women with epilepsy. Though results are somewhat mixed, there appears to be no relationship between age at onset or duration of epilepsy and depression. Depression appears to be more common in individuals with focal epilepsy than in those with primarily generalized epilepsy. Lateralization of seizure foci may be related to depression, with left-sided foci more commonly associated with depression.

Pharmacological treatment of epilepsy may contribute to depression and psychiatric symptoms in general. Table 8.14 notes commonly used antiepileptic drugs and their psychotropic effects. Medications associated with sedation (e.g., barbiturates and benzodiazepines) may lead to depression, fatigue, and mental slowing. Approximately 8-10% of patients with epilepsy experience an episode of depression following epilepsy surgery. These episodes tend to remit within 18 months of surgery. Increased mood lability and irritation are also common occurrences in the month following epilepsy surgery.

Tabic 8.14: Psychotropic effects of antiepileptic drugs

	Pmitine effects	*Negative effects*	*Complications*
Barbiturates, primidone	—	Aggression, depression, Withdrawal syndromes	ADHD in children
Benzodiazepines	Anxiolytic, sedative	Withdrawal syndromes	Disinhibition
I'tliDsuximide		Insomnia	Alternative psychoses
Phenytoin	—		Toxic schizophreniform psychoses, encephalopathy
Carbamazepine	Mood stabilizing, impulse control	Rarely mania and depression,	
Valproate	Mood stabilizing, anr/imamc		Acute and chronic encephalopathy
Vigabatrin		Aggression, depression, psychosis, withdrawal syndromes	ADHD, encephalopathy, alternative psychoses
Lamuirigini	Mood stabilizing, a nti depressive	Insomnia	Rarely psychoses
Felbamate	Stimulating?	Agitation	Psychoses possible
Gabapenrin	Anxiolytic, antidepressive?	Rarely aggression in children	
Tiagabine		Depression	Nonconvulsive status epilepticus
Top ira mate	Mood stabilizing?	Depression	Psychoses
Levetiraceram

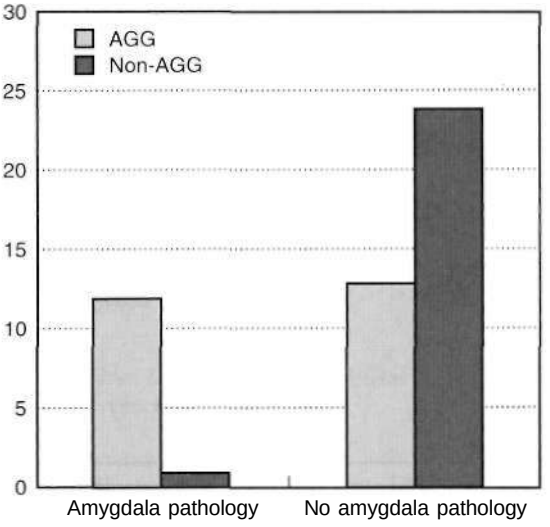
Although the phenomenology of depression in epilepsy may prove dissimilar from that in general patients with depression, similar treatments are efficacious in the treatment of depression. Supportive psychotherapy may prove beneficial, particularly after initial diagnosis as patients begin to adapl to rheii illness. 'Xiiiideprcssani medications are largely effective in the treatment of depression in the general population. However, few clinical trials have assessed the efficacy of antidepressant medications in patients with epilepsy. Older antidepressants and the antidepressant bupropion have been associated with increased seizures and thus should be avoided. SSRLs were reportedly also associated with increased seizures in early reports; however, newer research suggests that these antidepressants are less strongly associated with seizures than previously believed.

Psychosis

The association between epilepsy and psychosis has been debated throughout the past century. In 1931, Kracpelin noted an increased incidence of seizures in individuals with dementia praecox. More recent studies have suggested that 0.6-7,0% of individuals with epilepsy also exhibit psychotic symptoms (Torta and Keller 1999). individuals with epilepsy onset before age 20 years, duration of illness of greater than 10 years, history of complex partial seizures, and temporal lobe epilepsy are at increased risk of psychotic disturbances (Torta and Keller 1999). Epileptic patients with psychosis may experience exacerbations of their psychoses following epilepsy surgery, and it is unlikely that successful epilepsy surgery will result in complete cessation of psychoses. In addition, new psychotic disturbances appear after approximately 3.8-35.7% of temporal lobectomies. These new episodes occur more often with resections of the nondominant hemisphere and in patients with pre-existing personality disorders.

Aggression

The relationship between epilepsy and aggression remains controversial. Early research suggested that the prevalence of aggression in epilepsy ranged from 4.8-50.0%. Though controversial, rates of aggression are believed to be higher in individuals with temporal lobe epilepsy. Results vary because of definition of aggression and method of group selection. Interictal aggression may be described as episodic dyscontrol or, as in *Diagnostic and Statistical Manual of Mental Disorders,* fourth edition *(DSM-IV),* nosology, intermittent explosive disorder (IED), which is characterized by periods of largely unprovoked anger, rage, severe aggression, and violent behavior. Hippocampal sclerosis is less common in individuals with epilepsy and aggression. Aggression in epilepsy is associated with increased temporal lobe pathology. A subgroup of individuals with epilepsy and aggression had significant amygdala atrophy (Figure 8.11).



FIGURF, 8.11 Amygdala pathology in patients with temporal lobe epilepsy with and without aggression, Agg = aggrcssion. (Reprinted with permission from van Elsr, L. Tebartz, 2002, "A)',!',ivssiii]i and epilepsy," in *The Neuropsychiatry of Epilepsy,* eds M. Trimble *St* B. Schmitz, Cambridge University Press, Cambridge, U.K.)

Stroke

Defyression

Within the first year following a stroke, 30^40% of patients experience depression, with most developing depression within the first month post-stroke (Ballard and O'Brien 2002). Approximately 20% of patients will be diagnosed with major depression and another 20% will be diagnosed with minor depression. Depression following stroke is associated with age, time since stroke, cognitive impairment, social support, neuroticism, and history of depression.

Depression is associated with longer hospital stays, suggesting that it affects rehabilitation efforts. Depression is associated with poorer recovery of activities of daily living and increased morbidity (Figure 8.12). Studies assessing the relationship between disability and depression in stroke patients have been equivocal. Depression is associated with poorer quality of life in individuals who have had a stroke, even when neurological symptoms and disability ate held constant.

The relationship between depression and lesion location has been the focus of significant research and controversy. In 1982, Robinson and Price followed 103 individuals for 2 years following stroke and noted that left anterior lesions were associated with increased rates and severity of depression. Lesions nearer the left frontal pole or left caudate nucleus were associated with increased rates of depression. Some have replicated these findings, but others have failed to do so. A meta-analysis by Carson et al. (2000) assessed the relationship between lesion location and depression in post-stroke patients. This review noted that there is significant heterogeneity m previous studies,

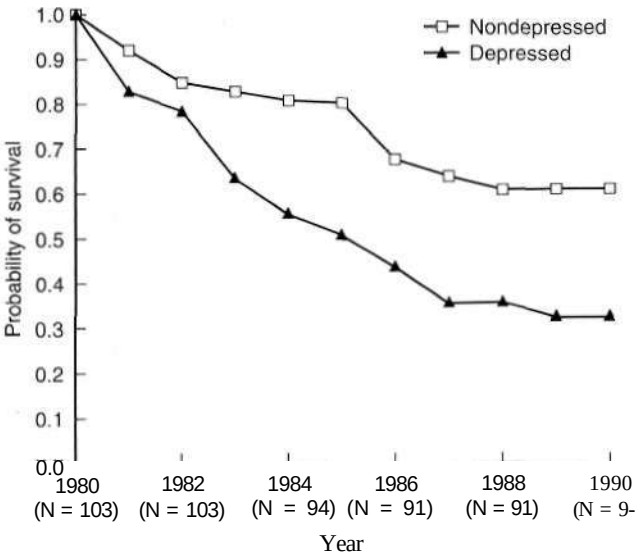


FIGURE 8.(2 Probability of survival following stroke for depressed and nondepressed patients. (Reprinred with permission from Morris, P. L. P., Robinson, R. G., Androzejewski, P., et al. 1993, "Association of depression with 10-year postsrroke mortality," *Am j Psychiatry,* vol. 49, pp. 11-33.)

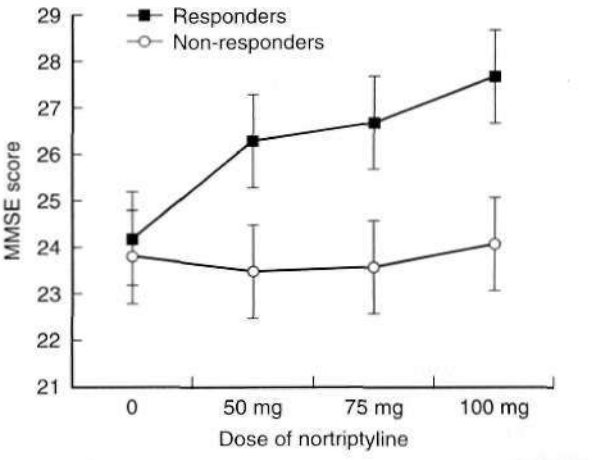

FIGURE 8.13 Mini-Mental Stare examination score with response to nortriptyline in stroke patients. Note: Treatment responders (n—13) show significantly greater improvement in cognitive function than n on responders (n=!8) (/? = .087). F.rmr bars represent standard errors of the mean. (Reprinted with permission from Kimura, M., Robinson, R. G., & Kosier, F. T. 2000, "Treatment of cognitive impairment after poststroke depression; A double-blind treatment trial," *Stroke,* vol. 31, pp. 1482-1486.)

particularly between different sample sources. Results of this meta-analysis did not support an overall relationship between left frontal lesions and depression following stroke.

The relationship between lesion location and depression in 60 patients followed for approximately 2 years post-stroke has been studied (Shimoda and Robinson 1999). Shimoda and Robinson (1999) noted that left-sided lesions closer to the frontal pole were associated with depression in hospitalized patients immediately following stroke. Depression was correlated with nearness of lesion to the frontal pole in either the right or rhe left hemisphere at approximately 4 months post-stroke. At 1-2 years post-stroke, depression was associated with nearness of lesion to the frontal pole in the right hemisphere. In addition, the authors noted that depression in short-term and long-term follow-up was associated with lesion volume and functional impairment. This heterogeneity in relationship between lesion location and depression may explain some of the divergent tesults reported in the literature.

Few studies have assessed the effectiveness of various treatments for depression in these patients. One study suggests that nortriptyline was more effective in the treatment of depression than cither placebo or fluoxetine (Robinson and Schultz 2000). Response to treatment of depression with nortriptyline is associated with improvement in cognitive and functional abilities. The relationship between MMSE score and response to nortriptyline is displayed in Figure 8.13,

Emotional Incontinence

A portion of individuals who are post-stroke experience emotional incontinence, that is, pathological laughing or crying (PLC) not under their control. Between 11% and 35% of individuals experience emotional incontinence after stroke. Emotional incontinence is associated with lesions of the frontal lobe, pons, and medulla, as well as cognitive dysfunction. Although no clinical trials have assessed treatments for pathological laughing or crying, case studies described patients effectively treated for pathological crying with paroxetine.

Aggression

Reports have suggested that individuals have difficulty controlling aggression and anger following a stroke. Approximately 32% of stroke patients experience inability to control anger or aggression (Kim et al. 2002). Many of those individuals (23%) exhibited anger or aggression without provocation. Inability to control anger or aggression was associated with increased motor dysfunction and dysarthria. Although sample six.c in the Kim et al. (2002) study was small, results suggest that lesions in the area supplied by the subcortical middle cerebral artery arc associated with inability to control anger or aggression.

Anxiety

Though less studied, anxiety disorders arc also common after stroke. Approximately 27% of individuals met criteria for GAD following stroke, which does not decrease in frequency within 3 years following stroke. In addition, a twofold increase in panic disorder post-srroke has been noted. Anxiety is associated with increased disability.

Traumatic Brain Injury

Significant behavioral and psychiatric disturbances are noted in individuals following TBI (Table 8.15). Rao and Lyketsos (2002) provide a comprehensive summary of recent literature regarding psychiatric symptoms following brain injury. Physical disabilities associated with TBI typically stabilize with time; however, mood and behavioral changes tend to become more disabling in years following TBI. Psychiatric disturbances remain elevated for decades following injury (Koponen ct ah 2002). Behavioral or mood disturbances are associated with decreased quality of life, increased caregiver burden, and more challenges to the treating physician. Overall, psychiatric disturbances following TBI are more common in individuals with a history of psychiatric illness, poor social functioning, alcoholism, arteriosclerosis, lower MMSE score, and fewer years of education.

Depression

Between 6% and 77% of individuals with TBI meet criteria for MDD following injury {Rao and Lyketsos 2002). Within the first year following TBI, approximately 26% of individuals meet criteria for MDD. Diagnosis of depression in TBI is complicated, because symptoms of depression (e.g., fatigue and sleep disturbances) are common symptoms following TBI. In addition, rates of depression in TBI vary as a function of severity of TBI assessed, method of depression diagnosis, and sample source. Early onset symptoms of depression are believed to be associated with distuption of brain circuitry, whereas persistent depression in TBI is theorized to he associated with psychological reaction to injury. Early onset depression is associated with left dorsolateral frontal or left basal ganglia lesions (1-3 months post-TBI), but late-onset depression is not. Although no large-scale clinical trials have been conducted, case studies suggest SSRIs, psychostimulants, and electroconvulsive therapy are effective treatments for depression in TBI.

Suicidal ideation (65%) and attempts (8.1%) are common following TBI. In contrast to sex differences reported in the general population, women with a TBI are more likely to commit suicide than men with a TBI. Furthermore, suicide was more common in individuals with more severe injury and those younger than 21 years or older than 60 years at the time of injury.

Anxiety

Less research has assessed the prevalence of anxiety disorders in TBI; however, studies suggest that 11-70% of individuals meet criteria for anxiety. A meta-analysis suggested that the mean prevalence of anxiety disorders following TBI is 29%. Panic disorder occurs in 3.2-9.0% of individuals with a TBI. Case studies suggest that SSRIs, naltrexone, and buspirone are effective in the treatment of anxiety in TBI.

Psychosis

Between 2% and 20% of patients post-TBI report psychotic symptoms (Rao and Lyketsos 2002), Psychosis following TBI is associated with severe closed-head injury, temporal lobe epilepsy, and head injury before adolescence.

Behavioral Dyscontrol Disorder

Behavioral dyscontrol disorder is characterized by disturbance in mood, behavior, and cognition (Rao and Lyketsos 2002). Some have considered this disorder consisting of two variants, major and minor. The major variant, which is present in 11-98% of individuals with TBI, is associated with agitation, impulsive behavior, and aggressive outbursts. Individuals with this syndrome often have very little insight into these difficulties. This syndrome is associated with lesions to the frontotcmporal regions.

An area of controversy in the behavioral disturbances following TBI is the existence of the minor variant of behavioral dyscontrol disorder, also called *postcancussian syndrome.* This syndrome is characterized by mood, cognitive, and somatic symptoms typically following mild TBI. Between 80% and 100% of individuals who experience a mild closed-head injury report some or all of the described symptoms of postconcussion syndrome. These symptoms typically resolve within *2-6* months after TBI; however, a small portion (15%) of individuals report symptoms 1 year following TBI.

Table 8.15: Lifetime prevalence of major psychiatric disorders by head injury status from the New Haven Epidemiologic Catchment Area Study (n = 5034)

	Head injury (%)	No *head injury* ***(%)***
Major depression (n = 242)	11.1	*S.I*
Dysthymia (n = 172)	5.5	*13*

Apathy

Symptoms of apathy are reported in 10-60% of individuals with a TBI. Apathy in TBI is associated with depressive symptoms, although a significant number of individuals (28%) report experiencing apathy, but not depression. Lesions effecting the right hemisphere and subcortical regions are more strongly associated with apathy than lesions affecting the left hemisphere.

Personality Change

The classic case of Phineas Gage is used to exemplify the frank behavioral changes that can follow TBI, particularly when lesions affect the orbito fronts I cortices. This behavioral syndrome has been called the *pseudopsychopathic syndrome.* Facctiousness, irritability, distractibility, impulsivity, sexual disinhibition, inappropriate social and personal behavior, and little concern for others characrerize this syndrome.

Chapter 9
Depression and Psychosis in Neurological Practice

John A. Bertelson and Bruce H. Price

Conditions primarily characterized by behavioral disturbances have traditionally been considered to be poorly understood and of little interest or relevance to most neurologists. However, the recent explosion of knowledge in basic and clinical neuroscience has led to an increased understanding of the underlying biology of behavior, These disturbances are now recognized as integral features, if not presenting symptoms, of many neurological disorders. The development of fields such as cognitive/behavioral neurology and neuropsychiatry has emphasized the existence of a shared body of knowledge and has encouraged collaboration and complementary approaches.

PRINCIPLES AND COMPLEXITIES OF DIFFERENTIAL DIAGNOSIS

The neurological investigation of psychiatric symptoms requires a paradigmatic shift from traditional neurological thinking. It presents challenges not ordinarily encountered in other neurological consultations. Guiding principles include the following:

1. Depression, mania, delusions, hallucinations, obsessions and compulsions, dissociation, and personality alterations are etiologically nonspecific symptoms. They are common in both primary neurological and psychiatric disease.
2. Persistent behavioral sequelae are often more disabling to the patient's personal and professional lives than elemental or cognitive neurological deficits.
3. Atypical presentations of neuropsychiatric syndromes are common. No single feature is present in all forms of neurological disease with behavioral disorders.
4. Disturbances of frontal, temporal, limbic, and striatal regions are most likely to produce psychiatric manifestations.

Considerable complexities must be taken into account as well.

1. A comprehensive assessment of mental status and elemental neurological examination may be impossible in the setting of agitation or psychosis.
2. A patient's decompensated behavior may be concordant with the past psychiatric profile. However, this concordance does not necessarily imply that decompensation is psychiatric in nature.
3. Normal findings on elemental examination, routine laboratory testing, brain imaging, electroencephalography, and cerebral spinal fluid analysis do not necessarily exclude diseases of neurological origin.
4. Psychopharmacologic medications often complicate the neurological picture.
5. Beneficial responses to neuroleptics, antidepressants, or even electroconvulsive therapy do not necessarily point to a specific disease or narrow the differential diagnosis.

DEFINITIONS OF PSYCHIATRIC TERMS

The increasing collaboration between neurology and psychiatry necessitates a shared vocabulary. Specific

Table 9.1: Key psychiatric terms of relevance to neurologists

Abulia is the state of reduced impulse to act and think associated with indifference about consequences of action.

Anxiety is the feeling of apprehension caused by anticipation of danger that may be internal or external,

Apathy is dulled emotional tone associated with detachment Of indifference.

Comportment refers to complex mental processes that include insight, judgment, self-awareness, empathy, and social adaptation.

Compulsion is the pathologic need to act on an impulse that, if resisted, produces anxiety. The action has no true end in itself other than to prevent something from occurring in rhe future.

Confusion is the inability to maintain a coherent stream of thought due to impaired attention and vigilance. Secondary deficits in
language, memory, and visual spatial skills are common.

Delusion is a false, unshakable conviction or judgment that is out of keeping with reality and with socially shared beliefs of the individual's background and culture.

Dementia is the insidious onset of progressive mental decline that gradually interferes with activities of daily living appropriate for age and background.

Depression is a sustained psycho pathologic feeling of sadness often accompanied by a variety of associated symptoms, particularly anxiety, agitation, feelings of worth lessn ess, suicidal ideas, abulia, psychomotor retardation, and various somatic symptoms and physiologic dysfunctions and complaints that cause significant distress and impairment in social functioning.

Hallucination is a sensory misperceprion in any modality occurring in the absence of the appropriate external stimulus.

Mania is a disorder in which mood is elevated out of keeping with the individual's circumstances. It may vary from irritability to carefree joviality to almost uncontrollable excitement. Elation is accompanied by increased energy, difficulties sustaining attention, marked distractibility, and impaired judgment. Self-esteem is often inflated with grandiose ideas.

Obsession is the pathologic persistence of an irresistible thought or feeling that cannot be eliminated from consciousness by logical effort despite the individual's knowledge that it is not true. It is associated with anxiety and rumination.

Paranoia is a descriptive term designating either morbid dominant ideas or delusions of self-reference concerning one or more of several themes, most commonly persecution, love, hate, envy, jealousy, honor, litigation, grandeur, or the supernatural.

Psychosis is a gross disorder of perception and thought. It is the misapprehension of the nature of reality.

Schizophrenia is a disorder characterized by fundamental and characteristic distortions of thinking and perception accompanied by an affect that is inappropriate or blunted, while clear consciousness and intellectual capacity are usually maintained. Although no strictly pathognomonic symptoms can be identified, the most important positive psychopathologic phenomena include thought echo, insertion, withdrawal, or broadcasting; delusions of control, influence, or passivity; perceptions of hallucinatory voices commenting on or discussing the patient in the third person; and disorders in the train of thought. Negative symptoms include poverty in quantity or con rent of speech; impairment of attention; psychomotor slowing; affective blunting; apathy; social withdrawal; and poor nonverbal communi carion, self-care, and social performance.

psychiatric terms which should be incorporated into a neurologist's practice are presented in Table 9.1 {See *DSM 1V-TR* 2000, for further details).

NEUROANATOMY OF AFFECTIVE **AND** PSYCHOTIC DISORDERS

The specific anatomic substrates of neuropsychiatric symptoms are less well understood than the more elemental aspects of neurology. The clinical heterogeneity of neuropsychiatric symptoms arising from similar focal lesions, the difficulty of measuring neuropsychiatric symptoms, and the bilateral otigin of many of these symptoms are complicating factots. However, given that the nature of the symptoms genetatcd is often more dependent upon the location of a lesion than the actual pathology, a brief review of the anatomy of behavior is useful.

The human cortex can be divided into five functional levels: primary sensory-motor, unimodal association, heteromodal association, paralimbic, and limbic cortices. The general cytoarchitectural trend is one of less organization (limbic cortex) to greater organization (primary cortex). Primary sensory-motor cortex is involved in the processing of direct interactions with extrapersonal space and is not believed to significantly contribute to complex emotional Of cognitive states. Unimodal association cortices provide modality specific, higher-order processing and relay of information between their adjacent primary sensory-mo tor cortices. Lesions at this level can produce selective perceptual deficits such as "pure word deafness," prosopagnosia, and achromatopsia. Heteromodal cortex, which includes prefrontal, lateral temporal, posterior parietal, and portions of parahippocampal cortices, has a widespread pattern of connectivity throughout the brain. Tasks mediated by heteromodal correx are extremely diverse, but include complex cognitive functions and behaviors such as motivation, attention, and problem-solving. Paralimbic cortex, consisting of the orbitofrontal cortex, insula, tempotal pole, patahippocampal cortex, and cingulate complex, is a key transition between limbic cortex and isocortcx. Anatomically, it forms a belt of tissue between limbic and heteromodal regions. Functionally, it serves a transitional role, merging cognitive, emotional, and visceral states. Limbic cortex consists of poorly laminated corticoid structures such as the amygdala and

Table 9,2: Cortical and subcortical structures implicated in selected psychiatric symptoms

	Thalamus	

substantia innominata, as well as allocortical structures such as the hippocampus. In addition to the significant connections to the hypothalamus and the "internal milieu" it subserves, limbic structures play a key role in memory, emotion, and drive.

The generation of aberrant behavior can occur in structures ranging from the brainstem to the prefrontal cortex. Table 9.2 presents a partial listing of structures that have been associated with specific psychiatric symptoms. Although attempts to detetmine absolute rules regarding behavior and lesion localization have proven difficult, observations have led to a number of widely accepted generalizations. The majority of studies suggest a greater incidence of post-stroke depression (PSD) with left prefrontal infarcts, whereas right prefrontal strokes are more likely to he associated with mania. There is an association between selective right hemisphere dysfunction and delusions, hallucinations, and impaired emotional communication. Disorders with predominant subcortical pathology can disrupt the connections of hehaviorally relevant frontal networks and are commonly associated with a variety of mood disorders and psychotic symptoms. Subcortical nuclei with particular behavioral relevance include the caudate nucleus, nucleus accumbens, and the ventral anterior and dorsomedial thalamic nuclei. Huntington's disease is a prototypical subcortical disease, where depression and psychosis are not only very common late in the disease, but may precede the onset of chorea and other abnormal movements by years. The disproportionate incidence of depression and psychosis in multiple sclerosis demonstrates the contribution of white matter to the pathogenesis of neuropsychiatry symptoms. **Finally,** there is evidence that midline cerebellar lesions are associated with abnormalities in the modulation of affect and cognition.

CLINICAL SYMPTOMS AND SIGNS SUGGESTING NEUROLOGICAL DISEASE

It is clear that ;s variety of neurological disorders can produce psychiatric symptoms. It is also clear that not every patient who carries a psychiatric diagnosis requires a neurological evaluation. However, both neurologists and psychiatrists should be aware of components of **the** history or physical examination that raise suspicion for the presence of an underlying neurological disease. Table 9.3 presents features from the medical history that suggest potential neurological etiologies of psychiatric symptoms. Table 9.4 reviews abnormalities in the elemental neurological examination associated with diseases that can manifest significant neuropsychiarric features.

Table 9.3: Historical features suggesting neurological disease in patients with psychiatric symptoms

- Patient has atypical psychiatric features:
  - Late age of onset with no prior psychiatric history
  - Acute or subacute onset
  - Lack of significant psychosocial stressors
  - Catatonia
  - Diminished comportment
  - Cognitive decline
  - Intractability despite adequate therapy
  - Progressive symptoms
- History of present illness includes:
  - New or worsening headache
  - Inattention
  - Somnolence
  - Incontinence
  - Anorexia
  - Neuroendocrine changes
- Patient has a history of:
  - Risk factors for cerebrovascular disease
  - Malignancy
  - Immune-compromised state
  - Significant head trauma
  - Seizures
  - Movement disorder
  - Hepatobiliary disorders
  - Abdominal crises (without known cause) and surgeries
  - Multiple first-degree relatives with similar diseases
- Patient has unexplained diagnostic abnormalities, including:
  - Screening laboratory studies
  - Electroencephalogram
  - Magnetic resonance imaging
  - Cerebrospinal fluid

PSYCHIATRIC MANIFESTATIONS OF NEUROLOGICAL DISEASES

Depression, the most common major psychiatric complication of neurological disease, and psychosis arc hut two of a myriad of psychiatric symptoms encountered in neurological practice. Virtually any abnormal process affecting the neuroanatomy substrates cited previously may have associated psychiatric symptoms at some point in its natural history. A sampling of specific diseases is presented in Table *9.5.* Psychiatric manifestations may be the initial and most salient symptoms of these disorders, preceding the

neurological symptoms by years or even decades in some degenerative diseases. A discussion of selected neurological diseases and their psychiatric manifestations follows. Disease-specific diagnostic investigations and therapeutic interventions are beyond the scope of this chapter and are covered elsewhere in this text.

Vascular

Stroke

Because it is the leading cause of neurological disability in the United States, the public health impact of cerebrovascular disease is profound. Unfortunately, the relatively frequent cognitive and behavioral manifestations of stroke are often under-appreciated. PSD occurs in .30-50% of stroke survivors, but is estimated to be under-diagnosed by nonpsychiatrists in more than 50% of cases. It is a misconception that depression is merely a normal psychological reaction to a devastating physical impairment; there appears to be a higher incidence of depression in stroke survivors than other patients with equally debilitating diseases. Middle cerebral artery, anterior cerebral artery, and subcortical lacunar strokes appear particularly prone In producing PSD. The greatest incidence of depression occurs in the first few months following infarction, Esta Wishing a diagnosis of PSD can be especially challenging. Patients with strokes, particularly those affecting the frontal lobe of the dominant hemisphere, may become depressed but (due to aphasia) lack the ability to verbally express their symptoms. In contrast, nondominant hemisphere infarctions can result in speech devoid of emotional expression (affective aprosody) but the patients may remain euthymic. These scenarios highlight the importance of observing for depressive behaviors, including abnormal sleep and eating patterns, anhedonia, fatigue, tearfulness, and social withdrawal. Features of obsessive compulsive disorder have also been associated with strokes, particularly stroke involving the caudate nucleus {Kwak and Jankovic 2002). Currently, the standard therapy of PSD remains pharmacology and supportive psychotherapy. Improvement in symptoms is usually observed 2-6 weeks following initiation of treatment with antidepressants.

Although much less common than PSD, mania and psychosis are known sequelae of stroke. Infarcrs in the right hemisphere, particularly the frontal, temporal, and parietal lobes, more often result in psychosis than left hemisphere strokes. Peduncular hallucinations are vivid visual hallucinations that can occur in ventral midbrain infarctions. Psychotic episodes can be the manifestations of complex partial seizures secondary to strokes; patients with poststroke psychosis are observed to be more prone to have comorbid epilepsy than are stroke survivors without psychosis. The psychosis may partially respond to anticonvulsants, whether or not overt seizures have been identified.

Multi-infarct Dementia

In addition to occurring secondary to a single stroke, neuropsychiatric symptoms often occur in the setting of multi-infarct dementia. Such patients generally have suffered multiple strokes in a variety of cortical or subcortical locations, resulting in impaired cognition. Generally, elemental neurological deficits arc seen, including visual field deficits, hemiparesis, or hemi-neglect. The presence of depression and psychosis is likely dependent upon the locations of infarcts. Bilateral fronto-temporal lobes, subcortical nuclei such as the caudate and puramen, and the interconnecting white matter are associated with an increased risk of psychotic and depressive symptoms.

Infectious

Acquired Immunodeficiency Syndrome

In addition to the effects of opportunistic infections and malignancies on behavior in patients with acquired immunodeficiency syndrome (AIDS), there are direct neurotoxic effects of the human immunodeficiency virus (HIV) itself. HIV-associatcd dementia (HAD, also known as the AIDS dementia complex and subacute encephalitis) is the AlDS-defimng illness in up to 10% of patients with HIV. Relevant pathologic changes may be present at autopsy in more than 50% of patients. The usual clinical presentation is that of a subcortical dementia, with bradyphrenia, apathy, memory decline, and impaired concentration. Autopsy studies demonstrate a concentration of viral load in the basal ganglia and hypothalamus. Elevated HIV ribonucleic acid (RNA) levels and reduced C1D4 counts are associated with a progressive!) increasing risk of developing HAD, with significantly increased risks with HIV RNA levels > 3000 copics/cc and CD4 <500 cells/mm . The development of HAD is a poor prognostic sign, with a median time to death of & months after onset.

Psychiatric manifestations are common in HAD, Delusions, hallucinations, anxiety, depression, apathy, emotional lability, and mania arc frequently encountered.

These symptoms tend to become more severe as the dementia progresses. Observational studies of the specific clinical presentations are complicated by frequent comorbidities of substance abuse and/or prior psychiatric diagnoses. In addition to therapy with antidepressants and antipsychotics, psychostimulants such as merhylphcnidare have demonstrated efficacy in treating various symptoms of depression.

Creutzfeldt-Jakob Disease

Sporadic Creutzfcldt-Jakob disease (sCJD) is the prototypical prion disease. It is a rare, rapidly progressive disorder of behavior, cognition, and motor function. Cognitive (especially short-term memory) and cerebellar difficulties are common initial symptoms. However, there are case reports of psychiatric manifestations, including hallucinations and delusions, preceding the typical motor signs. Depression, anxiety, and othet psychiatric symptoms generally become more prominent as the dementia progresses. New variant CJD (nvCJD) is a distinct entity from sCJD and was first reported in 1996. Since then, more than 100 cases have been documented. Unlike sCJD, nvCJD typically presents in much younger patients and with more prominent psychiatric manifestations. Spencer et al. reported that 63% demonstrated purely psychiatric symptoms at onset (i.e., dysphoria, anxiety, anhedonia), 15% had purely neurological symptoms, and 22% had features of both. Median duration of illness was 13 months, and by time of death, prominent neurological and psychiatric manifestations were universal. Delusions, hallucinations, and depressive symptoms occurred in a significant percentage of patients, as presented in Tabic 9.6.

Neurosyphilis

With the recent AIDS epidemic, there has been a resurgence of neurosyphilis, which had become rare in the industrialized world following the advent of antibiotics. Neurosyphilis can occur at both early and late stages of infection. Early neurosyphilis, seen in the first weeks to years of infection, is primarily a meningitic process in which the parenchyma is not typically involved. Complications of chronic, granulomatous meningitis may include cranial neuropathies, hydrocephalus, and arteritis, which can lead to infarction. Cognitive and behavior changes can occur with early neurosyphilis; however, they are typically secondary to the complications of stroke or hydrocephalus. Late neurosyphilis occurs as tabes dorsal is, general paresis, or commonly a combination of the two. General paresis typically occurs with a latency of 10-20 years or more following primary infection. This form presents as a slowly progressive dementia, which may be accompanied by Argyll Robertson pupils, tremor, seizures, and dysarthria. Psychiatric manifestations, including mania, depression, and psychosis, rarely present before significant cognitive decline.

Tabic 9.6: Psychiatric symptoms associated with new variant Creutzfcldt-Jakob disease, according to frequency and latency following initial presentation of disease

Adapted from Spencer, M. D., Knight, R. S. G., 8c Will, R. G. 2002, "First hundred cases of variant Crcutzfeldt-Jakob disease: Retrospective case note review of early psychiatric and neurological features," BM/, vol. 324, pp. 1479-1482.

Metabolic

Essentially any metabolic derangement, if severe enough, can adversely affect behavior and cognition. In general, the systemic and neurological signs and symptoms arise before significant psychopathology develops. Metabolic disorders should remain within the differential diagnosis when confronted by patients with psychiatric symptoms.

Thyroid Disease

Hypothyroidism results from a deficiency in circulating thyroxine (T4). It can result from impaired function at the level of the hypothalamus (tertiary hypothyroidism), the anterior pituitary (secondary hypothyroidism), or the thyroid gland (primary hypothyroidism, the most common cause of hypothyroidism). Elemental neurological symptoms include ataxia, seizures, and cranial neuropathies. Cognitive and behavioral symptoms, which typically progress over weeks, are manifested by cognitive slowing, apathy, depression, psychosis, and dementia, Psychosis with hypothyroidism, commonly referred to as myxedema madness, typically presents with paranoid delusions and auditory hallucinations. It can be fatal if untreated. The dementia associated with hypothyroidism may not fully remit despite the return to a euthyroid state,

Hyperthyroidism may be due to a number of etiologies that produce increased serum T4. With mild hyperthyroidism, patients typically arc anxious, irritable, emotionally labile, rachycardic, and tremulous. When apathy and depression are present, the term *apathetic hyperthyroidism* is often used. Thyroid storm results from an abrupt elevation in T4, often provoked by a significant stress such as a surgery. It can be associated with fever, tachycardia, seizures, and coma; untreated, it is often fatal. Psychosis and paranoia frequently occur during thyroid storm; they are rare with milder hyperthyroidism, as is mania.

Hashimoto's encephalopathy is a rare disorder involving autoimmunity to thyroid peroxisomes. It is associated with the subacute onset of confusion, delirium, seizures, myoclonus, and tremulousness. Psychosis can be prominent. It is characterized by elevated antithyroid peroxisomal antibodies, an encephalopathy electroencephalogram (EEG), and elevated CSF protein. Importantly, levels of thyroid-stimulating hormone (TSH) can be normal in Hashimoto's encephalopathy. The psychiatric manifestations tend to resolve with treatment, which generally involves high-dose steroids.

Vitamin B12 and Folic Acid Deficiency

Vitamin B12 (cyanocobalamin) is present in substantial amounts in products such as meat, fish, eggs, and cheese. The daily dietary requirement is low and the accumulated storage in the liver is so high that a deficiency state due to inadequate dietary intake or absorption generally takes years to develop. The most common sign of vitamin B12 deficiency is macrocytic anemia. However, signs and symptoms attributed to the central nervous system (CNS) are diverse and can occur in the absence of anemia or macroeytosis. Furthermore, a normal serum cobalamin level does not exclude the possibility of a clinical deficiency. Serum homocysteine, which is elevated in more than 90% of vitamin B12 deficiency states, can verify clinical disease in the appropriate settings.

Subacute combined degeneration (SCD) refers to the combination of spinal cord and peripheral nerve pathology associated with vitamin Bi_2 deficiency. Patients often complain of unsteady gait and distal paresthesias; the examination may demonstrate evidence of posterior column, pyramidal tract, and peripheral nerve involvement. Cognitive, behavioral, and psychiatric manifestations can occur in isolation or together with rhe elemental signs and symptoms. Personality change, cognitive dysfunction, mania, depression, and psychosis have been reported. Prominent psychotic features include paranoid or religious delusions and auditory and visual hallucinations. Dementia is often comorbid with cobalamin deficiency; however, the causative association is unclear.

Folate deficiency can produce a clinical picture similar to cobalamin deficiency, although some report that folate deficiency tends to produce more depression whereas vitamin B12 deficiency rends to produce more psychosis. Elevated serum homocysteine is also seen with a functional folate deticieno slate. Repletion of folate, it comorbid vitamin B12 deficiency is not first corrected, can result in an acute exacerbation of the neuropsychiatry symptoms.

Acute Intermittent Porphyria

The porphyrias are caused by enzymatic defects in the heme biosynthetic pathway. Acute intermittent porphyria (AIP) is the most common type of porphyria reported in the United States. AIP follows an autosomal dominant pattern of inheritance and is due to a mutation in the gene for porphobilinogen (PBG) deaminase. The disease is characterized by artacks lasting days to weeks, with relatively normal function between attacks. The attacks may be spontaneous, but are typically precipitated by a variety of factors, such as medications (including anticonvulsants, tricyclic antidepressants, and oral contraceptives), infection, alcohol, pregnancy, and anesthesia.

Porphyric attacks are characterized by the clinical triad of abdominal pain, peripheral neuropathy, and neuropsychiatric manifestations. Abdominal pain is the most common symptom, may be associated with ileus, constipation, and diarrhea, and can result in surgical exploration if the diagnosis of AIP is unknown. The peripheral neuropathy is primarily axonal and preferentially affects motor nerves. Seizures may also be seen. A variety of cognitive and behavioral changes can occur, including depression,

hallucinations, delusions, anxiety, and confusion. However, it is rare for the neuropsychiatry symptoms to occur in the absence of peripheral nerve or abdominal complaints.

The diagnosis of AIP should be suspected in the context of a young adult with severe abdominal pain, psychosis, and weakness or paresthesias. During attacks, there is increased urinary excretion of porphyrin precursors, which may result in urine that is deep red or brown. The urine can appear normal between attacks; in these situations diagnosis can be confirmed by examining cultured erythrocytes or fibroblasts. There is no cure; patients require supportive measures during attacks, and at all times care must be taken to avoid precipitating further attacks.

Inflammatory

Systemic Lupus Erythematosus

Systemic lupus erythematosus (lupus, SEE) is a multisystem inflammatory disorder that affects all ages, although young females are at significantly elevated risk. CNS involvement is common, with clinical manifestations seen at some point during their disease course in up to 90% of patients. The criteria for neuropsychiatric lupus (CNS-SEE) require seizures or psychosis in the setting of lupus and the absence of other contributing factors. However, neurological involvement can be much more extensive, including headache, strokes, seizures, peripheral neuropathy, and chorea. Small infarctions are more common than large vessel strokes; infarcts often are subclinical and can occur secondary to local vasculitis, antiphospholipid antibody-mediated thrombosis, and cardiogenic embolization.

Neuropsychiatric symptoms are common and often episodic. Depression and anxiety each occur in approximately 25% of patients; psychosis is more rare and tends to occur in the context of acute confusional states. Many of the neuropsychiatric symptoms in lupus can also occur secondary to corticosteroid therapy, which may lead to significant dilemmas in management. Cognitive manifestations eventually occur in many patients, ranging from mild attcntional difficulties to dementia. Relevant laboratory investigations include antinuclear antibody titers (which arc positive in 95% of patients with SLE), double-stranded deoxyribonucleic acid (DNA) antibodies (anti-dsDNA), and antibodies to Smith nuclear antigen (anti-Sm). A false-positive RPR may occur. Advances in immunosuppression have resulted in improved morbidity and mortality.

Demyelinating

Multiple Sclerosis

Multiple sclerosis (MS) likely represents a heterogeneous group of disorders that produce focal areas of CNS demyelination. In general, there is relative preservation of axons, although significant neuronal loss can occur. It primarily affects the young, with a peak age of onset in the mid-twenties, and affects females more than males at a 2:1 ratio. It is characterized cither by attacks of neurological deficits with variable remittance or by a steady, progressive course of neurological decline. There is no known cure, although there arc several immuuomodulating agents that reduce the frequency of attacks and can slow the radiographic progression of disease.

Ncuropsychiarric manifestations of MS are common, likely occurring in at least 60% of patients at some point in their disease. More severe symptoms arc correlated with greater lesion burden. Depression arises in about 50%, whereas mania is rare. Suicide risk is reported to be 7.5 times that of an age-matched general population. Psychosis occurs in 5-10%, with manifestations including delusions and hallucinations. The presence of psychiatric symptomatology does not preclude the use of corticosteroids to abbreviate clinical attacks of MS. Otherwise, pharmacological and behavioral treatment mirrors the management of depressed and psychotic patients without MS.

Toxic

Drug Abuse

Psychoactive chemicals have been a part of human society for thousands of years. The abuse of such substances represents a substantial public health concern. Up to 20% of Americans will suffer from a substance abuse disorder at some point in their lives. Common neurological manifestations are broad and include the direct effects of intoxication (i.e., tcspiratory depression from sedatives), side effects (i.e., stroke or vasculitis with stimulant abuse), and indirect effects (i.e., traumatic brain injury sustained as a result of an intoxicated state). However, neuropsychiatric manifestations are much more prevalent, occur with abuse of all classes of drugs, and are summarized in Table 9.7. There is growing evidence that drug use may promote the development of chronic neuropsychiatric states such as depression and impaired cognition due to changes in structural and functional neuroanatomy. Routine urine and serum toxicology assays may not screen for some of the less common or newer substances of abuse, such as barbiturates and 3,4-methylenedioxymethamphetamiue (MDMA, "ecstasy").

Neoplastic

There arc a variety of neoplasm-related causes of cognitive and behavioral disorders. Of particular relevance are mass lesions and paraneoplastic syndromes. Mass lesions can be single or multiple and can be primary to the CNS or

Table 9.7; Potential behavioral and cognitive manifestations of substance abuse

Panic attacks	Attention
Anxiety	Calculation
Hallucinations	Executive tasks
Delusions	Memory
Mania	Fatigue
Depersonalization	Impulsivity
Disinhibition	Sedation

metastatic. Sources of common metastatic tumors include primary lung, breast, renal, and skin (melanoma) malignancies. The number of patients presenting with a primary psychiatric diagnosis secondary to an unidentified brain tumor is likely to be less than 5%. However, 15-20% of patients with intracranial tumors may present with neuropsychiatric manifestations before primary neurological problems, such as motor or sensory deficits, develop. The behavioral manifestations of mass lesions are diverse and are related to a number of factors, including direct disruption of local structures or circuits, seizures, and increased intracranial pressure. Meningiomas are classic examples of tumors that can present solely with behavioral manifestations. Common locations include the olfactory groove and sphenoid wings, which can disrupt adjacent limbic structures such as the orbital frontal gyri and medial temporal lobes.

Depression, mania, psychosis, personality disorder, and cognitive abnormalities have all been reported secondary to CNS mass lesions. Certain generalizations can be made about the behavioral manifestations of brain tumors. Supratentorial masses are more likely to produce neuropsychiatric symptoms than infratentorial lesions. Aggressive tumors are more likely to produce delirium, agitation, and psychosis, whereas indolent tumors are more likely to produce affective disorders and alterations in personality. Older patients are more likely to develop significant cognitive changes than young patients.

Paraneoplastic syndromes represent remote, nonmctastatic manifestations of malignancy. Neurological paraneoplastic syndromes are primarily immune-mediated disorders that may develop as a result of antigens shared between the nervous system and tumor cells.

The most common primary malignancies that promote neurological paraneoplastic syndromes are ovarian and small-cell lung carcinomas (SCLC). These syndromes generally develop subacutely, often before the primary malignancy is identified, and may preferentially involve selected regions of the CNS. Typical sites of involvement include muscle, neuromuscular junction, peripheral nerve, cerebellum, and limbic structures. When involvement is widespread, the term *encephalomyelitis* is used. Limbic encephalitis produces a significant amnestic syndrome and may be associated with complex partial and generalized seizures. Common neuropsychiatric accompaniments of limbic encephalitis include delirium, psychosis, apathy, personality change, and depression. Magnetic resonance imaging (MRI) may document increased T2 signal abnormalities in the medial temporal structures and cingulare gyri. Relevant paraneoplastic markers include anti-Hu antibodies, associated with SCLC, and anti-Ta (Ma2) antibodies, associated with testicular neoplasms. If a paraneoplastic syndrome is suspected before diagnosis of a malignancy, aggressive investigation to identify the suspected tumor should occur. Paraneoplastic disorders are often progressive and refractory to therapy, although in some cases there is significant improvement following complete tumor resection.

Degenerative

Neuropsychiatric symptoms are common in most degenerative disorders that produce significant dementia. The individual presentations of such symptoms are related to a number of factors specific to the disease, including location of lesion burden, rate of progression of disease, and factors specific to the individual such as premorbid personality, education level, psychiatric history, and coping skills. This section reviews the salient neuropsychiatric manifestations of selected degenerative disorders.

Alzheimer's Disease

Alzheimer's disease (AD) is the leading etiology of dementia in the elderly, with an estimated prevalence in the United States of more than 2 million patients. The natural history, pathology, and clinical features of AD are described elsewhere in this text.

Most patients with AD experience significant neuropsychiatric manifestations. Depressive symptoms occur in approximately 50% and there may be an increased risk of suicide. In addition, there is evidence that the onset of depression in the elderly is associated with an increased risk of developing AD, Psychosis is rarely the presenting symptom of AD. However, as the illness progresses, psychotic symptoms such as hallucinations and delusions become prevalent. Psychosis been noted to occur in 30-40% of patients with AD over the course of their disease, with a recurrence rate of more than 90%. Delusions tend to be paranoid in nature, and a variety of delusional themes have been reported. Hallucinations occur almost as frequently as delusions. Hallucinations are generally visual; less often they are auditory, and rarely do they involve other sensory systems. Data supporting a relationship between the degree of dementia and depression or psychosis are equivocal. Mania is rare, occurring in <5% of patients.

Personality and behavior changes are perhaps the most common neuropsychiatric manifestations of AD. Apathy is the most commonly reported behavioral change, but

irritability, aggression, and disinhibition are also often noted. Behavioral abnormalities, rather than depression or psychosis, appear to be the leading neuropsychiatrie-symptom resulting in admission to inpatient services. There is evidence char personality and behavior problems correlate with degree of severity of the dementia. In mild to moderate cases of AD, patients typically retain social skills and interpersonal relationships.

Frontotemporal Dementia

Frontotcmporal dementia (FTD), the most common progressive focal cortical syndrome, is characterized by atrophy of the frontal and anterior temporal lobes. The age of presentation is typically between 45 and 65 years; the onset of FTD is rare after 75 years. It occurs equally in males and females; a significant minority have a positive family history of the disorder. There are two main manifestations of FTD: a behavioral presentation and a language presentation.

The behavioral form of FTD occurs when frontal atrophy predominates and is primarily characterized by deterioration in behavior. Apathy and disinhibition are the most prevalent features. As the disease progresses, a variety of behaviors may develop, including obsessive tendencies, impulsivity, and inappropriate sexual behavior. The patient generally has little insight or concern about his or her condition. In contrast, the language variant occurs when atrophy of the perisylvian regions of the dominant hemisphere predominates. Anomia is the prominent language deficit and deterioration is often to the point of muteness; fluency is variable but the most common presentation is a nonfluent aphasia. Behavioral and other cognitive domains are relatively spared early in this variant and can remain so for decades in some patients. Depressive symptoms are common in both forms of FTD, occurring in 30-40% of patients. However, the presence of significant apathy can make the diagnosis of depression difficult. Active suicidal behavior is rare.

Idiopathic Parkinson's Disease

In addition to the motor manifestations for which Parkinson's disease (PD) is well recognized, there is a significant neuropsychia trie component to this disorder. Depression is the most common psychiatric symptom, with a reported prevalence of approximately 40%. Establishing the diagnosis of depression in patients with PD is complicated by the common presence of comorbid symptoms including dementia, apathy, facial masking, hypophonia, and psychomotor retardation. Despite the high prevalence of depressive symptoms, the rate of completed suicide is no different than that of the general population.

Psychosis is also particularly prevalent. Hallucinations are typically visual and occur in 30% of treated patients, while auditory and olfactory hallucinations are rare. Visual hallucinations are associated with an impaired cognitive state, the use of anticholinergic medications, and impaired vision. However, a dose-dependent relationship between hallucinations and dopamine agonists is unclear. In contrast to the hallucinations associated with Lcwy body disease, patients with PD generally have at least partial insight into the nature of their hallucinations. Delusions are less common, occur in about 10% of patients, and arc often persecutory in nature.

Cognitive changes associated with PD occur to some degree in most patients. Approximately 40% will eventually develop frank dementia, the majority of whom will show comorbid AD pathology. Initial deficits can include cognitive slowing, diminished attention, visual spatial difficulties, and mild executive impairments. Memory problems early in the disease typically represent limitations in retrieval, but in advanced disease memory encoding and storage can become impaired. Primary language abilities are not typically involved until the disease has significantly progressed.

Dementia with Lewy Bodies

Dementia with Lewy bodies (DLB, Lewy body disease) is now estimated to account for 10-20% of cases of dementia in the elderly. It is characterized as a progressive dementing disorder that is strongly associated with cognitive fluctuations, visual hallucinations, delusions, parkinsonian features, and unprovoked falls. Although memory abilities arc impaired, they tend to be less affected than in AD. Visual spatial and executive functions may be worse in DLB patients when compared to patients with AD. The parkinsonian features associated with DLB are relatively mild and less functionally relevant than the cognitive or behavioral problems.

Psychotic symptoms are very common in patients with DLB. Visual hallucinations are present in 50-80% of patients at some point in their disease; they are often described as being well formed and quite distressing to the patient. Auditory hallucinations are less common, occurring in approximately 30% of patients. Olfactory hallucinations have been reported to occur in 5-10%. Delusions are present in up to 50% of patients over the course of their disease, with common themes of misidentification, paranoia, and phantom boarders. Treatment of the psychoses can be challenging secondary to the hypersensitivity to the adverse effects on the motor system from antidopaminergic neuroleptic agents. Depression occurs in patients with DLB at a greater incidence than that of the general population, and is probably at least as common as depression in AD.

Huntington's Disease

Huntington's disease (HD) is a degenerative disorder of autosomal dominant inheritance resulting from an

expanded trinucleotide (CAG) repeat on chromosome 4. Symptoms typically develop during the fourth or fifth decade, initially presenting with neurological ti/ntures, psychiatric features, or both,

Neurologically, patients often demonstrate generalized chorea, motor impersistence, and oculomotor dysfunction. In the juvenile form, the Westphal variant, early parkinsonian features are prominent, as are seizures, ataxia, and myoclonus. Significant cognitive impairment is inevitable and is often present early in the disease. There are features of a subcortical dementia, with significant cognitive slowing and memory disturbance secondary to retrieval rather than encoding deficits. The dementia that gradually ensues is profound and is responsible for the majority of the morbidity associated with this disease.

Psychiatric features are prominent in HD. Personality changes are uniform, most notably apathy, irritability, and aggression. Depression occurs in approximately 40% and can happen at any stage of the disease. The suicide rate is estimated to be greater than 10%, which is higher than in patients with depression and stroke or PD. Psychosis may occur in up to 25% and can manifest as hallucinations, delusions, or both. Psychosis tends to remit as the dementia progresses. Anxiety and obsessive tendencies may also occur.

Wilson's Disease

Wilson's disease (WD), also known as *hepatolenticular degeneration,* is an autosomal recessive disorder that localizes to chromosome 13 and is caused by widespread copper accumulation. Median age of onset is 16-17 years. The rule of thirds applies to irs presentation, with one third of patients each presenting with hepatic, neurological, or psychiatric symptoms. Neurological manifestations are largely extrapyramidal, including tremor, rigidity, dystonia, and chorea. Other symptoms include ataxia, dysarthria, dysphagia, and a fixed smile. Seizures occur in a minority. Dementia may occur but remains relatively mild.

Potential psychiatric symptoms are numerous but most notable are depression and personality changes. Depression occurs in about 30% of patients, whereas suicidal ideation is recognized in about 5-15%. Personality changes are reported in approximately 30-50% of patients, with irritability and aggression being most commonly noted, Psychosis is less common, occurring in approximately 5-10% of cases. Not surprisingly, these psychiatric manifestations tend to occur more commonly in association with primarily neurological WD rather than with primarily hepatic forms.

Diagnosis is suggested by identification of Kayser-Flcischer rings in patients with a clinical picture consistent with WD and confirmed by demonstrating reduced scrum ceruloplasmin and elevated urine copper. MRI studies show abnormal T2 signal in the putamen, pons, thalami, and other structures. Atrophy is commonly present. Treatment consists of copper chelating or depleting agents. Early treatment results in partial improvement of the MRI changes as well as most of the neurological and psychiatric symptoms. However, recovery is usually incomplete when treatment is delayed. Therapy is lifelong.

Tourette Syndrome

Another neurological disorder often associated with psychiatric and behavioral symptoms, including attention deficit, obsessive-compulsive behavior, impulsivity, and mood changes includes Tourette syndrome. Although most cases of Tourette syndrome exhibit no neurologic abnormalities except for motor and phonic tics, in many cases "tourettism" may be associated with structural cortical and subcortical brain lesions (Kwak and Jankovic 2002).

Other

Epilepsy

Approximately 0.5% of the U.S. population carries the diagnosis of epilepsy; approximately 5% of all Americans will have a seizure at some point in their lifetimes. The incidence of epilepsy tends to follow a bimodal distribution. The highest rate is in the first decade, it is low during most of adulthood, and it begins to increase during the seventh decade. Partial seizures are the most common, followed by generalized tonic-clonic seizures.

Seizure disorders are commonly associated with ncuropsychiatric manifestations. It is estimated that more than 60% of patients with epilepsy meet diagnostic criteria for at least one psychiatric disorder during their lifetime. Depression is the most common, with a lifetime risk of 30%. It generally occurs as a chronic, interictal phenomenon, However, in some patients depression is only significant during the preictal or postictal periods; in a minority of patients depression can be the sole manifestation of the ictus itself. Foci in the frontal or temporal lobes appear most likely to he associated with depression; the data suggesting laterality are equivocal. Other prominent psychiatric symptoms associated with epilepsy include panic disorders, anxiety, aggression, and personality disorders.

Psychosis in association with epilepsy is less well described. Interictal psychotic symptoms are more common in patients with temporolimbic foci; these patients primarily display the positive psychopathological phenomena of schizophrenia. In addition, psychosis can be a prominent postictal phenomenon and generally occurs after severe secondary generalized events or runs of complex partial scizutes. The psychosis generally does not develop

until after recovery from the seizures and may take several days to reach maximal severity. Finally, psychosis is rarely the primary manifestation of the seizure ictus. In patients with psychosis secondary to epilepsy, anticonvulsant medications are more efficacious in managing the psychosis than conventional neuroleptics, although a combination of medications from each class may be required.

Traumatic Brain Injury

Traumatic brain injury (TBI) is a leading cause of death and disability in the United States, with an estimated one to two million cases per year. The leading causes of TBI are motor vehicle accidents, falls, assaults, and recreational accidents. The pathologic correlates of moderate and severe traumatic brain injury are numerous, and include penetrating wounds, depressed skull fractures, diffuse axonal injury (DAI), petechial hemorrhages, contusions, hematomas, increased intracranial pressure, edema, and ischemia. The pathology associated with mild TBI is less well understood. Lesions such as subdural hematomas and contusions can be associated with relatively mild clinical deficits. However, other processes likely play a role, including the formation of axonal edema and the release of cytotoxic substances such as cytokines, free radicals, and excitatory amino acids.

There is a lack of consensus as to what clinical findings constitute mild TBI. The occurrence of loss of consciousness is believed by many to not be an absolute requirement. Rather, any traumatic process associated with a generalized alteration in cerebral function, including amnesia (retrograde or anterograde) or alteration in consciousness at the time of the accident, may be associated with a clinical brain injury. In contrast, postconcussive syndrome refers to the constellation of signs and symptoms that persist for weeks to years after the injury.

There is a body of evidence that reports the development of a variety of psychiatric disorders following traumatic brain injury. Depression occurs in up to 50% of patients. Both right and left hemisphere lesions have been implicated. Premorbid psychiatric history, family psychiatric history, level of education, occupational status, and history of abuse of alcohol or drugs may contribute to the development of depression following TBI. Psychosis is less commonly reported in TBI, with a reported incidence between 0,7% and 20%. A recent review suggests a profile typical for patients with TBI-rclated psychosis (Fujii and Ahmed 2002). There is a median latency to onset of 1 year, delusions arc present in more than 75% of patients, and hallucinations occur in almost 50%. Patients with TBI were differentiated from patients with schizophrenia by their relative lack of negative symptoms. Approximately 70% of patients were noted to have abnormal EEGs. When neuropsychological testing was done, almost 90% demonstrated abnormalities. The psychosis in the majority of patients eventually improved, and neuroleptics, followed by anticonvulsants, appeared to be the most efficacious medications.

SPECIAL CONSIDERATIONS

Three conditions—delirium, depression-related cognitive impairment (DRCI}, and catatonia—fall within the border between neurology and psychiatry and thus merit special consideration.

Delirium

Delirium represents one of the most common causes of acute neuropsychiatric disturbances in the hospital setting. It is characterized by impaired attention, fluctuation in mental status, and impaired sleep-wake cycles. Visual hallucinations are particularly common. Delirium is often multifactorial in origin. Advanced age is an independent risk factor for its development, as are a number of other factors including pre-existing CNS disease, metabolic derangements, infections, major surgeries, medications, sleep disruption, and sensory deprivation (especially impaired eyesight). In the elderly, a common comorbidity is an underlying dementia, which may not have been diagnosed previously. In these patients, return to their pre-delirium cognitive state may be prolonged or incomplete despite elimination of the offending agcnt(s). Compared to EEGs of mild to moderate cases of dementia, the EEC of delirium is almost always abnormal, often demonstrating a slow, disorganized background, triphasic waves, or ictal rhythmic patterns suggestive of elcctrographic seizures.

Depression-Related Cognitive Impairment

DRCI refers ro the complex pattern of cognitive impairment secondary to affective disorders such as major depression. Several factors distinguish DRCI from dementia. Patients with DRCI tend to complain of memory and concentration problems, whereas demented patients often deny that problems exist despite impairment that is obvious to their family members. DRCI patients may have a relatively normal bedside mental status examination. There are attention-mediated deficits in memory encoding and spontaneous retrieval, but recognition is generally intact. In AD, attention may be normal although spontaneous retrieval and recognition of memory is impaired. Language is generally well preserved in patients with DRCI, whereas aphasia often occurs with progressive dementias. Unfortunately, the distinction between dementia and DRCI is often difficult to achieve, in part because of the common comorbid nature of these two disorders in elderly patients, If depression appears to be comorbid with a degenerative

disorder, cognition may improve if the depression is adequately treated.

Catatonia

Catatonia is an uncommon but potentially lethal disorder that may be encountered in a general neurological practice. The specific manifestations of catatonia are variable and may include diminished motor function (including waxy flexibility), increased motor function that is characterized by purposeless and spontaneous movements, and mutism. Although the majority of catatonic patients have an underlying affective disorder, approximately 10-20% have significant medical or neurological conditions that contribute to their catatonic state. Stroke, demyelinating disease, encephalitis, trauma, medication, and CNS malignancy are individually associated with an increased risk of catatonia. Medical disorders that can result in catatonia include hyperthyroidism, diabetic ketoacidosis, and Cushing's disease. Treatment with intravenous benzodiazepines or electroconvulsive therapy (ECT) can result in dramatic improvement. The increased risk of mortality in patients with catatonia is secondary to the underlying medical or neurological disotder, poor nutrition and hydration, and infection.

TREATMENT PRINCIPLES

A comprehensive discussion of psychopharmacological interventions in neuropsychiatric disorders is beyond the scope of this chapter. However, there are several general principles that merit discussion. In many ways, the pharmacology of psychiatric symptoms is similar whether the underlying disease is primarily neurological or psychiatric. However, patients with underlying neurological disorders tend to be more susceptible to the adverse reactions of psychotropic medications, particularly to extrapyramidal and cognitive effects. These adverse reactions tend to be minimized, but not always eliminated, with use of the newer generation medications, for example the selective serotonin reuptake inhibitor class of antidepressants and atypical neuroleptics. Advetse reactions are also minimized when low doses are initiated and the rate of increase is slow. However, the minimum dose necessary for therapeutic benefit is often the same in neurological and psychiatric populations, so care must be taken not to discontinue the medication before a therapeutic dose has been attained. Finally, given the large number of medications many neuropsychiatric patients receive for their medical, neurological, and psychiatric disorders, a careful review of potential toxicities and drug interactions should be undertaken before prescribing new drugs. Fortunately, symptoms of both depression and psychosis often respond to pharmaceutical intervention when used appropriately.

ECT is staging a resurgence and, when patients are appropriately screened, may be the most efficacious antidepressant treatment available. Its adverse effects on cognition and memory are well known and thought to be only transient There are few absolute medical or neurological contraindications to ECT. Relative contraindications include increased intracranial pressure associated with mass lesions and recent stroke. Risk associated with cerebral aneurysms is unknown. However, given that the estimated prevalence of unruptured, intracranial aneurysms is up to 5% and that thousands of ECT procedures arc performed annually without evidence of rupture, the risk of aneurysmal rupture secondary to ECT is likely small.

CONCLUSIONS

We are just beginning to understand complex human behaviors in a coherent and verifiable manner. Progress in neuroscience, neurology, and psychiatry is inevitably drawing our specialties closer together, rendering the traditional boundaries increasingly indistinct. Fundamental changes in our practice paradigms are required. Clearly, multiple disciplines working in close collaboration are necessary to diagnose and treat complex behavioral and cognitive disorders.

Chapter 10
Intentional Motor Disorders and the Apraxias

Kenneth M. Heilman, Edward Valenstein,
Leslie J. Gonzalez Rothi, and Robert T. Watson

In humans the corticospinal motor system together with the motor units can mediate an almost infinite number of movements. Because the purpose of motor systems is to allow people to interact with their environment, the pyramidal motor neurons need to be guided by instructions or programs. For the motor system to deal effectively with the environment, it needs at least two major types of programs: *praxic* and *intentional.* The praxic programs provide the corticospinal system with the knowledge of *how* to make learned skilled movements. The intentional programs provide the corticospinal system with information about *when* to move. In this chapter, we first discuss disorders of the intentional, or "when," system and then we discuss praxic, or "how," system disorders.

INTENTIONAL (WHEN) DISORDERS

Unlike the praxic systems that program the temporospatial aspects of a movement, the intentional systems provide instructions about goals. There are four types of intentional instructions: (1) when to start a movement; (2) when not to start a movement; (3) when to continue or sustain a movement or posture; and (4) when to stop or complete a movement.

The inability to initiate a movement in the absence of a corticospinal or motor unit lesion is termed *akinesia. Hypokinesia* is a delay in initiating a response. The inability to withhold a response to a sensory stimulus is called *defective response inhibition.* The inability to sustain a movement or posture is called *motor impersistence,* and the inability to stop a movement or an action program is termed *motor perseveration.*

In the next section, we describe each of these intentional disorders, including subtypes of each category, and we discuss bow to examine patients for these disorders. We also discuss the pathophysiological and neuropsychological mechanisms that may be associated with these disorders.

Akinesia

An organism might fail to initiate a movement for many reasons, but comprehension, attentional, perceptual, and sensory disorders that lead to a failure of movement initiation should not be termed *akinesia.* Dysfunction of the motor system, including the motor unit (lower motor neuron, myoneural junction, and muscle) and the upper motor neuron (pyramidal or corticospinal system) may also be associated with a failure to initiate a movement. Disorders of these systems, however, cause weakness rather than akinesia, and akinesia is defined by an initiation failure that cannot be attributed to dysfunction in the corticospinal system or the motor units. Akinesia is caused by a failure of the systems that activate these corticospinal motor neurons.

There are three major methods by which a clinician can distinguish an akinesia from extreme weakness caused by dysfunction of the motor systems. One is behaviotal, the second depends on the pathological locus of a lesion, and the third uses stimulation of the corticospinal system and recording of motor evoked potentials. Regarding the behavioral method, certain types of akinesia are present under certain sets of circumstances and absent in others. If one can demonstrate that a patient makes movements in one set of circumstances and not in the other, then one

cannot attribute this failure to move purely to dysfunction in the motor system. However, if the akinesia is not limited to a set of circumstances but is global, then one may have to depend on brain imaging (e.g., computed tomography or magnetic resonance imaging), pathology, or physiological techniques such as magnetic stimulation to demonstrate that the brain lesion did not involve the motor system.

Types of Akinesia

There arc several forms of akinesia. For ease of discussion, we have divided them into three major categories: (1) body part, (2) action space, and (3) stimulus-response conditions. These three categories may be interactive.

1. Body part: Akinesia may involve the eyes, the head, a limb, or the total body.
2. Action space: Akinesia of the limbs, eyes, or head may depend on where in space the body part is moved or in what direction it is moved. There may also be a hemispatial or directional component to the akinesia. In *directional akinesia,* there is a reluctance to move in a specific spatial direction usually contralateral to a hemispheric lesion. For example, horizontal gaze palsy is a form of directional akinesia. Similarly, there may be directional akinesias of both head and arms that results in a reluctance to move these in a contralesional direction. *Spatial akinesia* has been described for the arm where independent of direction, an arm that fails to move or has decreased movements in contralesional hemispacc, as defined by the mid-sagittal plane of the body, can move in ipsilesional hemispace. Whether hemispatial akinesia that is totally independent of direction has been described for the eyes or head is not known.
3. Stimulus-response conditions: Movements can be produced in response to an external stimulus or they can occur in the absence of an external stimulus. We term movements that arc in response to a stimulus *exogenously evoked motor activation (exo-evoked),* and those that appear to be spontaneous *endogenously evoked activation (endo-evoked).* A patient may have both exo-cvoked and endo-evoked akinesia, which we term *mixed akinesia.*

Testing for Akinesia

When testing for akinesia, one may want to assess the various body parts discussed earlier. To determine whether a patient has endo-evoked akinesia, one has to observe spontaneous behavior or the lack of it. Patients with endo-evoked akinesia often have symptoms of *abulia,* an uncommon lack of spontaneous, goal-directed behavior that is seen predominantly with lesions of the basal ganglia and the frontal lobes. Patients with endo-evoked akinesia, despite having reduced spontaneous activity, may respond normally to external stimuli. For example, endo-evoked akinesia is usually associated with Parkinson's disease. The patient with severe Parkinson's disease will often fail to move spontaneously; however, when stimulated, such a patient may show almost normal movements (paradoxical kinesia).

When a patient has good strength and spontaneously moves but fails to move to a specific stimulus, the failure to move in response to a stimulus is often attributed either to an elemental sensory defect or to sensory inattention and neglect. Although sensory defects and sensory neglect may be responsible for a failure to respond, exo-cvoked akinesia is often confused with sensory defects and sensory neglect. The basic testing method used for dissociating sensory defects and sensory neglect from exo-evoked akinesia (motor neglect) is the *crossed response task.* This was first tested in monkeys by training a monkey to respond with its right arm to a left-sided stimulus and to respond with its left arm to a right-sided stimulus. If the animal failed to respond to a contralesional stimulus using the ipsilesional arm, it was considered to have sensory neglect. However, if the animal demonstrated no weakness of the contralesional extremity bur failed to move the contralesional extremity in response to ipsilesional stimuli, it was considered to have exo-evoked akinesia, or motor neglect. The crossed response task can be used not only to test the limbs but also to test the eyes, the head, or the whole body.

When assessing for akinesia, as a function of action space, one should test both directional and hemispatial movements of the eyes, the head, and the limbs. One may want to determine whether the directional or hemispatial movements are endogenously or exogenously evoked. When attempting to determine whether there is an endo-evoked directional akinesia of the eyes, one can observe the spontaneous eye movements and see whether there is ipsilesional deviation of the eyes or a failure of the patient to spontaneously look into contralesional space. To determine whether a patient has an exo-evoked directional akinesia of the eyes, one can use a modification of the crossed response paradigm in which the patient must look cither toward (ipsilesional direction) or away (contralesional direction) from ipsilesional and contralesional stimuli. For example, the examiner stands directly in front of a patient and asks the patient to fixate on the examiner's nose. The examiner raises both hands to eye level and keeps one hand in the patient's right visual field and the other in the left visual field. The patient is instructed to look away from the moving hand if the hand moves downward and toward the hand if it moves upward. When the contralesional hand is moved upward, a failure to look at the contralesional hand (moving in a contralesional direction) may be related to either a hemianopia, sensory neglect, or a directional akinesia. However, when the ipsilesional hand moves downward, a failure to look toward the contralesional hand suggests an exo-evoked directional akinesia of the eyes (Butter et al. 1988).

To test for directional and hemispatial akinesia of the head or an arm, one can use similar tests. To test fot a directional bias of an arm (similar to eye deviation), one can ask the patient to close his or her eyes and point to his or her sternum. The subject is then asked to point with his or her index finger to a point in space perpendicular to the sternum (e.g., the midsagittal plane). Patients with a motor (intentional) bias will point toward their lesioned hemisphere.

A task was developed that can be used to test for endo-evoked directional limb akinesia. In our modification, a patient is blindfolded and small objects such as pennies are randomly placed in wells that are scattered on a board in both body hemispatial fields within arm's reach. The patient is asked to retrieve as many pennies as possible. The task is considered endogenously evoked because the patient cannot see the pennies and must initiate exploratory behavior in the absence of an external stimulus. Patients with an endo-evoked directional akinesia of the arm may fail to move their arm fully into contralateral hemispace and explore for pennies.

To test for directional and hemispatial akinesia, one can also use one of the several video camera paradigms that allows one to dissociate deficits of perception and attention from those of intention and action (Coslett et al. 1990). In these paradigms, patients can see only their hand bisecting a line through a TV monitor. In this technique, the line (where the action takes place) can be positioned in contralesional or ipsilesional hemispace and the TV monitor can be independently placed in either hemispace or the image can be reversed. If, as demonstrated by Coslett et al., abnormal performance on the line bisection is not affected by the spatial position of the monitor or the reversal of the image on the monitor, it suggests that the patient has a hemispatial or directional akinesia of the arm.

Hypokinesia

Many patients with milder defects in their intentional ("when") systems may not demonstrate a total inability to initiate a response (e.g., akinesia); rather their intentional disorder may be primarily a delay in initiating a response. We have termed this delay *hypokinesia.* This hypokinesia may be defined in a manner similar to akinesia. Because a teaction time paradigm is required to detect hypokinesia, it cannot be divided into exo-evoked and endo-evoked subtypes.

Hypokinesia can be seen both in the limbs and in the eyes and may be either independent of direction or directionally specific such that when making directional movements, there is a greater delay initiating movements in a contralesional direction than there is initiating movements in an ipsilesional direction. Hypokinesia can also be hemispatial such that movements with the same limb may be slower in one hemispace than they are in the other hemispace.

Testing

The same patadigms that are used to test for akinesia of the eyes and limbs can be used to test for hypokinesia. Although some patients with hypokinesia have such markedly slowed initiation times that hypokinesia can easily be detected, others have more subtle defects and reaction time paradigms may be needed to observe their defects. Reaction times can be slowed for various reasons including impaired attention, bradyphrcnia, or hypokinesia. To detect hypokinesia, one should use simple reaction times that do not require cognition and therefore cannot be impaited by bradyphrcnia. Similarly, to test for hypokinesia, one has to use stimulus parameters that ensure that inattention cannot masquerade as hypokinesia.

Hypometria

Movements of a decreased amplitude are called *hypometria.* Hypometria may be directional or hemispatial or it may involve specific body parts such as a limb or the eyes. For example, as mentioned earlier, a patient with a right hemisphere lesion may at first be unable to saccade to the left. However, as the patient recovers, he or she may be delayed at initiating a leftward saccade or may make multiple small (hypometric) saccades. Hypometria may be related to akinesia or impersistence.

Motor Extinction

Patients with sensory extinction may be able to detect a single stimulus on the contralesional side of thcit body, but when presented with a simultaneous distracting stimulus, they may then be unaware of the contralesional stimulus. To test for milder forms of intentional deficits including akinesia and hypokinesia, one can use a similar extinction principle. For example, one patient made unilateral movements well and did not have sensory extinction. However, when he had to make bilateral simultaneous movements, he either did not move his contralesional arm or moved it after a prolonged delay.

Motor Impersistence

Motor impersistence is the inability to sustain a motor act. *Persistence* is the intentional equivalent of attentional vigilance, and impersistence may be analogous to increased attentional distractibility. Like akinesia, impersistence can be associated with various body parts including the limbs and eyes. However, impersistence may also include other body parts such as the eyelids, jaw, and tongue. Like akinesia, it may also be directional or hemispatial.

Testing

When testing for impersistence of midline structures, one can ask patients to keep their eyes closed for 20 seconds or to keep their mouth open or protrude their tongue for 20 seconds. Patients who can successfully persist at these acts may be further taxed by asking them to persist at two movements simultaneously. For example, they may be asked to both keep theit eyes closed and keep theit mouth open for 20 seconds.

Limb impersistence can be tested by asking a patient to maintain a posture such as keeping an atm extended for 20 seconds. Because limb impersistence can be hemispatial, one may want to test each limb in its own and in its opposite hemispace. i leinispatial impersisrence, in the absence of directional impersistence, has not been tepotted tor the bead or eyes, perhaps because it has never been tested. One could ask a patient to sustain upgaze (or downgaze) for 20 seconds while the eyes are directed either toward the right or toward the left. If the patient can maintain gaze in one hemispace (e.g., the right), but cannot do so in the other (e.g., left), it would suggest that the patient has hemispatial impersistence of the eyes. If a patient has a directional impersistence of the eyes, he or she may be unable to maintain his ot het eyes directed to either the right or the left hemispace, and therefote one may not be able to test for hemispatial impersistence. To test for directional impersistence of the eyes, one tequests the patient to look either to the left or to the right for 20 seconds. A similar procedure can also be used to test the head for directional impersistence.

Defective Response Inhibition

Defective response inhibition is defined as responding when no response of that body part is required. Defective response inhibition can be seen in the eyes, head, ot limbs. Directional defective tesponse inhibition has been reported for the eyes, but not for the limbs or head. However, it may never have been tested. Similarly, hemispatial defective response inhibition has not been reported; however, attain ll may never have been lusted.

Testing

There are several forms of defective response inhibition. **In** one **form,** when using the crossed response task, the ipsilesional limb moves when the correct response was a movement of the contralesional limb, or the eyes or head move in an ipsilesional direction when the correct response was a movement in the contralesional direction. This type of defective response inhibition may be termed *motor {limb* or *directional) allochiria* or *ipsilesional response disinhibition.* However, before one terms such a condition *motor allochiria* or ipsilateral disinhibition, one must be certain a perceptual problem has not induced the abnormal behavior, in which case it is not defective tesponse inhibition but true *allochiria* or *allesthesia.* In the second form of defective response inhibition, when performing the crossed response task, the patient's contralesional limb moves when it should not move or movement is in a contralesional direction when there should be either no movement or movements should have been in an ipsilesional direction. We call this *contralesional response disinhibition.* Contralesional response disinhibition can also be exogenously ot endogenously evoked. If a patient is able to understand complex instructions, the best way to test for both ipsilesional and contralesional exo-evoked response disinhibition of the limbs is to insttuct the patient to move or lift the opposite hand (off a table) when a hand is sttoked downward and to move the same hand as touched when it is sttoked upward. Before testing for the different forms of defective response inhibition, it is important to establish that the patient does not have a perceptual disorder and can correctly detect stimuli and recall instrucrions. If, when the contralesional hand is brushed up, the patient moves the ipsilesional atm rather than the contralesional, the patient has ipsilesional disinhibition ot motor allochiria. If, when the contralesional arm is brushed downward (which is a signal to move the ipsilesional arm), the contralesional arm is moved instead of the ipsilesional arm, the patient has a contralesional exo-evoked limb disinhibition. If this happens with both arms, the patient has bilateral exo-evoked disinhibition.

Patients with exo-evoked limb disinhibition may also fail on the types of go-no-go tasks described by Lufia. Fot example, the patient may be instructed to put up two fingers when the examiner puts up one finger and to put up no fingers if the examiner puts up two fingers. If the patient mimics the examiner such that when the examiner puts up one fingct, the patient puts up one finger and when the examiner puts up two fingers, the patient puts up two fingers, the patient has *echopraxia* (a third form of defective response inhibition).

A paradigm similar to that used for directional akinesia of the eyes can be used to determine wherher there is an ipsilesional, or a contralesional disinhibition of the eyes or head. The patient is told to fix the eyes on the examinet's nose. If either hand moves down, the patient is to direct the eyes to the opposite hand, and if the hand moves up, the patient is to direct the eyes to the hand that moved. If, when the hand in the patient's contralesional visual field moves up and instead of looking at that hand, the patient looks at the opposite hand, an ipsilatetal directional disinhibition is present. If, when the contralesional hand moves down, the patient looks at this hand ratber than looking in the opposite direction, a contralesional directional disinhibition (ot *visual grasp)* is present. This directional disinhibition or visual grasp may also be bilateral.

Motor Perseveration

Perseveration is when a patient incorrectly repeats a prior response. Although there are many types of perseveration and several classification systems, there seems to be a spectrum between cognitive and motor perseveration. Cognitive perseveration is when one uses a previously used cognitive strategy inappropriately for a new or different task. Sandson and Albert (1987) call this "stuck in set" perseveration. Luria discussed two types of motor perseveration, In one type of motor perseveration, the patient is unable to switch to a different motor program and repeats the prior program even though the task requirements have changed. Luria (1965) calls this *inertia of program action* and Sandson and Albert (1987) call this *recurrent perseveration.* In rhe second type, the patient continues to perform a movement even though the task is completed, but when instructed, the patient can switch to other movements. Luria (1965) called this *efferent perseveration,* This is similar to Sandson and Albert's (1987) *continuous perseveration.*

Both continuous and recurrent perseveration are forms of motor perseveration and may represent defects in the when or intentional system. This is a defect of when to stop a motor program. Patients may show motor (efferent) perseveration on drawing and copying tasks. For example, a patient can be asked to draw or copy a cube. Patients with motor perseveration will repeatedly draw over lines. When performing a cancellation task, patients with motor perseveration will perform multiple cancellations of the same target. When asked to draw or copy a double loop, patients with motor (efferent) perseverarion will draw more than two loops.

Pathophysiology of Intentional or When Disorders

Right-Left Asymmetries

In our introductory discussion, we advanced the hypothesis that there are generally two major types of programs that control the motor system, the how or praxis system and the when or intentional system. As we discuss in the next section, in right handers disorders of the praxis production system, as evidenced hy ideomotor apraxia (IMA), are almost always associated with left hemisphere dysfunction (Heilman and Rothi 1985). Although intentional disorders are often associated with bilateral hemispheric lesions, when the lesions that induce intentional disorders are unilateral, they arc more commonly associated with right hemisphere lesions. For example, limb akinesia is more often associated with right hemisphere lesions than left hemisphere lesions. The intentional defects associated with right hemisphere dysfunction, however, are often nor limited to the left limb. Using a reaction time paradigm, right hemisphere infarctions are associated with a greater slowing of reacrion times than left hemisphere infarctions even when rhe ipsilcsional arm is used and lesions arc matched for size. These patients may have hypokinesia.

Rehabilitation specialists have noted that it is more difficult to rehabilitate patients with left hemiplegia than those with right hemiplegia. In addition, patients with left hemiplegia are more likely to develop decubiti and pulmonary emboli. Both of these conditions may be related to a global akinesia associated with right hemisphere dysfunction. Directional kinesia of the limbs as determined by tasks such as those used by Heilman and Rothi (1985) were also more often reported with right hemisphere lesions. The case of hemispatial limb akinesia also had a right hemisphere lesion. Alrhough impersistence is often associated with bilateral hemispheric dysfunction, when it is associated with unilateral hemispheric disease, it most commonly occurs with right hemisphere lesions. Defective response inhibition of the eyes or arms may be seen with bilateral hemispheric dysfunction, but when it is seen with unilateral hemispheric disease, it has been associated with right hemispheric dysfunction. Lasdy, motor (or continuous) perseveration has also been reported to be associated with right hemisphere dysfunction.

The term *dominance* implies that one hemisphere contains specialised processing systems or representations (programs) cither that the other hemisphere does not contain or that are less developed. The nondominant hemisphere therefore by itself is not fully competent to mediate a specific activity. Although our discussion has provided evidence that the right hemisphere may be dominant for inrentional control of the motor systems, this evidence is indirect. However, several studies in normal subjects provide further evidence for right hemisphere intentional dominance.

Although the anatomic and physiologic basis for the right hemisphere's special role in intentional activity is unknown, the limbic system, which plays a critical role in motivation, has two major outputs to the cortex: one from the hippocampus and the other via the cingulate gyrus. Although bilateral medial temporal lobe lesions are associated with profound amnesia, severe motivational or intentional disorders have not been associated with these lesions. However, bilateral medial hemispheric lesions that involve the cingulate gyrus are associated with a profound intentional disorder termed *akinetic mutism,* suggesting that the cingulate gyrus provides motivational information to ncocortical areas. The right cingulate gyrus has more input into the neocortex than the left.

Intrabemispheric Networks

The intrahemisphcric networks that are important in mediating intention have also not been fully elucidated. However, studies of patients with focal lesions and studies of monkeys suggest that the frontal lobes may play a critical role in intentional activity. For example, motor neglect of

the limbs has been reported in monkeys from dorsolateral frontal lesions and although the ipsilesional limbs are not as akinetic as the contralcsional limbs, there is a hypokinesia of the ipsilesional limbs as measured by reaction times. Medial frontal lesions are also associated with limb akinesia. An ocular directional akinesia can also be seen with dorsolateral frontal lesions, and a directional limb hypokinesia may be seen with frontoparietal lesions (Heilman and Rothi 1985). In addition, motor impersistence is most frequently seen with dorsolateral frontal lesions defective response inhibition of the eyes is seen with dorsolateral frontal lesions, and defective response inhibition of the limbs is associated with medial frontal lesions. Lastly, motor perseveration may also be associated with frontal lesions.

The frontal cortex has strong projections to the striatum. The dorsolateral frontal lobe projects to the caudate, the supplementary motor area (SMA) projects to the putamen, and the cingulate gyrus projects to the ventral striatum. The striatum projects to the internal portion of the globus pallidus and the pars reticularis of the substantia nigra, which in turn projects to thalamic nuclei (e.g., VA, VL, and Ml)). These thalamic nuclei project back the same area of the frontal cortex where this frontal, basal ganglia, and thalamic loop was initiated including the dorsolateral frontal lobe, SMA, and cingulate gyrus.

Based on the previous discussion, it should not be surprising that intentional disorders may be associated with diseases that affect both the basal ganglia and the thalamus. The most common disorder that induces akinesia is Parkinson's disease. The akinesia associated with Parkinson's appears to be induced by a loss of the dopaminergic neurons that project to the striatum. Dopamine antagonists may also produce akinesia and dopamine agonists may reverse this akinesia. Thalamic lesions of VA/VL or the medial nuclei such as centromedian parafascicularis can also induce akinesia.

Not only do diseases that affect frontal lobe cortex, basal ganglia, and thalamus induce intentional disorders, but these disorders, especially akinesia, are also associated with diseases that affect the white matter that connects the frontal lobes with these subcortical structures. Therefore akinesia is often associated with white matter diseases such as arteriosclerotic encephalopathy (Binswanger's disease or multiple lacunar infarcts), advanced multiple sclerosis, and hydrocephalus.

Lastly, akinesia has also been reported with temporoparietal lesions, in both monkeys and humans. Although the akinesia associated with basal ganglia diseases such as Parkinson's disease appears to be endogenously evoked, the akinesias associated with frontal and parietal cortical dysfunction appear to be exogenously evoked.

Based on the pathological evidence cited, one can postulate that the frontal lobes play a central role in human's intentional network. The dorsolateral frontal lobes receive projections from both the parietal lobe, which is a polymodal association cortex, and the multimodal primary association cortices. The frontal lobes also have strong reciprocal connections to the cingulate gyrus, the medial thalamic nuclei, and nonreciprocal connections with the striatum, which project to the globus pallidus and substantia nigra and from there to the thalamus and hack to the cortex, as previously described.

The frontal lobe's connections with the inferior parietal lobe may provide the frontal lobe with stored knowledge (e.g., semantic and spatial information) and the limbic connections may provide the frontal lobe with motivational information. Unimodal sensory and polymodal sensory association areas may provide the frontal lobe with information about external stimuli that may call the organism to action. Afferents from the mesencephalic and thalamic reticular system may be important for modulating arousal and activation.

Physiological studies have provided support for the role of the frontal lobes in intention-motor activation. Neurons in the dorsolateral frontal lobe of monkeys who were trained to make a rapid movement to a stimulus were recorded. When the animal was prepared to make a movement, the cells were active. When the animal was **not** prepared to initiate a response, as determined by a delay in response time, these cells were less active. Stimulus parameters did not affect these cells' activity, suggesting that these cells were intentional neurons. The dorsolateral frontal lobes contained neurons that discharge before purposeful saccades. Lesions of the frontal lobe destroy these intentional cells, and in their absence, there is defective activation of the motor neurons.

The manner in which these frontal lobe intentional neurons influence the motor neurons has not been definitely established. However, as discussed, the dorsolateral frontal lobe and the thalamic areas such as the ventrolateral, dorsomedial, and intralaminar nuclei share anatomic connections with each other and form a network with the basal ganglia, premotor, and motor cortices. Because lesions in these structures (dorsolateral frontal lobe, basal ganglia, ventrolateral thalamus, medial thalamus) and premotor areas (i.e., SMAs) induce akinesia, Watson, Valenstein, and Heilman (1981) posited that this network mediates intentional activity.

We do not know whether the different forms of intentional activity we have discussed arc mediated by the same network or whether different systems or subsystems mediate different forms of intentional activity. Some of the intentional disorders we discussed may be related to the "release" of phylogenctically more primitive systems. For example, neurons in the dorsolateral frontal lobes have a role in the preparation of saccadic eye movements. One would predict that unilateral frontal lobe lesion would induce a directional akinesia of the eyes. However, patients with frontal lobe lesions have been reported unable to saccade away from a stimulus before they made a saccade toward the stimulus (defective response inhibition or

visual grasp). Directional akinesia and defective response inhibition would appear to be mutually incompatible behaviors, but a patient with a unilateral frontal lobe lesion was assessed using a crossed response task. Initially the patient showed both contra lesional sensory neglect and a directional contralcsional akinesia. Subsequently, the patient was able to detect contralcsional stimuli and move his eyes in a contralesional direction. However, in the crossed response task, when presented a contra-lesional stimulus that was a signal to move the eyes in an ip si lesional direction, the patient often incorrectly responded by first making a contralesional saccade before making an ipsilesional saccade. **Although** it has been demonstrated that neurons in the dorsolateral frontal lobe have a role in preparing for a saccade, collicular neurons can perform a similar function. Perhaps after frontal lobe damage, which initially was associated with a directional akinesia, recovery was mediated by the colliculus. Activity of the colliculus, however, unlike the frontal lobes, cannot be altered by task instructions. Perhaps normally the dorsolateral frontal lobes exert an inhibitory influence on the colliculus, which is absent aftct ftontal lesions. This inhibitory effect cannot be direct because no frontal lobe eye field cells have been reported that arc tonically active except during saccades. However, the pars reticulata of the substantia nigta projects to the colliculus and has tonic activity. The frontal lobe may influence the substantia nigra through its connections to the caudate. A similar release of inhibition may also be responsible for other nonocular defects whereby the brain-damaged patients cannot either withhold or terminate responses.

Clinical Pathology

Intentional disotders can be caused by any neurological disease that impairs the systems we have discussed. Neoplasms of the frontal lobes, the cingulatc corpus callosum region and colloid cysts of the third ventricle may all be associated with intentional disorders. However, vascular diseases including multiple lacunae and Binswanger's disease may be the most common cause of intentional disotders. Infarctions of the thalamus and ventral tegmental areas may also cause intentional disorders. Hydrocephalus and drugs that block dopamine receptors such as neuroleptics may also cause intentional disorders. Head trauma and central nervous system infections are other common causes of intentional disorders. Some infections and inflammatory diseases that must be considered include acquired immunodeficiency syndrome, syphilis, Lyme, prion diseases such as Creut/ieldt-Jakob disease, chronic meningitis (e.g., fungal, sarcoid), Whipple's, and progressive multifocal leukoencephalopathy. There are many degenerative diseases that also may present with intentional disorders. These include Pick's disease, and Pick's disease without Pick's bodies (frontotcmporal dementia), olivopontocerebellar atrophy, progressive supra-nuclear palsy, corticobasal degeneration, striatonigral degeneration, Shy-Drager syndrome, Parkinson's disease, Huntington's disease, Behcet's disease, and ftontal lobe dementia associated with motor neuron disease. De-myelinating diseases such as multiple sclerosis and the leukodystrophies may also have intentional components. Lastly, there are several toxic/metabolic diseases that may he associated with intentional disorders. These include chronic alcoholism with alcohol dementia and Marchiafava-Bignami disease, vitamin Bj2 deficiency, hypothyroidism, anoxia, hypoparathyroidism with basal ganglia calcification, Wilson's disease, and status dysmyelinatus (iton deposition in the basal ganglia with rigidity, athetosis, and mental degeneration).

PRAXIC (HOW) **DISORDERS**

The praxic programs provide several types of instructions:

1. How to position one's limb when petfotming **skilled** movements, including working with tools and objects.
2. How to move the limb in space or the spatial trajectory of the skilled movement. This program may contain both alloccmric (in relation to the object upon which the organism is acting) and egocentric (in relation to the organism's own body) information.
3. How to orient the limb toward the target of the limb's action,
4. How tapidly to move in space, or the timing of a skilled movement.
5. How to imitate a movement.
6. How to solve mechanical ptoblems.
7. How to order components of an act to achieve a goal.

Disorders of this how ot praxic system are called apraxias (Table 10.1). A loss of the ability to make precise and independent movement (i.e., a loss of deftness) is called *limb-kinetic apraxia.* Failure to correctly position a limb, move the limb correctly in space, and properly orient the limb is called *IMA.* Patients with IMA also make temporal errors. There are patients, however, who perform imitation worse than they gesture to command. **These** patients have what is called *conduction apraxia.* Patients with ***disassociation*** *apraxia* may be impaired when attempting to perform skilled movements in response to stimuli in one modality (e.g., verbal command) but be able to cotrectly perform movements in response to stimuli of a different modality (e.g., seeing a tool). The inability to solve mechanical problems is termed *conceptual apraxia.* Lastly, the inability to cotrectly order a series of movements is termed *ideational apraxia.* In the following sections, we discuss each of these disorders.

Although limb apraxia is defined as an inability to correctly perform skilled movements with a limb, when

Table 10.1: Error types associated with each of the apraxii: syndromes

Dissociation	+++-	+++	+++	—	—	—	—
Ideation	—	—	—	—	—	Mr	—
Conceptual	—	—	—	—	—	—	

Note: This tahle lists the error types that define each apraxia syndrome. However, often patients may have more than one apraxic disorder. +++ = severe; ++ = moderate; + = less severe.

this inability to perform skilled movements is not caused by sensory loss or by more elemental motor disorders such as weakness, tremors, dystonia, chorea, ballismus, athetosis, myoclonus, ataxia, and seizures. Patients with severe cognitive, memory, motivational, and attentional disorders may also have difficulty performing skilled acts. Whereas the presence of these disorders does not preclude that the patient also has apraxia, before diagnosing apraxia, the clinician should be certain that these behavioral disorders do not fully account for the patient's inability to perform skilled acts.

Apraxia often goes unrecognized and there are several possible reasons for poor recognition. The apraxia associated with hemispheric injury such as strokes and trauma is often associated with an injury to the dominant hemisphere. Thus these patients often have a hemiparesis of theit preferred arm and hand. When these patients attempt to perform skilled acts with their nonpreferred arm and find that they are impaired, they may attribute their difficulty to premorbid clumsiness of the nonpreferred arm. However, even when these patients are able to use their preferred arm, apraxic patients may be anoSOgnosic for their deficits. Unfortunately, many health professionals also do not test for limb apraxia, and they are not fully aware of the nature of errors associated with apraxia.

Limb apraxia has been noted to be a heterogeneous group of disorders with both different clinical pictures and anatomic substrates. In the following sections, we discuss several forms of limb apraxia. These types are defined by both the nature of errors made by the patient and the means by which these errors are elicited. Liepmann {1920) was the first to systematically study limb apraxia. He discussed three types of limb apraxia: melokinetic (or limb kinetic), ideomotor, and ideational. In addition to describing these forms of apraxia, we also discuss three other forms of apraxia which we have called *disassociation apraxia, conduction apraxia,* and *conceptual apraxia.* Although dressing and constructional apraxia are disorders of learned skills that do involve limb use, these disorders are often associated with neglect and visual perceptual disorders, so we do not discuss these here.

Limb-Kinetic Apraxia

Patients with limb-kinetic apraxia demonstrate a loss of deftness or the ability to make finely graded, precise, independent finger movements.

Testing

There are several means by which deftness can be tested. In most patients, both hands should be tested, A small flat object such as a dime may be placed on a table and the patient is asked to pick up the dime. Patients with limb-kinetic apraxia will not be able to use a pincher grasp, which requires independent movements of the thumb and index finger, to pick up the dime. Another aspect of deftness can be tested by measuring rapid finger tapping and by tests that use a pegboard (e.g., Purdue). We have found that one of the most sensitive bedside tests is asking patients to rotate a coin between their thumb, index finger, and middle finger as rapidly as they can. Patients with limb-kinetic apraxia have trouble rotating the coin.

Pathophysiology

Limb-kinetic apraxia most often occurs in the limb contralateral to a hemispheric lesion. Monkeys with lesions confined to the corticospinal system do not show severe weakness but have difficulty making independent finger movements including the pincher grasp. In the clinic, however, patients with limb-kinetic apraxia often have injured their premotor cortex. Recent studies have revealed that when limb-kinetic apraxia is induced by injury to the hemisphere opposite the preferred hand, limb-kinetic apraxia may also be present in the nonpreferred hand, suggesting that the dominant hemisphere may in part have ipsilateral projections.

Ideomotor Apraxia (IMA)

IMA is probably the most common type of apraxia. As discussed in a later section, when patients with

IMA perform learned skilled movements including the performance of pantomimes, imitations, and using actual objects, they make spatial and temporal errors.

Testing

When possible, both the right and the left arm and hand should be tested. When one arm is weak or has another motor disorder that would preclude testing, the nonparctic limb should be tested. Testing of praxis involves selectively varying input as well as varying task demands, When possible, the same items should be used for all subtests. First, patients should be requested to pantomime to verbal command (e.g., "Show me how you would use a bread knife to cut a slice of bread"). Both transitive (i.e., using tools and instruments) and intransitive gestures (i.e., communicative gestures such as waving good-bye) should be tested. Independent of the results of the gesture to command tests, patients should be asked to imitate the examiner performing both meaningful and meaningless gestures. The patient should also be allowed to hold actual tools or objects and to demonstrate how to use the tool or object. In addition to having a patient pantomime to a verbal command, the examiner may want to show the patient pictures of tools or objects and have the patient pantomime in response to these stimuli. The examiner may also want to show the patient real tools or the objects that tools work on (e.g., nail) and without having the patient hold the tool or object request that the patient pantomime the action associated with the tool or object. It may be valuable to see whether the patient can name or recognize transitive and intransitive pantomimes made by the examiner and discriminate between well and poorly performed pantomimes.

When performing skilled acts, patients with IMA make ptimarily spatial and temporal production errors. Spatial errors can be divided into several subtypes including postural (or internal configuration), spatial movement, and spatial orientation. Regarding postural errors, Goodglass and Kaplan (1963) noted that when apraxic patients are asked to pantomime, they often used a body part as the tool. For example, when patients with IMA are asked to pantomime using a pair of scissors, they may use their fingers as if they were the blades. Many normal subjects make similar errors and it is important that the patient be instructed not to use a body part as a tool. Unlike normal subjects who imptove with these instructions, patients with IMA may continue using their body patts as tools (Raymer et al. 1997). When not using their body parts as tools, patients with IMA will often fail to cortectly position their hands as if they were holding the tool or object.

When norma] subjects are asked to use a tool, they will orient that tool to an imaginary target of that tool's action. Patients with IMA often fail to correctly orient their foreiimbs to an imaginary target. For example, when asked to pantomime cutting a piece of paper in half with scissors, rather than keeping the scissors oriented in the sagittal plane, cither the scissors may be oriented laterally (Rothi et al. 1988) or the scissors may not maintain any consistent plane of movement.

When patients with IMA attempt to make a learned skilled movement, they will often make the correct core movement {e.g., twisting, pounding, cutting), but the trajectory of their limb through space is often incorrect (Rothi et al. 1988; Poizner et al. 1990). These spatial trajectory errors are caused by incorrect joint movements. Apraxic patients will often stabilize a joint that they should be moving and move joints they should not be moving, For example, when pantomiming the use of a screwdriver, patients with IMA may rotate their arm at the shoulder and fix their elbow. Shoulder rotation moves the hand in arcs when the hand should be rotating on a fixed axis. When multiple joint movements must be coordinated, patients with apraxia may be unable to coordinate multiple joint movements to get the desired spatial trajectory. For example, when asked to pantomime slicing bread with a knife, the shouldet and elbow joints must be alternately flexed and extended. When the joint movements are not well coordinared, these patients may make primarily chopping or stabbing movements.

Poizner et al. (1990) have noted that patients with IMA may also make timing errors including a long delay before initiating a movement and brief multiple stops (stutteting movements). When normal subjects make a curved movement, they reduce the speed of their movement, and when they move in a straight line, they increase the speed of their movement. Patients with IMA, howevet, do not demonstrate a smooth sinusoidal hand speed when performing cyclic movements such as cutting with a knife.

Path op bysiology

In right-handed individuals IMA is almost always associated with left hemisphere lesions, but in left-handed people, IMA is usually associated with right hemisphere lesions. IMA is associated with lesions in a variety of structures including the corpus callosum, the inferior parietal lobe, and the premotor areas. IMA has also been reported with subcortical lesions that involve the basal ganglia and white matter. We discuss each of these anatomic areas and also attempt to develop a model of how the brain mediates learned purposive movements.

Lesions of the Corpus Callosum. A male patient was described by I.iepmann and Mass (1907) with a right hemiparesis from a lesion of the pons. The patient also had a lesion of his corpus callosum. This patient was unable to correctly pantomime to command with his left atm. Because this patient had a right hemiparesis, his right hand could not be tested. Since the work of Broca, it has been known that the left hemisphere of right-handed people is dominant for language. The patient's inability to

p.um>mime could lie associated with a disconnection between language and motor areas such that the left hemisphere that mediates comprehension of the verbal command could not influence the right hemisphere's motor areas that are responsible for controlling the left hand. This patient, however, could also nor imitate gestures or correctly use actual tools or objects. Therefore a lan-^iLi^-inmiii' disconnection could 1101 account tor these findings. Thus Liepmann and Mass posited that the left hemisphere of right handers contains movement formulas and that the callosal lesion in this patient disconnected these movement formulas from the right hemisphere's motor areas.

Gazzaniga et al. (1967) also found that their patients with callosal disconnection could not correctly pantomime to command with their left hand, but unlike the patient described by Liepmann and Mass, their patients could imitate and correctly use actual tools and objects with their left hand. The preserved ability to imitate and use actual tools and objects suggests that the inability to gesture to command in these patients with callosal lesions was induced by a language-motor disconnection, rather than a movement formula-motor disconnection. In addition, a disconnection between movement formula and motor areas should produce spatial and temporal errors, but many of the errors made by the patient discussed by Liepmann and Mass appeared to be content errors. Watson and Heilman (1983), however, described a patient with an infarction limited to the body of the corpus callosum, Watson and Heilman's patient had no weakness in her right hand and performed all tasks flawlessly with her right hand. In contrast, with her left hand, she could not correctly pantomime to command, imitate, or use actual tools. Immediately after her cerebral infarction, she made some content errors, but subsequently she made primarily spatial and temporal errors. Her performance indicated that not only language but also movement representations were stored in her left hemisphere and her callosal lesion disconnected these movement formulas from the right hemisphere's motor areas.

Lesions of the Inferior Parietal Lobe. It has been proposed by Heilman et al. (1982) that the movement re presentations or movement formulas are stored in the left parietal lobe of right handers and that destruction of the left parietal lobe should induce not only a production deficit (apraxia) but also a gesture comprehension-discrimination disorder. Apraxia induced by (1) premotor lesions, (2) lesions of the pathways that connect premotor areas to motor areas, and (3) lesions of the pathways that lead to the premotor areas from the parietal lobe may also cause production deficits. In contrast to parietal lesions, however, these premotor lesions should not induce gesture comprehension and discrimination disorders. Patients with anterior and posterior lesions have been tested (Heilman et al. 1982); although both groups of patients were apraxic, the patients with a damaged parietal lobe had comprehension and discrimination disturbances, but those without parietal lesions did not.

Liepmann and Mass (1907) proposed that handedness was related to the hemispheric laterality of the movement representations. However, it is not unusual to see right-handed patients with left hemisphere lesions who are not apraxic. Although it is possible that such patients' lesions did not destroy one of the left hemispheric areas important for praxis, many of these patients' lesions arc large and do involve the parietal lobe and other critical left hemisphere areas. As we discussed, not all callosal lesions cause an IMA of the left hand. These results suggest that not all right handers have movement formulas entirely represented in their left hemisphere. Some people may have cither bilateral movement representations or even right hemisphere representations. Apraxia from a right hemisphere lesion in a right hander is rare but has been reported, suggesting that hand preference is not entirely determined by the laterality of the movement representations and may he multifactorial. Whereas the laterality of the movement formula may be the most important factor, there are other factors including deftness (i.e., speed, precision), strength, and even environmental factors.

Supplementary Motor Area Lesions. Muscles move joints, and motor nerves from the spinal cord activate these muscles. The spinal motor nerves are acrivated by corticospinal neurons and the corticospinal neurons are activated by the premotor areas. The premotor areas must instruct the motor area on which neurons to fire and in what order these should he tired.

For each specific skilled movement there is a set of spatial loci that must be traversed in a specific temporal pattern. We proposed that movement formulas represented in the inferior parietal lobe are stored in a three-dimensional supramodal code (Heilman and Rothi 2003). For the corticospinal neurons to properly activate the motor nerves, the stored spatial temporal knowledge has to be transformed into a motor program.

The medial premotor cortex or SMA appears to play an important role in mediating skilled movements. Whereas electrical stimulation of the primary motor cortex induces simple movements, SMA stimulation induces complex movements that may include the entire forelimb. The SMA receives projections from parietal neurons and projects to motor neurons. SMA neurons discharge before neurons in the primary motor cortex. Studies of cctebtal blood flow, an indicator of cerebral metabolism and synaptic activity, have revealed that single repetitive movement increases activation of the contralateral primary motor cortex, but complex movements increase flow in contralateral motor cortex and bilaterally in the SMA. When subjects remain still and think about making complex movements, blood flow is increased to the SMA but not rhe primary motor cortex. Watson et al. (1986)

reported several patients with left-sided medial frontal lesions that included the SMA who demonstrated an IMA when tested with cither arm. Unlike patients with parietal lesions, these patients could both comprehend questions or pantomimes and discriminate between correctly and incorrectly performed pantomimes.

Apraxia has also been reported to be associated with lesions of the convexity premotor cortex. The convexity premotor cortex may be important in coordinating the synchronous actions of multiple joints. Figure 10.1 provides a model for the action processing system we have described thus far. In this figure the label "praxicon" is the theoretical store of the temporospatial representations of learned skilled movements. When performing a skilled act, these representations are transformed into innervatory patterns by SMA and convexity premotor cortex. By the term *innervatory patterns* we mean the program that activates the motor neurons such that the extremity moves in the correct spatial trajectory with the correct timing of each movement.

Conduction Apraxia

A patient was reported who, unlike patients with IMA was more impaired when imitating than when pantomiming to command (Ochipa et al. 1994). Because this patient was similar to the conduction aphasic who repeats poorly, the researchers termed this disorder *conduction apraxia.*

Testing

Testing for conduction apraxia is the same as testing for IMA. Whereas most patients with IMA will improve with imitation, patients with conduction apraxia appear to perform worse with imitation than they do to command.

Patbnphysio logy

The patient with conduction apraxia in the study by Ochipa et al. (1994) could comprehend the examiner's pantomimes and gestures. Wc therefore believe that the patient's visual system could access the movement representations or what we have termed *praxicons,* and these movement representations could activate semantics. It is possible that decoding a seen gesture requires accessing different movement representations than programming an action. Therefore there may be two different stores of movement representations, an input praxicon and an output praxicon. In the verbal domain a disconnection of the hypothetical input and output lexicons induces conduction aphasia, and in the praxis domain a disconnection between the input and output praxicons could induce conduction apraxia.

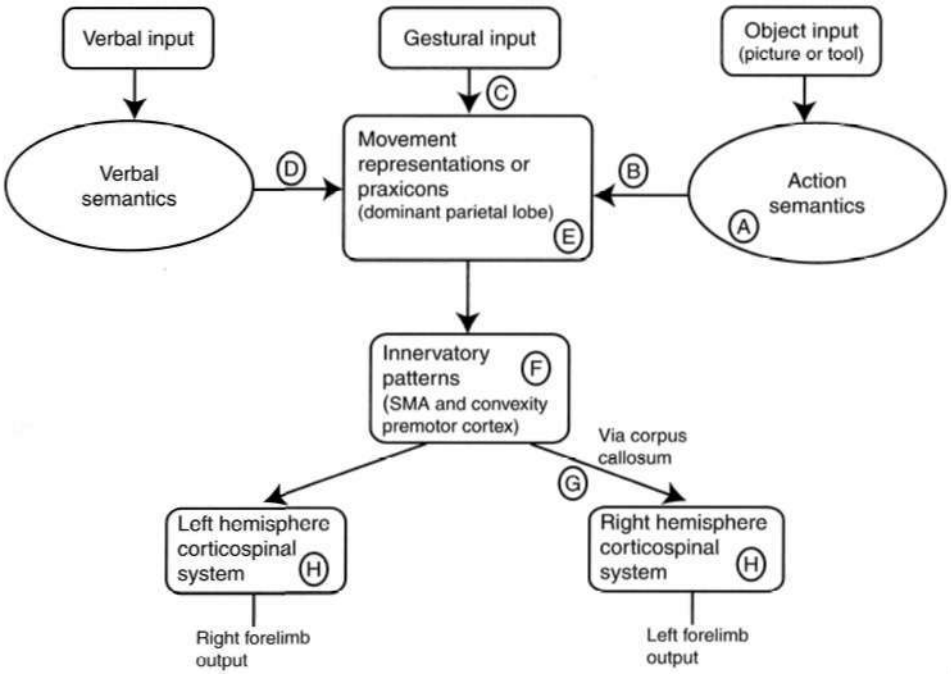

FIGURE 10.1 Diagrammatical model of the praxis system. Degradation of action semantics *(A)* produces conceptual apraxia. Lesions that prevent afferent stimuli from activating movement representations (B, C, D) induce dissociation apraxia. Degradation of the movement representations *(F.)* causes ideomotor apraxia with impaired gesture discrimination and comprehension. Dysfunction of the premotor cortex (F) where the movement representations are converted to motor programs or innervatory patterns induces an ideomotor apraxia with preserved discrimination and comprehension of transitive gestures. Injury to the corpus eallosum (G) produces an ideomotor apraxia of the nonpreferred limb, and injury to the motor cortex *(H)* induces a loss of independent finger movement and precision called *limb-kinetic apraxia.* SMA = supplementary motor area.

Wheteas the lesions that induce conduction aphasia are usually in the supramarginal gyrus, the arcuate fasciculus, ot Wernicke's atea, the lesions that induce conduction apraxia arc unknown.

Dissociation Apraxia

Heilman (1973) described three patients who, when asked to pantomime to command, looked at their hand but would not perform any recognizable actions. Unlike patients with ideomotot or conduction apraxias described earlier, these patients' imitation and use of objects were flawless. Other researchers not only reported patients similar to those reported by Heilman (1973) but also other patients who had a similat defect in other modalities. For example, when asked to pantomime in response to visual or tactile stimuli, they may have been unable to do so but could correctly pantomime to vetbal command.

Testing

The testing that is performed to assess for this disorder is the same as that used for IMA.

Pathopb ysiology

Callosai lesions may not only be associated with an IMA, but callosai disconnection may also cause dissociation apraxia. The subjects of Gazzaniga, Bogcn, and Sperry (1967) and others had dissociation apraxia of theit left hand. With their left hand they could not gesture normally to command but perfotmed well with imitation and actual tools. Whereas language in these patients was mediated by the left hemisphere, movement representations may have been bilaterally represented. Thetefore their callosai lesion induced a dissociation apraxia only of the left hand because the verbal command could not get access to the movement representations stored in the right hemisphere. Whereas the patient with callosai dissociation apraxia will not be able to correctly perform skilled purposive movements of the left arm to command, these patients can imitate normally and use actual tools with their left hand. They perform normally because these tasks do not need vetbal mediation and the movement representations stored in their right hemisphere can be activated by tactile or visual input.

Right-handed patients who have both language and movement formulas represented in their left hemisphere may show a combination of dissociation and IMA with callosai lesions (Watson and Heilman 1983). When asked to pantomime with their left hand, they perform no recognizable movement (disassociation apraxia), but when imitating or using actual rools, they may demonstrate the spatial and temporal errors seen with IMA.

Left banders may demonstrate an IMA without aphasia from a right hemisphere lesion. These left handers are apraxic because their movement tepresentations are stored in their right hemisphere and their lesions destroyed these representations (Heilman 1973; Valenstein and Heilman 1979). These left handers were not aphasic because language was mediated by their left hemispheres (as is the case in most left handers). If these left banders had a callosai lesion, they may have demonstrated a dissociation apraxia of theit left arm and an IMA of their right arm.

These patients reported by Heilman (1973) and those of othct studies probably have an intrahemispheric language-movement formula, visual-movement formula, or somesrhetic-movement formula dissociation. The locations of the lesions that cause these intrahemispheric dissociation apraxias are not known.

Ideational Apraxia

Unfortunately, use of the term *ideational apraxia* has been confusing, with the term erroneously used to label a variety of disorders. For example, Heilman (197,3) used this term when he first desctibed dissociation apraxia. Patients with IMA usually improved when using actual tools and objects, but other researches have reported patients who made errors with the use of actual tools and objects, Heilman (1973) also termed this disturbance *ideational apraxia.* Although the inability to use actual tools and objects may be associated with a conceptual disorder, a severe production disotder may also impair object use. Lastly, the term has also been used to desctibe patients who make conceptual errors. These patients are discussed in the next section. The inability to catry out a series of acts or sequence of actions, an ideational plan that leads to a goal, has also been called *ideational apraxia.* In this chapter, we also define *ideational apraxia* as an inability to correctly sequence a scries of acts that lead to a goal.

Testing

Unfortunately there are no standatdized tests that assess fot ideational apraxia. To test for ideational apraxia, the patients should be tested for their ability to perform multistep sequential tasks, bor example, the examiner may place two slices of bread, mustard, a knife (not too sharp), several slices of ham, and a sandwich bag in front of the patient and ask the patient to prepare a sandwich for work. If the subject fails to perform each step in the correct order that subject may have ideational apraxia.

Path ophysioiogy

Ideational apraxia is most often associated with degenerative dementia but may also be associated with focal lesions of the left hemisphere.

Conceptual Apraxia

To perform a skilled act, we require two types of knowledge: conceptual knowledge and production knowledge. Whereas dysfunction of the praxis production system induces IMA, defects in the knowledge needed to successfully select and use the tools and objects we term *conceptual apraxia.* Therefore patients with IMA make production errors (e.g., spatial and temporal errors), and patients with conceptual apraxia make content and tool-selection errors. The patients with conceptual apraxia may not recall the type of actions associated with specific tools, utensils, or objects (tool-object action knowledge) and therefore make content errors (DcRenzi and Luccelli 1988; Ochipa, Rothi, and Heilman 1989). For example, when asked to demonstrate the use of a screwdriver either by pantomiming or using the tool, the patient with the loss of tool-object action knowledge may pantomime a hammering movement or use the screwdriver as if it were a hammer.

Content errors (i.e., using a tool as if it were another tool) can also be induced by an object agnosia. However, Ochipa et al. (1989) reported a patient who could name tools (and therefore was not agnosic) that he used inappropriately.

Patients with conceptual apraxia may be unable to recall which specific tool is associated with a specific object (tool-object association knowledge). For example, when shown a partially driven nail, they may select a screwdriver rather than a hammer from an array of tools. This conceptual defect may also be in the verbal domain such that when an actual tool is shown to a patient, the patient may be able to name it (e.g., hammer), but when this patient with conceptual apraxia is asked to name or point to a tool when its function is described, he or she cannot. The patient may also be unable to describe the functions of tools.

Patients with conceptual apraxia may also have impaired mechanical knowledge. For example, if they are attempting to drive a nail into a piece of wood and there is no hammer available, they may select a screwdriver rather than a wrench or pliers (which are hard, heavy, and good for pounding) (Ochipa et al. 1992). Mechanical knowledge is also important for tool development and patients with conceptual apraxia may also be unable to correctly develop tools (Ochipa et al. 1992).

Testing

In one test of associative knowledge (tool or object-action), patients may be shown tools such as a screwdriver or objects that tools work on, such as nails, and asked to demonstrate the action that is associated with this tool or object. Patients with conceptual apraxia may make content errors such that they demonstrate the actions of tools other than the one they wetc asked to pantomime. In another test of associative knowledge (tool-object), the patients may be shown an object such as a screw and then are asked to select the proper tool from a group of five tools.

To test mechanical knowledge in patients with normal associative knowledge, one can show them an object such as a partially driven in nail and have them select from five tools the one that would work best for completing the task. The tools from which they may select could include a wrench, a knife, a hand saw, a screwdriver, and scissors. Unfortunately, tests of tool fabrication require special equipment.

Pathophysiology

Licpmann (1920) thought that conceptual knowledge was located in the caudal parietal lobe and DeRenzi and Luccelli (1988) placed it in the temporoparietal junction. The patient reported by Ochipa et al. (1989) was left handed and rendered conceptually apraxic by a lesion in the right hemisphere, suggesting that both production and conceptual knowledge have lateralized representations and that such representations are contralateral to the preferred hand. Further evidence that these conceptual representations are lateralized contralateral to the preferred hand comes from the observation of a patient who had a callosal disconnection and demonstrated conceptual apraxia of the nonpreferred (left) hand (Watson and Heilman 1983). More recently, it has been demonstrated that conceptual apraxia in people who prefer their right hand is most often associated with left hemisphere lesions (Heilman et al. 1997). Conceptual apraxia is perhaps most commonly seen m degenerative dementia of the Alzheimer type (Ochipa et al. 1992). Although both IMA and conceptual apraxia co-occur, Ochipa et al. also noted that the severity nl conceptual and IMA did not always correlate. The observation that patients with IMA may not demonstrate conceptual apraxia and patients with conceptual apraxia may not demonstrate IMA provides support for the postulate that the praxis production and praxis conceptual systems are independent. Although Heilman et al. (1997) demonstrated that lesions located in the hemisphere opposite the preferred hand induce conceptual apraxia, these investigators did not find a specific anatomic area that appeared critical, suggesting that conceptual representations might be widely distributed.

Clinical Pathology

The different forms of limb apraxia discussed in this chapter are most commonly associated with strokes and degenerative dementia of the Alzheimer's and Pick's types. Aptaxia may be seen with many other diseases of the central nervous system including tumors and trauma. Certain forms of apraxia (i.e., limb kinetic and ideomotor)

may be the presenting symptom of basal ganglia disorders such as corticobasal degeneration.

CONCLUSION

Although cognitive-motor disorders are a common, disabling, and enduring sequelae of brain damage, these may be the least recognized neuropsychological disorders associated with cerebral disease. The proper evaluation and diagnosis of these cognitive-motor disorders may not only aid in the diagnosis of the underlying neurological disease but knowledge of these disabilities may help the physician provide the patient and caregiver with information that may help optimize residual resources and thereby improve the patient's quality of life. When possible, the underlying disease should he treated. Although there are no proven specific pharmacologic treatments, cognitive rehabilitation may be of help to some of these patients.

Chapter 11
The Agnosias

Todd E. Feinberg and Martha J. Farah

The word *agnosia* is Greek for "not knowing" and refers to a class of neu to psycho logical disorders in which patients fail to recognize familiar objects despite seemingly adequate perception, memory, language, and general intellectual ability. The very idea that a patient could "not know" an object or face by sight, for example, yet retain other prerequisite abilities seems paradoxical to some and was once fiercely contested in the neurological literature. As recently as the 1950s, it was suggested that pure visual agnosia does not exist but is merely an effect of the combination of subtle perceptual problems and genctal intellectual impairment. As we have come to understand more about perception, however, the appearance of paradox has receded. We now know that perception involves many levels of internal representation, ranging from lower level sensory images to more abstract representations of object shapes, sounds, feels, and so on. When perception is viewed in this way, it can be seen how various interruptions in processing along this cascade of representations could interfere with recognition while preserving at least some perceptual abilities, as well as language, memory, and intellect. From this perspective, it also follows that there should be a range of agnosic disturbances, depending on the perceptual modality affected and the level of processing at which it is affected. In this chapter, we focus on the three best known types of agnosia: visual, auditory, and tactile agnosia. Within visual agnosia, we delineate subtypes of clinical and theoretical interest. We review the clinical features of each disorder, along with their anatomy and their theoretical implications for basic neuroscience.

VISUAL AGNOSIA

Perhaps because the **human** brain has devoted more tissue to vision than to any of the other senses, visual agnosias appear to be the most common form of agnosia, with the largest number of distinct subtypes. In any case, more is known about the visual agnosias than agnosias in other senses, and our review accordingly treats visual agnosia in greatest detail.

Appcrceptive-Associative Distinction

Understanding of visual agnosia began in 1890, when Lissauer first suggested that disorders of visual recognition could be divided into two types: apperceptive agnosia and associative agnosia. According to Lissauer, apperceptive agnosics have a disorder of complex visual perceptual processes. They arc not blind because they can describe their visual experience; however, they do not have sufficient higher level visual perception to enable object recognition.

In contrast to apperceptive agnosia, Lissauer suggested that perception could be normal in associative agnosia, and the problem could lie downstream in the process of associating a perceptual representation with more general knowledge. Associative visual agnosics set' ":i normal percept stripped of its meaning." The apperceptivc-associative dichotomy is useful insofar as it distinguishes between two broad but fairly distinct classes of patients: those with frank perceptual impairments and those without. However, the underlying theoretical assumption that perception is at fault only in agnosics in the apperceptive group is no longer held; many cases of so-called *associative agnosia* are believed to result from the loss of highct level visual processes.

Within the broad classes of apperceptive and associative agnosia, many finer distinctions can be made. For example, disruption of different types of perceptual processes can result in different agnosias with pronounced perceptual impairment. Among the associative agnosias, recognition

of different types of visual stimuli may be disproportionately impaired. Each major subtype of apperceptive and associative visual agnosia is reviewed here.

Apperceptive Visual Agnosia

Apperceptive visual agnosia is sandwiched, clinically and theoretically, between cortical blindness and associative visual agnosia. These patients arc not cortically blind; they have conscious visual experience, yet their visual perceptual processes are grossly abnormal and are clearly the cause of the object-recognition impairment. It could be argued that given the definition offered—of agnosia as a disorder of object recognition not resulting from a more basic perceptual impairment—these patients should not even be considered agnosic at all. The difference between apperceptive visual agnosia and patients who fall outside the exclusionary criteria is the relatively preserved primary visual capacities of the apperceptive visual agnosic, including acuity, brightness discrimination, color vision, motion perception, and other elementary visual capacities (Farah and Feinberg 1997), It is in contrast to these capacities that their shape perception and hence object recognition seem disproportionately impaired.

The dramatic impairment of shape perception is suggested by the performance of one typical apperceptive agnosic (whose agnosia was secondary to carbon monoxide poisoning) in a shape-matching task, shown in Figure 11.1A. The patient's attempts at copying simple geometric figures are shown in Figure 11.IB, Recognition of real objects may be somewhat better than recognition of geometric shapes, although performance is still very poor and depends on nonshapc cues, such as size, color, texture, and specularity. In several cases of apperceptive agnosia, motion facilitates shape perception. This is true whether the motion is of the whole object or whether a simple shape, such as a letter or geometric figure, is "drawn" in the air with a finger. In most cases of apperceptive agnosia, the brain damage is diffuse and posterior, with carbon monoxide poisoning a common cause.

One way of interpreting apperceptive agnosia is in terms of a disorder of grouping processes that normally operate over the array of local features representing contour, color, depth, and so on at each point in the visual field. Outside of their field detects, apperceptive agnosics have surprisingly good perception of local visual properties. They fail when they must exttact more global structure from the image. Motion is helpful because it provides another cue to global structure in the form of correlated local motions. The perception of structure from motion may also have different neural substrates from the perception of structure from static contour (Marcar and Cowey 1992), and this may conttibutc to its sparing in apperceptive agnosia.

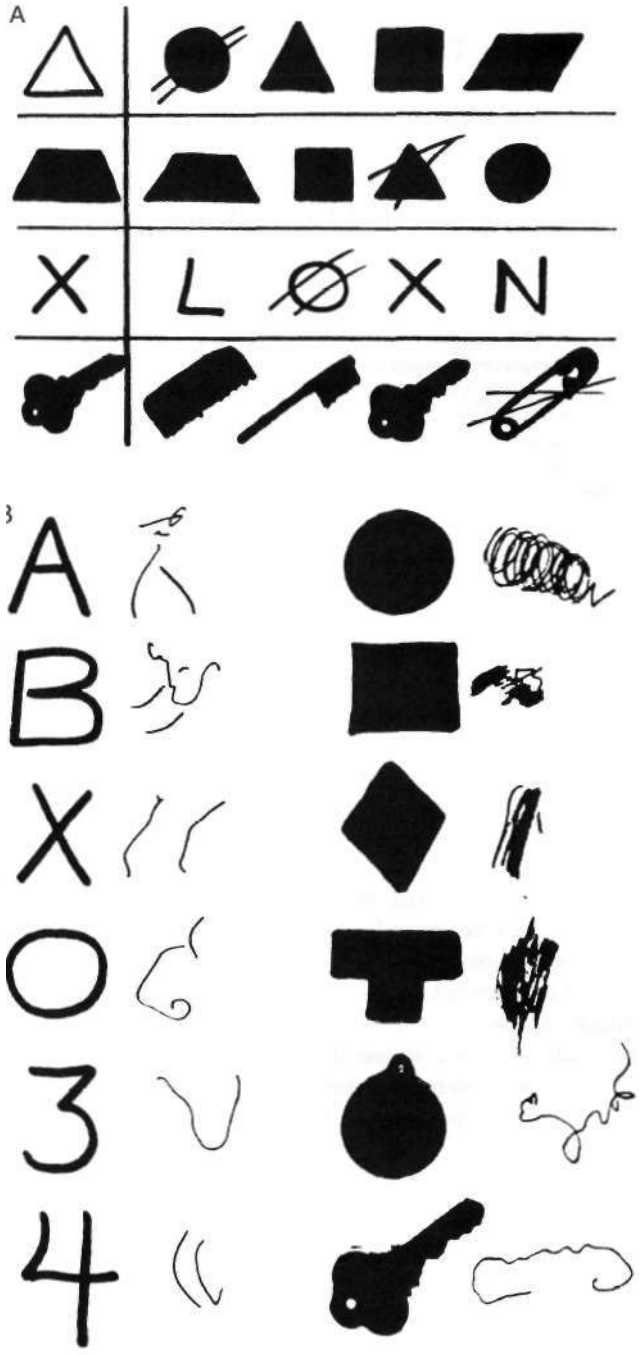

FIGURE 11.1 Evidence of impaired shape matching (A) and copying ability (B) in a patient with apperceptive agnosia. (Reprinted with permission from Benson, R. & Greenberg, J, P. 1969, "Visual form agnosia. A specific defect in visual discrimination," *Arch Neurol*, vol. 20, pp. 82-89.)

Related Syndromes

Some authors have grouped other types of visually impaited patients with the ones cited here as cases of apperceptive agnosia. A description of these disorders follows.

SiniitltiiHtiguosiii is a term used to describe impaired perception of multi element or multipart visual displays. When shown a complex picture with multiple objects or people, simultanagnosics typically describe them in a piecemeal manner, sometimes omitting much of the material entirely and therefore failing to interpret the overall nature of the scene being depicted.

In dorsal simultanagnosia, patients have an attentional limitation that prevents them from seeing more than one object at a time. Occasionally, their attention may be captured by just one part of an object, leading to misidentification of the object and the appearance of petception confined to relatively local image features. The similarity to apperceptive agnosia is limited, however. Once they can attend to an object, dotsal simultanagnosics recognize it quickly and accurately, and even their "local" errors encompass much more global shape information than that available to apperceptive agnosics. Their lesions are typically in the posterior parietal cortex bilaterally.

In ventral simultanagnosia, patients can recognize whole objects but are limited in how many objects can be recognized in a given period. Their descriptions of complex scenes are slow and piecemeal, but unlike apperceptive agnosics, their perception of single shapes is not obviously impaired. This impairment is most apparent when reading because the individual letters of words are recognized in an abnormally slow and generally serial manner. Unlike dorsal simultanagnosics, their detection of multiple stimuli appears normal; the bottleneck is in recognition *per se.* Unlike apperceptive agnosics, they perceive individual shapes reasonably well. In fact, the perceptual disorder of these patients is mild compared with both dorsal simultanagnosics and apperceptive agnosics, and for this reason it may be more sensible to consider them to have a form of associative agnosia. Indeed, they are discussed later in this chapter in rhe context of associative agnosia, ["heir lesions are typically in rhe left inferior tcmporo-occipital cortex.

A final category of impairment whose relation to apperceptive agnosia should be made clear is perceptual categorization deficit. It is equivalent to the impairment that Warrington termed *apperceptive agnosia* but is quite distinct from what we and most other writers mean by the term. The hallmark of perceptual categorization deficit is poor performance at recognizing or matching objects seen from unusual views or illuminated in unusual ways so as to produce confusing shadows, such as the pictures shown in Figure 11,2. This impairment has been interpreted as a breakdown in the mechanisms of object shape constancy, that is, the visual mechanisms that allow us to appreciate the equivalence of an object's three-dimensional shape across different views and under different lighting conditions. Two considerations suggest that we should be cautious before accepting this interpretation. First, the impairment has been demonstrated only with unusual views, in which major axes arc foreshortened or salient features occluded, whereas a rrue loss of shape constancy affects the matching of any views that differ from each other, whether or not they are unusual. Second, the impairmenr is often seen in patients who have no problems with everyday object recognition. Thus perceptual categorization deficit may represent a loss of a certain type of visual problem-solving ability, rather than loss of an essential component of object recognition.

Associative Visual Agnosia

Associative visual agnosia refers to a visual object-recognition impairment due neither to a more basic perceptual deficit, as seen in apperceptive visual agnosia, nor to a

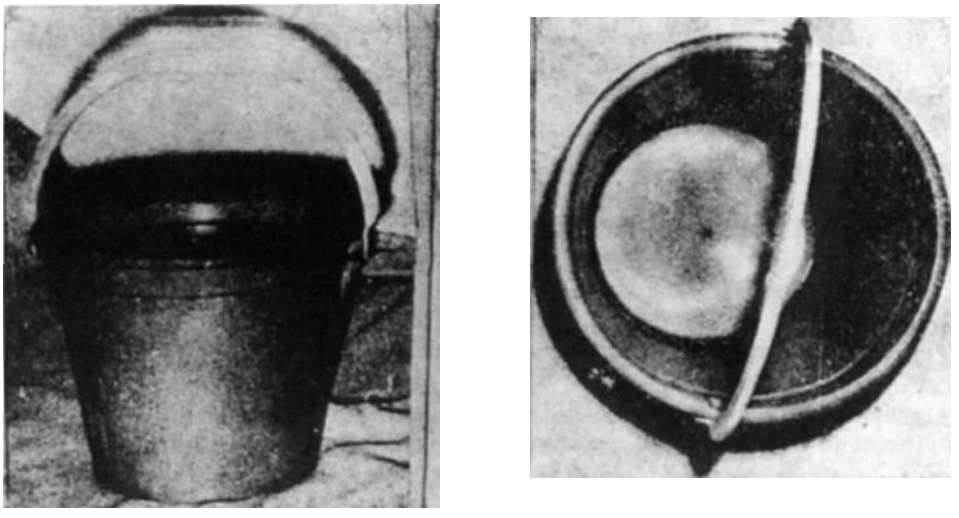

FIGURE 11.2 Unusual views of common objects pose particular problems for patients with "perceptual categorization deficit.

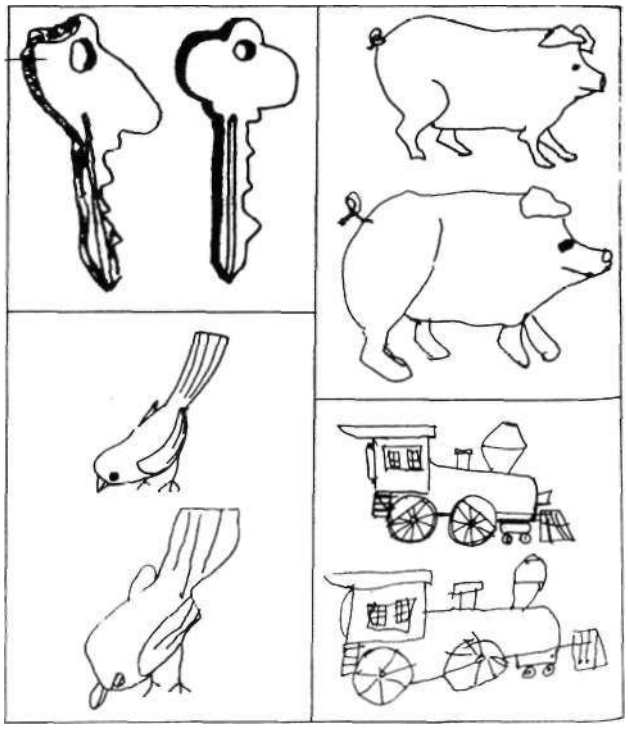

FIGURE 11.3 Example of the preserved copying ability of associative agnosic patients.

higher order disorder of language, communication, intellectual impairment, or other deficits (Weinberg et al. 1994). Unlike the patient with apperceptive agnosia, associative visual agnosics are able to make good copies of objects they cannot recognize. Figure 11.3 shows examples of such copies. The preservation of copying seems to demonstrate that perception is not at fault in associative agnosia, but this conclusion is probably not correct. By its very nature, copying requires piecemeal processing because lines can he drawn only one at a time, whereas normal object recognition requires seeing the whole object simultaneously. When tested directly, the ability of associative visual agnosics to apprehend the whole of an object is impaired. The errors of agnosics often reflect their reliance on local features (e.g., calling a fork "a comb" on the basis of the tines) or an impoverished overall view of the object (e.g., calling a salt shaker "a barrel"). The functional locus of damage in associative visual agnosia is therefore presumed to be high-level visual perceptual representations of object shape.

Dissociations within Associative Visual Agnosia

Associative visual agnosics vary in the scope of their recognition impairment, with some encountering difficulty primarily with faces, others with printed words, and others showing sparing of these categories of stimuli. The dissociations among visual stimulus categories are of interest, theoretically, for what they tell us about the organization of normal visual recognition processes.

Prosopagnosia

Prosopagnosics cannot recognize familiar people by their faces alone and must rely on other cues for recognition, such as voice, distinctive clothing, or hairstyle. The disorder can be so severe that even close friends and family members are not recognized. Although many prosopagnosics have some degree of difficulty recognizing objects other than faces, in some cases the deficit appears strikingly selective for faces. Some writers have suggested that prosopagnosia is simply a mild agnosia and that faces are simply the most difficult type of object to recognize. Evidence is accumulating against this position. Prosopagnosics have been found to be *disproportionately* impaired with faces, when the recognition difficulty for normal subjects has been taken into account relative to a variety of comparison stimuli, including sheep faces {McNeil and Warrington 1993), eyeglass frames (Farah, Klein, and Levinson 1995), and inverted faces {Farah et al. 1995). Further evidence that prosopagnosia represents damage to a distinct system for face recognition comes from agnosic patients who show relative preservation of face recognition (Feinberg er al. 1994).

Pure Alexia

The impairment of visual word recognition, in the context of intact auditory word recognition and writing ability, is known as *pure alexia* and may be found alone or in association with visual object agnosia. Although visual-verbal disconnection plays a role in some cases, impairment of visual letter and word representations is invariably found. As with prosopagnosia, the opposite dissociation also exists, namely, spared word recognition with impaired object and face recognition.

Neuropathology of Associative Visual Agnosia

A variety of lesion locations have been reported to be responsible for cases of associative visual agnosia. Almost invariably, the lesions are posrerior and inferior, affecting ventral temporal and occipital regions. Damage is frequently bilateral, although in some cases only the left or right hemisphere is affected. The precise location of damage appears to correlate with the scope of the agnosic impairment. In patients who are agnosic for objects, faces, and printed words, damage is bilateral. If the impairment mainly affects faces, damage may be bilateral or confined to the right hemisphere (De Renzi et al. 1994), as in Figure 11.4. When face recognition is spared, the damage is generally confined to the left hemisphere, with medial structures, including the parahippocampal, fusiform, and lingual gyri, generally involved, as shown in

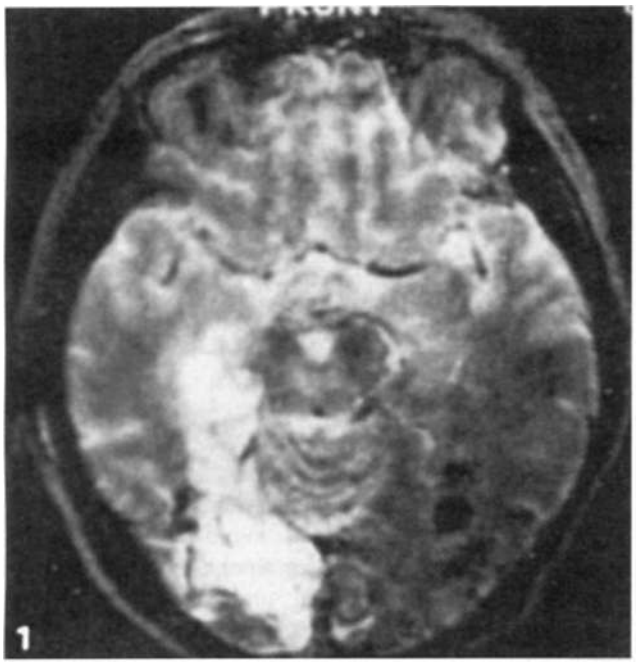

FIGURE 11,4 Typical partem of brain damage in a case of associative agnosia with prosopagnosia. (Reprinted with permission from De Renzi, E., Perani, D., Carlesimo, G. A., et a). 1994, "Prosopagnosia can be associated with damage confined to the right hemisphere: An MRI and PET study and a review of the literature," *Neuropsychologic,* vol. 32, pp. 893-902.)

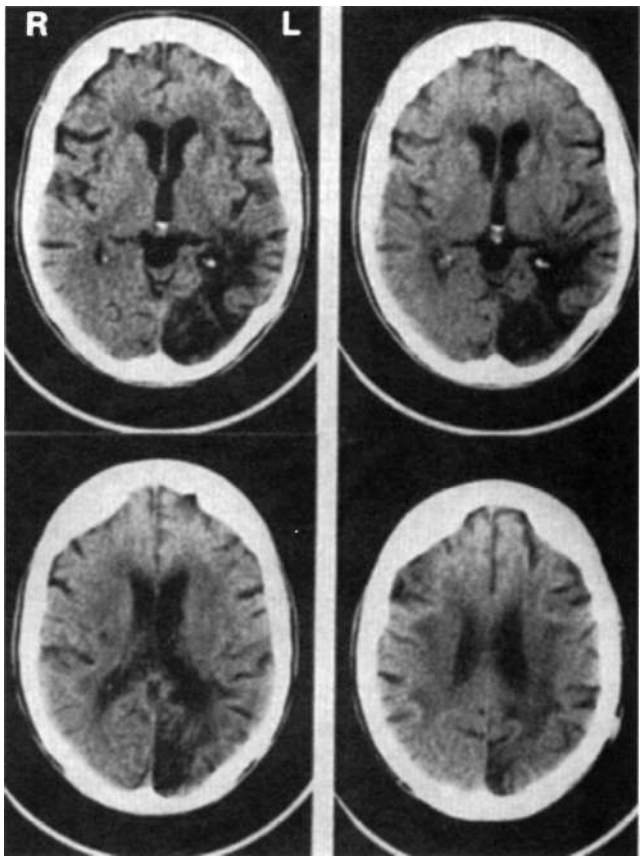

FIGURE 11.5 Typical pattern of brain damage in a case of associative agnosia sparing face recognition. (Reprinted with permission from Feinberg, T. E., Schindler, R. J., Ochoa, E., et al. 1994, "Associative visual agnosia and alexia without prosopagnosia," *Cortex,* vol. 30, pp. 395-412.)

Figure 11.5 (Feinberg et al, 1994). When face recognition alone is impaired, or when face and object recognition are impaired but reading is spared, the lesions are generally cither in the right occipitotemporal region or bilateral. When reading alone is impaired, or when reading and object recognition are impaired but face recognition is spared, the lesions are generally on the left.

Recently, several investigations have studied object recognition using functional magnetic resonance imaging (fMRI). Kanwisher et al. (1996) compared regional brain activity as measured by fMRI while subjects viewed photographs of either objects or faces. These investigators initially found an inferolateral area located at the occipitotemporal junction that was activated during the extraction of processing of an object's shape. Further investigations (Kourrzi and Kanwisher 2000} suggested that an area known as the lateral occipital complex (LOC), a region composed of the lateral and ventral occipital cortex that extends into the posterior temporal lobe, is activated during the processing of an object's shape. The activation of this territory during shape discrimination was independent of the image cues that defined the shape (lines, shading, texture, etc.). Similar fMRI results regarding the role of the LOC in object shape processing were reported by Mazer and Gallant (2000).

Ear et al. (2001) investigated fMRI activation during a task that required subjects to recognize briefly presented photographs of masked objects. They found ventral temporal activation eatly in the process of object identification. Furthermore, the degree of activation in this region correlated with the degree of object identification. Finally, awareness of an object's identity correlated with more anterior activation, and full awareness of an object's identity was associated with activation as far anterior as anterior fusiform gyrus. The authors argue that these findings suggest there is a gradient t>t object identification that spreads from posterior to more anterior visual areas as explicit object identification unfolds.

Related Syndromes

As with apperceptive agnosia, the term *associative agnosia* has been applied to a number of distinct but related syndromes. Two that merit discussion here are semantic memory impairments and optic aphasia. In the fonnct, patients lose general knowledge about the world (termed *semantic memory* by cognitive psychologists), resulting in an inability to name, or otherwise indicate recognition of, visually presented objects {Farah and Grossman 1997).

The impairment may affect all types of stimuli, as when it occurs in Alzheimer's disease or in the selective loss of semantic memory known as *semantic dementia,* or it may disproportionately affect knowledge from specific categories, such as living things. Because the functional locus of damage is postperccptual, in semantic memory, these patients also perform poorly in entirely nonvisual tasks, such as answering verbal questions about objects. Optic aphasics encounter difficult)' when naming visually presented objects. They can convey their recognition of a visual stimulus by pantomime (e.g., a drinking motion when shown a cup) or sorting semantically related stimuli together and can name stimuli in modalities other than vision. Most authors currently distinguish between associative agnosia and optic aphasia, although patients with the latter have sometimes been called *associative agnosics.* The underlying impairment in optic aphasia is unclear. To the extent that optic aphasics are able to derive semantic understanding of visual stimuli, it seems strange that they should be unable to name them.

Assessment of Visual Agnosia

The first step in the assessment of visual agnosia is to establish the preservation of adequate elementary visual abilities, including tests of visual acuity and visual fields. If these are not sufficiently preserved to allow successful object recognition, the patient fails to meet a key exclusionary criterion for agnosia. Computed tomographic (CT) or magnetic resonance imaging (MRI) scans should be obtained and compared with the known patterns of neuropathology for associative visual agnosia and, although they are often less clear, for apperceptive visual agnosia. Difficulty with naming (anomia) can be distinguished from difficulty with visual recognition by comparing visual and tactile naming, naming of verbally described objects, and sorting of objects or pictures by semantic category (e.g., putting kitchen items together, separate from sports equipment). Patients with semantic memory impairment also, like anomics, fail to produce a name for touched or described objects and fail to sort. A purely anomic patient may be able to indicate the identity of a visually presented object by circumlocution and pantomime, even if the name escapes him or her. Patients with optic aphasia can be identified by assessing naming of objects through techniques other than vision and by assessing visual recognition nonverbally. These patients are generally able to name objects by touch or description (in contrast to patients with anomia and semantic memory impairment), as well as to circumlocute and pantomime an identification response to visually presented objects and sort semantically related objects (all in contrast to visual agnosics). Error types are also useful diagnostically. Visual agnosics generally misidentify an object as one that is visually similar (e.g., snake for hose, a "visual error"), whereas patients with semantic memory impairment or optic aphasia make more "semantic errors" (e.g., lettuce for cucumber). Perseverative errors often predominate in optic aphasia.

The distinction between the apperceptive and associative agnosias can be made by gauging the patient's perception of relatively simple shapes with tasks such as matching and copying. Associative agnosics perform these tasks accurately, whereas apperceptive agnosics do poorly on them.

AUDITORY AGNOSIA

Like visual agnosia, auditory agnosia is not one disorder but a group of disorders, characterized by a failure to recognize verbal or nonverbal sounds. In this section, we focus on a few specific conditions that may exist in relatively pure form, with the understanding that most clinical cases have a unique profile of deficits representing a mixture of these characteristics.

The auditory agnosias can be thought of as a spectrum of disorders, bounded by cortical deafness on one end and disorders of language and thought at the other. A patient who is cortically deaf fails to meet one of the primary exclusionary criteria for auditory agnosia, namely, elementary perceptual processes that are adequate for sound recognition. Such patients commonly demonstrate a host of auditory perceptual deficits, including abnormal pure-tone audiology, sound localization, and temporal auditory analysis. Cortical deafness has generally been described in patients with cerebrovascular disease resulting in bilateral infarcts of the temporal lobes destroying Heschl's gyri. The classic clinical presentation is of a patient with a pre-existing unilateral lesion of one temporal lobe who suddenly develops deafness because of a second lesion in the opposite hemisphere. In the process of recovery from cortical deafness, the patient may pass through one or another of the auditory agnosic disorders described here.

Nonverbal Auditory Agnosia

The auditory agnosia that seems most analogous to visual associative agnosia is nonverbal auditory agnosia, also known as *auditory sound agnosia* or *environmental sound agnosia.* The patient with this condition fails to recognize common objects and events by their sounds, such as a dog barking, keys jingling, or a door slamming. Although the patients are not cortically deaf, most reported cases initially present with the clinical picture of cortical deafness. They then recover to the point that standard audiometry is near normal or normal, but auditory recognition remains impaired. Just as visual agnosics' errors tend to be visual, auditory agnosics are often acoustically based. For instance, one patient misidentified a telephone ring as

"sound of railroad crossing," a car honk as "hoot," and thunder as "fireworks."

Just as visual agnosias may affect the recognition of some classes of visual stimuli more than others (e.g., words and faces), so auditory agnosia may affect recognition of certain classes of sounds more than others. The impairment of environmental sound recognition described here is usually found in conjunction with impaired recognition of speech sounds, although selective nonverbal auditory agnosias have been reported. "When the recognition deficit is largely restricted to nonverbal sounds, there is a tendency for right hemisphere lesions to predominate (Bauer and Zawacki 1997).

Engelien et al. (1995} and Engclien, Stern, and Silbersweig (2001) performed a positron emission tomography (PET) study of a patient with bilateral perisylvian strokes and auditory agnosia. During one stage in recovery, the patient remained word deaf but made a partial recovery in his ability to make semantic judgments on meaningful nonverbal auditory stimuli. During this period, the investigators compared this subject's PET activation during passive listening of environmental sounds to PET activation during active semantic categorization of meaningful nonverbal sounds. The authors found that the patient's recovery of auditory nonverbal recognition was associated with "bilateral activation of a distributed network comprising prefrontal, middle temporal, and inferior parietal cortices." The authors suggest that in normal subjects during this auditory recognition task, this pattern of activation occurs exclusively in the left hemisphere.

Auditory agnosias also exist for spoken words (analogous to pure alexia), for voices (analogous to prosopagnosia), and for music. It is to these more domain-specific forms of agnosia that we now turn.

Pure Word Deafness

Pure word deafness (also known as *auditory agnosia for speech* or *verbal auditory agnosia)* is characterized by a disturbance in comprehension of spoken language not explainable by the more generalized auditory processing defects seen in cortical deafness or the broader linguistic impairments typical of Wernicke's aphasia or transcortical sensory aphasia. Pure word deafness is distinguished from cortical deafness by the patient's relative preservation of prrmary sensory processing, as judged by pure-tone audiometry and other psycho acoustic measures. The patient's relatively preserved recognition of nonverbal environmental sounds, such as the ringing of a telephone or the whistling of a bird, separates the disorder from generalized auditory agnosia. It is further distinguished from Wernicke's aphasia by the relative preservation of reading, writing, and normal spontaneous speech. Unlike the patient with transcortical sensory aphasia, the patient with pure word deafness has impaired word repetition.

A variety of auditory perceptual processing deficits may be found in pure word deafness. For example, a generalized disturbance in the temporal resolution of the auditory stimuli, abnormal click-fusion thresholds, difficulties with phonemic discrimination, and abnormalities on dichotic listening tasks showing prominent right ear suppression have been reported (Bauer and Zawacki 1997). In reality, all cases of so-called "pure word deafness" that were adequately studied show other perceptual or agnosic disturbances. In spite of this, the term is still useful because cases do occur in which the primary deficit in word agnosia is the outstanding impairment and occurs out of proportion to whatever other cortical auditory defects may be present,

As is the case with cortical deafness, pure word deafness most commonly occurs as a result of bilateral temporal cortical-subcortical infarcts. It may occur as a stage of recovery in a new onset Wernicke's aphasia or in a patient with a recovered Wernicke's aphasia with a new right temporal lobe infarction. It follows therefore that the lesions reported in pure word deafness are of two varieties. One circumstance is that of bilateral lesions located in the anterior or middle portions of the first temporal gyri, often with some sparing of Hcschl's gyri (area 41). A second localization is a single lesion involving Heschl's gyrus of the dominant hemisphere, as well as the subjacent white matter. In the latter case, the white matter lesion is presumed to destroy the auditory projection from the ipsilatcral medial geniculate nucleus, as well as the callosal fibers from the opposite superior temporal region. In both cases, the lesions arc presumed to isolate the Wernicke's areas from auditory input, resulting in a patient who is neither deaf nor aphasic but in whom auditory input cannot reach language areas necessary for auditory comprehension.

Other Auditory Agnosias

Auditory amusia and *sensory amusia* are terms used to describe the condition in which a patient has lost the ability to recognize a range of features of heard music, such as distinguishing a particular singing voice or recognizing previously learned melodies. Due to the multifactorial nature of music appreciation and the effect of premorbid musical ability and training, it is difficult to make clear-cut clinicopathological correlations. It appears that both hemispheres normally contribute to music cognition. On the basis of two cases of auditory amusia, Peretz et al. (1994) suggested that bilateral lesions of auditory association cortices that spare Heschl's gyri are the critical lesions sufficient to impair melody, voice, and speech prosody discrimination or recognition.

Pbonagnosia refers to a condition comparable to prosopagnosia, in which patients lose the ability to recognize familiar voices. This specific disorder in recognition of familiar voices has been linked to pathology to the right parieral lobe.

Assessment of Auditory Agnosia

The first step in the detection and diagnosis of auditory agnosia is to assess primary auditory perception. This can range from the simple detection of softly spoken words or finger snaps at the bedside through a complete audiologic evaluation, including pure-tone audiometry and speech detection thresholds. Brainstem auditory evoked responses should also be obtained. The examiner must also rule out aphasia as the cause of the patient's auditory recognition disturbance. Thus in addition to assessment of verbal repetition and comprehension, a full assessment should be made of reading silently for comprehension, the ability to follow written commands, and visual naming, as well as a close observation of spontaneous speech for the presence of aphasia. Finally, the subtype of auditory agnosia can be distinguished by the relative disturbance in verbal versus nonverbal material, spoken speech, and melody appreciation. Melody appreciation can be assessed using various subtests of the Seashore Test of Musical Talent. CT scan or MRI should be helpful in distinguishing focal brain pathology as a cause of an agnosic disturbance from impairment resulting from more generalized dementias.

TACTILE AGNOSIA

Tactile agnosia refers to a disorder of object recognition via the tactile modality that cannot be attributed to a more basic somatosensory impairment, language dysfunction, hemispatial neglect, or generalized intellectual impairment. The existence of a pure tactile agnosia has been disputed {Caselli 1997). One likely reason is that tactile agnosia is often subtle and escapes clinical detection. The lack of precise quantitative testing of somatosensory function for most clinical cases has also added to the difficulty of documenting a dissociation between tactile agnosia and more basic somatosensory disorders. Another complicating factor is that we normally recognize objects through vision and occasionally through sound, only rarely using purely tactual information (e.g., searching for keys or lipstick at the bottom of a handbag), and therefore it is not obvious what normal performance is.

As with vision and hearing, tactile perception can break down at a number of stages. Caselli (1997) divides somesthetic functions into basic, intermediate, and complex types. Basic somesthetic functions include light touch, vibration, position sense, superficial pain and temperature, and two-point discrimination. Intermediate somesthetic functions include weight and texture discrimination and the type of simple form discrimination that would generally fall under the category of astereognosis. Complex somesthetic functions are those that are disturbed in the pure forms of tactile agnosia. In detailed somesthetic and psychologic testing of a tactile agnosic, Reed and colleagues (Reed and Caselli 1994; Reed, Caselli, and Farah 1996) found that the simple and intermediate functions mentioned earlier were intact. They also found that tactual memories were intact (assessed by questions such as "Which is smoother, an orange skin or a golf ball?") but that the integration of complex tactile form information was impaired. Figure 11.6 shows a parienr's drawing of an object that she was unable to recognize. The two holes of the cassette were repeatedly touched in the course of her attempt to identify the object, and she was apparently unable to integrate the informarion from the separate touches into an accurate representation of the overall shape of the object. It is important to note that her spatial integration ability for separately encoded features of a visual stimulus was normal. Tactile agnosia is typically a unilateral disorder, which enables the examiner to use the normal hand as a control.

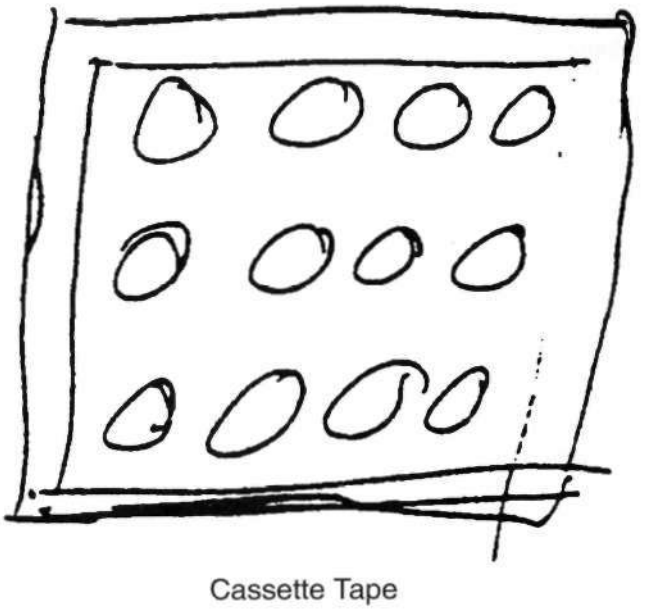

FIGURE 11.6 The attempt of a tactile agnosic to draw a cassette tape that she felt but could not recognize.

Anatomical Considerations

Figure 11.7 shows the anatomy of somatosensory cortex in the human brain. The first somatosensory area (SI) receives the primary thalamic projections for cortical

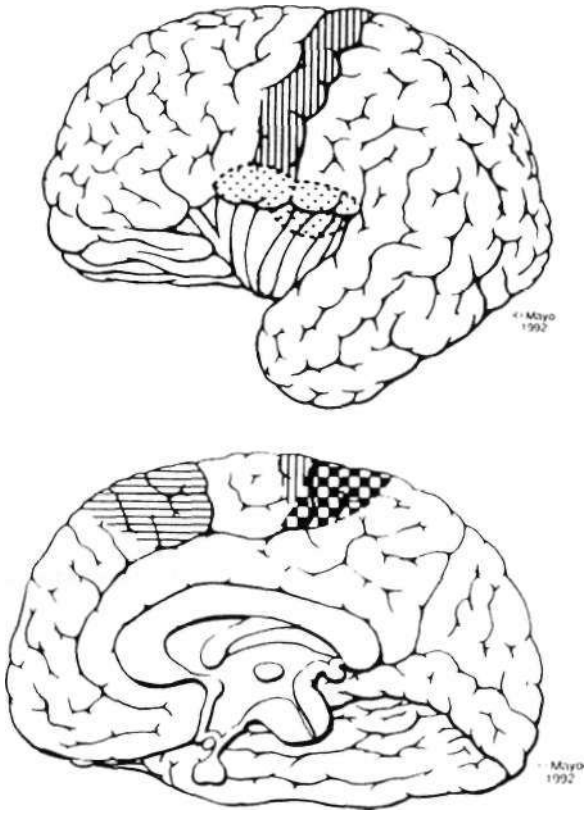

FIGURE 11.7 Areas of the human brain involved in somatosensory perception and recognition, (Reprinted with permission from Caselli, R. J. 1993, "Ventrolateral and dorsomedial somatosensory association cortex infarction produce distinct sonicsthetic syndromes," *Neurology,* vol. 43, pp. 762-771.)

somatosensory functioning. It includes Brodmann's areas 3a, 3b, 1, and 2. Neurons in these regions are responsible for initial cortical sensory processing. Lesions in the region of SI produce impairment in basic and intermediate sense modalities, Caselli (1997) suggested that pure tactile agnosia results from lesions located in ventrolateral association cortices, in a region corresponding to the second somatosensory area (SII), located largely within the parietal operculum. He felt that the posterior insula may play a role in higher order tactile object identification. He also found that lesions in dorsomedial association cortex (the supplementary sensory area) produced a profound disturbance in basic somatosensory processing resembling that of patients with SI lesions, and these patients were additionally found to have severe contralateral limb apraxia. Furthermore, with time, these patients improved considerably and a chronic tactile agnosia occurred only in patients with ventrolateral damage. The role of the SII in higher order tactile rccogntion has found additional support from the fMRI study of Reed et al. (1999) who found selective activation of SII during tactile identification of common real objects.

Assessment of Tactile Agnosia

As with visual or auditory agnosia, basic perceptual functions must be assessed and found adequate for object recognition. These include light touch, vibration, position sense, superficial pain and temperature, and two-point discrimination, as well as weight and texture discrimination and simple form discrimination, such as distinguishing flat from curved surfaces and edges. Language and other cognitive functions required for object identification through any modality must also be examined. Because the ipsilesional hand is available as a control, norma! naming of palpated objects with that hand provides good evidence that higher order linguistic and cognitive factors are not the cause of the tactile agnosia. MRI or CT scans should be evaluated relative to the known anatomy of this disorder.

Chapter 12
Language and Speech Disorders

A. APHASIA

Howard S. Kirshner

The study of language disorders involves the analysis of the most human of attributes, the ability to communicate through common symbols. Language has provided the foundation of human civilization and learning, and **its** study has been the province of philosophers and physicians. When language is disturbed by neurological disorders, analysis of the patterns of abnormality has practical usefulness in neurological diagnosis. Historically, language was the first higher cortical function to be correlated with specific sites of brain damage. It continues to serve as a model for the practical use of a cognitive function in the localization of brain lesions and for the understanding of human cortical processes in general.

Aphasia is defined as a disorder of language that is acquired secondary to brain damage. This definition, adapted from Alexander and Benson (19.97), separates aphasia from several related disorders. First, aphasia is distinguished from congenital or developmental language disorders, called *dysphasias.* {Contrary to British usage, in the United States, the term *dysphasia* applies to developmental language disorders rather than partial or incomplete aphasia.}

Second, aphasia is a disorder of language rather than speech. Speech is the articulation and phonation of language sounds; language is a complex system of communication symbols and rules for their use. Aphasia is distinguished from motor speech disorders, which include dysarthria, dysphonia (voice disorders), stuttering, and speech apraxia. Dysarthrias arc disorders of articulation of single sounds. Dysarthria may result from mechanical disturbance of the tongue or larynx or from neurological disorders, including dysfunction of the muscles, neuromuscular junction, cranial nerves, bulbar anterior horn cells, corticobulbar rracts, cerebellar connections, or basal ganglia. Apraxia of speech is a syndrome of misarticulation of phonemes, especially consonant sounds. Unlike dysarthria, in which certain phonemes are consistently distorted, apraxia of speech contains inconsistent distortions and substitutions of phonemes. The disorder is called an apraxia because there is no primary motor deficit in articulation of individual phonemes. Clinically, speech-a praxic patients produce inconsistent articulatory errors, usually worse on the initial phonemes of a word and with polysyllabic utterances. Apraxia of speech, so defined, is commonly involved in speech production difficulty in the aphasias.

Third, aphasia is distinguished from disorders of thought. Thought involves the mental processing of images, memories, and perceptions, usually but not necessarily involving language symbols. Psychiatric disorders derange thought and alter the content of speech without affecting its linguistic structure. Schizophrenic patients, for example, may manifest bizarre and individualistic word choices, with loose associations and a loss of organization in discourse, together with vague or unclear references and communication failures (Docherty, DeRosa, and Andreasen 1996). Lk'int'iirary language and articulation, however, are intact. Abnormal language content in psychiatric disorders is therefore not considered aphasia. Language disorders associated with diffuse brain diseases, such as encephalopathies and dementias, do qualify as aphasias, but the involvement of other cognitive functions distinguishes them from aphasia secondary to focal brain lesions.

An understanding of language disorders requires an elementary review of linguistic components. *Phonemes* are the smallest meaning-carrying sounds; *morphology* is the use of appropriate word endings and connector words for tenses, possessives, and singular versus plural; *semantics* refers to word meanings; the *lexicon* is the internal dictionary; and *syntax* is the grammatical construction of phrases and sentences. *Discourse* refers to the use of these elements to create organized and logical expression of thoughts. Specific language disorders affect one or more of these elements.

Language processes have a clear neuroanatomic basis. In simplest terms, the reception and processing of spoken language takes place in the auditory system, heginning with the cochlea and proceeding through a series of way stations to the auditory cortex, Heschl's gyrus, in each superior temporal gyrus. The decoding of sounds into linguistic information involves the posterior part of the left superior temporal gyrus, Wernicke's area or Brodmann's area 22, which gives access to a network of cortical associations to assign word meanings. For both repetition and spontaneous speech, auditory information is transmitted to Broca's area in the posterior inferior frontal gyrus. This area of cortex "programs" the neurons in the adjacent motor cortex, subserving the mouth and larynx, from which descending axons travel to the brainstem cranial nerve nuclei. The inferior parietal lobule, especially the supramarginal gyrus, may also be involved in phoneme processing in language comprehension and in phoneme production for repetition and speech (Hickok and Poeppel 2000). These anatomic relationships are shown in Figures 12A.1 and 12A.2. Reading requires the perception of visual language stimuli by the occipital cortex, followed by correlation with auditory language information, via the intermodal association cortex of the angular gyrus. Writing involves the activation of motor neurons projecting to the arm and hand.

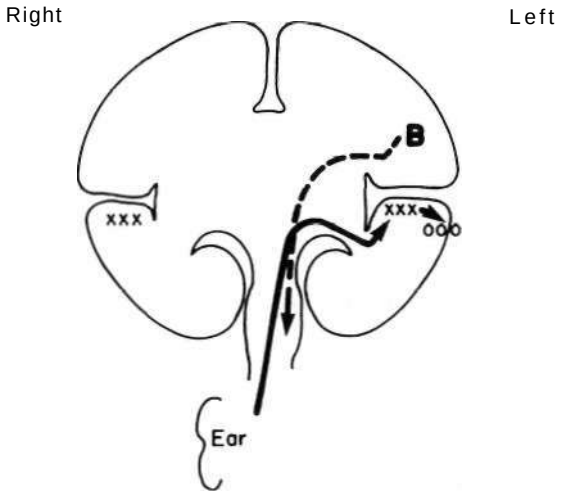

FIGURE 12A.2 Coronal plane diagram of the brain, indicating the inflow of auditory information from the cars to the primary auditory cortex in both superior temporal regions *(xxx),* and then to Wernicke's area *[poo)* in the left superior temporal gyrus. The motor outflow of speech descends from Broca's area *[&)* to the cranial nerve nuclei of the brainstem via the corticobulbar tract *[dashed arrow).* In actuality, Broca's area is anterior to Wernicke's area, and the two areas would not appear in the same coronal section.

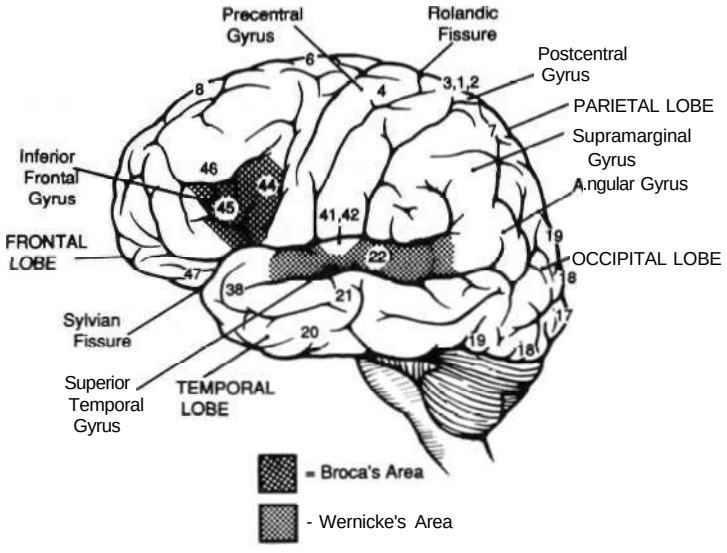
These pathways, and doubtless others, constitute the cortical circuitry for language comprehension and expression. In addition, other cortical centers involved in cognitive processes project into the primary language cortex, influencing the content of language. Finally, subcortical structures play increasingly recognized roles in language functions. The thalamus, a relay for the reticular activating system, appears to alert the language cortex, and lesions of the dominant thalamus often produce fluent aphasia. Nuclei of the basal ganglia involved in motor functions, especially the caudate nucleus and putamen, participate in expressive speech. It is no wonder, then, that



HGURK I 2A. I The lateral surface of the left hemisphere, showing a simplified gyral anatomy and the relationships between Wernicke's area and Broca's area. Not shown is the arcuate fasciculus, which connects the two cortical speech centers via the deep subcortical white matter.

language disotdcrs are seen in a wide variety of brain lesions and are important in practical neurological diagnosis and localization.

In right-handed people, and in most left-handers, clinical syndromes of aphasia result from left hemisphere lesions. Rarely, aphasia may result from a right hemisphere lesion in a right-handed patient, a phenomenon called *crossed aphasia* (Bakar, Kirshncr, and Wert?. 1996). In left-handed persons, language disorders are usually similar to those of right-handed persons with similar lesions, but occasional cases present with atypical syndromes that suggest a right hemisphere capability for at least some language functions. For example, a patient with a large left frontal temporo-parietal lesion may have preserved comprehension, suggesting right hemisphere language comprehension. For the same reason, recovery from aphasia may be better in some left-handed than right-handed patients with left hemisphere strokes.

SYMPTOMS AND DIFFERENTIAL DIAGNOSIS OF DISORDERED LANGUAGE

Muteness, a total loss of speech, may represent severe aphasia (see Aphemia, later in this chapter). Muteness can also be a sign of dysarthria; frontal lobe dysfunction with akinetic mutism; severe extrapyramidal system dysfunction, as in Parkinson's disease; non-neurological disorders of the larynx and pharynx; or even psychogenic syndromes, such as catatonia. Caution must therefore he taken in diagnosing the mute patient as aphasic. A good rule of thumb is that if the patient can write or type and the language form and content are normal, the disorder is probably not aphasic in origin. If the patient cannot speak or write but makes apparent effort to vocalize, and if there is also evidence of deficient comprehension, aphasic muteness is likely. Associated signs of a left hemisphere injury, such as right hemiparesis, also aid in diagnosis. Finally, if the patient gradually begins to make sounds containing paraphasic errors, aphasia can be identified with confidence.

Hesitant speech is a symptom not only of aphasia, but also of motor speech disorders, such as dysarthria or stuttering, and may be a manifestation of a psychogenic disorder. A second rule of thumb is that if one can transcribe the utterances of a hesitant speaker into normal language, the patient is not aphasic. Hesitancy occurs in many aphasia syndromes for varying reasons, including difficulty in speech initiation, imprecise articulation of phonemes, deficient syntax, or word-finding difficulty.

Anomia, or the inability to produce a specific name, is generally a reliable indicator of a language disorder, although it may also reflect memory loss. Anomia is manifest in aphasic speech by word-finding pauses and circumlocutions or use of a phrase when a single word would suffice.

Paraphasic speech refers to the presence of errors in the patient's speech output. Paraphasic errors arc divided into literal or phonemic errors, involving substitution of an incorrect sound (e.g., shoon for spoon), and verbal or semantic errors, involving substitution of an incorrect word (e.g., fork for spoon). A related language symptom is perseveration, the inappropriate repetition of a previous response. Occasionally, aphasic utterances involve nonexistent word forms called *neologisms.* A pattern of paraphasic errors and neologisms that so contaminate speech that the meaning cannot be discerned is called *jargon speech.*

Another cardinal symptom of aphasia is the failure to comprehend the speech of others. Most aphasic patients also have difficulty with comprehension and production of written language (reading and writing).

Fluent, paraphasic speech usually makes an aphasic disorder obvious. The chief differential diagnosis here involves aphasia, psychosis, acute encephalopathy or delirium, and dementia. Aphasic patients are usually not confused or inappropriate in behavior; they do not appear agitated or misuse objects, with occasional exceptions in acute syndromes of Wernicke's or global aphasia. By contrast, most psychotic patients speak in an easily undet-**stood,** grammatically appropriate manner, but their behavior and speech content are abnormal. Only rarely do schizophrenics speak in "clang association" or "word salad" speech. Sudden onset of fluent, paraphasic speech in a middle-aged or elderly patient should always be suspected of representing a left hemisphere lesion with aphasia.

Patients with acute encephalopathy or delirium may manifest paraphasic speech and "higher" language disorders, such as inability to write, but the grammatical expression of language is less disturbed than is its content. These language symptoms, moreover, are less prominent than accompanying behavioral disturbances, such as agitation, hallucinations, drowsiness, or excitement, and cognitive difficulties, such as disorientation, memory loss, and delusional thinking.

Chronic encephalopathies, or dementias, pose a more difficult diagnostic problem because involvement of the language cortex produces readily detectable language deficits, especially involving naming, reading, and writing. **These** language disorders (see Language in Dementing Diseases, later in this chapter) differ from aphasia secondary to focal lesions mainly by the involvement of other cognitive functions, such as memory and visuospatial processes.

BEDSIDE LANGUAGE EXAMINATION

The first part of any bedside examination of language is the observation of the patient's speech and comprehension during the clinical interview. A wealth of information about language function can be obtained if the examiner pays deliberate attention to the patient's speech patterns and responses to questions. In particular, minor word-finding

difficulty, occasional paraphasic errors, and higher-level deficits in discourse planning and in the pragmatics of communication, such as the use of humor and irony, can he detected principally during the informal interview.

D. Frank Benson and Norman Gcschwind popularized a bedside language examination of six parts, and it has been updated by Alexander and Benson (1997) (Table 12A.1). This examination provides useful localizing information about lira in dysfunction and is well worth the few minutes it takes.

The first part of the examination is a description of spontaneous speech. A speech sample may be elicited by asking the patient to describe the weather or the reason for coming to the doctor. If speech is sparse or absent, recitation of lists, such as counting or listing days of the week, may be helpful. The most important variable in spontaneous speech is fluency: Fluent speech flows rapidly and effortlessly; nonfluent speech is uttered in single words or short phrases, with frequent pauses and hesitations. Attention should first be paid to such elementary characteristics as initiation difficulty, articulation, phonation or voice volume, rate of speech, prosody or melodic intonation of speech, and phrase length. Second, the content of speech utterances should be analyzed in terms of the presence of word-finding pauses, circumlocutions, and errors such as literal and verbal paraphasias and neologisms.

Naming, the second part of the bedside examination, is tested by asking the patient to name objects, object parrs, pictures, colors, or body parts to confrontation. A few items from each category should be tested because anomia can be specific to word classes. Proper names of persons are often affected severely. The examiner should ask questions to be sure that the patient recognizes the items or people that he or she cannot name.

Auditory comprehension is tested first by asking the patient to follow a series of commands of one, two, and three steps. An example of a one-step command is "stick out your tongue"; a two-step command is "hold up your left thumb and close your eyes." Successful following of commands ensures adequate comprehension, at least at this simple level, but failure to follow commands does not automatically establish a loss of comprehension. The patient must hear rhc command, understand the language the examiner speaks, and possess the motor ability to execute it, including absence of apraxia. *Apraxia* (sec Chapter 10 for full discussion) is defined operationally as the inability to carry out a motor command despite normal comprehension and normal ability to carry out the motor act in another context, such as by imitation or with use of a real object. Because apraxia is difficult to exclude with confidence, it is advisable to test comprehension by tasks that do not require a motor act, such as yes-no questions, or by commands that require only a pointing response. The responses to nonsense questions (e.g., "Do you vomit every day?") quickly establish whether the patient comprehends. Nonsense questions often produce surprising results, given the tendency of some aphasics to cover up comprehension difficulty with social chatter.

Tabic 12A.1: Bedside language examination

1. Spontaneous speech
   a. Informal interview
   b. Structured task
   c. Automatic sequences
2. Naming
3. Auditory comprehension
4. Repetition
5. Reading
   a. Reading aloud
   h. Ri-iiJnii; comprehension
6. Writing
   a. Spontaneous sentences
   b. Writing to dictation
   c. Copying

Repetition of words and phrases should be deliberately tested. Dysarthric patients have difficulty with rapid sequences of consonants, such as "Methodist Episcopal," whereas aphasics have special difficulty with grammatically complex sentences. The phrase "no ifs, ands, or huts" is especially challenging for aphasics. Often, aphasics can repeat familiar or "high-probability" phrases much better than unfamiliar ones.

Reading should be tested both aloud and for comprehension. The examiner should carry a few printed commands to facilitate a rapid comparison of auditory to reading comprehension. Of course, the examiner must have some idea of the patient's premorbid reading ability.

Writing, the element of the bedside examination most often omitted, not only provides a further sample of expressive language but also allows an analysis of spelling, which is not possible with spoken language. A writing specimen may be the most sensitive indicator of mild aphasia, and it provides a permanent record for future comparison. Spontaneous writing, such as a sentence describing why the patient has come for examination, is especially sensitive for the detection of language difficulty. When this fails, writing to dictation and copying should be tested as well.

Finally, the neurologist combines the results of the bedside language examination with those of the rest of the mental status examination and of the neurological examination in general. These "associated signs" help classify the type of aphasia and localize the responsible brain lesion.

DIFFERENTIAL DIAGNOSIS OF APHASIC SYNDROMES

Broca's Aphasia

In 1861, the French physician Paul Broca described two patients, establishing the aphasic syndrome that now bears

his name. The speech pattern is nonfluent; on hedsidc examination, the patient speaks hesitantly, often producing the principal, meaning-containing nouns and verbs but omitting small grammatical words and morphemes. This pattern is called *agrammatism* or *telegraphic speech.* An example is "wife come hospital." Patients with acute Broca's aphasia may be mute or may produce only single words, often with dysarthria and apraxia of speech. They make many phonemic errors, inconsistent from utterance to utterance, with substitution of phonemes usually differing only slightly from the correct target (e.g., *p* for *b).* Naming is deficient, but the patient ofren manifests a "tip of the tongue" phenomenon, getting out the first letter or phoneme of the correct name. Paraphasic errors in naming arc more often of the literal type than the verbal type. Auditory comprehension seems intact, but detailed testing usually reveals some deficiency, particularly in the comprehension of complex syntax. For example, sentences with embedded clauses involving prepositional relationships cause difficulty for Broca's aphasics in comprehension and in expression. A recent positron emission tomography (PET) study in normal subjects (Caplan, Alpert, and Waters 1998) showed activation of the Broca area in the frontal cortex during tests of syntactic comprehension. Repetition is hesitant in these patients, resembling their spontaneous speech. Reading is often impaired despite relatively preserved auditory comprehension. Benson termed this reading difficulty of Broca's aphasics the "third alexia," in distinction to the two classic types of alexia (see Aphasic Alexia, later in this chapter). Patients with Broca's aphasia may have difficulty with syntax in reading, jusr as in auditory comprehension and speech. Writing is virtually always deficient in Broca's aphasics. Most patients have a right hemiparesis, necessitating use of the nondominant, left hand for writing, but this left-handed writing is far more abnormal than the awkward renditions of a normal, right-handed patient. Many patients can scrawl only a few letters.

Associated neurological deficits of Broca's aphasia include right hemiparesis, hemisensory loss, and apraxia of the oral apparatus and the nonparalyzed left limbs. Apraxia in response to motor commands is important to recognize because it may be mistaken fot comprehension disturbance. Comprehension should be tested by responses to yes-no questions or commands to point to an object. The common features of Broca's aphasia arc listed in Table 12A.2.

An important clinical feature of Broca's aphasia is its frequent association with depression (Robinson 1997). Patients with Broca's aphasia are typically aware of and frustrated by their deficits. At times they become withdrawn and refuse help or therapy. Usually, the depression lifts as the deficit recovers, although it may be a limiting factor in rehabilitation.

The lesions responsible for Broca's aphasia usually include the traditional Broca's area in the posterior part of the inferior frontal gyrus, along with damage to the adjacent cortex and subcortical white matter. Most patients with

lasting Broca's aphasia, including Broca's original cases, have much larger left frontoparietal lesions, including most of the territory of the upper division of the left middle cerebral artery. Such patients typically evolve from global to Broca's aphasia over weeks to months. Patients who manifest Broca's aphasia immediately after their strokes, by-contrast, have smaller lesions of the inferior frontal region, and their deficits generally resolve quickly. In computed tomography (CT) scan analyses at the Boston Veterans Administration Medical Center, lesions restricted to the lower precentral gyrus produced only dysarthria and mild expressive disturbance. Lesions involving the traditional Broca's area (Brodmann's areas 44 and 45) resulted in difficulty initiating speech, and lesions combining Broca's area, the lower precentral gyrus, and subcortical white matter yielded the full syndrome of Broca's aphasia. In studies by the same group, damage to two subcortical white matter sites—-the rostral subcallosal fasciculus deep to Broca's area and the periventricular white matter adjacent to the body of the left lateral ventricle—was required to cause permanent nonfluency. Figute 12A.3 shows a magnetic resonance imaging (MR1) scan from a case of Broca's aphasia.

Aphcmia

A rare variant of Broca's aphasia is aphemia, a nonfluent syndrome in which the patient is initially mute and then able to speak with phoneme substitutions and pauses. All other language functions are intact, including writing. This rare and usually transitory syndrome results from small lesions either of Broca's area or its subcortical white matter or of the inferior precentral gyrus. Because written expression and auditory comprehension are normal, aphemia is not a true language disorder; aphemia may be equivalent to pure apraxia of speech.

Wernicke's Aphasia

Wernicke's aphasia may be considered a syndrome opposite to Broca's aphasia, in that expressive speech is

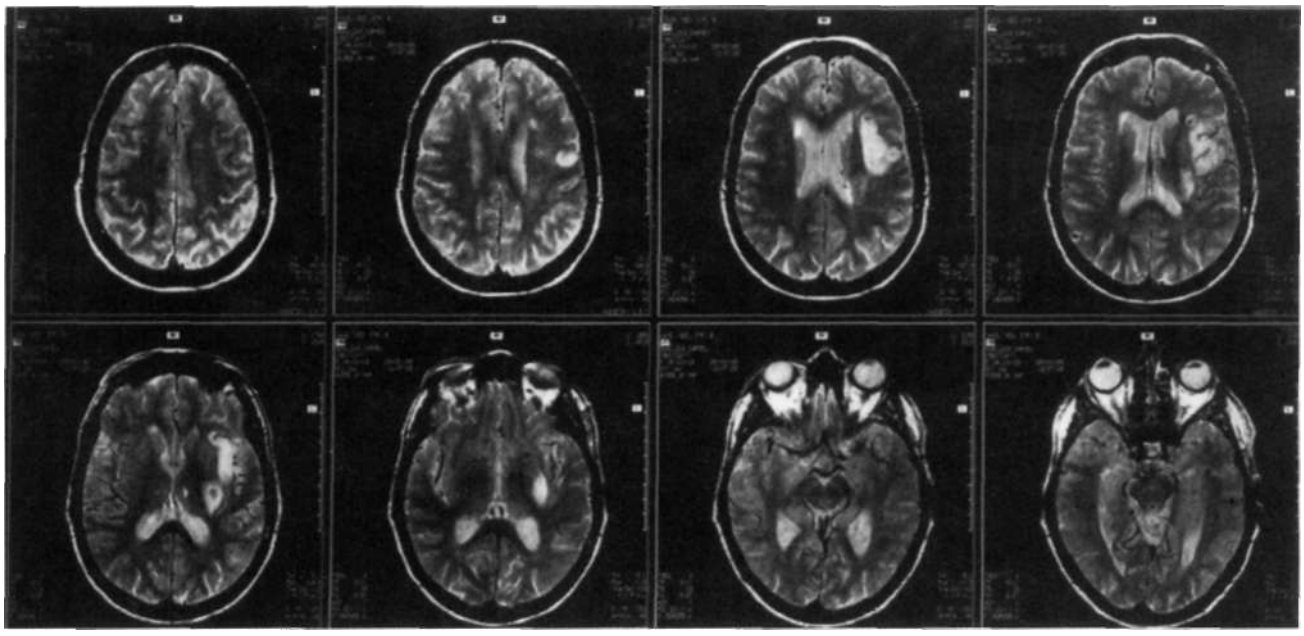

FIGURE 12A.3 Magnetic resonance imaging scan from a patient with Broca's aphasia. In this patient, the cortical Broca's area, subcortical white matter, and the insula were all involved in the infarction. The patient made a good recovery.

fluent but comprehension is impaired. The speech pattern is effortless and sometimes even excessively fluent (lognrrhea). A speaker of a foreign language would notice nothing amiss, but a listenet who shares the patient's language detects speech empty of meaning, containing verbal paraphasias, neologisms, and jargon productions. Neurolinguists refer to this pattern as *paragrammatism.* In milder cases, the intended meaning of an utterance may be discerned, but the sentence goes awry with paraphasic substitutions. Naming in Wernicke's aphasia is deficient, often with bizarre, paraphasic substitutions for the correct name. Auditory comprehension is impaired, sometimes even for simple nonsense questions. Auditory perception of phonemes is deficient in Wernicke's aphasia, but deficient semantics is the major cause of the comprehension disturbance; disturbed access both to semantics and to the internal lexicon is central to the deficit of Wernicke's aphasia. Repetition is impaired; whispering a phrase in the patient's ear, as in a hearing test, may help cue the patient to attempt repetition. Reading comprehension is usually affected similarly to auditory comprehension, but some patients show greater deficit in one modality. The discovery of spared reading ability in Wernicke's aphasics is important in allowing these patients to communicate. In addition, neurolinguistic theories of reading must include access of visual language images to semantic interpretation, even in the absence of auditory comprehension. Writing is also impaired, but in a manner quite different from that of Broca's aphasia. The patient usually has no hemiparesis and can grasp the pen and write easily. Written productions are even more abnormal than oral ones, however, in that spelling errors are also evident. Writing samples are especially useful in the detection of mild Wernicke's aphasia.

Associated signs are limited in Wernicke's aphasia; most patients have no elementary motor or sensory deficits, although a partial or complete right homonymous hemianopia may be present. The characteristic bedside examination findings in Wernicke's aphasia are summarized in Table 12A.3.

The psychiatric manifestations of Wernicke's aphasia are quite different from those of Broca's aphasia. Depression is less common; many Wernicke's aphasics seem unaware of or unconcerned about their communicative deficits. With time, some patients become angry or paranoid about the inability of family members and medical staff to understand them. This behavior, like depression, may hinder rehabilitative efforts.

The lesions of patients with Wernicke's aphasia are usually in the posterior portion of the superior temporal

Table 12A.3: Bedside features of Wernicke's aphasia

gyrus, sometimes extending into the inferior parietal lobule. Figure 12A.4 shows a typical example. The exact confines of Wernicke's area have been much debated. Damage to Wernicke's area (Brodmann's area 22) has been reported to correlate most closely with persistenr loss of comprehension of single words, although others (Kertesz, Lau, and Polk 1993) have found only larger temporoparietal lesions in patients with lasting Wernicke's aphasia. In the acute phase, the ability to match a spoken word to a picture is quantitatively related to decreased perfusion of Wernicke's area on perfusion-weighted MR1 scans, indicating less variability during the acute phase than after recovery has taken place (Hillis et al. 2001). Electrical stimulation of Wernicke's area produces consistent interruption of auditory comprehension, supporting the importance of this region for decoding of auditory language. A receptive speech area in the left inferior temporal gyrus has also been suggested by electrical stimulation studies and by a few descriptions of patients with seizures involving this area (Kirshner et al. 1995), but aphasia has not been recognized with destructive lesions of this area. Extension of the lesion into the inferior parietal region may predict greater

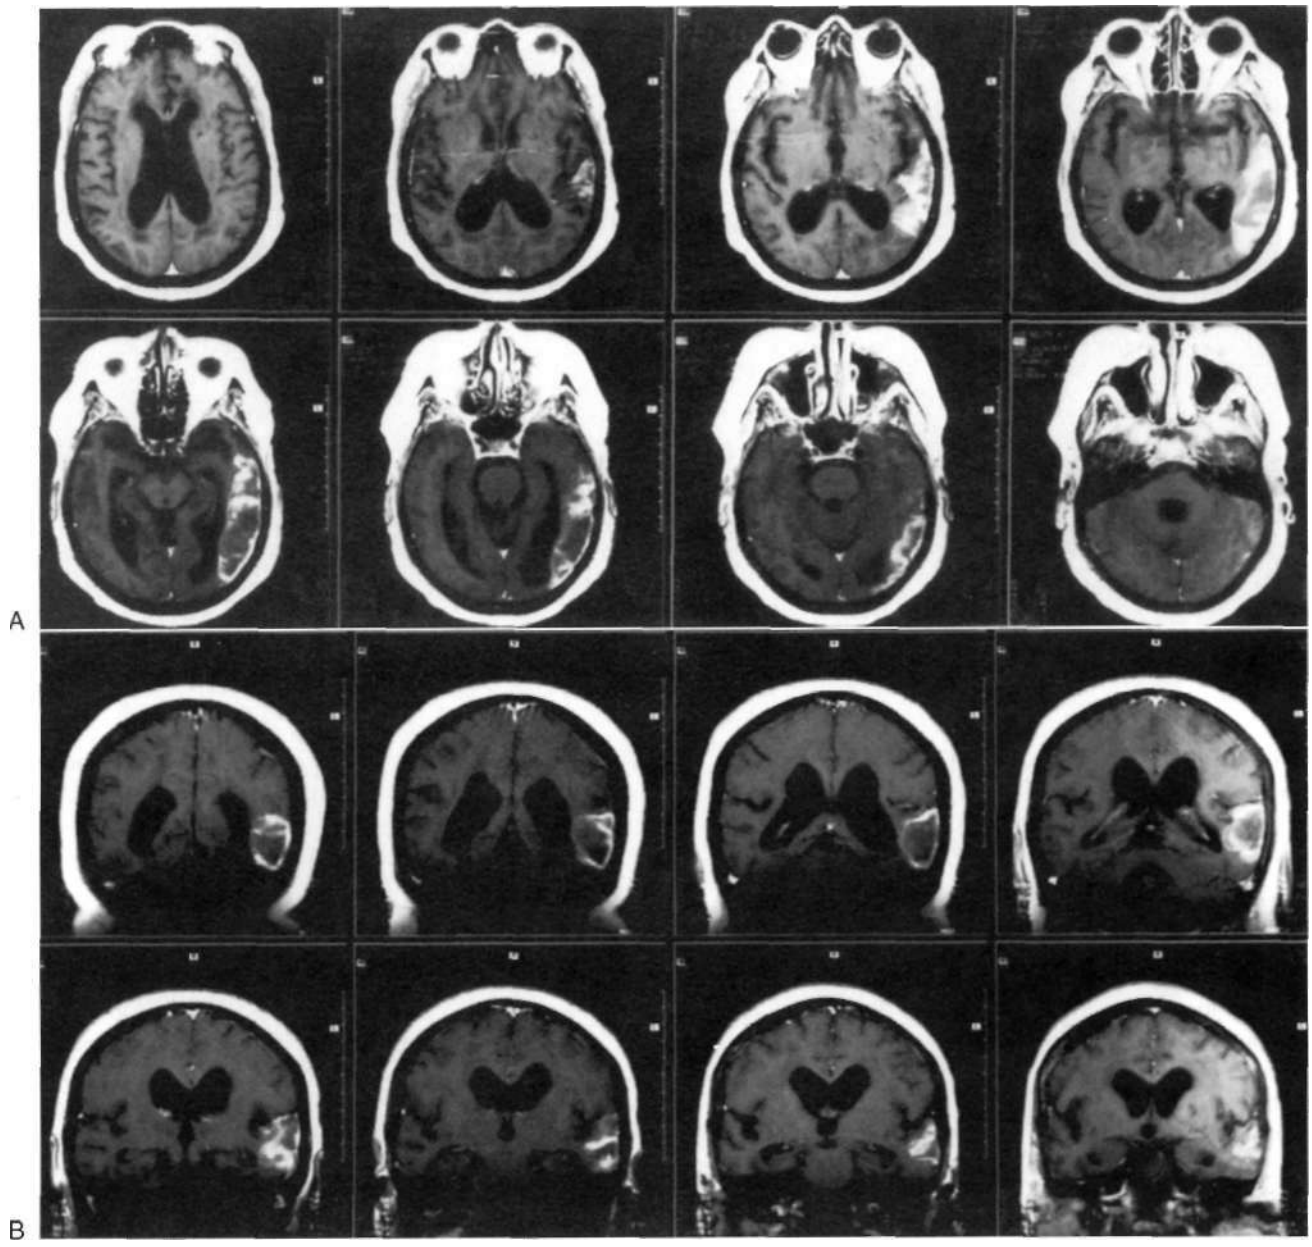

FIGURE 12A.4 Axial and coronal magnetic resonance imaging slices (A and B), and an axial positron emission tomographic (PET) scan view (C) of an elderly woman with Wernicke's aphasia. There is a large left superior temporal lobe lesion. The onset of the deficit was not clear, and the PET scan was useful in showing that the lesion had reduced metabolism, favoring a stroke over a tumor.

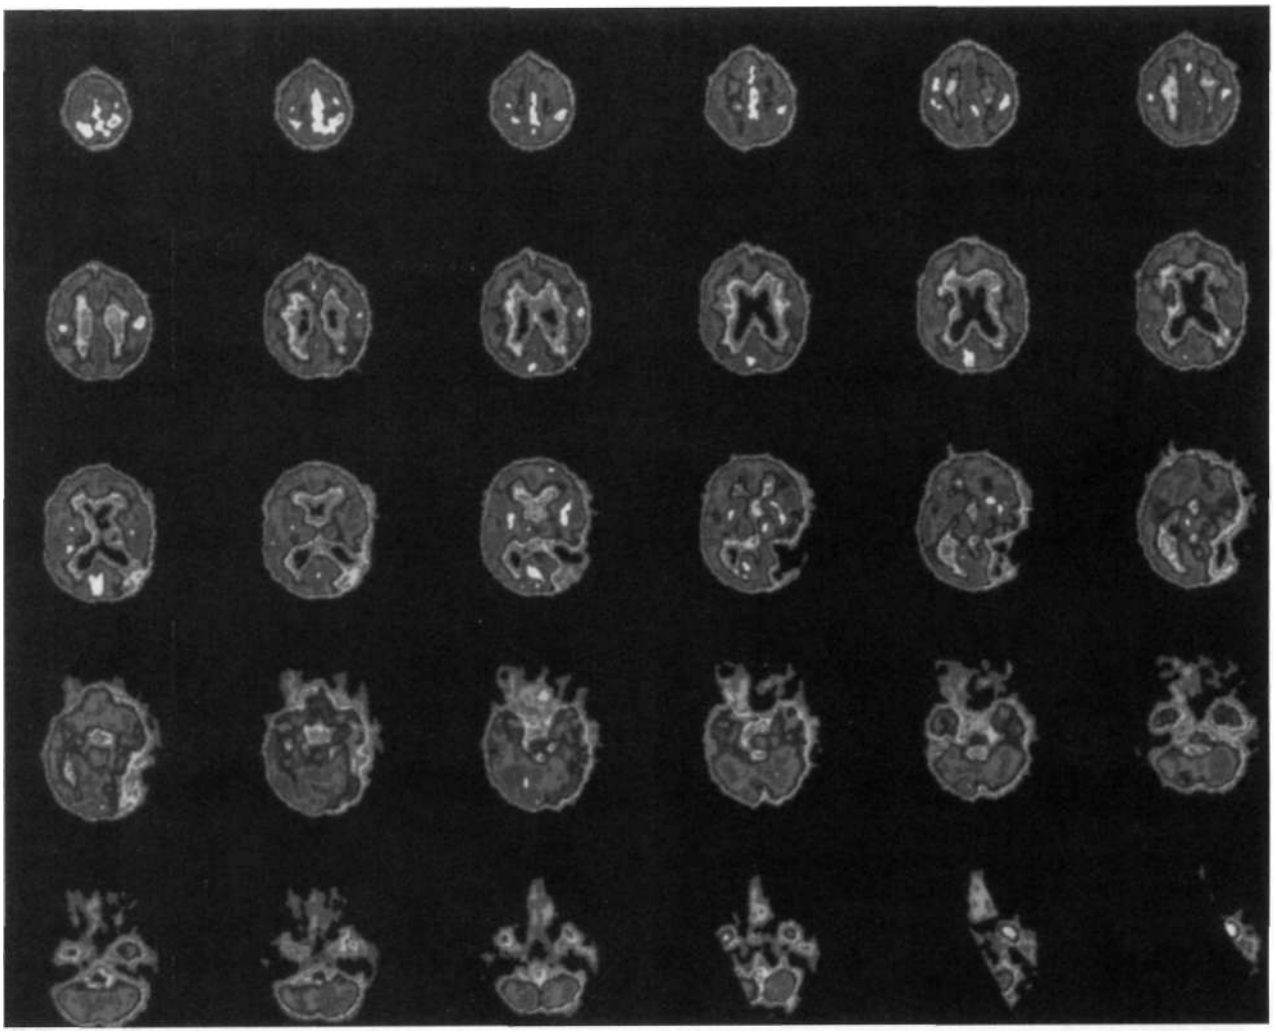

FIGURE 12A.4, cont'd.

involvement of reading comprehension. In terms of vascular anatomy, Wernicke's area lies within the territory of the inferior division of the left middle cerebral artery.

Pure Word Deafness

Pure word deafness is a rare but striking syndrome of isolated loss of auditory comprehension and repetition, without any abnormality of speech, naming, reading, or writing. Hearing for pure tones and for nonverbal noises, such as animal cries, is intact. Most cases have mild aphasic deficits, especially paraphasia speech. Classically, the anatomic substrate is a bilateral lesion, isolating Wernicke's area from input from both Heschl's gyri. Pure word deafness is thus an example of a "disconnection syndrome," in which the deficit results from loss of white matter connections rather than of gray matter language centers. Some cases of pure word deafness, however, have unilateral left temporal lesions. These cases closely resemble Wernicke's aphasia with greater impairment of auditory comprehension than of reading.

Global Aphasia

Global aphasia may be thought of as a summation of the deficits of Broca's aphasia and Wernicke's aphasia. Speech is nonfluent or mute, but comprehension is also poor, as are naming, repetition, reading, and writing. Most patients have dense right hemiparesis, hemisensory loss, and often hemianopia, although few patients have little hemiparesis. Milder aphasic syndromes in which all modalities of language are affected are often called *mixed aphasias.* The lesions of patients with global aphasia are usually latge, involving both the inferior frontal and superior temporal regions, and often much of the parietal lobe in between. This lesion represents most of the territory of the left middle cerebral artery. Patients in whom the superior temporal gyrus is spared tend to recover their auditory

comprehension and to evolve toward the syndrome of Broca's aphasia. Recovery in global aphasia may be prolonged; global aphasics may recover more during the second month than in the first *6* months after a stroke. Characteristics of global aphasia are presented in Table 12A.4.

Conduction Aphasia

Conduction aphasia is an uncommon but theoretically important syndrome that can be remembered by its striking deficit of repetition. Most patients have relatively normal spontaneous speech, although some make literal paraphasic errors and hesitate frequently for self-correction. Naming may be impaired, but auditory comprehension is preserved. Repetition may be disturbed to seemingly ridiculous extremes, such that a patient who can express himself or herself at a sentence level and comprehend conversation may be unable to repeat even single words. One such patient could not repeat the word "boy" but said "I like girls better," Reading and writing are somewhat variable, but reading aloud may share some of the same difficulty as repeating. Associated deficits include hemianopia in some patients; right-sided sensory loss may be present, but right-sided hemiparesis is usually mild or absent. Some patients have limb apraxia, creating a misiinpressioti that comprehension is impaired. Bedside examination findings in conduction aphasia are summarized in Table 12A.5.

The lesions of conduction aphasia are usually in either the superior temporal or inferior parietal regions. Benson et al. suggested that patients with limb apraxia have parietal lesions, whereas those without apraxia have temporal lesions. Conduction aphasia may represent a stage of recovery in patients with Wernicke's aphasia in whom the damage to the superior temporal gyrus is not complete.

Conduction aphasia has been advanced as a classic disconnection syndrome. Wernicke originally postulated that a lesion disconnecting Wernicke's and Broca's areas would produce this syndrome; Geschwind later pointed to the arcuate fasciculus, a white matter tract traveling from the deep temporal lobe, around the sylvian fissure to the frontal lobe, as the site of disconnection. Anatomic involvement of the arcuate fasciculus is present in most, if not all, cases of conduction aphasia, but there is usually also cortical involvement of the supramarginal gyrus or temporal lobe. The supramarginal gyrus appears to be involved in auditory immediate memory and in phoneme perception related to word meaning, as well as phoneme generation (Hickok and Poeppel, 2000). Lesions in this area are associated with conduction aphasia and phonemic paraphasic errors. Others have pointed out that lesions of the arcuate fasciculus do not always produce conduction aphasia. Another theory of conduction aphasia has involved a defect in auditory verbal short-term memory.

Anomic Aphasia

Anomic aphasia refers to aphasic syndromes in which naming, or access to the internal lexicon, is the principal deficit. Spontaneous speech is normal except for the pauses and circumlocutions produced by the inability to name. Comprehension, repetition, reading, and writing are intact, except for the same word-finding difficulty in written productions. Anomic aphasia is common but less specific in localization than other aphasic syndromes. Isolated, severe anomia may indicate focal left hemisphere pathology. Alexander and Benson (1997) refer to the angular gyrus as the site of lesions producing anomic aphasia, but lesions there usually produce other deficits as well, including alexia and the four elements of Gerstmann's syndrome: agraphia, right-left disorientation, acalculia, and finger agnosia, or inability to identify fingers. Isolated lesions of the temporal lobe can produce pure anomia, and PET studies of naming in normal subjects have also shown consistent activation of the superior temporal lobe. Inability to produce nouns is characteristic of temporal lobe lesions, whereas inability to produce verbs occurs more with frontal lesions (Damasio 1992). Even specific classes of nouns may be selectively affected in some cases of anomic aphasia. Anomia is also seen with mass lesions elsewhere in the brain and in diffuse

degenerative disorders, such as Alzheimer's disease (AD), Anomic aphasia is also a common stage in the recovery of many aphasic syndromes. Anomic aphasia thus serves as an indicator of left hemisphere or diffuse brain disease, but it has only limited localizing value. The typical features of anomic aphasia are presented in Table 12A.6.

Transcortical Aphasias

The transcortical aphasias arc syndromes in which repetition is normal, presumably because the causative lesions do not disrupt the perisylvian language circuit from Wernicke's area through the arcuate fasciculus to Broca's area. Instead, these lesions disrupt connections from other cortical centers into the language circuit (hence the name *transcortical).* The transcortical syndromes are easiest to think of as analogues of the syndromes of global, Broca's, and Wernicke's aphasias, with intact repetition. Thus mixed transcortical aphasia, or the syndrome of the isolation of the speech area, is a global aphasia in which the patient repeats, often echolalically, but has no prepositional speech or comprehension. This syndrome is rare, occurring predominantly in large, watershed infarctions of the left hemisphere or both hemispheres that spare the perisylvian cortex or in advanced dementias. Transcortical motor aphasia is an analogue of Broca's aphasia in which speech is hesitant or telegraphic, comprehension is relatively spared, bur repetition is fluent. This syndrome occurs with lesions in the frontal lobe, anterior to Broca's area, and hence within the territory of the anterior cerebral artery. Disruption of the supplementary motor area or disconnection of this area from Broca's area by subcortical frontal white matter lesions may produce the syndrome. The occurrence of transcortical motor aphasia in an arterial territory other than the middle cerebral artery separates this syndrome from the many middle cerebral artery syndromes discussed previously. The third transcortical syndrome, transcortical sensory aphasia, is an analogue of Wernicke's aphasia in which fluent paraphasic speech, paraphasic naming, impaired auditory and reading comprehension, and abnormal writing coexist with normal repetition. This syndrome is relatively uncommon, occurring in strokes of the left temporo-occipital area and in dementias. Bedside examination findings in the transcortical aphasias are summarized in Table 12A.7.

Subcortical Aphasias

A current area of interest in aphasia research involves the "subcortical" aphasias. Although all the syndromes discussed so far are defined by behavioral characteristics that can be diagnosed on the bedside examination, the subcortical aphasias are defined by lesion localization in the basal ganglia or deep cerebral white matter. As knowledge about subcortical aphasia has accumulated, two major groups of aphasic symptomatology have been described: aphasia with thalamic lesions and aphasia with lesions of the subcortical white matter and basal ganglia.

Left thalamic hemorrhages often produce a Wernickc-like fluent aphasia, with better comprehension than cortical Wernicke's aphasia. A fluctuating or "dichotomous" state has been described, alternating between an alert state with nearly normal language and a drowsy state in which the patient mumbles paraphasically and comprehends poorly. Luria has called this a *quasi-aphasic abnormality of vigilance,* in that the thalamus plays a role in alerting the language cortex. Thalamic aphasia can occur even with a right thalamic lesion in a left-handed patient, indicating that hemispheric language dominance extends to the thalamic level. Whereas some skeptics have attributed thalamic aphasia to pressure on adjacent structures and secondary effects on the cortex, cases of thalamic aphasia have been described with small ischemic lesions, especially those involving the paramedian or anterior nuclei of the thalamus, in the territory of the tuberothalamic artery. Because these lesions produce little or no mass effect, such cases indicate that the thalamus and its connections play a definite role in language function.

Lesions of the left basal ganglia and deep white matter also cause aphasia. As in thalamic aphasia, the first syndromes described were in basal ganglia hemorrhages, especially those involving the putamen, the most common site of hypertensive intracerebral hemorrhage. Here the aphasic syndromes are more variable but most commonly involve global or Wcrnickc-Iikc aphasia. As in thalamic lesions, ischemic strokes have provided better localizing information. The most common lesion is an infarct involving the anterior putamen, caudate nucleus, and anterior limb of the internal capsule. Patients with this lesion have an "anterior subcortical aphasia syndrome" involving dysarthria, decreased fluency, mildly impaired repetition, and mild comprehension disturbance (Mega and Alexander 1994). This syndrome most closely resembles Broca's aphasia, but with greater dysarthria and less language dysfunction. Figure 12A.5 shows an example of this syndrome. More restricted lesions of the anterior putamen, head of caudate, and periventricular white matter produce hesitancy or slow initiation of speech but little true

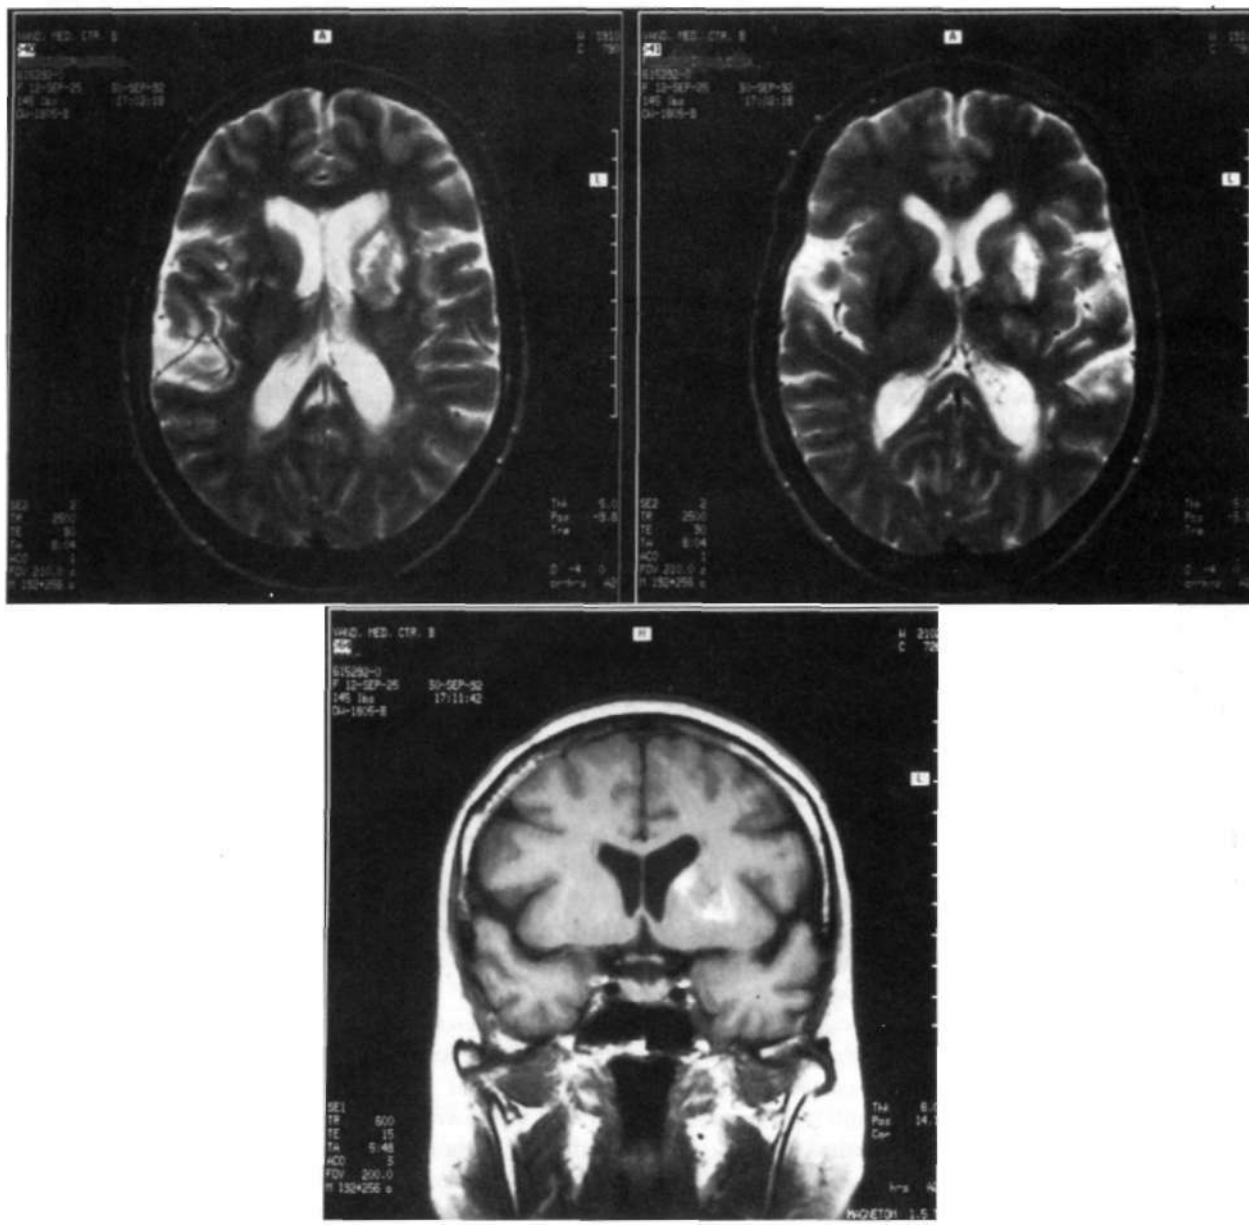

FIGURE 12A.S Magnetic resonance imaging (MRI) scan slices in the axial, coronal, and sagittal planes from a patient with subcortical aphasia. The lesion is an infarction involving the anterior caudate, putamen, and anterior limb of the left internal capsule. The patient presented with dysarthria and mild, nonfluent aphasia with anomia, with good comprehension. The advantage of MRI in permitting visualization of the lesion in all three planes is apparent. *Continued*

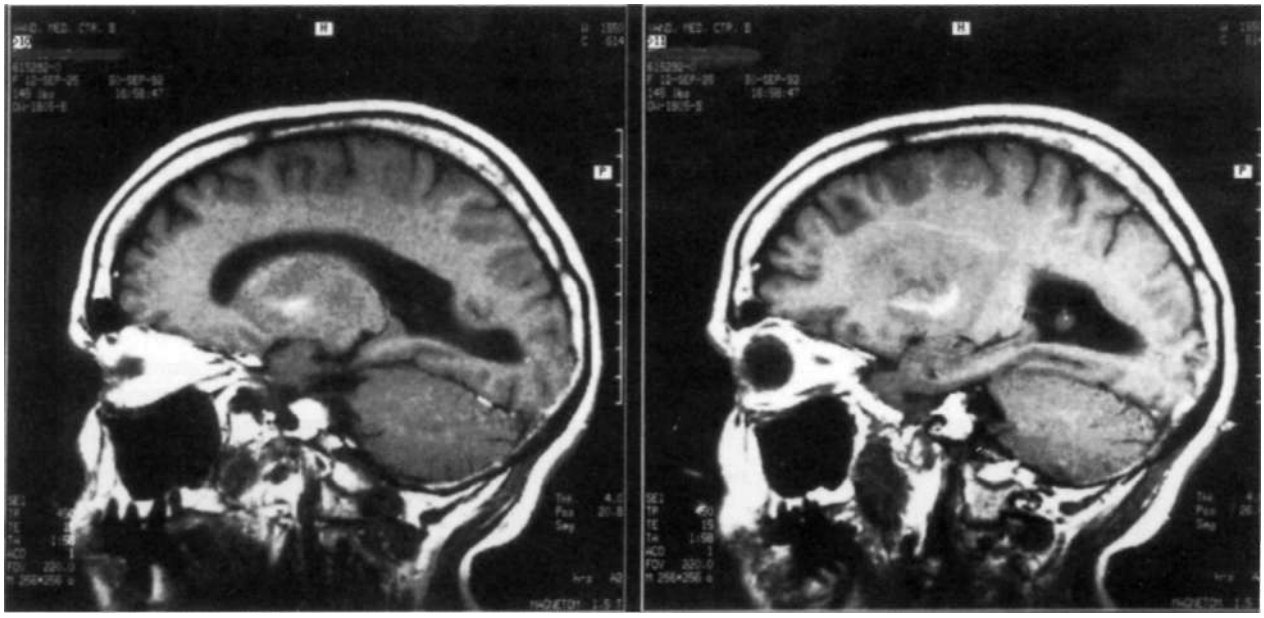

FIGURE 12A.5, cont'd.

language disturbance. More posterior lesions involving the putamen and deep temporal white matter, referred to as the *temporal isthmus,* are associated with fluent paraphasic speech and impaired comprehension resembling Wernicke's aphasia. Small lesions in the posterior limb of the internal capsule and adjacent putamen cause mainly dysarthria, but mild aphasic deficits may occasionally occur. Finally, larger subcortical lesions involving both the anterior and posterior lesion sites produce global aphasia. A wide variety of aphasia syndromes can thus be seen with subcortical lesion sites. Nadeau and Crosson (1997) discussed the anatomic model of the basal ganglia involvement in speech and language based on the known motot functions and fiber connections of these structures. Evidence from PET studies indicates that basal ganglia lesions affect language, both directly and indirectly, via decreased activation of cortical language areas.

The "insula," a cortical structure that shares a deep location with the subcortical structures, may also be important to speech and language function. Dronkers (1996) reported that involvement of this area is closely associated with the presence of apraxia of speech in aphasic patients.

In clinical terms, subcortical lesions do produce aphasia, although less commonly than cortical lesions, and the language characteristics of subcortical aphasias are often atypical. The presentation of a difficult-to-classify aphasic syndrome, in the presence of dysarthria and right hemiparesis, should lead to suspicion of a subcortical lesion.

Pure Alexia without Agraphia

"Alexia," or the acquired inability to read, is a form of aphasia by the definition given at the beginning of this chapter. The classic syndrome of alexia, pure alexia without agraphia, was described by the French neurologist Dejerine in 1892. This syndrome may be thought of as a linguistic blindfolding: Patients can write but cannot read their own writing. On bedside examination, speech, auditory comprehension, and repetition arc normal. Naming may be deficient, especially for colors. Patients initially cannot read at all; as they recover, they learn to read letter by letter, spelling out words laboriously. They cannot read words at a glance, as normal readers do. By contrast, they quickly understand words spelled orally to them, and they can spell normally. Some patients can match words to pictures, indicating that some subconscious awareness of the word is present, perhaps in the right hemisphere. Associated deficits include a right hemianopia or right upper quadrant defect in nearly all patients and, frequently, a deficit of short-term memory. There is usually no hemiparesis or sensory loss.

The causative lesion in pure alexia is nearly always a stroke in the territory of the left posterior cerebral artery, with infarction of the medial occipital lobe, often the splenium of the corpus callosum, and often the medial temporal lobe. Dejerine postulated a disconnection between the intact right visual cortex and the left hemisphere language centers, particularly the angular gyrus. (Figure 12A.6 is an adaptation of Dejerine's original diagram.) Gcschwind later rediscovered this disconnection hypothesis. Although Damasio and Damasio found splenial involvement in only 2 of 16 cases, they postulated a disconnection within the deep white matter of the left occipital lobe. As in the disconnection hypothesis for conduction aphasia, the theory fails to explain all the behavioral phenomena, such as the sparing of single letters. A deficit in short-term memory for visual language elements

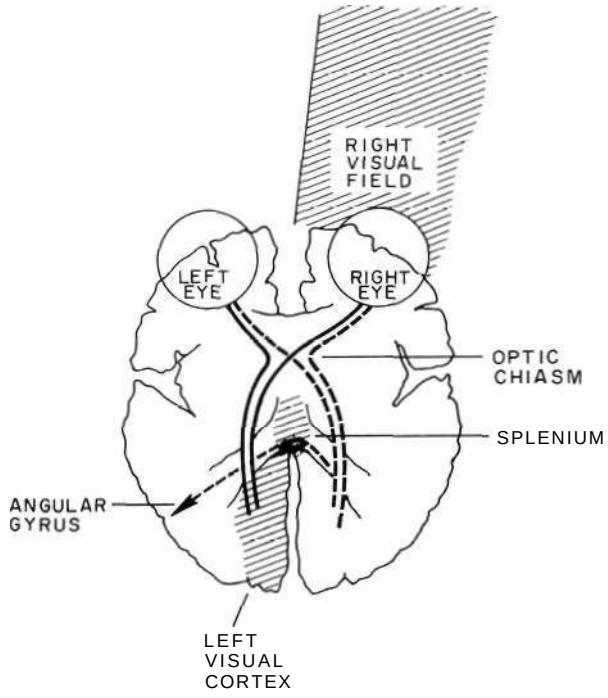

FIGURE 12A.6 Horizontal brain diagram of pure alexia without agraphia, adapted from that of Dejerine, in 1892. Visual information from the left visual field reaches the right occipital cortex but 15 "disconnected" from the left hemisphere language centers by the lesion in the splenium of the corpus callosum.

or an inability to perceive multiple letters at once (simultanagnosia) can also explain many features of the syndrome. Typical findings of pure alexia without agraphia are presented in Table 12A.8.

Alexia with Agraphia

The second classic alexia syndrome, alexia with agraphia, described by Dejerine in 1891, may be thought of as an acquired illiteracy, in which a previously educated patient is rendered unable to read or write. The oral language modalities ol speech, naming, auditory comprehension, and repetition are largely intact, but many cases manifest a fluent paraphasic speech pattern with impaired naming.

Table 12A.8: Bedside features of pure alexia without agraphia

Feature	*Syndrome*
Spontaneous speech	Intact

Writing	Intact
Associated signs	Right hemianopia or superior quadrantanopia
	Short-term memory loss
	Motor, sensorx signs usually absent

Table 12A.9: Bedside features of alexia with agraphia

I Ciiturc	*Syndrome*
Spontaneous speech	Fluent, often some paraphasia
Naming	ilmpaired
Comprehension	Intact, or less impaired than reading
Repetition	Intact
Reading	Severely impaired
Writing	Severely impaired
Associated signs	Right hemianopia
	Motor, sensory signs often absent

This syndrome thus overlaps Wernicke's aphasia, especially in cases in which reading is more impaired than auditory comprehension. Associated deficits include right hemianopia and elements of Gerstmann's syndrome: agraphia, acalculia, right-left disorientation, and finger agnosia. The lesions are typically in the inferior parietal lobule, especially the angular gyrus. Etiologies include strokes in the territory of the angular branch of the left middle cerebral artery or mass lesions in the same region. Characteristic features of the syndrome of alexia with agraphia are summarized in Table 12A.9.

Aphasic Alexia

In addition to the two classic alexia syndromes, many patients with aphasia have associated reading disturbance. Examples already cited are the "third alexia" syndrome of Broca's aphasia and the reading deficit of Wernicke's aphasia. Neurolinguists and cognitive psychologists have divided alexias according to breakdowns in specific stages of the reading process. The linguistic concepts of surface structure versus the deep meanings of words have been instrumental in these new classifications. Four patterns of alexia (or dyslexia, in British usage) have been recognized: letter-by-letter, deep, phonological, and surface dyslexia. Figure 12A.7 diagrams the steps in the reading process and the points of breakdown in the four syndromes. Letter-by-letter dyslexia is equivalent to pure alexia without agraphia. Deep dyslexia is a severe reading disorder in which patients recognize and read aloud only familiar words, especially concrete imageable nouns and verbs. They make semantic or visual errors in reading and fail completely in reading nonsense syllables or nonwords. Word reading is not affected by word length or by regularity of spelling; one patient, for example, could read ambulance but not am. Most patients have severe aphasia, with extensive left frontoparietal damage.

Phonologic dyslexia is similar to deep dyslexia, with poor reading of nonwords, but single nouns and verbs are read in a nearly normal fashion, and semantic errors are rare. Patients appear to read words without understanding. The fourth type, surface dyslexia, involves spared ability to read laboriously by grapheme-phoneme conversion **but** inability to recognize words at a glance. These patients can

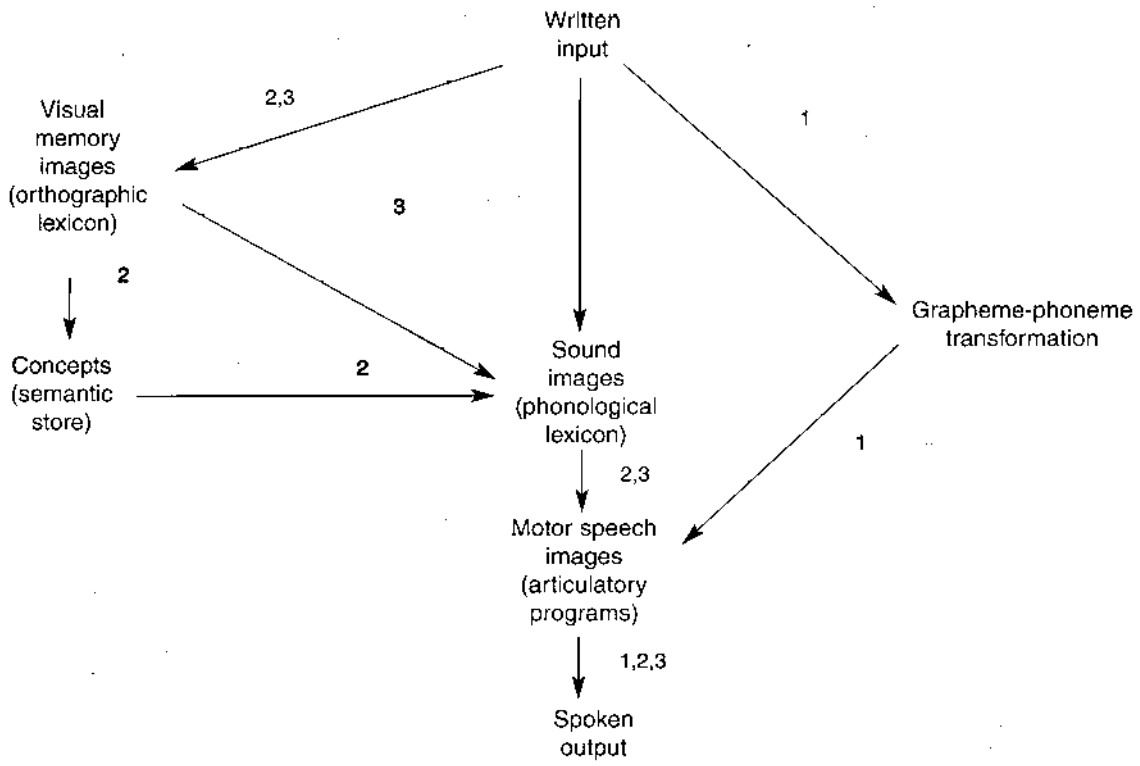

FIGURE 12A.7 Neurolinguistic model of the reading process. According to evidence from the alexias, there are three separate routes to reading: Route 1 is the phonologic (or grapheme-phoneme conversion) route; route 2 is the semantic (or lexical-semantic-phonologic) route; and route 3 is the nonlexical phonologic route. In deep dyslexia, only route 2 can operate; in phonological dyslexia, route 3 is the principal pathway; in surface dyslexia, only route 1 is functional. (Adapted with permission from Margolin, D. I. 1991, "Cognitive neuropsychology. Resolving enigmas about Wernicke's aphasia and other higher cortical disorders," *Arch Neurol,* vol. 48, pp. 751–765.)

read nonsense syllables but not words of irregular spelling, such as colonel or yacht. Their errors tend to be phonologic rather than semantic or visual (e.g., pronouncing *rough* and *though* alike).

Agraphia

Like reading, writing may be affected either in isolation (pure agraphia) or in association with aphasia (aphasic agraphia). In addition, writing can be impaired by motor disorders, by apraxia, and by visuospatial deficits. Isolated agraphia has been described with left frontal or parietal lesions.

Agraphias can be analyzed the same way as the alexias (Figure I2A.S). Thus phonologic agraphia involves the inability to convert phonemes into graphemes or write pronounceable nonsense syllables, in the presence of ability to write familiar words. Deep dysgraphia is similar to phonologic agraphia, but the patient can read nouns and verbs better than articles, prepositions, adjectives, and adverbs. In lexical or surface dysgraphia, patients can write regularly spelled words and pronounceable nonsense words but not irregularly spelled words. These patients have intact phoneme-graph erne conversion but cannot write by a whole-word or "lexical" strategy.

LANGUAGE IN RIGHT HEMISPHERE DISORDERS

Language and communication disorders are important even in parienrs with right hemisphere disease. First, left-handed patients may have right hemisphere language dominance and may develop aphasic syndromes from right hemisphere lesions. Second, right-handed patients occasionally become aphasic after right hemisphere strokes, a phenomenon called *crossed aphasia* (Bakar, Kirshner, and Wertz 1996), These patients presumably have crossed or mixed dominance. Third, even right-handed persons with typical left hemisphere dominance for language have subtly altered language function after right hemisphere damage. Such patients are not aphasic, in that the fundamental mechanisms of speech production, repetition, and comprehension are undisturbed. Affective aspects of language arc impaired, however, so the speech sounds flat and unemotional; the normal prosody, or emotional intonation, of speech is lost. Syndromes of loss of emotional aspecrs of speech are termed *aprosodias* Motor aprosodia involves loss of expressive emotion with preservation of emotional comprehension; sensory aprosodia involves loss of comprehension of affective language, also called *affective agnosia.* More than just emotion, stress and emphasis within a sentence are also affected by right hemisphere

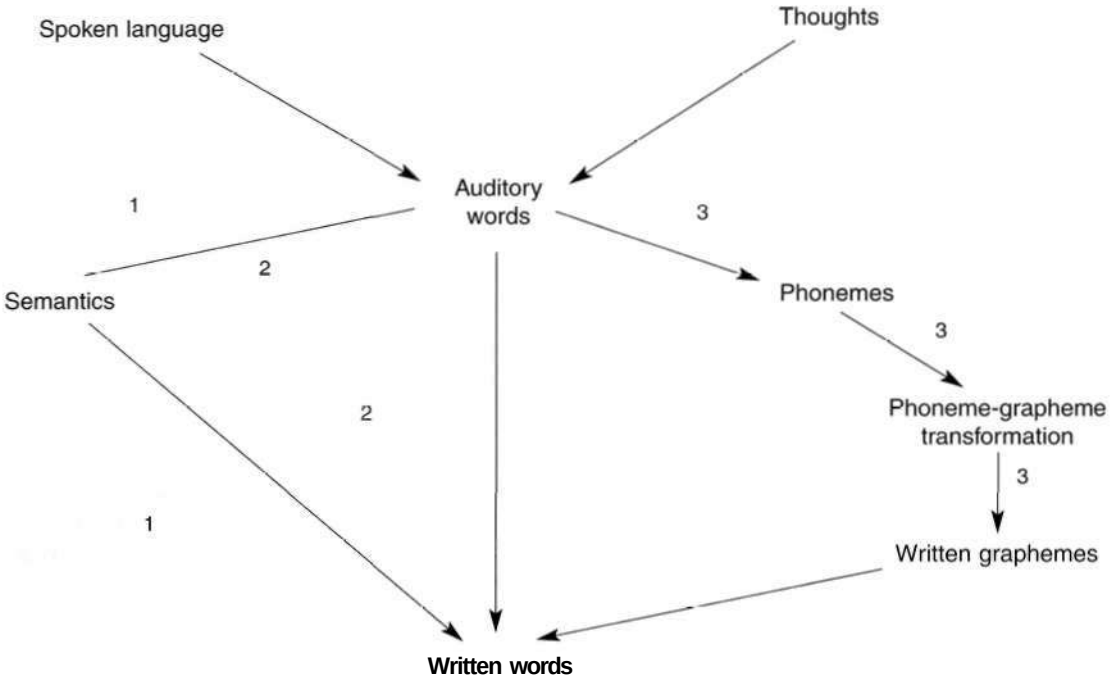

FIGURE 12A.8 Neurolinguistic model of writing and the agraphias. In deep agraphia, only the semantic (phonological-scmantic-lexkal) route (route 1) is operative; in phonologic agraphia, route 2, the nonlexical phonologic route produces written words directly from spoken words; in surface agraphia, only route 3, the phone me-grapheme pathway, can be used to generate writing.

dysfunction. More importantly, such vital aspects of human communication as metaphor, humor, sarcasm, irony, and related constituents of language that transcend the literal meaning of words are especially sensitive to right hemisphere disease. These deficits significantly impair patients in the pragmatics of communication. In other words, patients with right hemisphere damage understand what is said, but not how it is said. They may have difficulty following a complex story. Such higher level language deficits are related to the right hemisphere disorders of inattention and neglect, discussed in Chapters 4 and 38.

LANGUAGE IN DEMENTING DISEASES

Language impairment is commonly seen in patients with dementia. Despite considerable variability from patient to patient, two patterns of language dissolution can be described. The first, the common presentation of AD, involves early loss of memory and general cognitive deterioration. In these patients, mental status examination results are most remarkable for deficits in short-term memory, insight, and judgment, but language impairments can be found in naming and in discourse, with impoverished language content and loss of abstraction and metaphor. The mechanics of language—grammatical construction of sentences, receptive vocabulary, auditory comprehension, repetition, and oral reading—tend to remain preserved until later stages. By aphasia testing, patients with early AD have anomic aphasia. In later stages, language functions become more obviously impaired. In terms of the components of language mentioned earlier in this chapter, the semantic aspects of language tend to deteriorate first, then syntax, and finally phonology. Reading and writing—the last-learned language functions—are among the first to decline. Auditory comprehension later becomes deficient, whereas repetition and articulation remain normal. The language profile may then resemble that of transcortical sensory or Wernicke's aphasia. In terminal stages, speech is reduced to the expression of simple biological want--; eventually, even muteness can develop. By this time, most patients are institutionalized or bedridden.

The second pattern of language dissolution in dementia, considerably less common than the first, involves the gradual onset of a progressive aphasia, often without other cognitive deterioration. Auditory comprehension is involved early in the illness, and specific aphasic symptoms are evident, such as paraphasic or nonfluent speech, misnaming, and errors of repetition. These deficits worsen gradually, mimicking the course of a brain tumor or mass lesion rather than a typical dementia (Grossman et al. 1996; Mesulam 2001), The syndrome is generally referred to as *primary progressive aphasia.* CT scans may show focal atrophy in the left perisylvian region, whereas electroencephalographic (EEG) studies may show focal slowing. **PET** has shown prominent areas of decreased metabolism in the left temporal region and adjacent cortical areas. The pathology underlying primary progressive

aphasia varies (Kertesz et al. 2000). Some cases show the frontotemporal lobar atrophy of Pick's disease and localized spongiform degeneration. In Fnglnnd, this pattern of clinical syndrome and neuropathology is referred to as *frontotemporal dementia,* a term gaining popularity in the United States. In one study of 10 patients with primary progressive aphasia followed prospectively until they became nonfluent or mute, Kertesz and Munoz (2003) found that at autopsy all had evidence of frontotemporal dementia: corticobasal degeneration in 4, Pick body dementia in 3, and tau- and synuclein-negativc ubiquinated inclusions of the motor neuron disease in 3. Imaging studies have shown that primary progressive aphasia is often associated with atrophy in the left frontotemporal region, and other areas such as the fusiform and precentral gyri and intraparietal sulcus are activated, possibly as a compensatory neuronal strategy (Neary and Snowden 1996; Sonty et al. 2003). Familial cases of frontotemporal dementia have recently been linked to chromosome 17 (Heutink et al. 1997). Cases of isolated aphasia secondary to Creutzfeldt-Jakob disease and corticobasal degeneration have also been reported. Finally, a few patients with pathologically proven AD have presented with focal involvement of the language cortex, always with fluent aphasia.

INVESTIGATION OF THE APHASIC PATIENT

Clinical Tests

The bedside language examination is useful in forming a preliminary impression of the type of aphasia and the localization of the causative lesion. Follow-up examinations are also helpful; as in all neurological diagnoses, the evolution of a neurological deficit over time is the most important clue to the specific disease process. For example, an embolic stroke and a brain tumor might both produce Wernicke's aphasia, but strokes occur suddenly, with improvement thereafter, whereas tumors produce gradually worsening aphasia.

In addition to the bedside examination, a large number of standardized aphasia test batteries have been published. The physician should think of these tests as more detailed extensions of the bedside examination. They have the advantage of quantitation and standardization, permitting comparison over time and, in some cases, even a diagnosis of the specific aphasia syndrome. Research on aphasia depends on these standardized tests. For neurologists, the most helpful battery is the Boston Diagnostic Aphasia Examination, or its Canadian adaptation, the Western Aphasia Battery. Both tests provide subtest information analogous to the bedside examination, and therefore meaningful to neurologists, as well as aphasia syndrome classification. The Porch Index of Communicative Ability quantitates performance in many specific functions, allowing comparison over time. Other aphasia tests arc designed to evaluate specific language areas. For example, the Boston Naming Test evaluates a wide variety of naming stimuli, whereas the Token Test evaluates higher level comprehension deficits. Further information on neuropsychologic tests can be found in Chapter 38.

Further diagnosis of the aphasic patient rests on the confirmation of a brain lesion by neuroimaging (Figure 12A.9). The CT brain scan (discussed in Chapter 37B) revolutionized the localization of aphasia by permitting "real-time" delineation of a focal lesion in a living patient; previously, the physician had to outlive the patient to obtain a clinicopathologic correlation at autopsy. MRI scanning provides better resolution of areas difficult to see on CT, such as the temporal cortex adjacent to the petrous bones, and more sensitive detection of tissue pathology, such as early changes of infarction. The anatomic distinction of cortical from subcortical aphasia is best made by MRI. Acute strokes are visualized early on diffusion-weighted MRI.

The EEG is helpful in aphasia in localizing seizure discharges, interictal spikes, and slowing seen after destructive lesions, such as traumatic contusions and infarctions. The EEG can provide evidence that aphasia is an ictal or postictal phenomenon and can furnish early clues to aphasia secondary to mass lesions or to herpes simplex encephalitis. In research applications, electrophysiologic resting via subdural grid and depth electrodus. or stimulation mapping of epileptic foci in preparation for epilepsy surgery, have aided in the identification of cortical areas involved in language.

Cerebral arteriography is useful in the diagnosis of aneurysms, arteriovenous malformations (AVMs), arterial occlusions, vasculitis, and venous outflow obstructions. In preparation for epilepsy surgery, the Wada test, or infusion of amobarbital through an arterial catheter, is useful in the determination of language dominance. Other related studies by language activation with functional MRI (fMRI) or PET are beginning to rival the Wada test for the study of language dominance (Ahou-Khalil and Schlaggar 2002).

Single-photon emission CT (SPECT), PET, and fMRI (see Chapter 38} arc contributing greatly to the study of language. Patterns of brain activation in response to language stimuli have been recorded, mainly in normal persons, and these studies have largely confirmed the localizations based on pathology such as stroke over the past 140 years. In addition, these techniques can be used to map areas of the brain that activate during language functions after insults such as strokes, and the pattern of recovery can be studied. Some such studies have indicated right hemisphere activation in patients recovering from aphasia (Cappa et al. 1997}, hut others have found that only left hemisphere activation is associated with full recovery (Hciss et al. 1999}. Subcortical contributions to aphasia and language in degenerative conditions have been studied

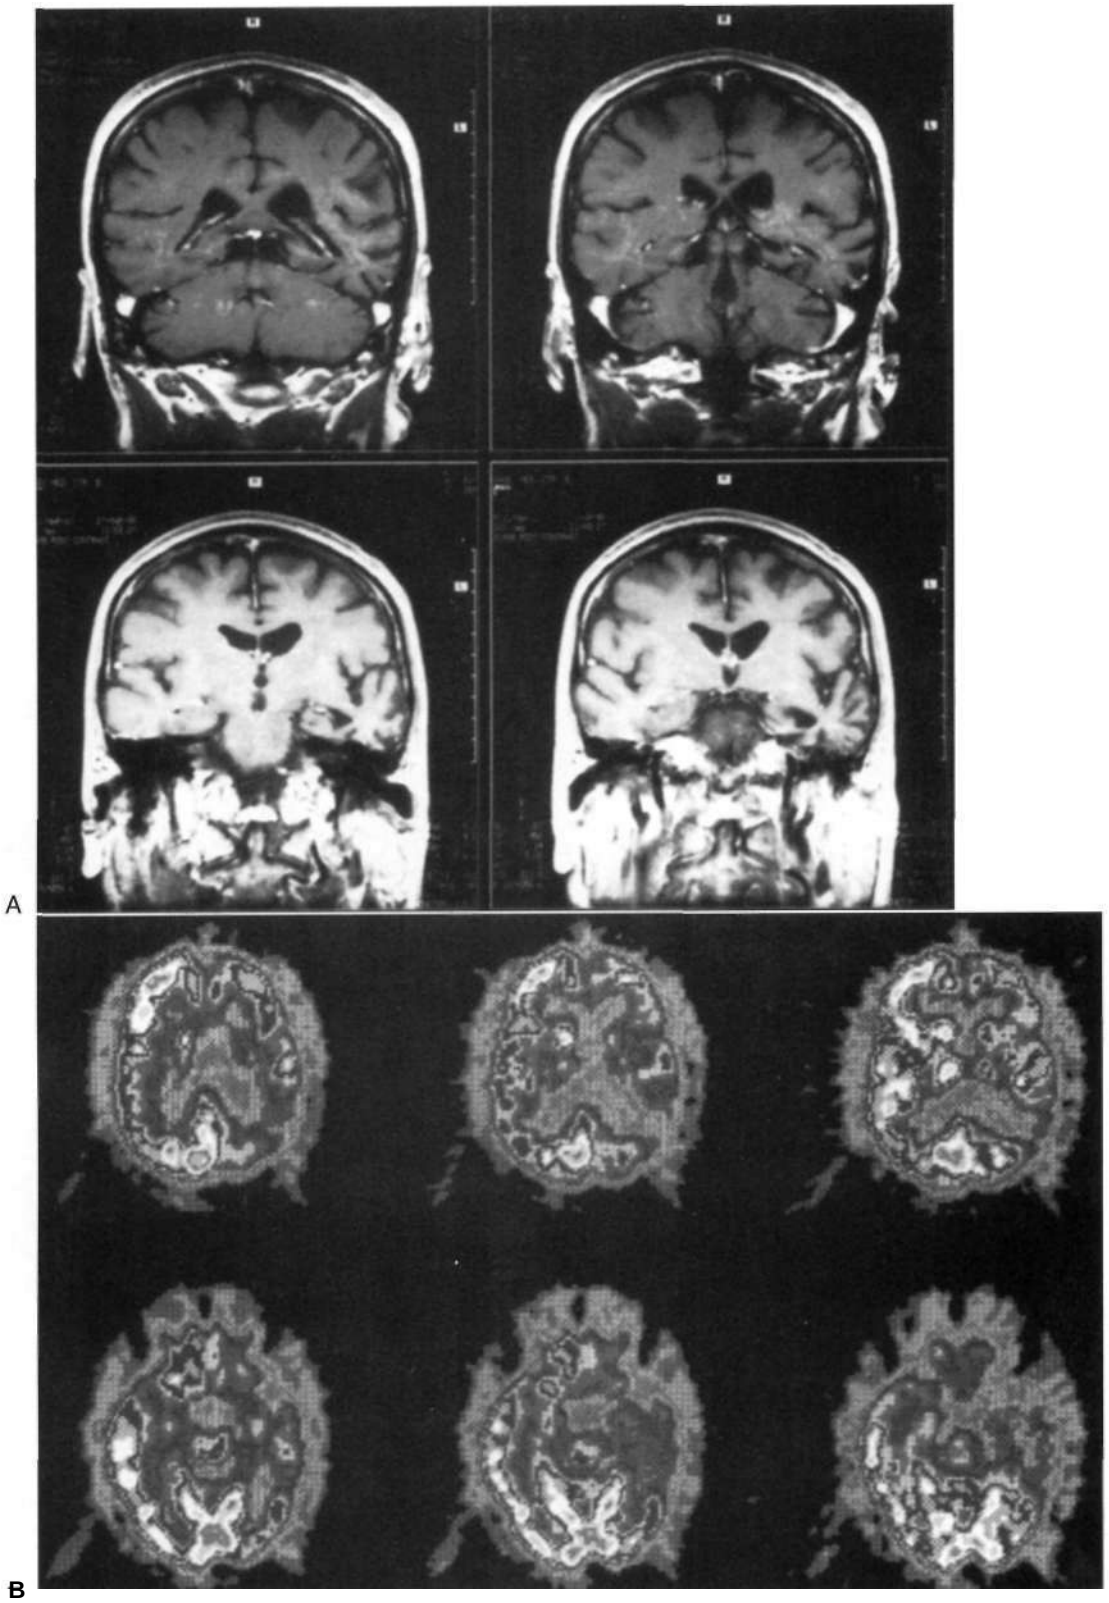

FIGURE 12A.9 (A) Coronal Tl-weighted magnetic resonance imaging scan of a patient with primary progressive aphasia. Note the marked atrophy of the left temporal lobe. (B) Axial fluorine-2-deoxyglucose positron emission tomographic scan showing extensive hypometabolisin in the left cerebral hemisphere, especially marked in the left temporal lobe.

with PET. These techniques provide the best correlation between brain structure and function currently available and should help advance our understanding of language disorders and their recovery.

DIFFERENTIAL DIAGNOSIS

Vascular lesions, especially ischemic strokes, are the most common causes of aphasia. Historically, most research studies in aphasia have used patients who have had a stroke because stroke is an "experiment" of nature in which one area of the brain is damaged while the rest remains theoretically intact. Strokes are characterized by the abrupt onset of a neurological deficit in a patient with vascular risk factors. The precise temporal profile is important: Most embolic strokes are sudden and maximal at onset, whereas thrombotic strokes typically wax and wane or increase in steps. The bedside aphasia examination is helpful in delineating the vascular territory affected. For example, the sudden onset of Wernicke's aphasia nearly always indicates an embolus to the inferior division of the left middle cerebral artery. Global aphasia may be caused by an embolus to the middle cerebral artery stem, thrombosis of the internal carotid artery, or even a hemorrhage into the deep basal ganglia. Whereas most aphasic syndromes involve the territory of the left middle cerebral artery, transcortical motor aphasia is specific to the anterior cerebral territory, and pure alexia without agraphia is specific to the posterior cerebral artery territory. The clinical features of the aphasia are thus of crucial importance to the vascular diagnosis.

Hemorrhagic strokes are also an important cause of aphasia, most commonly the basal ganglionic hemorrhages associated with hypertension. The deficits tend to worsen gradually over minutes to hours, in contrast to the sudden ot stepwise onset of ischemic strokes. Headache, vomiting, and obtundation are more common with hemorrhages. Because hemorrhages compress cerebral tissue without necessarily destroying it, the ultimate recovery from aphasia is often better in hemorrhages than in ischemic strokes, although hemorrhages are more often fatal. Other etiologies of intracerebral hemorrhage include anticoagulant use, head injury, blood dyscrasias, thrombocytopenia, and bleeding into structural lesions, such as infarctions, tumors, AVMs, and aneurysms. Hemorrhages from AVMs mimic strokes, with abrupt onset of focal neurological deficit. Patients with ruptured aneurysms, on the other hand, present with severe headache and stiff neck or with coma; most patients have no focal deficits, but delayed deficits (e.g., aphasia) may develop secondary to vasospasm. Lobar hemorrhages may occur in elderly patients without hypertension. These hemorrhages occur near the cortical surface, sometimes extending into the subarachnoid space, and they may be recurrent. Pathological studies have shown amyloid deposition in small arterioles, or amyloid angiopathy. A final vascular cause of aphasia is cerebral vasculitis (see Chapter 57G).

Traumatic brain injury is a common cause of aphasia. Cerebral contusions, depressed skull fractures, and hematomas of the intracerebral, subdural, and epidural spaces all cause aphasia when they disrupt or compress left hemisphere language structures. Trauma tends to be less localized than ischemic stroke, and thus aphasia is often admixed with the general effects of the head injury, such as depressed consciousness, encephalopathy or delirium, amnesia, and other deficits. Head injuries in young people may be associated with severe deficits but excellent long-term recovery. Language deficits, especially those involving discourse organization, can be found in most cases of significant closed-head injury. Gunshot wounds produce focal aphasic syndromes, which rival stroke as a source of clinicoanatomic correlation. Subdural hematomas are infamous for mimicking other neurological syndromes. Aphasia is occasionally associated with subdural hematomas overlying the left hemisphere, but it may be mild and may be overlooked because of the patient's more severe complaints of headache, memory loss, and drowsiness.

Tumors of the left hemisphere frequently present with aphasia. The onset of the aphasia is gradual, and other cognitive deficits may be associated because of edema and mass effect. Aphasia secondary to an enlarging tumor may thus be difficult to distinguish from a diffuse encephalopathy or early dementia. Any syndrome of abnormal language function should therefore be investigated for a focal dominant-hemisphere lesion.

Infections of the nervous system may cause aphasia. Brain abscesses can mimic tumors in every respect, and those in the left hemisphere can present with progressive aphasia. Chronic infections, such as tuberculosis or syphilis, can result in focal abnormalities that run the entire gamut of central nervous system symptoms and signs. Herpes simplex encephalitis has a predilection for the temporal lobe and orbital frontal cortex, and aphasia can be an early symptom, along with headache, confusion, fever, and seizures. Aphasia is often a permanent sequela in survivors of herpes encephalitis. Acquired immunodeficiency syndrome (AIDS) is rapidly becoming a common cause of language disorders. Opportunistic infections can cause focal lesions anywhere in the brain, and the neurotropic human immunodeficiency virus agent itself produces a dementia (AIDS-dementia complex), in which language deficits play a part.

Aphasia is frequently caused by the degenerative central nervous system diseases. Reference has already been made to the focal, progressive aphasia in patients with Pick's disease and spongiform degenerations as compared with the more diffuse cognitive deterioration characteristic of AD. Language dysfunction in AD may be more common in familial cases and may predict poor prognosis. Cognitive deterioration in patients with Parkinson's disease may also include language deterioration similar to that of AD,

although Parkinson's disease tends to involve more fluctuation in orientation and greater tendency to active hallucinations and delusions, A striking abnormality of speech (i.e., initial stuttering followed by ttue aphasia and dementia) has been described in the dialysis dementia syndrome. This disorder may be associated with spongiform degeneration of the frontotcmporal cortex, similar to Creutzfeldt-Jakob disease. Paraphasic substitutions and nonsense speech are also occasionally encountered in acute encephalopathies, such as hyponatremia or lithium toxicity.

A final cause of aphasia is seizures. Seizures can be associated with aphasia in children as part of the Landau-Kleffner syndrome or in adults as either an ictal or a postictal Todd's phenomenon. Epileptic aphasia is important to recognize, in that anticonvulsant drug therapy can prevent the episodes, and unnecessary investigation or treatment for a new lesion, such as a stroke, can be avoided. As mentioned earlier, localization of language areas in epileptic patients has contributed greatly to the knowledge of language organization in the brain. The work of Ojemann (1991) has shown that more than 15% of young epileptic patients have no Broca's or no Wernicke's area. In addition, a new language area, the basal temporal language area, has been discovered through epilepsy stimulation studies and only later confirmed in patients with spontaneous seizures (Kirshner et al. 1995).

RECOVERY AND REHABILITATION OF APHASIA

Patients with aphasia from acute disorders, such as stroke, generally show spontaneous improvement over days, weeks, and months. In general, the greatest recovery occurs during the first 3 months, but improvement may continue over a prolonged period, especially in young patients and in global aphasics. The aphasia type often changes during recovery: Global aphasia evolves into Broca's aphasia, and Wernicke's aphasia into conduction or anomic aphasia. Language recovery may be mediated by shifting of functions to the right hemisphere or to adjacent left hemisphere regions. As mentioned earlier, studies of language activation PET and SPECT scanning techniques are advancing our understanding of the neuroanatomy of language recovery (Heiss et al. 1999). In addition, study of patients in the very acute phase of aphasia, with techniques of diffusion- and perfusion-weighted MRI, has suggested less variability in the correlation of comprehension impairment with left temporal ischemia than has been suggested from testing of chronic aphasia, after recovery and compensation have commenced (Hillis et al. 2001).

Speech therapy, provided by speech-language pathologists, attempts to facilitate language recovery by a variety of techniques and to help the patient compensate for lost functions (see Chapter 54), Repeated practice in articulation and comprehension tasks has traditionally been used to stimulate improvement. Other techniques include melodic intonation therapy, which uses melody to involve the right hemisphere in speech production; visual action therapy, which uses gestural expression; and treatment of aphasic perseveration, which aims to reduce repetitive utterances. Two other therapeutic techniques are functional communication therapy, which takes advantage of extralinguistic communication, and cVIC or Lingraphica, a computer program originally developed for primate communication. Patients who cannot speak can learn to produce simple sentences via computer. Augmentative devices make language expression possible through use of printers or voice simulators. Speech therapy has remained controversial: Some studies have suggested that briefly trained volunteers can induce as much improvement as speech-language pathologists, but large randomized trials have clearly indicated that patients who undergo formal speech therapy recover better than untreated patients (Robey 1998).

A new approach to language rehabilitation is the use of pharmacological agents to improve speech. Albert and colleagues first reported that the dopaminergic drug bromocriptine promotes spontaneous speech output in transcortical motor aphasia. Several other studies have supported the drug in nonfluenr aphasias, although one controlled study showed no benefit. Stimulant drugs are also heing tested in aphasia rehabilitation. As new information accumulates on the neurochemistry of cognitive functions, other pharmacologic therapies may he forthcoming.

Chapter 12
Language and Speech Disorders

B. DYSARTHRIA AND APRAXIA OF SPEECH

Howard S. Kirshner

MOTOR SPEECH DISORDERS

Motor speech disorders are syndromes of abnormal articulation, the motor production of speech, without abnormalities of language. A patient with a motor speech disorder should be able to produce normal expressive language in writing and to comprehend both spoken and written language. If a listener transcribes into print or type the speech of a patient with a motot speech disorder, the text should read as normal language. Motor speech disorders include dysarthrias, disorders of speech articulation, apraxia of speech, a motor programming disorder for speech, and five rarer syndromes: aphcmia, foreign accent syndrome, acquited stuttering, primary progressive anarthria, and the opercular syndrome. In an analysis of speech and language disorders at the Mayo Clinic, Duffy (1995) reported that 46.3% of the patients had dysarthria, 27.1% had aphasia, 4.6% had apraxia of speech, 9% had other speech disorders (such as stuttcting), and 13% had other cognitive or linguistic disorders.

DYSARTHRIAS

Dysarthrias involve the abnormal atticulation of sounds or phonemes because of abnormal activation of the otomandibular pharyngeal muscles, affecting the speed, strength, timing, range, or accuracy of speech (Duffy 1995). Dysarthria is generally neurogenic, related to dysfunction of the central nervous system, nerves, neuromusculat junction, and muscle, with a contribution of sensoty deficits in some cases, but local structural problems of the palate, tongue, ot larynx may also cause speech abnormalities. Dysarthria can affect not only articulation, but also phonation, breathing, or prosody (emotional tone) of speech. Total loss of ability to articulate is called *anarthria,* wheteas dysarthria usually involves the distortion of consonant sounds.

Like the aphasias, dysatthtias can be analyzed in terms of the specific brain lesion sites associated with specific-patterns of speech impairment. Analysis of dysarthria at the bedside is useful for the localization of neurological lesions and the diagnosis of neurological disorders. An experienced examiner should be able to tecognize and categorize the majoi types of dysarthria, rather than referring to "dysarthria" as a single disorder.

The examination of speech at the bedside should include repeating syllables, words, and sentences. Repeating consonant sounds (such as /p/, /p/, /p/) or shifting consonant sounds (/p/, /t/, *Ik!)* can help identify which consonants consistently cause trouble.

The Mayo Clinic classification of dysarthria (Duffy 1995), widely used in the United States, includes six categories: (1) flaccid, (2) spastic and "unilateral upper motor neuron" (UMN), (3) ataxic, (4) hypokinetic, (5) hyperkinetic, and (6) mixed dysarthria. These types of dysarthria are summarized in Table 12B.1.

Flaccid dysarthria is associated with disorders involving lower moror neuron weakness of the bulbar muscles, such as polymyositis, myasthenia gtavis, and bulbar poliomyeliris. The speech pattern is breathy and nasal, with indistinctly pronounced consonants. In the case of myasthenia gtavis, the patient may begin reading a paragraph with normal enunciation, but by the end of the paragraph, the atticulation is soft, breathy, and frequently interrupted by labored respirations.

Spastic dysarthria occurs in patients with bilateral lesions of the motor cortex or corticobulbat tracts, such as bilateral strokes. The speech is harsh or "strain strangle" in vocal

Table 12B.1: Bedside features of transcortical aphasias

Type	*Localization*	*Auditory signs*	*Diseases*
Flaccid	Lower motor nei	Breathy, nasal voice, imprecise consonants	Stroke, myasthenia gravis
Spastic	Bilateral upper motor neuron	Strain strangle, harsh voice; slow rate; imprecise consonants	Bilateral strokes, tumors, primary lateral sclerosis
Unilateral upper motor neuron	Unilateral upper motor neuron	Consonant imprecision, slow rate, harsh voice quality	Stroke, tumor
Ataxic	(.i.Tcbi'llum	Irregular articulatory breakdowns, excessive and equal stress	Sttoke, degenerative disease
Hypokinetic	Extrapyramidal	Rapid rate, reduced loudness, monopitch and monoloudness	Parkinson's disease
] ty perk im-tic	Extrapyramidal	Prolonged phonemes, variable rate, inappropriate silences, voice stoppages	Dystonic, Huntington's disease
Spastic flaccid	Upper and lower motor neuron	Hypernasality; strain strangle, hatsh voice, slow rate, imprecise consonants	Amyotrophic lateral sclerosis, multiple strokes

Adapted with permission from Duffy, J, R. 1995, *Motor Speech Disorders: Substrates, Differential Diagnosis, and Management,* Mosby, St. Louis; and Kirshner, H. S. 2002, *Behavioral Neurology: Practical Science of Mind and Brain* , Butterworth-Hcinemann, Boston,

quality, with reduced rate, low pitch, and consonant errors. Patients often have the features of "pseudobulbar palsy," including dysphagia, exaggerated jaw jerk and gag reflexes, and easy laughter and crying (emotional incontinence or pathological laughter and crying). Another variant is the "opercular syndrome" (see Opercular Syndrome, later in this chapter).

A milder variant of spastic dysarthria, *"unilateral UMN"* dysarthria, is associated with unilateral UMN lesions (Duffy 1995). This type of dysarthria has similar features to spastic dysarthria, only in a less severe form. Unilateral UMN dysarthria is one of the most common types of dysarthria, occurring in patients with unilateral strokes.

Ataxic dysarthria or "scanning speech," associated with cerebellar disorders, is characterized by one of two patterns: irregular breakdowns of speech with explosions of syllables interrupted by pauses or a slow cadence of speech with excessively equal stress on every syllable. The second pattern of ataxic dysarthria is referred to as *scanning speech.* A patient with ataxic dysarthria, attempting to repeat the phoneme /p/ as rapidly as possible, produces either an irregular rhythm, resembling popcorn popping, or a very slow rhythm. Causes of ataxic dysarthria include cerebellar strokes, tumors, multiple sclerosis, and cerebellar degenerations.

Hypokinetic dysarthria, the typical speech pattern in Parkinson's disease, is notable for decreased and monotonous loudness and pitch, rapid rate, and occasional consonant errors. In a recent stud) of brain activation by positron emission tomography (PET) methodology (Liotti et al. 2003), premotor and supplementary motor area activation was seen in untreated patients with Parkinson's disease and hypokinetic dysarthria, but not in normal subjects. Following a voice treatment protocol, these premotor and motor activations diminished, whereas right-sided basal ganglia activations increased. Hypokinetic dysarthria responds both to behavioral therapies and to pharmacologic treatment of Parkinson's disease.

Hyperkinetic dysarthria, a pattern in some ways opposite to hypokinetic dysarthria, is characterized by marked variation in tate, loudness, and timing, with distortion of vowels, harsh voice quality, and occasional sudden stoppages of speech. This speech pattern is seen in hyperkinetic movement disorders such as Huntington's disease. The final category, *mixed* dysarthria, involves combinations of the other five types. One common mixed dysarthria is a spastic-flaccid dysarthria seen in amyotrophic lateral sclerosis (ALS). The patient with ALS has the harsh strain-strangle voice quality of spastic dysarthria, combined with the breathy and hypernasal quality of flaccid dysarthria. Multiple sclerosis may feature a spastic - flaccid-ataxic or spastic-ataxic mixed dysarthria, in which slow rate or irregular breakdowns arc added to the other characteristics seen in spastic and flaccid dysarthria. Wilson's disease can involve hypokinetic, spastic, and ataxic features,

The management of dysarthria includes speech therapy techniques to strengthen muscles, train more precise articulations, slow the rate of speech to increase intelligibility, or teach the patient to stress specific phonemes. Devices such as pacing boards to slow articulation, palatal lifts to reduce hypernasality, amplifiers to increase voice volume, communication boards for subjects to point to pictures, and augmentative communication devices and computer techniques can be used when the patient is unable to communicate in speech. Injections of collagen into the vocal folds and surgical procedures such as a pharyngeal

flap to reduce hypcrnasality or vocal fold transposition surgery to increase loudness may help the patient speak more intelligibly.

APRAXIA OF SPEECH

Apraxia of speech is a disorder of the programming of articulation of sequences of phonemes, especially consonants. The motor speech system makes errors in selection of consonant phonemes, in the absence of any "weakness, slowness, or incoordination" of the muscles of speech articulation (Wert/., LaPointe, and Roscnbek 1991). The phrase "apraxia of speech" implies that the disorder is one of a skilled, sequential motor activity (as in other apraxias), rather than a primary motor disorder. Consonants are often substituted rather than distorted, as in dysarthria. Patients have special difficulty with polysyllabic words and consonant shifts, as well as in initiating articulation of a word. Errors arc inconsistent from one attempt to the next, in contrast to the consistent distortion of phonemes in dysarthria.

The four cardinal features of apraxia of speech are (1) effortful, groping, or rrial-and-error" attempts at speech, with efforts at self-correction; (2) dysprosody; (3) inconsistencies in articulation errors; and (4) difficulty initiating utterances. Usually the patient has the most difficulty with the first phoneme of a polysyllabic utterance. The patient may make an error in attempting to produce a word on one trial, a different error the next time, and a normal utterance the third time.

Apraxia of speech is rare in isolated form, but it frequently contributes to the speech and language deficit of Broca's aphasia. A patient with apraxia of speech, in addition to aphasia, will often write better than he or she can speak, and comprehension is relatively preserved. Dronkers (1996) presented evidence from computed tomographic (CT) and magnetic resonance imaging (MRI) scans indicating that although the anatomic lesions vary, patients with apraxia of speech virtually always have damage in the left hemisphere insula, whereas patients without apraxia of speech do not.

Testing of patients for speech apraxia includes the repetition of sequences of phonemes (pa/ta/ka), as discussed previously (see Dysarthria). Repetition of a polysyllabic word (e.g., "catastrophe" or "television") is especially likely to elicit apraxic errors.

Oral or Buccolingual Apraxia

Apraxia of speech is not the same as oral-buccolingual apraxia, or ideomotor apraxia for learned movements of the tongue, lips, and larynx. Oral apraxia can be elicited by asking a subject to lick his or her upper lip, smile, or stick out the tongue. Oral apraxia is discussed in Chapter 13. Both oral apraxia and apraxia of speech can coexist with Broca's aphasia.

APHEMIA

Another differential diagnosis with both apraxia ol speech and dysarthria is the syndrome of *aphemia,* Broca first used the term *aphemie* to designate the syndrome later called "Broca's aphasia," but recently, the term has been reserved for a syndrome of near muteness, with normal comprehension, reading, and writing. Aphemia is clearly a motor speech disorder, rather than an aphasia, it written language and comprehension are indeed intact. Patients are often anarthric, with no speech whatever, and then effortful nonfluent speech emerges. Some patients have persisting dysarthria, with dysphonia and sometimes distortions of articulation that sound similar to foreign accents (see The "Foreign Accent Syndrome," later in this chapter). Alexander, Nacscr, and Palumbo (1990) associated pure anarthria with lesions of the face area of motor cortex. Functional imaging studies also suggest that articulation is mediated at the level of the primary motor face area (Riecker et al. 2000), and disruption of speech articulation can be produced by transcranial magnetic stimulation over the motor face area (Epstein et al. 1999). Controversy remains over whether aphemia is equivalent to apraxia of speech, as suggested by Alexander, Benson, and Stuss (1989). In general, aphemia is likely to involve lesions in the vicinity of the primary motor cortex and perhaps Broca's area, whereas apraxia of speech may be localized to the insula.

THE "FOREIGN ACCENT SYNDROME"

The "foreign accent syndrome" is an acquired form of motor speech disorder, related to the dysarthrias, in which the patient acquires a dysflucncy resembling a foreign accent, usually after a unilateral stroke (Kurowski, Blumstcin, and Alexander 1996; Takayama et al. 1993). Lesions may involve the motor cortex of the left hemisphere. The disorder can also be mixed with aphasia.

ACQUIRED STUTTERING

Another uncommon motor speech disorder following acquired brain lesions is a pattern resembling developmental stuttering, referred to as *acquired* or *cortical stuttering.* Acquired stuttering involves hesitancy in producing initial phonemes, with an associated dysrhythmia of speech. Acquired stuttering clearly overlaps with apraxia of speech but may lack the other features of apraxia of speech discussed earlier in this chapter. Acquired stuttering has been described most often in patients with left

hemisphere cortical strokes {Franco et al. 2000; Turgut, Utku, and Balci 2002), but the syndrome has also been reported with subcortical lesions including infarctions of the pons, basal ganglia, and subcortical white matter (Ciabarra ct al. 2000). Recurrence of childhood stuttering has been reported in patients with Parkinson's disease, suggesting involvement of the dopaminergic system (Shahcd and Jankovic2001).

PRIMARY PROGRESSIVE ANARTHRIA

A few cases have been described of progressive motor speech difficulty, usually leading to complete muteness. These cases are closely related to the syndrome of primary progressive aphasia (sec Chapter 12A). Most such patients have a progressive language disorder, but a few have had either dysarthria or apraxia of speech (Tyrrell ct al. 1991; Kertesz et al. 1994; Chapman ct al. 1997), These cases have all had lobar degeneration of the frontal cortex, some with involvement also of the temporal and parietal lobes. The clinical diagnoses of these patients have included fronto-temporal dementia or cortical basal ganglionic degeneration. We studied a patient whose final pathology was most consistent with multiple system atrophy.

OPERCULAR SYNDROME

The opercular syndrome, also called Foix-Chavany-Marie syndrome, Worster-Drought syndrome, or cheiro-oral syndrome (sensory disturbance in one hand and the ipsilateral otal corner) (Bakar, Kirshner, and Nia?. 1998), is a severe form of pseudobulbar palsy in which patients with bilateral lesions of the pcrisylvian cortex or subcortical connections become completely mute. These patients can follow commands involving the extremities but not of the cranial nerves; for example, they may be unable to open or close their eyes or mouth or smile voluntarily, yet they smile when amused, yawn spontaneously, and even utter cries in response to emotional stimuli. **The ability to follow** limb commands shows that the disorder is not an aphasic disorder of comprehension. The discrepancy between automatic activation of the cranial musculature and inability to perform the same actions voluntarily has been called an *automatic-voluntary dissociation.* The syndrome is usually seen in patients with multiple strokes, but rare cases of progressive disease, as in the syndrome of primary progressive anarthria, may occur.

Chapter 13
Neurogenic Dysphagia

Ronald F. Pfeiffer

Swallowing is like a wristwarcb. It appears, at first glance, to be a simple, even mundane, mechanism but under the unassuming face is a process that is both tremendously complex and fascinating. When operating properly, it functions unobtrusively and is afforded scant attention. Malfunction can go completely unnoticed for a time, but when it finally becomes manifest, serious, and sometimes catastrophic, consequences can ensue.

Impaired swallowing, or dysphagia, can originate from disturbances in the mouth, pharynx, or esophagus and can involve mechanical, musculoskeletal, or neurogenic mechanisms. Although mechanical dysphagia is an important topic, this chapter primarily focuses on neuromuscular and neurogenic causes of dysphagia because processes in these categories are what the neurologist is most likely to encounter.

Dysphagia is actually a quite common problem in neurological patients and can occur in a broad array of neurological or neuromuscular conditions. It has been estimated that neurogenic dysphagia develops in approximately 400,000-800,000 people per year (Robbins 1999) and that dysphagia is present in roughly 50% of inhabitants of long-term care units (Lin et al. 2002). Moreover, dysphagia can lead to superimposed problems such as inadequate nutrition, dehydration, recurrent upper respiratory tract infections, and frank aspiration with consequent pneumonia and even asphyxia. It thus constitutes a formidable and common problem confronting the neurologist in everyday practice.

NORMAL SWALLOWING

Swallowing is a surprisingly complicated and intricate phenomenon, comprising a mixture of voluntary and reflex or automatic actions that arc engineered and carried out by a combination of 26 pairs of pharyngeal and laryngeal muscles (not counting muscles used for chewing) and 5 cranial nerves that in turn receive directions from centers within the central nervous system (Wuttge-Hanning and Hannig 1995). Reflex swallowing is coordinated and carried out at the brainstem level, where centers act directly on information received from sensory structures within the oropharynx and esophagus. Volitional swallowing is not surprisingly accompanied by additional activity that originates not only in motor and sensory cortices, but also in other cerebral structures (Hamdy et al. 1999; Zald and Pardo 1999).

The process of swallowing can conveniently be broken down into three distinct stages or phases: oral, pharyngeal, and esophageal. These components have also been distilled into what have been termed the *horizontal* and *vertical subsystems,* reflecting the direction of bolus flow in each component (when the individual is upright when swallowing). The oral phase of swallowing comprises the horizontal subsystem and is largely volitional in character, whereas the pharyngeal and esophageal phases comprise the vertical subsystem and are primarily under reflex control.

In the oral, or swallow preparatory, phase food is taken into the mouth and if needed is chewed; saliva is secreted to provide both lubrication and the initial "dose" of digestive enxymes, and the food bolus is formed and shaped by die tongue. The tongue then propels the bolus backward to the pharyngeal inlet where, in a piston-like action, it delivers the bolus into the pharynx. This in turn initiates the pharyngeal phase in which a cascade of intricate, extremely rapid, and exquisitely coordinated movements seal off the nasal passages and protect the trachea while the cricopharyngeal muscle, which functions as the upper esophageal sphincter (UES), relaxes and allows the bolus to enter the

pharynx. As an example of the intricacy of movements during this phase of swallowing, the UES, prompted in part by traction produced by elevation of the larynx, actually relaxes just before arrival of the food bolus, creating suction that assists in guiding the bolus into the pharynx. The bolus then enters the esophagus where peristaltic contractions usher it distally and, upon relaxation of the lower esophageal sphincter, into the stomach.

NEUROPHYSIOLOGY OF SWALLOWING

Central control of swallowing has traditionally been ascribed to brainstem structures, with cortical supervision and modulation emanating from the inferior precentral gyrus. However, recent positron emission tomography (PET) (Zald and Pardo 1999) and transcranial magnetic stimulation (TMS) (Hamdy et al. 1996) studies of volitional swallowing reveal a considerably more complex picture in which a broad network of brain regions are active in the control and execution of swallowing.

It is, perhaps, not surprising that the strongest activation in PET studies of volitional swallowing docs occur in the lateral motor cortex within the inferior precentral gyrus, wherein lie the cortical representations of tongue and face (Hamdy et al. 1999; Zald and Pardo 1999), There is disagreement among investigators, however, in that some have noted bilaterally symmetrical activation of the lateral motor cortex (Zald and Pardo 1999), whereas others have noted a distinctly asymmetrical activation, at least in a portion of subjects tested (Hamdy et al. 1999).

Some additional, and perhaps somewhat surprising, brain areas arc also activated during volitional swallowing (Hamdy et al. 1999; Zald and Pardo 1999). The supplementary motor area may play a role in preparation for volitional swallowing and the anterior cingulate cortex may be involved with monitoring autonomic and vegetative functions. Another area of activation during volitional swallowing is the anterior insula, particularly on the right. It has been suggested that this activation may provide the substrate that allows gustatory and other intraoral sensations to modulate swallowing. PET studies also consistently demonstrate distinctly asymmetrical, left-sided activation of the cerebellum during swallowing. This activation may reflect cerebellar input concerning coordination, timing, and sequencing of swallowing. Activation of putamen has also been noted during volitional swallowing, but it has not been possible to differentiate this activation from that seen with tongue movement alone.

Within the brainstem, swallowing appears to be regulated by central pattern generators that contain the programs directing the sequential movements of the various muscles involved with swallowing. These pattern generators reside in the medial reticular formation of the rostral medulla and the reticulum adjacent to the nucleus tractus soiitarius (Hunter et al. 1997). These centers then project to the nucleus ambiguus and the dorsal motor nucleus of the vagus, which directly control motor output to the pharyngeal musculature and proximal esophagus.

It has thus become evident that a large network of structures participates in the act of swallowing, especially volitional swallowing. The presence of this network presumably accounts for the broad array of neurological disease processes that can produce dysphagia as a part of their clinical picture.

MECHANICAL DYSPHAGIA

Structural abnormalities, both within and adjacent to the **mouth,** pharynx, and esophagus, can interfere with swallowing on a strictly mechanical basis, despite fully intact and functioning nervous and musculoskeletal systems (Table 13.1). Within the mouth macroglossia., temporomandibular joint dislocation, certain congenital anomalies, and intraoral tumors can impede effective swallowing and produce mechanical dysphagia. Pharyngeal function can be compromised by processes such as retropharyngeal tumor or abscess, cervical anterior osteophyte formation, Zenker's diverticulum, or thyroid gland enlargement. An even broader array of structural lesions can interfere with esophageal function, including malignant or benign esophageal tumors, metastatic carcinoma, esophageal stricture from numerous causes, vascular abnormalities such as aortic aneurysm or aberrant origin of the subclavian artery, or even primary gastric abnormalities such as hiatal hernia. Gastroesophageal reflux can also produce dysphagia. Individuals with these problems, however, are more likely to wind up in the hands of a gastrocntcrologist rather than a neurologist.

NEUROMUSCULAR DYSPHAGIA

A variety of neuromuscular disease processes of diverse etiology can involve the oropharyngeal and esophageal musculature and produce dysphagia as part of their broader neuromuscular clinical picture (Table 13.2). Certain muscular dystrophies, inflammatory myopathies, and mitochondrial myopathies all can display dysphagia, as can disease processes affecting the myoneural junction, such as myasthenia gravis.

Oculopharyngeal Muscular Dystrophy

Oculopharyngeal muscular dystrophy (OPMD) is a rare autosomal dominant disorder that is most frequently encountered in individuals with a French Canadian ethnic background. It is the consequence of a GCG trinucleotide repeat expansion in the poly{A)-binding protein nuclear 1 gene (also called poly|A]-binding protein 2, or PABP2,

gene) on chromosome 14 (Hill et al. 2001). OPMD is unique among the muscular dystrophies because of its appearance in older individuals, with symptoms typically first appearing between ages 40 and 60 years (Brais et al. 1999). It is characterized by slowly progressive ptosis, dysphagia, and proximal limb weakness. Because of the ptosis, patients with OPMD may assume an unusual posture characterized by raised eyebrows and extended neck.

Dysphagia in OPMD is due to impaired function of the oropharyngeal musculature. Although ir evolves slowly over many years, OPMD can eventually result not only in difficulty or discomfort with swallowing, but also in weight loss, malnutrition, and aspiration (Christopher et al. 2001). No specific treatment for the muscular dystrophy itself is available, but cricopharyngeal myotomy affords dysphagia relief in more than 80% of treated individuals (Fradet et al. 1997). More recently, botulinum toxin injections have been successfully used to treat dysphagia in OPMD (Restivo et al. 2000).

Myotonic Dystrophy

Myotonic dystrophy is an autosomal dominant disorder whose phenotypic picture includes not only skeletal muscle, but also cardiac, ophthalmologic^!, and endocrinological involvement. Mutations at two distinct locations have now been associated with the clinical picture of myotonic dystrophy. Type 1 myotonic dystrophy is due to a CTG expansion in the DMPK gene on chromosome 19, whereas type 2 is the consequence of a CCTG repeat expansion in the ZNF9 gene on chromosome 3 (Ranum and Day 2002).

Gastrointestinal (GI) symptoms develop in more than 50% of individuals with the clinical phenotype of myotonic dystrophy and may be the most disabling component of the disorder in 25%. GI symptoms may actually antedate the appearance of other neuromuscular features. Subjective dysphagia is one of the most prevalent GI features and has been repotted to be present in 37-56% of patients (Fate-kin et al. 2001). Coughing when eating, suggestive of aspiration, may occur in 33%. Objective measures paint a picture of even more pervasive impairment, demonstrating disturbances in swallowing in 70-80% of persons with myotonic dystrophy (Errekin et al. 2001). In one study,

75% of patients asymptomatic for dysphagia were still noted to have abnormalities on objective testing.

A variety of abnormalities in objective measures of swallowing have been documented in myotonic dystrophy. Abnormal cricopharyngeal muscle activity is present in 40% of patients during electromyographic (EMG) testing (Ertekin ct al. 2001). Impaired esophageal peristalsis has also been noted in affected individuals studied with esophageal manometry. In vidcofluoroscopic testing, incomplete relaxation of the UES and esophageal hypotonia are the most frequently noted abnormalities. Both muscle weakness and myotonia are felt to play a role in the development of dysphagia in persons with myotonic dystrophy, and in at least one study, a correlation was noted between the size of the CTG repeat expansion and the number of radiologic abnormalities in myotonic patients.

Other Muscular Dystrophies

Although less well characterised, dysphagia also occurs in other types of muscular dystrophy. Difficulty swallowing and choking while eating occur with increased frequency in children with Duchenne's muscular dystrophy. Dysphagia has also been documented in patients with limb-girdle dystrophy and facioscapulohumeral muscular dystrophy (Williget al. 1994).

Inflammatory Myopathies

Dermatomyositis and polymyositis arc the most commonly occurring of the inflammatory myopathic disorders. Both are characterized by progressive, usually symmetrical, weakness affecting proximal muscles more prominently than distal. Fatigue and myalgia may also occur. Malignant disease is associated with the disorder in 10-15% of patients with dermatomyositis and 5-10% of those with polymyositis. In individuals older than *65* years, more than 50% are found to have cancer.

Although dysphagia can develop in both conditions, it more frequently is ptesent, and when present more severe, in dermatomyositis. Dysphagia is present in 20-55% of individuals with dermatomyositis, but in only 18% with polymyositis (Parodi et al. 2002). It is the consequence of involvement of striated muscle in the pharynx and proximal esophagus. Involvement of pharyngeal and esophageal musculature in polymyositis and dermatomyositis is an indicator of poor prognosis and can be the source of significant morbidity (Marie et al. 1999). The resulting dysphagia can be severe enough to require enteral feeding. Acute total obstruction by the cricopharyngeal muscle has been reported in dermatomyositis, necessitating cricopharyngeal myotomy. Dysphagia in both conditions may respond to corticosteroids, and intravenous immune globulin (IVIG) therapy has produced dramatic improvement in dysphagia in individuals who were unresponsive to steroids (Marie et al. 1999).

Although dysphagia develops less often in inclusion body myositis, it can occur. In fact, in a group of individuals in whom inclusion body myositis mimicked and was confused with motor neuron disease, dysphagia was present in 44%. A focal inflammatory myopathy involving the pharyngeal muscles and producing isolated pharyngeal dysphagia has also been described in elderly individuals older than 69 years. It has been suggested that this is a distinct clinical entity characterized by cricopharyngeal hypertrophy, although polymyositis localized to the pharyngeal musculature has also been reported.

Mitochondrial Disorders

The mitochondrial disorders are a family of diseases that develop as a consequence of dysfunction in the mitochondrial respiratory chain. Most are the result of mutations in mitochondrial deoxyribonucleic acid (DNA) genes, but nuclear DNA mutations may be responsible in some. Mitochondrial disorders are by nature multisystemic, but myopathic and neurological features often predominate and symptoms may vaty widely, even between individuals within the same family.

In addition to the classic constellation of symptoms that include progressive external ophthalmoplegia, retinitis pigmentosa, cardiac conduction defects, and ataxia, individuals with Kcarns-Sayre syndrome may also develop dysphagia (Katsanos et al. 2001, 2002; Kornblum et al. 2001). Severe abnormalities of pharyngeal and upper esophageal peristalsis have been documented in this disorder. Cricopharyngeal dysfunction is common, but impaired deglutitive coordination may also develop (Kornblum et al. 2001). Dysphagia has also been described in other mitochondrial disorders, but descriptions are only anecdotal and formal study has not been undertaken.

Myasthenia Gravis

Myasthenia gravis (MG) is an autoimmune disorder characterized by the production of autoantibodies directed against the postsynaptic i/| muscle nicotinic acetylcholine receptors at the neuromuscular junction, with destruction of the receptors and reduction in their number. The clinical consequence of this process is the development of fatigable muscle weakness that progressively increases with repetitive muscle action and improves with rest. MG occurs more often in women than men, and although symptoms can develop at any age, the reported mean age at onset in women is 28-35 years and in men 42—49 years (Kalb et al. 2002). Although myasthenic symptoms tcmain confined to the extraocular muscles in about 20% of

patients, in most individuals more widespread muscle weakness becomes evident (Kalb et al. 2002; Wirtz et al. 2002).

Involvement of bulbar musculature, with resultant dysphagia, is relatively common in MG. In approximately 6-30% of patients, bulbar involvement is evident from the beginning (Wirtz et al. 2002), but most patients eventually develop bulbar symptoms such as dysphagia and dysarthria as the disease progresses. Dysphagia in MG can be due to dysfunction at oral, pharyngeal, or even esophageal levels. Oral phase involvement can be due to fatigue and weakness of the tongue or masticatory muscles. In patients with MG who have bulbar symptoms, repetitive nerve stimulation studies of the hypoglossal nerve have demonstrated abnormalities (Lo et al. 2002), whereas studies using EMG of the masticatory muscles recorded while chewing have also revealed impaired performance (Weijnen et al. 2002). Pharyngeal dysfunction is also common in patients with MG who have dysphagia, as demonstrated with videofluoroscopy. Aspiration, often silent, may be present in 35% or more of these individuals (Colron-Hudson ct al. 2002); in elderly patients, the frequency of aspiration may be considerably higher. Motor dysfunction involving the striated muscle of the proximal esophagus has also been documented in MG. In one study, 96% of patients with MG demonstrated abnormalities, such as decreased amplitude and prolongation of the peristaltic wave, in this region on testing with esophageal manometry. Cricopharyngeal sphincter pressure was also noted to be reduced.

NEUROGENIC DYSPHAGIA

A variety of disease processes originating in the central and peripheral nervous systems can also disrupt swallowing mechanisms and produce dysphagia. Processes affecting cerebral cortex, subcortical white matter, subcortical gray matter, brainstem, spinal cord, and peripheral nerves can elicit dysphagia as a component of their clinical picture (Table 13.3).

Stroke

Cerebrovascular disease is an extremely common neurological problem and stroke is the third leading cause of death in the United States, It has been estimated that 500,000-750,000 strokes occur in the United States each year and that approximately 150,000 persons die following stroke annually. The mechanism of stroke is ischemic in 80-85% of cases, and in the remaining 15-20%, it is hemorrhagic (Shah and Biller 1998). Approximately 25% of ischemic strokes are due to small-vessel disease, 50% to large-vessel disease, and 25% to a cardioembolic source. Although stroke can occur at all ages, 75% of strokes occur in individuals older than 75 years.

Dysphagia develops in 45-51% of individuals following stroke and its presence is associated with increased likelihood of severe disability or death (Lawrence et al. 2001; Mann, Hankey, and Cameron 2000). Aspiration is the most widely recognized complication of dysphagia following stroke, but undernourishment and even malnutrition occur with surprising frequency (Ullman and

Reding 1996). Reported frequencies of nutritional deficits in patients with dysphagia following stroke range from 48-65%. The presence of dysphagia following stroke has been noted as an independent risk factor for severe disability and death (Sharma et al. 2001).

Although it is commonly perceived that the presence of dysphagia following stroke indicates a brainstem localization for the stroke, this is not necessarily so. Impaired swallowing has been documented in a significant proportion of strokes involving cortical and subcortical structures. The pharyngeal phase of swallowing is primarily impaired in brainstem infarction, whereas in hemispheric strokes, the most striking abnormality often is a delay in initiation of voluntary swallowing (Aydogdu et al. 2001). Dysphagia has been reported as the sole manifestation of infarction in both the medulla and the cerebrum (Celifarco er al. 1990).

Approximately 50-55% of patients with lesions in the posteroinferior cerebellar artery distribution, with consequent lateral medullary infarction (Wallenberg's syndrome:, develop dysphagia (Tcasell et al, 2002). The fact that unilateral medullary infarction can produce bilateral disruption of the brainstem swallowing centers suggests that they function as one integrated center (Vigderman et al. 1998). Infarction in the distribution of the anteroinferior cerebellar artery can also result in dysphagia.

Following stroke within the cerebral hemispheres, dysphagia can develop by virtue of damage to either cortical or subcortical structures involved with volitional swallowing. Bilateral hemispheric damage is more likely to produce dysphagia, hut it can also occur in the setting of unilateral damage. Infarction of the frontoparietal operculum bilaterally may result in the anterior operculum (Maric-Foix-Chavany) syndrome, which is characterized by inability to perform voluntary movements of the face, jaw, tongue, and pharynx with fully preserved involuntary movements of the same muscles (Billith, Jorgler, and Baumhackl 2000). Impairment of volitional swallowing may be a component of this syndrome. Individuals with subcortical strokes have a higher incidence of dysphagia and aspiration than those with cortical damage. In one study, more than 85% of individuals with unilateral subcortical strokes demonstrated videofluoroscopic evidence of delayed initiation of the pharyngeal stage of swallowing, and in 75%, some radiographic aspiration was noted. Although tongue deviation is classically associated with medullary lesions damaging the hypoglossal nucleus, it has also been documented in almost 30% of persons with hemispheric infarctions (Umapathi et al. 2000). When present in hemispheric stroke, tongue deviation is always associated with facial weakness and dysphagia is present in 43% of affected patients.

Aspiration is a potentially life-threatening complication of stroke. Studies have documented its occurrence in 30-55% of stroke patients (Teasell et al. 2002). In one study, videofluoroscopic evidence of aspiration was observed in 36% of patients with unilateral cerebral stroke, 46% with bilateral cerebral stroke, 60% with unilateral brainstem stroke, and SO",, with bilateral brainstem lesions. Other studies have suggested that the incidence of aspiration in brainstem strokes may be considerably higher—more than 80%—and that subcortical strokes may result in aspiration in 75% of cases (Horner et al. 1991). The risk of developing pneumonia is almost seven times greater in persons experiencing aspiration post-stroke compared with those who do not (Holas, Del'ippo, and Reding 1994). Individuals in whom aspiration occurs post-stroke do not always experience clinical symptoms such as coughing or choking during food or liquid ingestion. Furthermore, an absent gag reflex does not help differentiate those aspirating from those who are not. Therefore the employment of objective testing measures to detect the presence and predict the risk of aspiration has been advocated. Modified barium swallow (MBS) testing using vidcofluoroscopy is the gold standard to do this, but simple bedside techniques, such as a water swallowing test, have also been advocated as practical, though somewhat less sensitive, alternatives (Marietal. 1997),

Swallowing often improves spontaneously in the days and weeks following stroke. Tube feeding can temporarily provide adequate nutrition and buy time until swallowing improves sufficiently to allow oral feeding but does entail some risks itself, such as increasing the possibility of reflux wirh consequent aspiration. Various methods of behavioral swallow therapy can be useful in managing persistent post-stroke dysphagia, but in a small percentage of individuals, placement of a percutaneous endoscopic gastrostomy (PEG) will be necessary.

Dysphagia can also develop in the setting of various other cerebrovascular processes. Within the anterior circulation, dysphagia has been reported with carotid artery aneurysms, and within the posterior circulation, processes such as elongation and dilatation of the basilar artery, posterior inferior cerebellar artery aneurysm, intracranial vertebral artery dissections, and cavernous malformations within the medulla may produce dysphagia in addition to other symptoms.

Multiple Sclerosis

Multiple sclerosis (MS) is an inflammatory demyelinating disease of the central nervous system that primarily, though not exclusively, affects young adults. The mean age at onset is approximately 30 years. In its most common guise, MS is characterized by exacerbations and remissions, although some individuals may follow a chronic progressive course right from the start. The etiology of MS is uncertain, but an autoimmune process is suspected.

Dysphagia is a common, but often overlooked, problem in MS (Wiesncr et al. 2002). Survey studies have indicated the presence of dysphagia in 24-34% of individuals with

MS (Hartelius and Svcnsson 1994; Calcagno et al. 2002). The prevalence of dysphagia in MS rises with increasing disability, reaching *65%* in the most severely affected (De Pauw et al. 2002). Individuals with scvcte brainstem involvement as parr of their MS are especially likely to experience dysphagia (Thomas and Wiles 1999).

Objective studies demonstrate a somewhat higher frequency of dysphagia than their survey study counterparts. In fact, in such studies, approximately 50% of individuals with ob]ective abnormalities were not aware of any difficulty swallowing (Thomas and Wiles 1999), Abnormalities in oral, pharyngeal, and even esophageal phases of swallowing have been documented. Rare instances of the anterior operculum syndrome, with buccolingual facial apraxia, have been reported in MS. Abnotmalities in the oral phase of swallowing are common in patients with MS who have mild disability, but additional pharyngeal phase abnormalities develop in those with more severe disability. Disturbances in both the sequencing of laryngeal events and the functioning of the pharyngeal constrictor muscles are typically present in persons experiencing dysphagia. Pharyngeal sensory impairment may also play a role in the development of dysphagia in some patients (Groher 1996).

Parkinson's Disease

Parkinson's disease (I'D) is a neurodegenerative disorder m which symptoms typically emerge between the ages of *55* and 65 years. Although the most prominent neuropathology in PD involves the pigmented dopaminergic neurons in the substantia nigra, neuronal loss in other areas of the nervous system, including wirhin the enteric nervous system, has also been documented.

Dysphagia was first documented in PD by James Patkinson himself in his original description of the illness in 1817 (Parkinson 1817). Recent survey studies have confirmed that dysphagia is indeed a common phenomenon in PD. Reported frequencies of dysphagia in these studies range from 30-82% (Edwards et al. 1991; Clarke et al. 1998), with the broad range probably reflecting differences in the detail within the questionnaires. Objective testing indicates an even higher frequency of dysphagia in PD and has allowed its separation into two categories, oropharyngeal and esophageal (Pfeiffer 2003).

Studies using MBS testing have demonstrated some abnormality in the oropharyngeal phase of swallowing in 75-97% of persons with PD (Fuh et al. 1997; Leopold and Kagel 1997). Even individuals asymptomatic for dysphagia frequently display abnormalities on MBS testing. Within the oral phase, difficulty with bolus formation, delayed initiation of swallowing, repeated tongue pumping, and other abnormalities have been described (Nagaya et al. 1998), although pharyngeal dysmotility and impaired relaxation of the cricopharyngeal muscle constitute examples of abnormalities noted in the pharyngeal phase (Byrne, Pfeiffer, and Quigley 1994; Ali et al. 1996; Pfeiffer 2003).

Esophageal dysfunction can also trigger dysphagia in PD. Studies using esophageal manometry have demonstrated abnormalities in 61-73% of patients with PD (Bassotti et al. 1998), and videofluoroscopic studies show a broader range with some abnormality reported in 5-86% of individuals (Stroudley and Walsh 1991; Edwards et al. 1994; Leopold and Kagel 1997). A wide variety of abnormalities of esophageal function have been described, including slowed esophageal transit, both segmental and diffuse esophageal spasm, ineffective or tertiary contractions, and even aperistalsis. Lower esophageal sphincter dysfunction may also be present in PD and can produce symptoms of reflux and dysphagia.

Aspirarion has been noted to be present in 15-56% of patients with PD (Robbins, Logemann, and Kirshner 1986; Stroudley and Walsh 1991; Ali et al. 1996; Nagaya et al. 1998), and completely silent aspiration in 15-33% {Robbins, Logemann, and Kirshner 1986). Even more striking is a study in which vallecular residue, believed to indicate an incteased risk of aspiration, was found to be present in 88% of patients with PD who do not have clinical dysphagia.

Dysphagia demonstrates an inconsistent response to L-dopa or dopamine agonist therapy (Pfeiffer 2003). Objective improvement in swallowing, documented by MBS testing, has been observed in 33-50% of patients in some, but not all, studies (Fuh et al. 1997; Hunter et al. 1997). In patients with cricopharyngeal muscle dysfunction, both cricopharyngeal myotomy (Born et al. 1996) and botulinum toxin injections (Restivo, Palmcri, and Marchese-Ragona 2002} have been used successfully. Behavioral swallowing therapy approaches are of benefit to some individuals. On rare occasions, PEG placement may be necessary.

Other Basal Ganglia Disorders

In the parkinsonism-plus syndromes, such as progressive supranuclear palsy (PSP), multiple system atrophy (MSA), corticobasal degeneration (CBD), and dementia with Lewy bodies (DLB), dysphagia is a common problem and, in contrast to PD, often develops relatively early in the course of the illness (Litvan, Sastry, and Sonies 1997; Muller et al. 2001). Although the median latency to the development of dysphagia in PD is more than 130 months, it is 67 months in MSA, 64 months in CBD, 43 months in DLB, and 42 months in PSP (Muller et al. 2001). In fact, the appearance of dysphagia within 1 year of symptom onset virtually eliminates PD as a diagnostic possibility, although it does not help distinguish between the various parkinsonism-plus syndromes (Muller et al. 2001).

Dysphagia can be a prominent problem in patients with Wilson's disease and is frequently a component of the

clinical picture in neuroacanthocytosis (Rampoldi, Danek, and Monaco 2002). A unique basal ganglia process characterized by the presence of subacute encephalopathy, dysarthria, dysphagia, rigidity, dystonia, and eventual quadriparesis has been shown to improve promptly and dramatically to biotin administration (Ozand et al. 1998),

Dysphagia is also a well-documented complication of botulinum toxin injections for cervical dystonia, presumably as a consequence of diffusion of the toxin {Cornelia et al. 1992). It should be noted, however, that 11% of patients with cervical dystonia experience dysphagia as parr of the disease process itself and 22% may display abnormalities on objective testing (Cornelia et al. 1992).

Amyotrophic Lateral Sclerosis

Amyotrophic lateral sclerosis (ALS) is the most common form of motor neuron disease. It is characterized by progressive loss of motor neurons in the cortex, brainstem, and spinal cord, which results in a clinical picture of progressive weakness that combines features of both upper motor neuron dysfunction, with spasticity and hyper-reflexia, and lower moror neuron dysfunction, with atrophy, fasciculations, and hyporeflexia (Borasio and Miller 2001). The mean age at symptom onset is 54-58 years (Borasio and Miller 2001).

Although dysphagia eventually develops in most individuals with ALS, bulbar symptoms can be the presenting feature in approximately 25% of patients. A sensation of solid food sticking in the esophagus may provide the initial clue to emerging dysphagia, but abnormalities in the oral phase of swallowing are most often evident in patients with early ALS (Kawai et al. 2003). Impaired function of lips and tongue, particularly its posterior portion, due to evolving muscle weakness typically appears first, followed next by involvement of jaw and suprahyoid musculature and finally by weakness of pharyngeal and laryngeal muscles (Hillel and Miller 1989). Lip weakness can result in spillage of food from the mouth, whereas tongue weakness leads to impaired food bolus formation and transfer (Groher 1996). Inadequate mastication due to the jaw muscle weakness adds to the difficulty with bolus formation, and the eventual development of pharyngeal and laryngeal weakness opens the door for aspiration. Neurophysiologic testing in patients with ALS who have dysphagia demonstrates delay in and eventual abolishment of triggering of the swallowing reflex for voluntarily initiated swallows, with relative preservation of spontaneous reflexive swallows until the terminal stages of the disease (Ertekin et al. 2000).

Spasm of the UES, with hyper-reflexia and hypertonicity of the cricopharyngeal muscle, has been reported in patients with ALS who have bulbar dysfunction, presumably as a consequence of upper motor neuron involvement, and has been considered an important cause of aspiration (Ertekin et al. 2000). This has prompted the employment of cricopharyngeal myotomy as a treatment measure in such patients, but this approach should be limited to those with objectively demonstrated UES spasm.

Control of oral secretions can be a difficult problem for patients with ALS. Because ^-adrenergic stimulation increases production of protein and mucus-rich secretions, which may thicken saliva and make it especially difficult for patients to handle, administration of beta blockers has been proposed to reduce thickness of oral, nasal, and pulmonary secretions. Surgical procedures to reduce salivary production, such as tympanic neurectomy and submandibular gland resection, have also been employed but not extensively studied.

Behavioral therapy approaches can be useful in treating mild to moderate dysphagia in ALS. Alterations in food consistency (such as thickening liquids), swallowing compensation techniques and voluntary airway protection maneuvers all provide benefit and can be taught by speech/swallowing therapists (Groher 1996). Eventually, however, enteral feeding becomes necessary in many individuals with advanced ALS. Placement of a PEG can stabilize weight loss, relieve nutritional deficiency, and improve quality of life for individuals with advanced ALS and severe dysphagia (Borasio, Voltz, and Miller 2001; Chio et al. 1999; Kasarskis et al. 1999).

Brainstem Processes

Any process damaging the brainstem swallowing centers or lower cranial nerve nuclei can lead to dysphagia. Therefore in addition to stroke and MS, a number of other processes affecting brainstem function may display dysphagia as part of their clinical picture. Brainstem tumors, both primary and metastatic, may be responsible for dysphagia, as can central pontine myelinolysis, progressive multifocal leukocncephalopathy, and leukoencephalopathy due to cyclosporin toxicity. Brainstem encephalitis, produced by organisms such as *Listeria* and Epstein-Barr virus (Follet-Bouhamed er al. 1999) may also result in dysphagia.

Cranial Neuropathies

Pathological processes involving the lower cranial nerves can produce dysphagia, usually as a part of a broader clinical picture. Dysphagia can be prominent in the Miller Fisher variant of acute inflammatory demye I mating polyneuropathy (Guillain-Barre syndrome). Response to plasmapheresis is expected in this situation. Dysphagia may also be present in herpes-zoster infection, where it has been attributed to cranial ganglionic involvement. Examples of other processes from which cranial nerve involvement can result in dysphagia include Charcot-Marie-Tooth disease and primary or metastatic tumors involving the skull base. Severe, but reversible, dysphagia with significantly

prolonged esophageal transit time has been attributed to vincristine therapy (Wang et al. 2000).

EVALUATION OF DYSPHAGIA

Various diagnostic tests, ranging from simple bedside analysis to sophisticated tadiologic and neurophysiology procedures, have been developed to evaluate dysphagia (Logemann 1996). Although most are actually performed by specialists other than neurologists, it is important for neurologists to have an awareness of them so they can be employed when clinical citcumstanccs arc appropriate (Table 13.4).

Clinical examination is somewhat limited because of the inaccessibility of some structures involved with swallowing, but both history and examination results can provide useful clues to localization and diagnosis (Table 13.5). Difficulty initiating swallowing or the need for repeated attempts to succeed at swallowing suggests an oropharyngeal source for the dysphagia, whereas a sensation of food "hanging up" in a retrosternal location implicates esophageal dysfunction. Individuals who report dysphagia for solid food hut not liquids are more likely to have a mechanical obstruction, whereas dysphagia for both solids and liquids equally is more typical for an esophageal motility disorder. Lip and rongue function can be easily assessed during routine neurological examination, and both palatal and gag reflexes can be evaluated.

Cervical auscultation is not widely used to evaluate swallowing but may be useful to assess coordination between respiration and swallowing (Table 13.6 and Figure 13.1) (Logemann 1996). In the normal situation, swallowing occurs during exhalation, which reduces the risk of aspiration. Dys-coordinatcd swallowing in the midst of inhalation, conversely, increases the possibility that food might be drawn into the tespiratory tract.

Timed swallowing tests, which require repetitive swallowing of specific amounts of water, have also been employed in the evaluation of dysphagia. Individuals with swallowing impairment may display a number of abnormalities, including slower swallowing speed (<1() nil. pet second) and coughing, which may indicate the presence of dysphagia or aspiration (Logemann 1996). Some concern has been voiced, however, that the relatively large amounts of fluid used in these timed tests could present a significant risk for pulmonary complications as a consequence of aspiration, even if it is water that is used (Logemann 1996),

A standardized 3-ounce water swallow test has been advocated as a simple bedside evaluation of oropharyngeal dysphagia. The presence of cough on swallowing during this test has been reported to provide a positive predictive value with regard to the presence of aspiration of 84% and a negative predictive value of 78% (Mari et al. 1997). The test, however, does not provide any information regarding the specific mechanism of dysphagia in the patient.

Table 13.4: Diagnostic tests

- Oropharyngeal
  - Clinical examination
  - Cervical auscultation
  - Timed swallowing tests
  - 3-ounce water swallow test
  - Modified barium swallow test
  - Pharyngeal videoendoscopy
  - Pharyngeal manometry
  - Videomanofluorometry
  - Electromyographic recording
- Esophageal
  - Endoscopy
  - Esophageal manometry
  - Videofluoroscopy

Table 13.5: Dysphagia clues

l)it(ii:iill\ iniliatini; swallowing	Oropharyngeal dysfunction
Repetitive swallowing	Oropharyngeal dysfunction
Retrosternal "hanging up" sensation	l'.snplia,nfLil dysfunction
Difficulty with solids, hut not liquids	Mechanical obstruction
Difficulty with both solids and liquids	Esophageal dysmotility
Regurgitation of undigested food	Zenker's diverticulum
Halitosis	Zenker's diverticulum

Table 13.6: Dysphagia testing

- If oral phase dysfunction suspected:

- If esophageal dysfunction suspected:
  - Primary test:
    - Videofluoroscopy
    - Endoscopy
  - Complementary test:
    - Esophageal manometry

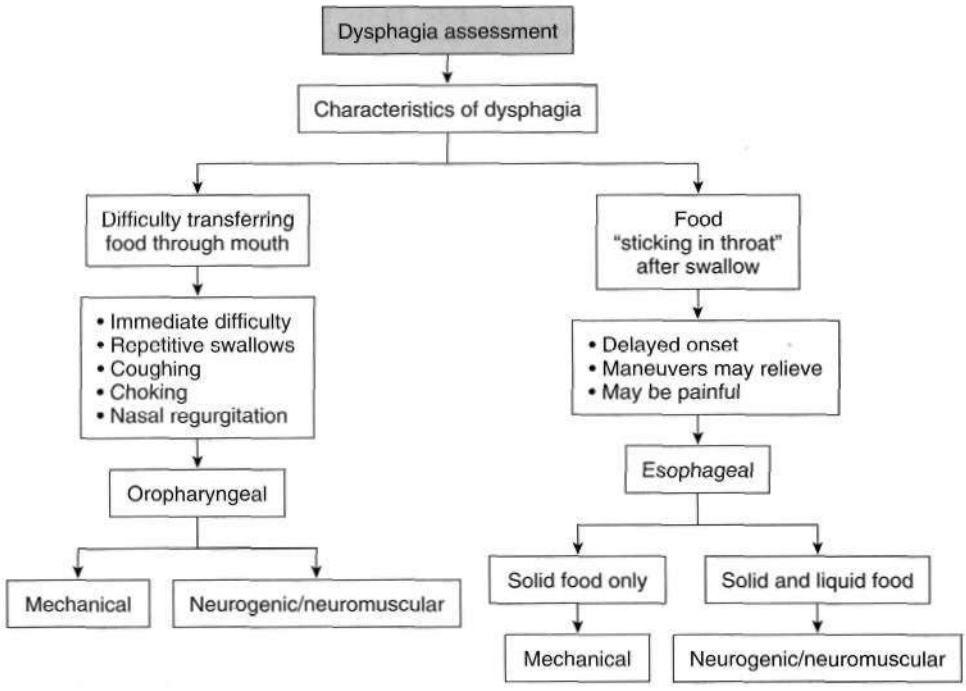

FIGURE **13.1** Dysphagia assessment.

The MBS test has become a standard method for assessing oropharyngeal dysphagia (Logemann 1396). Patients are observed via videofluoroscopy swallowing barium-impregnated **food of** differing consistencies (thin liquid, pudding, cookie). Both oral and pharyngeal function can be characterized, the presence of aspiration can be accurately documented, and the response to corrective measures, such as positioning techniques, can also he evaluated.

Video endoscopy of the pharynx, via the nasal passageway, allows direct visualization of the pharyngeal component of swallowing before and after passage of the food bolus. Its primary value is to demonstrate the presence of residual material in the pharynx after a swallow, indicative of increased risk of aspiration,

Pharyngeal manometry provides physiologic information regarding function of both the pharynx and the UES (Hila, Castell, and Castell 2001). The information derived is complementary to that obtained by videofluoroscopy and a combined procedure, termed *videomanofluorometry,* in which both videofluoroscopy and manometry are performed simultaneously, can also be used (Higo ct al. 2002). Though very useful, this procedure is not always readily available,

Evaluation of esophageal function can be assessed by endoscopy, esophageal manometry, and videofluoroscopy. Scintigraphic procedures can also be employed to evaluate oral, pharyngeal, and esophageal function but are not widely used (Galli et al. 2000),

More sophisticated electrodiagnostic procedures have also been developed to study dysphagia. EMG recording of cricopharyngeal function and integrated submental activity has been useful in a research setting to characterize aspects of swallowing, but this procedure has not yet come into general use.

CONCLUSION

Because of the broad nerwork of structures involved with the control and execution of swallowing, dysphagia can be an important component of the clinical picture in patients with a wide variety of neurological diseases. Determination of the specific mechanism responsible for dysphagia in individual patients can be of great value in both diagnosis and treatment of this disorder.

Chapter 14
Vision Loss

Robert L. Tomsak

Vision loss commonly accompanies neurological illness and is one of the most disturbing symptoms a patient may experience. Loss of vision is often due to a benign or treatable process, but it may be the first sign of a blinding or life-threatening disease. Common causes of impaired vision include uncorrected refractive errors, corneal problems, cataracts, glaucoma, retinal and choroidal diseases, strabismus, and amblyopia. Ocular causes of loss of vision often are not apparent to the nonophthalmologist. Conversely, neurological causes of visual deterioration often confuse ophthalmologists. Thus the approach to evaluating vision loss must be systematic and methodical so that important causes are not missed and simple causes ate not evaluated to the extreme. This chapter deals primarily with the symptoms of visual loss; examination techniques are discussed in Chapter 40, and the appearance of specific funduscopic abnormalities is covered in Chapter 15.

TYPE AND SEVERITY OF VISION LOSS

Central Visual Field Loss

Any defect in the field of vision is called a *scotoma,* from the Greek word meaning "darkness." Loss of central vision, resulting in a central or centrocecal scotoma, is usually quickly noticed and reported. Peripheral visual field defects, such as homonymous hemianopia, may be asymptomatic, or they may be referred to the eye with the larger homonymous hemifield (Figure 14.1), Central and centrocecal scotomas arc usually due to disease involving the central retina or optic nerve anywhere along its intraocular, intraorbital, intracanalicular, or intracranial course. In the case of predominantly one-sided involvement of the optic chiasm, a central scotoma may be associated with a contralateral silent temporal hemianopia (Figure 14,2). Therefore visual function of each eye should be assessed separately in history-taking and during the examination.

In general, scotomas caused by macular disease are positive, meaning that they are perceived as a black or gray spot in the visual field. Patients with macular vision loss may also complain of distortion of images, so that straight edges or geometric figures appear crooked or distorted. This symptom, called *metamorphopsia,* is almost always caused by a retinal problem; only rarely docs metamorphopsia represent a disorder of the visual correx.

Optic nerve lesions characteristically produce negative scotomas, or areas of absent vision not otherwise perceptible, often in conjunction with decreased appreciation of color and light brightness. On occasion, paradoxical photophobia, especially to fluorescent lighting, is a prominent symptom of optic nerve damage. Photopsias (light flashes) may be perceived with vitreoretinal traction, retinal disease (e.g., cancer-associated retinopathy), drugs (e.g., digitalis), or optic nerve disease (e.g., during the healing phase of optic neuropathies), Photopsias may also be part of migraine visual aura,

Aside from ocular diseases, bilateral central visual loss can be produced by optic nerve or chiasmal lesions or by bilateral lesions in the macular portion of the visual cortex. The possibility of psychogenic vision loss must also be considered (see Chapter **40),**

PATTERNS OF VISUAL FIELD LOSS

For simplicity, visual field defects can be classified in one of three groups: prechiasmal, chiasmal, or retrochiasmal. Unilateral prechiasmal lesions affect the visual field in one eye only; chiasmal lesions affect the fields of both eyes in a nonhomonymous fashion; and retrochiasmal lesions

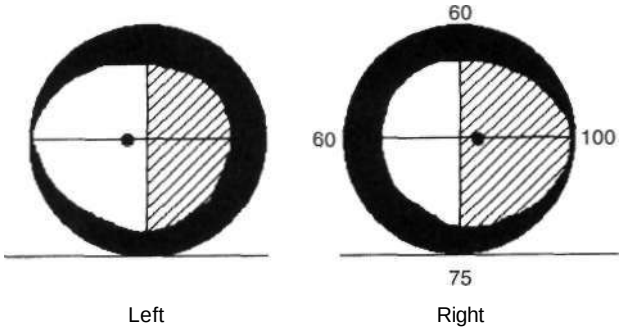

FIGURE 14.1 Right homonymous hemianopia. Vision loss may be referred to the right eye because the temporal visual field is larger than the nasal visual field. Numbers refer to normal extent of visual field in degrees.

cause homonymous field defects with variable degrees of congruiry, depending on their location (Figure 14.3) (Glaser 1999). See Chapter 40 for additional discussion of patterns of visual field loss.

TEMPORAL PROFILE OF VISION LOSS

Vision Loss of Sudden Onset

Vision loss of sudden onset can be divided into three temporal patterns: transient (Table 14.1), nonprogressive, or progressive.

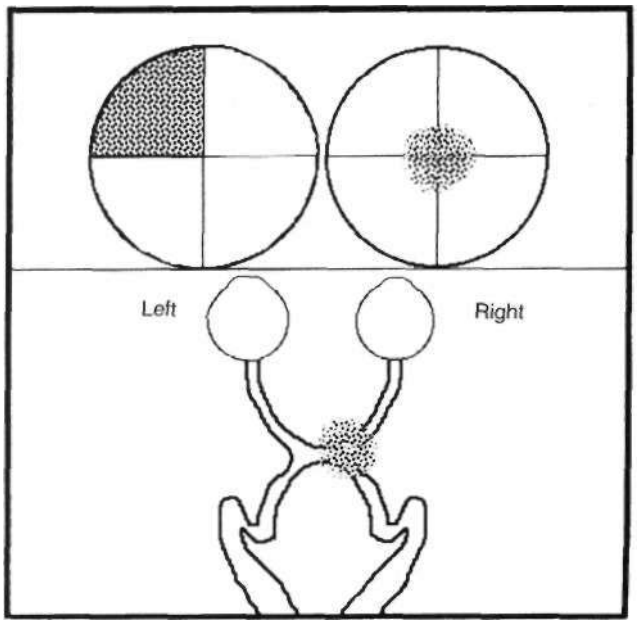

FIGURE 14.2 Junction scotoma with chiasmal lesion. The right optic nerve is primarily involved, leading to centroeecal scotoma. Crossing fibers are also affected, resulting in an upper temporal visual field defect; this is often asymptomatic and must be documented by visual field testing (see Chapter 40).

Unilateral Transient Vision Loss

Amaurosis Fugax. The term *amaurosis fugax* is commonly reserved for transient monocular blindness (TMB) caused by emboli to the retinal circulation from carotid vessels or from the heart. Typically, these attacks are sudden in onset, last 5-15 minutes, and are accompanied by scotomas that often arc described as a shade or curtain being pulled in front of the eye (usually downward) {Donders 2001). The vision loss may also be quadrantic or total. Ipsilateral hemispheric symptoms may or may not be present.

Retinal Artery Vasospasm. TMB can be caused by retinal artery vasospasm and is called "retinal migraine" only if accompanied by migraine headache. Vasospastic TMB is usually benign and often responds to calcium-channel blockers (Winterkorn et al. 1993).

Angle-Closure Glaucoma. Subacute attacks of angle-closure glaucoma should also be considered in the differential diagnosis of intermittent monocular vision loss, especially if the patient complains of halos around lights. This latter symptom results from corneal edema related to rapid elevarions of intraocular pressure that may not be associated with eye pain or redness.

Vision Loss in Bright Light. Some patients with severe impairment of blood flow to the eye lose vision in bright light, presumably as a result of impaired regeneration of photopigments secondary to ocular ischemia. This symptom can be thought of as a pathologic variant of the macular photo-stress phenomenon (see Chapter 40) and most often indicates complete internal carotid artery occlusion or high grade stenosis (Kaiboriboon et al. 2001). A variety of ocular abnormalities, most commonly retinal hemorrhages, are seen in this setting and collectively are termed the "ocular ischemic syndrome" (Ishikawa et al. 2002), Other retinal diseases, such as cone dystrophy and age-related macular degeneration, cause evanescent visual worsening in bright light, otherwise known as hemeralopia or day blindness.

Uhthoff's Phenomenon. Temporary loss of vision with elevation of body temperature (Uhthoff's phenomenon) most often occurs in optic neuritis associated with demyelinating disease but can be experienced with other optic neuropathies.

Transient Visual Obscurations. Vision loss (unilateral or bilateral) lasting seconds in patients with chronic swelling of the optic discs is called a transient visual obscuration. The visual disturbance may be described as a gray-out, is often brought on by postural change or straining, and probably represents transient hypoperfusion of the swollen nerve or nerves. Transient visual obscurations that are

1. F.mbolic cerebrovascular disease
2. Migraine (vasospasm)
3. Hypoperfusion (hypotension, hyperviscosity, hypercoagulability)
4. Ocular (intermittent angle-closure glaucoma, hyphema, optic disc edema, partial retinal vein occlusion)
5. Vasculitis (e.g., giant cell arteritis)
6. Other (Uhthoff's phenomenon/ idiopathic, psychogenic)

^Temporary decrease in acuity consequent to exercise or other causes of increased body temperature in patients with demyelinating opric neuropathy.

gaze-evoked are a hallmark of orbital tumors but may also occur with systemic hypotension, temporal arteritis, or retinal venous stasis.

Other Remitting Vision Loss. Recurrent remitting vision loss may be secondary to cystic lesions, such as sphenoid sinus mucocele, craniopharyngioma, and pituitary tumor (Wray 1995).

Bilateral Transient Vision Loss

Other than transient visual obscurations in patients with bilateral optic disc swelling, simultaneous complete

Tabic 14.2: Causes of bilateral transient vision loss

1. Migraine
2. Cerebral hypoperfusion
   a. Thromboembolism
   b. Systemic hypotension
   c. Hyperviscosity
   d. Vascular compression
3. Epilepsy
4. Papilledema (transient visual obscurations)

or incomplete loss of vision in both eyes is virtually always evidence of transient visual cortex dysfunction. This symptom is usually due to decreased cerebral perfusion resulting from vasospasm, thromboembolism, systemic hypotension, hyperviscosity, or vascular compression (Table 14,2) (Glaser 1999). Transient post-traumatic blindness may occur, especially in children, and may represent a variant of migraine. Hysteria or malingering may also be causes (see Chapter 40), Epileptic visual hallucinations can be elementary or complex in character depending on the location of the seizure focus (Bien et al. 2000), Cortical blindness as an epileptic phenomenon occurs mainly as part of the syndrome of benign occipital epilepsy in childhood (see Chapter 73).

In most neuro-ophthalmological practices, visual migraine auras are the most common cause of bilateral transient visual disturbances, especially when they occur in patit'nrs younger than 40 years (see Chapter 75).

Nonprogressive Unilateral Sudden Vision Loss

Ischemic events affecting the optic nerve or retina are characteristically of sudden onset and are usually nonprogressive, although rarely a stuttering decline in vision may occur,

Anterior ischemic optic neuropathy presents mostly as infarction of the optic disc that is readily observable with the direct ophthalmoscope. In patients younger than 60 years, it is caused by as yet undefined abnormalities affecting the microcirculation to the optic nerve head (Table 14.3) and may be the result of nocturnal hypotension (Hayreh 2000). Congenital structural features of optic-disc anatomy may also play a role. In patients older than 60 years, cranial (temporal or giant cell) arteritis must be considered. Retrobulbar optic nerve infarction, also termed *posterior ischemic optic neuropathy*, is far less common but may occur in the setting of severe perioperative hypotension and other causes of hemodynamic shock. Optic nerve infarction of embolic cause, or related to migraine, is exceptionally rare.

Table 14.3: Causes of unilateral sudden vision loss—nonprogressive

1. Branch or central retinal artery occlusion
2. Anterior ischemic optic neuropathy—arteritic or nonarteritic
3. Branch or central retinal vein occlusion
4. Traumatic optic neuropathy
5. Central serous choroidopathy
6. Retinal detachment
7. Vitreous hemorrhage
8. Functional (psychogenic) vision loss

By contrast, branch or central retinal artery occlusions are mostly caused by embolic or thrombotic events; opacification of the retinal nerve fiber layer with a cherry-red spot at the macula is the classic ophthalmoscopic presentation of central retinal artery occlusion (see Chapter 15). Altitudinal, quadrantic, or complete unilateral visual field loss may occur wirh retinal arterial occlusions.

Occlusion of the central retinal vein presents as sudden vision loss with a characteristic hemorrhagic retinopathy. It usually occurs in adults with systemic hypertension or diabetes and results from venous thrombosis at the level of the lamina cribrosa of the sclera. A dense central scotoma with spared peripheral visual field is characteristic.

Idiopathic central serous chorioretinopathy can present as the sudden onset of a positive scotoma, often with symptoms of metamorphopsia or micropsia and a positive photo-stress test result (see Chapter 40). This condition results from leakage of fluid into the subretinal space and occurs most often in men 20-45 years old. The diagnosis may be difficult to make without the aid of fluorescein angiography. Spontaneous recovery usually occurs within a period of weeks to months, but occasionally laser photocoagulation is needed to seal leaking vessels.

Seemingly mild periocular contusion injuries can result in permanent optic nerve dysfunction. The mechanisms for traumatic optic neuropathy include contusion or laceration of the optic nerve in its canal or shearing of nutrient vessels with subsequent ischemia.

Nonprogressive Bilateral Sudden Vision Loss

Sudden, permanent vision loss affecting bilateral vision, if not caused by trauma, is usually the result of an infarct in the visual radiations causing a homonymous hemianopia (Table 14.4) (Glaser 1999). In patients who are otherwise neurologically asymptomatic, the site of the insult is commonly the occipital lobe. Bilateral occipital lobe infarcts can result in tubular visual fields, checkerboard visual fields (see Figure 14.3), or total cortical blindness. Cortical blindness from bilateral occipitoparietal lobe infarcts may be accompanied by denial of the visual defect and confabulation, also known as *Anton's syndrome.*

Sudden, bilateral loss of vision may also accompany pituitary apoplexy. This condition is usually associated with severe headache, diplopia, and alteration of mental status (Glaser 1999).

Table 14,4: Causes of bilateral sudden vision loss—nonprogressive

1. Occipital lobe infarctions
2. Pituitary apoplexy
3. Functional (psychogenic) vision loss
4. Head trauma

Vision Loss of Sudden Onset with Progression

Unilateral vision loss that appears suddenly and progressively worsens is often due to optic nerve demyelination (optic neuritis). The usual period for worsening is hours to days but almost never longer than 2 weeks. An unusual presentation of bilateral optic neuritis combined with transverse myelitis is called *Devic's disease* (neuromyelitis optica). Less often, long-standing vision loss may be suddenly discovered and misinterpreted as being of sudden onset; in these cases, the examiner should consider a compressive problem (Table 14.5),

Leber's hereditary optic neuropathy is a maternally transmitted disease associated with mitochondrial deoxyribonucleic acid (DNA) mutations in the genes encoding subunits of respiratory chain complex I. Primary mutations have been identified at positions 11,778; 3460; 15,257; and 14,484 (Miller and Newman 1999) (see Chapter 69). This condition presents as acute or subacute, often permanent, loss of central vision, usually in men during early adulthood. Most often, both eyes are affected within 1 year, but rarely simultaneously. Visual recovery is variable and somewhat dependent on the mitochondrial DNA mutation with the 11,778 mutation having the worst prognosis and the 14,484 mutation the best. In the acute phase, the classic triad of findings includes circumpapillary telangiectatic microangiopathy, nonedematous elevation of the optic disc (pseudoedema), and absence of fluorescein leakage during angiography. Arteriolar narrowing can be marked, and vascular tortuosity is often a clue early in the disease. Although Leber's hereditary optic neuropathy may cause loss of vision in women, it tends to be less severe than in men.

Table 14.5; Causes of progressive vision loss

1. Anterior visual pathway inflammation
   a. Optic neuritis
   b. Sarcoidosis
   c. Meningitis
2. Anterior visual pathway compression
   a. Tumors

   c. Dysthyroid optic neuropathy
3. Hereditary optic neuropathies
   a. Leber's hereditary optic neuropathy
4. Optic nerve drusen
5. Low-tension glaucoma
6. Chronic papilledema
7. Toxic and nutritional optic neuropathies
8. Drugs (e.g., cthambutol)
9. Radiation damage to anterior visual pathways
10. Paraneoplastic retinopathy or optic neuropathy

Vision Loss of Gradual Onset

Gradual onset is the hallmark of a compressive lesion affecting the prcchiasmal or chiasmal visual pathways. Common causes include pituitary tumors, aneurysms, craniopharyngiomas, meningiomas, and gliomas (see Table 14.5) (Glaser 1999; Miller and Newman 1999). Granulomatous involvement of the optic nerve from sarcoidosis or tuberculosis can cause chronic progressive vision loss. Compression of the optic nerve at the orbital apex from ocular dysthyroidism may occur with minimal periocular signs of ocular motility disturbance. As noted previously, the vision loss may be so insidious as to go unnoticed until it is fortuitously discovered by the patient or during a routine examination.

Heredirary or degenerative diseases of the optic nerve or retina also must be included in the differential diagnosis. The familial optic atrophies are bilateral and are usually discovered in the first two decades of life (Miller and Newman 1999). Vision loss may range from mild to severe and can be asymmetrical. Central and centrocecal scotomas with sparing of the peripheral fields are generally found. Temporal pallor of the discs sometimes occurs in association with a focal area of cupping. Color vision is usually abnormal, with red-green and blue-yellow defects predominating. Nystagmus, as well as other neurological and endocrine abnormalities, may be present.

Drusen of the optic nerve, a common form of pseudopapilledema, are often associated with visual field defects (see Chapter 15). Approximately 75% of patients have some form of visual field loss, which may include arcuate defects, sectorial scotomas, enlargement of the blind spot, and generalized visual field constriction. Loss of central visual acuity is unusual and is most commonly the result of a subretinal neovascular membrane forming with subsequent hemorrhage into the macula or from anterior ischemic optic neuropathy (Kamath et al, 2000). If loss of central visual acuity occurs with optic disc drusen without obvious retinal pathology, a search for a retrobulbar compressive lesion should be undertaken. Drusen represent extracellular deposition of plasma proteins and a variety of inorganic materials that compress optic nerve axons near the surface of the nerve head. They are often imaged by computed tomography and appear as calcifications (Kurz-Levin and Landau 1999).

Normal-tension glaucoma (NTG) is often a diagnostic and therapeutic conundrum because it can masquerade

as other conditions causing progressive visual loss and because other diseases can mimic it {Tomsak 1997). True NTG is a condition in which glaucomatous disc and field changes develop in the presence of normal levels of intraocular pressure. It is bilateral in 70% of patients and the average age at diagnosis is *66* years. Women are affected approximately twice as frequently as are men. Small disc hemorrhages are seen in approximately 10% of patients. A history of cardiovascular shock is acknowledged by approximately 5% of patients. The disease may be either progressive or static (Anderson etal. 2001).

Chronic papilledema from pseudotumor cerebri can become a bilateral progressive optic neuropathy. It is characterized by the development of a milky gray color to the discs. Sheathing of peripapillary retinal vessels occurs commonly. Visual fields tend to become constricted, with nasal defects progressing to involve fixation. Opticociliary shunt vessels can develop, as can sudden vision loss from ischemic optic neuropathy in rare cases. On occasion, optic atrophy progresses despite the relief of elevated intracranial pressure, possibly from an apoptotic mechanism.

Toxic and nutritional amblyopias also are bilateral and usually progressive (Tomsak 1997; Miller and Newman 1999). This subject is controversial, and the disease is difficult to define. The nutritional variety is characterized by a history of a poor diet, gradual painless onset of visual impairment over weeks to months, impairment of color vision early, centrocecal scotomas, and development of optic atrophy late in the disease. Most cases of tobacco-alcohol amblyopia are probably related to vitamin B deficiencies. Other conditions that lead to nutritional deficiency states, such as jejunoileal bypass and ketogenic diet, may cause bilateral optic neuropathy as well.

Medications that may be toxic to the optic nerve in certain situations include ethambutol, amiodarone, isoniazid, chloramphenicol, and diiodohydroxyquin. Retinal toxins include vigabatrin (Nicolson et al. 2002), digitalis, chloroquine, hydroxychloroquine, and phenothiazines.

Slowly progressive vision loss from radiation damage to the anterior visual pathways, especially the retina, may result from direct radiation therapy to the eye for primary ocular tumors or metastases or may occur after periocular irradiation for basal cell carcinoma, sinus carcinoma, and related malignancies {Guy and Schatz 1995). It may also occur after whole-brain irradiation for metastases of gliomas or after parasellar radiation therapy for pituitary tumors or other neoplasms in this region. Radiation retinopathy becomes clinically apparent after a variable latent period of 3 months to a few years after radiation therapy and is usually irreversible. It is directly related to fraction size, total dose of radiation, and the use of concomitant chemotherapy (Guy and Schatz 1995). Radiation-induced retinal capillary endothelial cell damage is the initial event that triggers a retinopathy usually indistinguishable from diabetic retinopathy.

A rapidly progressive paraneoplastic retinopathy (cancer-associated retinopathy syndrome) causes bilateral vision loss in some patients with cancer over weeks to months. Small cell carcinoma of the lung is the most often associated malignancy, but gynecologic, endocrine, breast, and other tumors have also been described. The vision loss, usually associated with photopsias, often precedes the diagnosis of cancer and is associated with circulating antibodies directed at the tumor and retinal and optic nerve antigens (see Chapter 58H). Retinitis pigmentosa-likc signs and symptoms arc present, including night blindness, constricted visual fields, and a subnormal to extinguished electroretinogram. No effective treatment is available. Melanoma-associated retinopathy is also well described. Autoimmune-related retinopathy and optic neuropathy occurs in patients who do not have cancer (Keltner et al. 2001).

Chapter 15
Abnormalities of the Optic Nerve and Retina

Roy W. Beck and Laura J. Balcer

Disorders of the optic nerve and retina are common causes of afferent visual loss in clinical neurology. The diagnosis of optic neuropathy should be considered when the following clinical features arc present: (1) visual loss in association with a swollen, pale, or anomalous optic disc; or (2) a normal disc appearance in the setting of vision loss (visual acuity, color vision, or visual field) combined with an afferent pupillary defect (APD) (see Chapter 17). The specific etiology for optic neuropathy in a given patient often can be established without the need for neuro-imaging on the **basis of clinical** history (i.e., character/ progression of vision loss), whether one or both eyes are involved, the pattern of visual field loss, and the optic disc appearance. Chapter 14 describes the various patterns of visual field loss and clinical history typically elicited in patients with specific optic nerve disorders. This chapter presents the differential diagnosis for optic neuropathies based on the optic disc appearance. Many of the entities described in this chapter are discussed in more detail in Chapter 40.

Acquired optic neuropathies can be classified according to whether the optic disc appears normal, swollen, or pale. Table 15.1 provides a differential diagnosis based on the appearance of the optic disc.

SWOLLEN OPTIC **DISC**

In assessing an elevated optic disc, the examiner must first determine whether acquired disc edema (true disc swelling) is present, or if the disc appearance is that of pscudo-papilledema.

Pseudopapilledema

In patients with pseudopapilledema, visible optic disc druscn (hyaline bodies) may be present (Plate 15.1 and Plate **15.11).** Even when disc drusen (hyaline bodies) are not apparent, the distinction between true disc swelling and pseudopapilledema can almost always be made on the basis of ophthalmoscopic findings (Table 15.2). The most important distinguishing feature is the clarity of the peripapillary nerve fiber layer. In patients with true disc edema, the nerve fiber layer is hazy, obscuring the underlying retinal vessels. Because pseudopapilledematous discs usually do not show spontaneous venous pulsations (SVP), evaluation for SVP is not helpful in these patients. Hemorrhages may be present in patients with pseudo-papilledema (particularly in the setting of optic disc drusen) and therefore do not exclude this possibility in the setting of optic disc elevation.

Optic disc druscn arc a common cause of pseudopapille-dema, and may be inherited in an autosomal dominant pattern. The prevalence is approximately 2% within the general population. Optic disc druscn are much more common in patients of white descent than in African Americans. The pathogenesis of optic disc drusen has been postulated to be related to axonal degeneration ftom altered axoplasmic flow. In children, disc drusen tend to be buried, whereas in adults, they often are visible on the

disc surface. The progression from buried to surface drusen in individual patients has been well documented.

Optic disc drusen generally do not produce visual symptoms, although rarely a patient may experience transient visual obscurations similar to those described by patients with papilledema (optic disc swelling caused by increased intracranial pressure). Visual field defects are common, however, occurring in approximately 70% of eyes with visible disc drusen and in *3>5%* of those with pseudopapillcdcma but no visible drusen. These visual field defects generally follow a nerve fiber bundle distribution, with inferior nasal visual field loss being the most common. Enlargement of the blind spot and generalized field constriction may also occur. Progression of visual field defects is well documented, but visual acuity loss is rare. If decreased visual acuity is present in a patient with optic disc drusen, evaluation for alternative causes should be performed. Visual field loss in the setting of optic disc drusen may also occur secondary to hemorrhage, or to an associated retinal degeneration. Approximately 2% of patients with retinitis pigmentosa also have optic disc drusen; the potential combination of these two entities should be considered in patients with otherwise unexplained bilateral disc elevation and visual field loss.

Unilateral Optic Disc Edema

If true optic disc edema is determined to be present, it is useful to distinguish patients with bilateral disc swelling from those with unilateral swelling. Whether optic nerve function is normal or abnormal is likewise an important diagnostic feature.

The most common causes of unilateral optic disc edema are optic neuritis (termed *papillitis* when disc swelling is present), anterior ischemic optic neuropathy (AION), and orbital compressive lesions. As a rule, optic nerve function is abnormal in each of these entities. Although characteristics of the optic disc appearance may overlap between optic neuritis, AION, and compressive optic

I able 1>,2: Differentiation oi early papilledema and pseudopapillcdcma

Feature	*Papilledema*	*Pseudopapiltedema*
Disc color	Hyperemic	Pink, yellowish pink
Disc margins	Indistinct early at superior and inferior poles, later entire margin	Irregularly blurred, may be lumpy
Disc elevation	Minimal	Minimal to marked; center of disc most elevated
Vessels	Normal distribution, slight fullness; spontaneous venous pulsations absent	Emanate from center, frequent anomalous pattern, ± spontaneous venous pulsations
Nerve fiber layer	Dull as a result of edema, which may obscure blood vessels	No edema: may glisten with circumpapillary halo of feathery light reflections
Hemorrhages	Splinter	Subretinal, retinal, vitreous

neuropathies, certain features may be more suggestive of a specific diagnosis. Disc hemorrhages, for example, are much more common in AION than in optic neuritis or compressive lesions (Plate 15.111). A cellular reaction in the vitreous overlying the optic disc, and the presence of retinal exudates, are both highly suggestive of optic neuritis (Plate 15.IV). In patients with acute demyelinating optic neuritis (the most common form of optic neuritis, associated with multiple sclerosis [MS]), optic disc swelling is present in about 33% of patients. Disc hemorrhages arc uncommon in these patients, however, and their presence should suggest an alternative diagnosis,

Both optociliary shunt vessels and glistening white bodies on the disc surface (pscudodrusen) can be seen with chronic disc edema due to compressive lesions (Plate 15.V), but would not be expected in patients with acute optic neuritis or AION. Optociliary shunt vessels represent communications between the ciliary and retinal venous circulations. In addition to occurring with orhu.il tumors, such as optic nerve sheath meningiomas, shunt vessels can be seen in retina) vein occlusions, glaucoma, malignant hypertension, chronic papilledema, and as a congenital variant.

Although it is often not possible to distinguish optic neuritis, AION, and compressive optic neuropathies on the basis of disc appearance alone, the diagnosis can usually be made based on the clinical history (acute presentation vs. progression of vision loss) and the pattern of the visual field deficit. Vision loss is generally slowly progressive in patients with compressive lesions, is sudden with subsequent improvement in those with optic neuritis, and is sudden with no or incomplete improvement in patients with AION, Both optic neuritis and compressive lesions generally produce some form of central visual loss (central scotoma), while AION typically produces a nerve fiber bundle type field defect (originating from, and involving, the physiologic blind spot). However, there is considerable overlap in the patterns of visual field loss for optic neuropathies. Chapter 14 describes these features in further detail.

Consecutive involvement of the fellow eye is also an important clinical feature that may distinguish optic neuropathies with respect to etiology. For example, AION affects the two eyes consecutively in up to 25% of cases. When the second eye is affected in AION, the presence of optic atrophy in one eye and disc edema in the fellow eye occurs (pseudo-Foster Kennedy syndrome) (Figure 15.1). A true Foster Kennedy syndrome is produced by a tumor that causes optic atrophy in one eye caused by compression and papilledema in the fellow eye secondary to increased intracranial pressure.

Compressive lesions producing disc edema almost always involve the intraorbital portion of the optic nerve. Meningiomas of the optic nerve sheath or sphenoid wing are common causes of compressive unilateral disc edema (see Plate 15.V). Intracranial compressive lesions only rarely produce disc edema, unless they arc large enough to raise intracranial pressure, A nontumor cause of compressive disc edema is Graves' ophthalmopathy (thyroid eye disease).

When optic neuritis, with associated disc swelling, is associated with macular exudates (often in a star pattern), the condition is termed *ncuroretinitis.* Recognition of retina! exudates in patients with unilateral optic disc swelling is important for distinguishing neuroretinitis from acute demyelinating optic neuritis or AION.

Uncommon Causes of Unilateral Disc Edema

Less common causes of unilateral optic disc edema include central retinal vein occlusion/obstruction and infiltrative disorders, such as leukemia and lymphoma. Retinal vein obstruction occasionally manifests primarily as optic-disc edema with minimal or no retinal hemorrhages. Papillophlebitis is a syndrome of presumed retinal vein inflammation producing optic disc edema in young adults (Plate 15.VI). The disc elevation is often marked, and the retinal veins are generally dilated. Other than enlargement of the blind spot, the visual field is usually normal. This condition tends to resolve wirhout residual vision loss. In older patients, retinal vein obstruction may be caused by compression of the vein by an atherosclerotic artery. The disc typically appears extremely hyperemia, but edema is usually mild (Plate 15.VII). Optociliary shunt vessels may also be present. As with papillophlebitis, visual function is usually not affected, but the disc edema tends to persist chronically.

Infiltration of the optic nerve can occur secondary to carcinomatous, lymphoreticular, and granulomatous processes. One or both optic nerves may be affected, Optic discs may appear swollen or normal, the latter indicating a retrobulbar involvement. Occasionally, optic-nerve infiltration produces optic disc edema without affecting visual function, but more often there is a decrease in visual acuity and visual field loss. Almost any form of carcinoma can metastasize to the optic nerve; breast and lung carcinomas are the most common. Carcinomatous meningitis is often associated. Lymphomas and leukemias also can involve rhe optic nerve. Sarcoidosis often presents with a characteristic disc appearance, including disc edema and whitish nodules on the disc surface (Plate 15.VIII).

Optic neuropathy as a delayed effect of radiation therapy can occur with or without disc edema. When this rare complication occurs, it usually follows the radiation by 6 to 24 months. There are a number of other causes of unilateral optic disc edema. Some of the entities described under the section Bilateral Optic Disc Edema, including diabetic papillopathy, occasionally produce only unilateral edema.

Leber's hereditary optic neuropathy (LHON) is an uncommon optic nerve disorder that occurs predominantly in males. Although not a cause of true disc edema, the

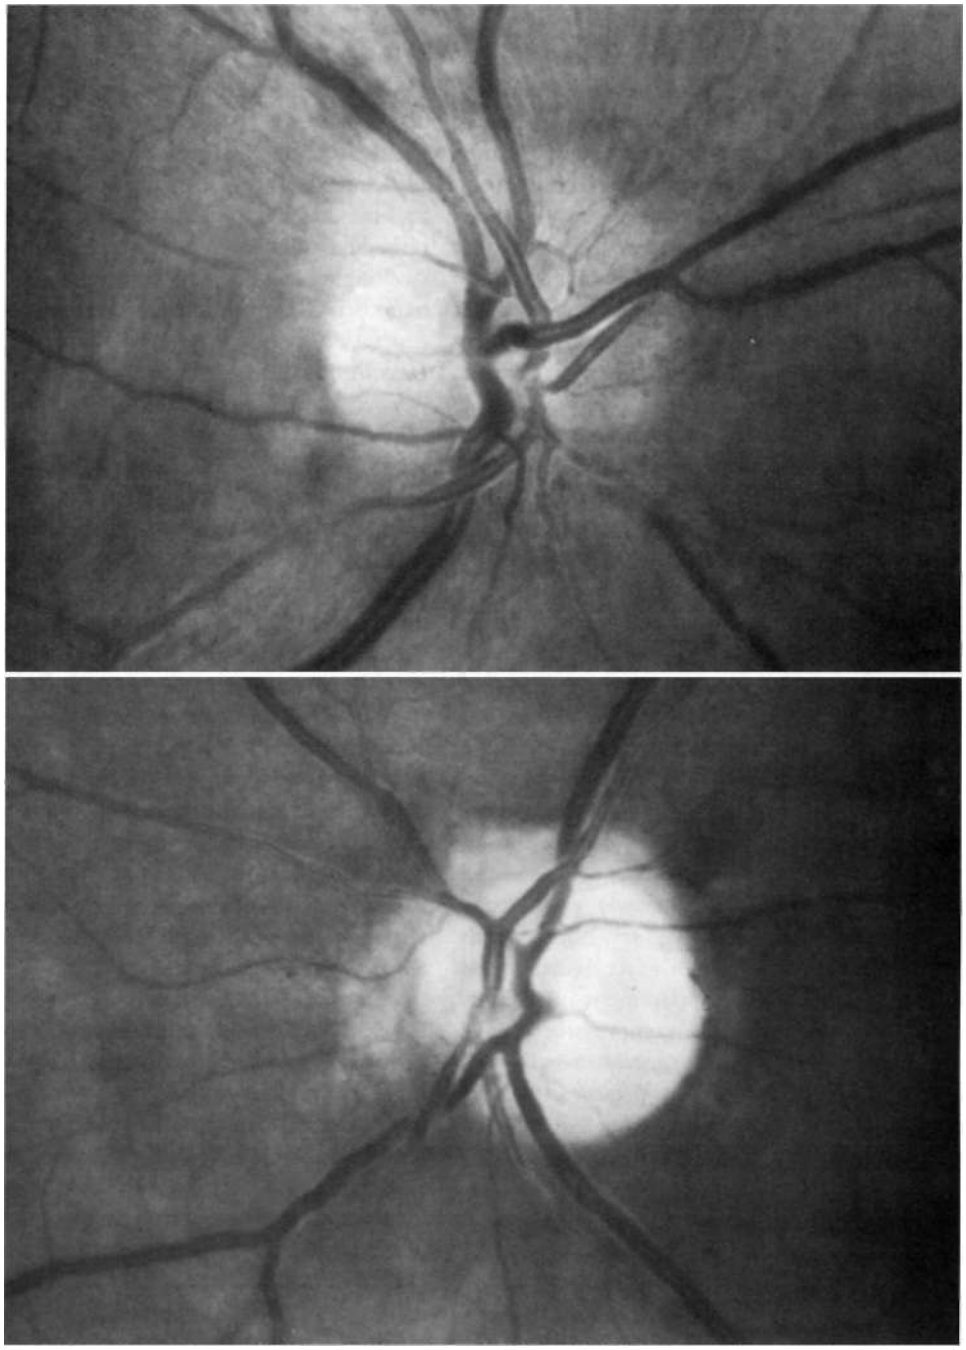

FIGURE 15.1 Pseudo-Foster Kennedy syndrome from (A) acute ischemic optic neuropathy in the right eye (disc edema) and from (B) previous ischemic optic neuropathy in the left eye (optic atrophy} in a 53-ycar-old man. optic disc may appear hyperemic and mildly swollen in the acute phase (Plate 15.IX). If fluorescein angiography is performed, however, there is no leakage from the disc, as would be present in true disc edema. Telangiectatic vessels, frequently present in the peripapillary nerve fiber layer, are an important clue to the diagnosis. These funduscopic changes may also be noted in pre symptom a tic eyes. Thus a patient may present with symptoms of involvement of only one eye, hut be suspected of having LHON clinically based on characteristic disc changes in both eyes. Genetic diagnosis of LHON is based upon the identification of related mitochondrial DNA mutations (see Chapter 69).

Bilateral Optic Disc Edema

Papilledema

The term *papilledema* refers specifically to optic disc swelling that occurs secondary to increased intracranial pressure. In the acute phase of papilledema, optic nerve function, particularly central visual acuity, is generally normal. The most common visual field defects encountered in patients with early or acute papilledema are enlargement of the physiologic blind spot, concentric constriction, and inferior nasal field loss.

Disc swelling in papilledema results from blockage of axoplasmic flow in nerve fibers, with a consequent increase in the volume of axoplasm in the optic disc. Based on the chronicity and funduscopic appearance, papilledema can be divided into four stages: early, fully developed (acute), chronic, and atrophic.

In early papilledema, swelling is most prominent at the superior and inferior poles of the optic disc (Plate 15.X). The retinal veins may he slightly distended, and the disc may appear mildly hyperemic. Spontaneous venous pulsations are usually absent.

With further development of papilledema, swelling encompasses the disc surface more uniformly, and the degree of disc elevation increases. The physiological cup becomes increasingly obscured, and retinal venous distension becomes more prominent. Splinter hemorrhages develop on the disc and at its margin in acute (fully developed) papilledema (Plate 15.XI), As papilledema becomes chronic, usually after weeks to months, the disc appearance changes. The nerve fiber layer may take on a gliotic appearance. Hemorrhages are less prominent (or may have resolved completely), and small glistening white bodies (pseudodrusen) are noted (Plate 15.XII). With further chronicity, a characteristic champagne-cork disc appearance develops (Plate 15.XIII).

With prolonged increased intracranial pressure and papilledema, optic nerve axons are damaged, and visual field loss develops. At this stage, optic disc swelling lessens, and disc pallor develops (atrophic papilledema) (Plate 15.XIV).

Patients with end-stage papilledema therefore manifest optic nerve atrophy (disc pallor), without evidence of swelling. Chronic and atrophic papilledema, unlike the early and acute phases, are often characterized by visual acuity as well as visual field loss (i.e., ccnttal acuity is generally spared until late in the course of papilledema).

Malignant Hypertension

A marked elevation in blood ptcssure may produce bilateral optic disc swelling rh.it is indistinguishable from papilledema (Plate 15.XV). Encephalopathy signs are usually but not always present. Disc edema tends to develop at a lower blood pressure in patients with renal failure than in those without renal disease. Peripapillary cotton-wool spots arc also a prominent funduscopic feature in patients with malignant hypertension.

Diabetic Papillopatby

Diabetic papillopathy is a rare cause of bilateral (or sometimes unilateral) disc swelling in patients with Type I diabetes. This entity is distinct from AION in that there is often bilateral, simultaneous optic nerve involvement; often there is no visual field loss with the exception of an enlarged physiologic blind spot. Disc edi'inn is accompanied by marked capillary telangiectasias overlying the disc surface (Plate 15.XVI). Measurement of cerebrospinal fluid pressure (after neuroimaging ro rule out intracranial mass lesions or venous sinus thrombosis) may be necessary to distinguish this condition from papilledema. In many cases, the optic disc edema resolves without residual visual deficit.

Other Causes of Bilateral Disc Edema

Anemia, hyperviscosity syndromes, pickwickian syndrome, hypotension, and severe blood loss are less common causes of bilateral optic disc swelling. The clinical setting generally provides clues to diagnosis. Any of the entities described under unilateral optic disc edema (see Table 15.1) can cause bilateral disc swelling, particularly infiltrative disorders. In children, for example, optic neuritis is commonly bilateral and is often associated with papillitis (disc swelling). Bilateral AION should prompt immediate suspicion and treatment for giant cell (temporal) arteritis in individuals older than 55 years. Although most toxic optic neuropathies present with normal-appearing optic discs, disc edema is characteristic of methanol poisoning and may also occur in patients with ethambutol toxicity.

OPTIC NEUROPATHIES WITH NORMAL-APPEARING OPTIC DISCS

Many optic neuropathies present initially with a completely normal disc appearance; these are classified as retrobulbar optic neuropathies. The differentia! diagnosis depends upon whether unilateral or bilateral optic nerve involvement is present.

Unilateral Cases

The most common causes of unilateral retrobulbar optic neuropathy are optic neuritis (most commonly acute demyelinating optic neuritis) and compressive lesions. The time course of vision loss is usually helpful in distinguishing these two entities. There is no definite way to distinguish these disorders on examination, but the detection of a superior temporal field defect in the fellow eye is highly suggestive of a compressive lesion affecting the anterior

optic chiasm as well as the posterior optic nerve. Retrobulbar ischemic optic neuropathy is a rare condition in patients with giant cell arteritis, other vascuhtides, and after shock or severe blood loss. For practical purposes, there is no retrobulbar correlate to nonarteritic AlON.

Bilateral Cases

Bilateral optic neuropathies in which the optic discs appear normal include nutritional optic neuropathy (including tobacco-alcohol amblyopia), vitamin B, > or folate deficiencies, toxic optic neuropathy (heavy metals), drug-related optic neuropathy (chloramphenicol, isoniazid, ethambutol, cthchlorvynol, chlorpropamide, and others), and inherited optic neuropathies. When these conditions are chronic, optic atrophy may ensue. Other diagnostic considerations in this category include bilateral compressive lesions and bilateral retrobulbar optic neuritis.

OPTIC NEUROPATHIES WITH OPTIC ATROPHY

Any optic neuropathy that produces damage to the optic nerve may result in optic atrophy. At this stage, the optic disc appearance is rarely helpful in determining the underlying cause. The presence of gliotic changes suggests that the disc was previously swollen. Deep disc cupping is, of course, typical of glaucoma, but it is also common after AION as a result of giant cell arteritis, Dominantly inherited optic atrophy often has a characteristic disc appearance, with pallor and excavation of the temporal portion of the disc. Rarely, disc cupping is acquired in the setting of intracranial lesions that cause nerve compression.

Optic atrophy also occurs as consequence of disorders of the retina, optic chiasm, and optic tract. A specific pattern of disc pallor is noted in patients with optic-tract lesions; this pattern, termed bow-tie atrophy, is characterized hy temporal pallor of the ipsilateral disc and both nasal and temporal pallor of disc contralateral to the lesion. Acquired geniculocalcarine lesions (posterior to the optic tract) do not produce disc pallor, although congenital lesions in this area may do so.

CONGENITAL OPTIC DISC ANOMALIES

Optic disc drusen were discussed earlier in this chapter. Other congenital optic nerve anomalies include a tilted optic disc and optic nerve dysplasia.

Tilted Optic Disc

A tilted optic disc is usually easily recognized on ophthalmoscopy. The disc may appear foreshortened on one side, and one portion may appear elevated with the opposite end depressed (Plate 15.XVII). Often, the retinal vessels run in an oblique direction. Tilted optic discs are of neurological importance in that they ate usually bilateral and may be associated with temporal field loss, thus mimicking a chiasmal syndrome. Differentiation from chiasmal disease is virtually always possible based on the pattern of visual field loss. Unlike chiasmal field loss, visual field defects in patients with tilted discs generally do not respect the vertical meridian.

Optic Nerve Dysplasia

There are several types of optic nerve dysplasia. Optic nerve hypoplasia is the most common and is often associated with midline craniofacial anomalies that are of interest to the neurologist. In this condition, the optic disc appears small, and the nerve substance is surrounded by choroid and retinal pigment changes that resemble a double ring (Plate 15.XVIII). The abnormality may be unilateral or bilateral. In most cases, a specific cause cannot be identified. The frequency of optic nerve hypoplasia appears to be increased in children of mothers with diabetes mcllitus or mothers who ingested antiepileptic drugs, quinine, or lysergic acid diethylamide during pregnancy. Endocrine abnormalities and midline craniofacial anomalies may he associated, particularly in bilateral cases. De Morsier's syndrome (septo-optic dysplasia) is characterized by bilateral optic nerve hypoplasia, absent septum peilucidum, and pituitary gland dysfunction (classic growth hormone deficiency) (see Chapter 66). Nystagmus is commonly present when visual loss is severe. Optic nerve aplasia, or complete absence of the optic discs, is extremely rare.

Optic nerve coloboma is more common than optic nerve hypoplasia and results from incomplete closure of the fetal fissure (Plate 15.XIX). It may occur as an isolated finding or as part of a congenital disorder, such as Aicardi's syndrome, trisomy 13, or Goldenhar's syndrome. Another type of congenital anomaly, the optic pit, is manifested as a small grayish area, usually located in the inferior temporal portion of the optic disc.

In some optic nerve dysplasias, the disc appears enlarged. This is true of the so-called "morning glory disc," in which a large whitish concavity is surrounded by pigmentation that resembles a morning glory flower. This condition may be associated with other developmental anomalies, such as basal encephalocele.

RETINAL, DISORDERS IN NEUROLOGICAL DISEASE

Several retinal disorders are of interest to neurologists. The reader is referred to ophthalmology texts for more detailed descriptions of common and less common retinal diseases.

Retinal Arterial Disease

Retinal arterial disease can present as a central retinal artery occlusion or branch retinal artery occlusion (CRAO/BRAO), or as amaurosis fugax (transient monocular visual loss). Carotid artery atherosclerotic disease is the most common cause; cardiac valvular disease must also be considered. The evaluation and treatment of retinal arterial disease are similar to that of stroke and cerebrovascular disease in general (see Chapter 57a). Acute retinal artery occlusion (CRAO/BRAO) is characterized by retinal whitening (edema) secondary to infarction. In CRAO, these findings are usually more prominent in the posterior pole than they are in the periphery (Plan." I 5,XX). A marked narrowing of the retinal arterioles is often noted. Because there are no retinal ganglion cells in the fovea (the center of the macula), this area retains its normal reddish-orange color, producing the characteristic cherry-red spot. The retinal edema usually recovers fairly rapidly over days to weeks. After resolution, the retinal appearance typically returns to normal, although the prognosis for visual recovery is generally poor,

When present, retinal emboli are most often located at arteriolar bifurcations (Figure 15.2). Retinal emboli take on a glistening or whitish/yellowish appearance, and may be located on or near the optic disc or in the retinal periphery. There are three major types of retinal emboli: (1) cholesterol (Hollenhorst plaques; most common source carotid artery); (2) platelet-fibrin (cardiac valves most common source); and (3) calcific (carotid or cardiac source). With impaired blood flow after a CRAO, a portion of a retinal arteriole may take on a whitish appearance. This does not represent an embolus but, rather, stagnant lipid in the blood or changes in the arteriole wall.

Vasculitis

In vasculitis, focal areas of retinal infarction develop. These areas, known as *cotton-wool spots,* are usually bilateral and may be extensive (Plate 15.XXI).

Branch Retinal Artery Occlusions and Encephalopathy (Susac's Syndrome)

Branch retinal artery occlusions and encephalopathy (Susac's syndrome) is a rare disorder of unknown etiology characterized by multiple branch retinal artery occlusions and neurological dysfunction, Susac's syndrome most commonly affects women between the ages of 20 and 40 years. A viral syndrome may precede the development of ocular and neurological signs. The most prominent neurological manifestations are impaired mentation and sensorineural hearing loss. Cerebrospinal fluid in patients with Susac's syndrome shows a mild lymphocytic pleocytosis and elevated protein. Antinuclear antibody (ANA) testing and cerebral arteriography are generally normal, but brain magnetic resonance imaging (MRI) most often demonstrates multiple areas of high signal on T2-weighted images that resemble demyelinating plaques.

Ocular Ischemic Syndrome

Generalized ocular ischemia indicates involvement of both retinal and ciliary circulations in the eye. Signs of optic nerve and retinal ischemia may be present as well as evidence of anterior segment ischemia (iris atrophy, loss of pupil reactivity, cataract formation, rubeosis iridis). Carotid

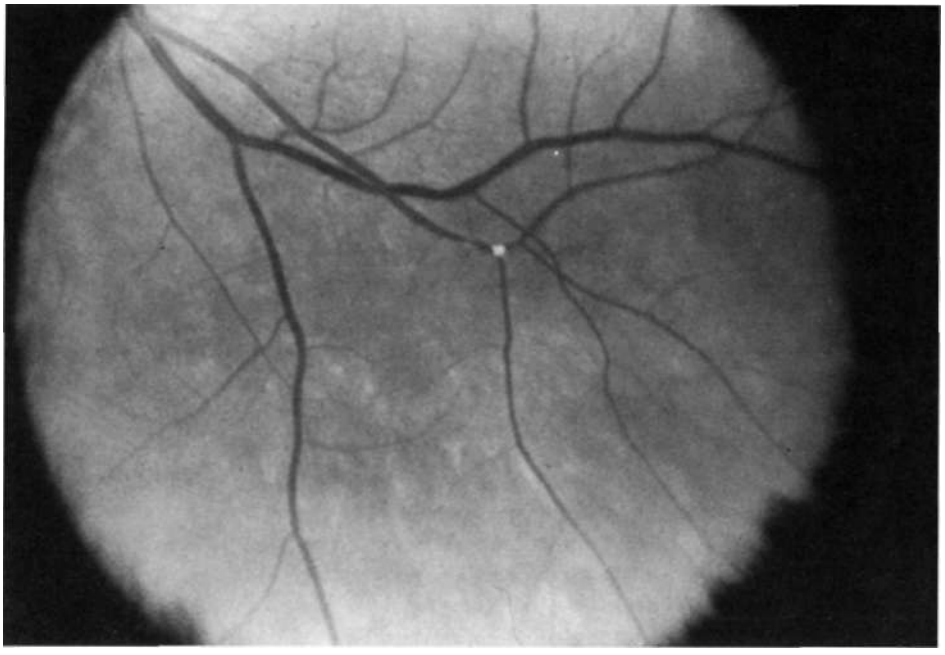

FIGURE 15.2 Hollenhorst plaque at a retinal arteriole bifurcation, (Reprinted with permission from Beck, R. W. Be Smith, C. H. 1988, *Neuro-Ophtbaimology: A Problem-Oriented Approach,* Little, Brown, Boston.)

attcry occlusion/dissection and giant cell arteritis arc the primary considerations in patients with ocular ischemia.

RETINAL VEIN OCCLUSION

Central or branch retinal vein occlusions rarely occur in patients younger than 50 years. The diagnosis is established clinically by the presence of diffuse (central retinal vein occlusion) or focal (branch retinal vein occlusion) retinal hemorrhages (Plate 15.XXII). Disc edema is often present and, in some cases, is the predominant funduscopic feature (see earlier discussion in Uncommon Causes of Unilateral Disc Edema). There are no direct associations between retinal vein occlusion and carotid artery atherosclerotic disease. Patients should be evaluated for vascular risk factors, but carotid imaging/ultrasound is generally not indicated. Bilateral cases of retinal vein occlusion should be evaluated for hyperviscosity syndromes or hypercoagulable states.

NEUROLOGICAL DISEASES WITH RETINAL FINDINGS

Retinal Degenerations

There are a multitude of retinal degenerations, many of which may be associated with neurological disease. Retinitis pigmentosa (RP) is caused by degeneration of the retinal rods and cones. Early in the course of RP, rods are predominantly affected, thus impairing night vision. Visual field loss occurs first in the midperiphery and progresses to severe field constriction.

Pigmentary changes in the retina look like bony spicules and are the hallmark of RP (Plate 15.XXIII). In some cases, however, pigment changes are not prominent, and the visual field loss may mistakenly be thought to have a neurological basis. Even without bone spicule-type changes, the diagnosis of RP is usually obvious to the astute observer because of the retinal thinning, narrowing of retina! arterioles, and waxy optic disc pallor. Regardless of the degree of pigment change, electroretinography is the test of choice for diagnosing RP.

RP usually appears without systemic findings. However, a retinal degeneration of this type may be seen in Kearns-Sayre syndrome, Laurence-Moon-Bardct-Biedl syndrome, Marie's ataxia, Cockayne's syndrome, Refsum's syndrome, Batten's disease, inherited vitamin E deficiency, and spinocerebellar ataxia type 7.

Retinal photoreceptor degenerations can also occur as a remote effect of cancer (cancer-associated tetinopathies [CAR]). This entity has been best characterized in association with small-cell lung carcinoma and with melanoma. Arteriolar narrowing is a consistent finding, but pigmentary changes in the retina arc variable. Elcctrorctinogtaphy is markedly abnormal (showing reduced to extinguished rod and cone components), and antiphotoreceptor antibodies can often be identified in the serum.

Progressive cone dystrophies are retinal degenerations occurring most commonly through autosomal dominant inheritance. Typically, vision loss develops in both eyes beginning in the teens and worsens over several years. Early in the course of cone dystrophy, the fundus may appear normal; with time, however, pigmentary changes develop in the macula, and electroretinography demonstrates characteristic losses of the photopic response.

Uveoretinal Meningoencephalitis Syndromes

Uveoretinal meningoencephalitis syndromes produce inflammatory changes in both the eye and the central nervous system, Vogt-Koyanagi-Harada syndrome, the most common uvcomeningoencephalitis syndrome, is marked by exudative retinal detachments. Table 15.3 lists causes of ocular and central nervous system inflammation.

Phakomatoses

Retinal findings arc common in phakomatoses that affect the nervous system, particularly tuberous sclerosis and

von Hippel-Lindau disease. Neurological features of phakomatoses are described in Chapter 71. In tuberous sclerosis, retinal astrocytic hamartomas are characteristic (Plate 15.XXIV). These are usually multiple and may appear cither as a fullness in the retinal nerve fiber layer or as a nodular refractile lesion (mulberry type}. Von Hippel-Lindau disease is characterized by one or more retinal angiomas that appear as reddish masses with a feeding artety and a draining vein (Figure 15.3). Wybum-Mason disease is characterized by racemose arteriovenous malformations in the retina (Figure 15.4),

Chapter 16
Eye Movement Disorders: Diplopia, Nystagmus, and Other Ocular Oscillations

Patrick J. M. Lavin

This chapter discusses disorders of extraocular muscle function that cause diplopia, strabismus, nystagmus, ocular flutter, opsoclonus, and other ocular oscillations. A brief outline of the anatomy, physiology, and innervation of the extraocular muscles is followed by a discussion of the mechanisms and types of nystagmus. The reader is guided through the clinical assessment of a patient with an ocular motility disorder, from analysis of symptoms to specialized clinical tests used in evaluating eye movement abnormalities. Therapeutic strategies are discussed at appropriate points throughout the chapter. The development and suptanuclear control of the ocular motor system, supranuclear gaze disorders, and oculographic recording techniques are discussed in Chapter 39.

The human fovea is a highly sensitive part of the retina capable of resolving angles of less than 20 arc seconds. The ocular motor system places images of objects of regard on the fovea and maintains foveation if the object, ot head, moves. Each eye has six extraocular muscles (Table 16.1), yoked in pairs (Table 16.2), that move the eyes **conjugately** (versions) to maintain alignment of the visual axes (Figure 16.1). The actions of the medial and lateral recti are essentially confined to the horizontal plane. The actions of the superior and inferior recti are solely vertical when the eye is abducted 23 degrees; the oblique muscles, the main cyclotortors, also act as pure vertical movers when the eye is adductcd 51 degrees (Figure 16.2). For practical purposes, the vertical actions may be tested at 30 degrees of adduction and abduction. According to HeHng's law of dual innervation, yoked muscles receive equal and simultaneous innervation while their antagonists are inhibited (Sherrington's law of reciprocal inhibition), thereby allowing the eyes to move conjugately and with great precision. The pulling actions of the extraocular muscles evolved to move the eyes in the planes of the semicircular canals, which are not strictly horizontal or vertical. These pulling actions are influenced by both the conventional insertions of the global layer of each extraocular muscle directly into the eyeball, as well as by the insertion of the orbital layer into the fibtomuscular connective tissue sheath that envelopes each rectus muscle (Figure 16.3). This arrangement forms a pulley system that is actively innervated (Demer 2002), stabilizes rotation of the globes in three dimensional space during complex eye movements (for example when a horizontal muscle contracts during upgaze), and prevents excessive **retraction of** the globe within the orbit during extraocular muscle contraction.

Images of the same object must fall on corresponding points of each retina to maintain binocular single vision (fusion) and stereopsis (Figure 16.4). If the visual axes are not aligned, the object is seen by noncortesponding (disparate) points of each retina, and diplopia results (Figure 16.5). In patients with paralytic strabismus, the image from the nonfixating paretic^ eye is the false image and is displaced in the direction of action of the weak

'^In nonparalytic (comitant) strabismus, the image is projected in the direction opposite the deviation.

Table 16.1: Actions of extraocular muscles

Muscle	*Primary*	*Secondary*	*Tertiary*
Medial rectus	Adduction		
Lateral rectus	Abduction		
Superior rectus	Elevation	Intorsion	Adduction
Inferior rectus	I (epression	Excursion	Adduction
Superior oblique	intorsion	I Vjirvssioii	Abduction
Inferior oblique	Extorsion	Elevation	Abduction

muscle. Thus a patient with esotropia has uncrossed diplopia (sec Figure 16.5A), and one with exotropia has crossed diplopia (sec Figure 16.5B). After a variable period, the patient learns to ignore or suppress the false image. If suppression occurs before visual maturity (approximately 6 years of age) and persists, central connections in the afferent visual system will fail to develop fully and lead to permanent visual impairment in that eye (developmental amblyopia). Amblyopia is mote likely to develop in esotropic than in exotropic patients because exotropia is commonly intermittent. After visual maturity, suppression and amblyopia do not occur; instead the patient learns to avoid diplopia by ignoring the false image.

HETEROPHORIAS AND HETEROTROPIAS

When the degree of misalignment—that is, the angle of deviation—of the visual axes is constant, the patient has a comitant strabismus {heterotopia). When it varies with gaze direction, the patient has a noncomitant (paralytic or restrictive) strabismus. In general, comitant strabismus is ophthaltnological in origin, whereas noncomitant strabismus is neurological. Some form of ocular misalignment is present m .3-4% of preschool children.

Most people have a latent tendency for ocular misalignment, *beteropboria,* which may become manifest (a *heterotopia)* under conditions of stress, such as fatigue; bright sunlight; or ingestion of alcohol, anticonvulsants, or sedative medications. Divergent eyes are designated exotropic and convergent eyes are esotropic. Vertical misalignment of the visual axes, which is less common, is termed *hypertropia* (determined by the higher eye, irrespective of which eye is paretic; for example, when the right eye is higher, a right hypertropia exists}. When stress unmasks such a latent tendency for the visual axes to deviate, the diplopia is usually present in most directions of gaze (relatively comitant). Asymptomatic hypertropia on lateral gaze is often a congenital or "physiologic hyperdeviation."

(1R = inferior rectus; LLA = lateral levator aponeurosis; LP = levator palpebrae; LR = lateral rectus; MR = medial rectus; SO = superior oblique; SR = superior rectus.) (Redrawn from Demer, J. L. 2002, "The orbital pulley system: A revolution in concepts of orbital anatomy," *Ann NY Acad Sci,* vol. 956, pp. 17-32.)

Comitant Strabismus

Comitant strabismus occurs early in life; the degree of misalignment (deviation) is constant in all directions of gaze, and each eye has a full range of movement (ductions). It probably occurs because of failure of the central synchronizing mechanism in the brain to keep the eyes aligned. Infantile (congenital) esotropia may be associated with maldevelopment of the afferent visual system, including the visual cortex. Cases of comitant esotropia that present between the third and fifth year of life are caused by hyperopia resulting in *accommodative esotropia.*

Occasionally, children with Chiari malformations or posterior fossa tumors present with isolated esotropia before developing other symptoms or signs. Features that suggest a structural cause for the esotropia include: presentation after 6 years of age; complaints such as diplopia or headache; incomitance in horizontal gaze; esotropia greater at distance than near; and neurological findings such as abduction deficits, ataxia, optic disc edema, pathological nystagmus (see section on nystagmus below), and saccadic pursuit (see Chapter 39). Adults who develop isolated esotropia, particularly when they become presbyopic in their early forties, should have a cycloplegic refraction to detect *latent hyperopia.* Other causes of adult-onset esotropia include Chiari malformations and acute thalamic hemorrhage (see Table 39.6).

Noncotnitant (Incomitant) Strabismus

Noncomitam strabismus occurs when the degree of misalignment of the visual axes varies with the direction of gaze as a result of weakness or restriction of one or more extraocular muscles. When a patient with a noncomitant strabismus fixates on an object with the nonparctic eye, the angle of misalignment is referred to as the *primary deviation;* if the patient fixates with the paretic eye, the angle of misalignment is referred to as the *secondary deviation.* Secondary deviation is always greater than primary deviation in noncomitant strabismus because of Hering's law ol dual innervation and may mislead die examiner to believe that the eye with the greater deviation is the weak one (Figure \6.6).

Diplopia

Theoretically, the onset of double vision should be abrupt. However, in practice the history of the onset may be vague. This occurs because the patient may interpret subtle diplopia as blurring unless one eye is covered, either inadvertently or intentionally; or, the onset may be uncertain because the diplopia is intermittent initially, of small amplitude, or compensated for by head position, as may be the case in disorders such as congenital

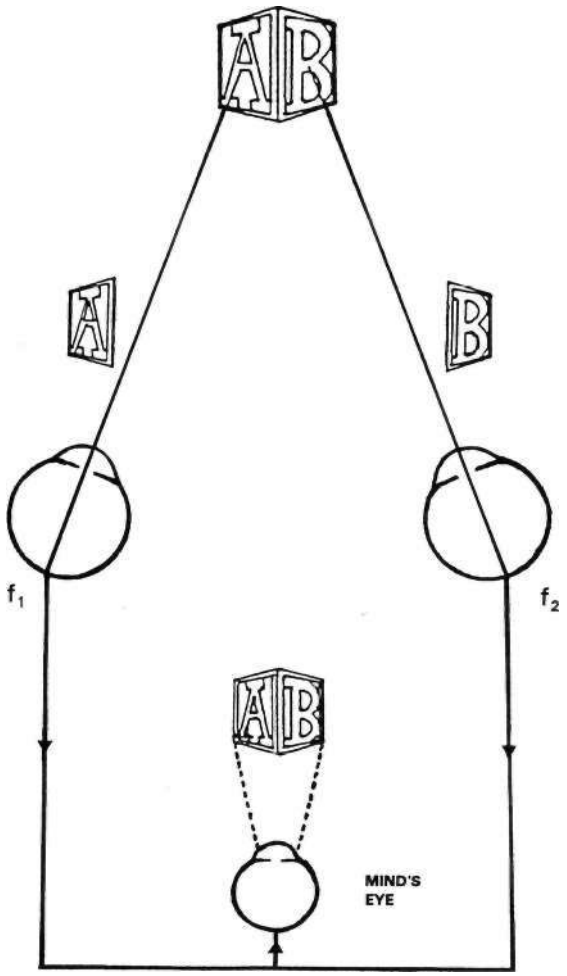

FIGURE 16.4 Each eye views the target AB from a different angle. The fovea of the left eye *(f\)* views the "A" side of the target; the fovea of the right eye *if2)* views the "B" side of the target. The occipital cortex—the cyclopcan (mind's) eye—integrates the disparate images so that a three-dimensional image *{AB)* of the target is perceived. This phenomenon is called *sensory fusion.*

superior oblique palsy, ocular myasthenia, and thyroid orbitopathy. Guidelines for evaluation of diplopia are presented in Table 16.3.

Most adult patients with acquired heterotopia complain of frank double vision. If the images are close together, however, the patient may not be aware of frank diplopia but merely perceive blurring or strain. Others may be aware of overlapping images (ghosting). Occasionally, visual confusion occurs because each fovea fixates a different object, causing the perception of two objects in the same place at the same time (Figure 16.7).

Anxious or histrionic subjects may misinterpret physiologic diplopia, a normal phenomenon, as a pathologic symptom. Physiologic diplopia occurs when *a* subject fixates an object in the foreground and then becomes aware of another object farther away but in the direction of gaze; the nonfixated object is seen by noncorresponding parts of each retina and is perceived by the mind's cyclopean eye as double (Figure 16.R). Alternatively, when the subject fixates a far object, a near object may appear double.

Isolated vertical diplopia (Table 16.4) is most commonly caused by superior oblique muscle palsy (90%). If the palsy is acquired, one image is virtually always tilted, an infrequent finding when the palsy is congenital. If recently acquired diplopia is worse in downgaze, the weak muscle is a depressor; if worse in upgaze, it is an elevator. If one image is tilted, then the weak muscle is more likely an oblique than a vertically acting rectus.

Spread of comitance—that is, the tendency for the ocular deviation to "spread" to all fields of gaze—occurs in long-standing cases; the diplopia then no longer obeys the usual rules.

If double vision persists when one eye is covered, the patient has monocular diplopia; monocular diplopia may be bilateral. The most common cause of monocular diplopia is optical aberration (refractive error) and a need for appropriate spectacles (Table 16.5). Less commonly, monocular diplopia is psychogenic; occasionally, it can he attributed to dysfunction of the retina or the cerebral cortex. The pinhole test quickly settles the matter. The patient is asked to look through a pinhole. If the cause is refractive, the diplopia abates because optical distortion is eliminated as the light rays entering the eye through the pinhole are aligned along the visual axis and thus not deflected. Oscillopsia may be misinterpreted as diplopia.

Occasionally, disorders that displace the fovea, such as a subretinal neovascular membrane, can cause binocular diplopia by disrupting the alignment of tin- photoreceptors (foveal displacement syndrome). The diplopia probably results from rivalry between central and peripheral fusional mechanisms (Brazis and Lee 1998).

Clinical Assessment

History

Table 16,6 shows the procedure for assessing patients with diplopia. The following points should be clarified, if the patient has not volunteered the information: Is the diplopia telieved by covering either eye? (If not, it is monocular diplopia; see Table 16.5). Is it worse in the morning or in the evening? Is it affected by fatigue? Are the images separated horizontally, vertically, or obliquely? If obliquely, is the horizontal or vertical component more obvious? Is the distance between images constant despite the direction of gaze, or does it vary? Is the diplopia worse for near vision or for distance? Is one image tilted? Do the eyelids droop? Is the diplopia influenced by head posture? Has this condition remained stable, improved, or deteriorated? Are there any general health problems? Are thetc associated symptoms, such as headache, dizziness, vertigo,

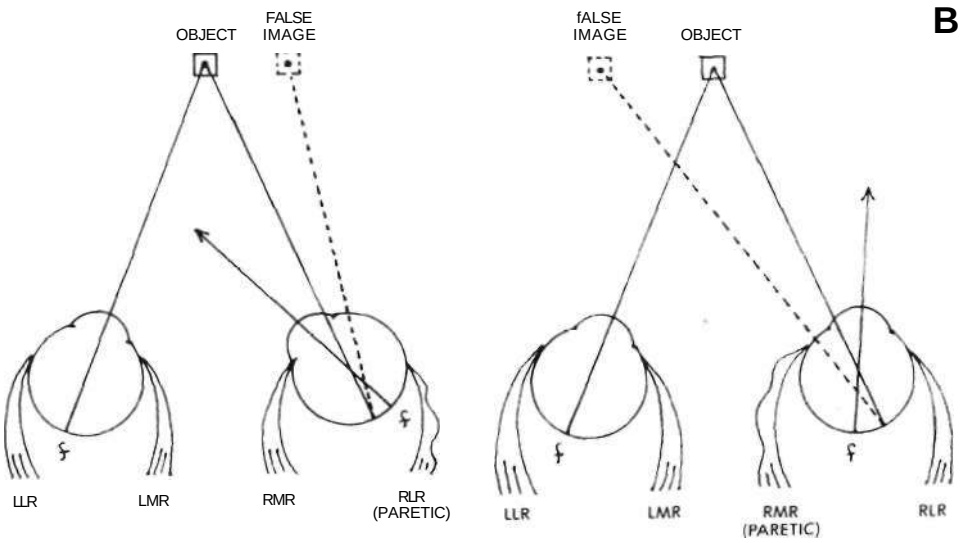

FIGURE 16.5 Misalignment of the visual axes. (A) Esotropia caused by a right lateral rectus (RI.R) palsy results in the right eye turning inward so that the image falls on the retina, nasal to the fovea (f), and is projected, by the mind's eye, ro the temporal field. That is, the false image is projected in the direction of action of the paretic muscle, causing uncrossed (homonymous) diplopia. (B) Fxorropia caused by a paretic right medial rectus muscle (RMR) results in the image falling on the retina temporal to the fovea with projection to the nasal field, in the direction of the action of the paretic RMR, causing crossed (heteronymous) diplopia LLR = left lateral rectus; LMR = left medial rectus,

or weakness? What medications are taken? Is there a family history of ocular, neurological, autoimmune, or endocrine disease? Has the patient had a "lazy" eye, worn a patch, or had strabismus surgery?

For example, latetal rectus muscle weakness causes diplopia that is worse at distance and worse on looking to the side of the weak muscle. Acutely, superior oblique weakness causes diplopia that is worse on looking downward to the side opposite the weak muscle and causes difficulty with tasks such as reading, watching television in bed, going down a staircase, and walking on uneven ground. Medial rectus muscle weakness causes diplopia that is worse for near than for distance vision and is worse to the contralateral side.

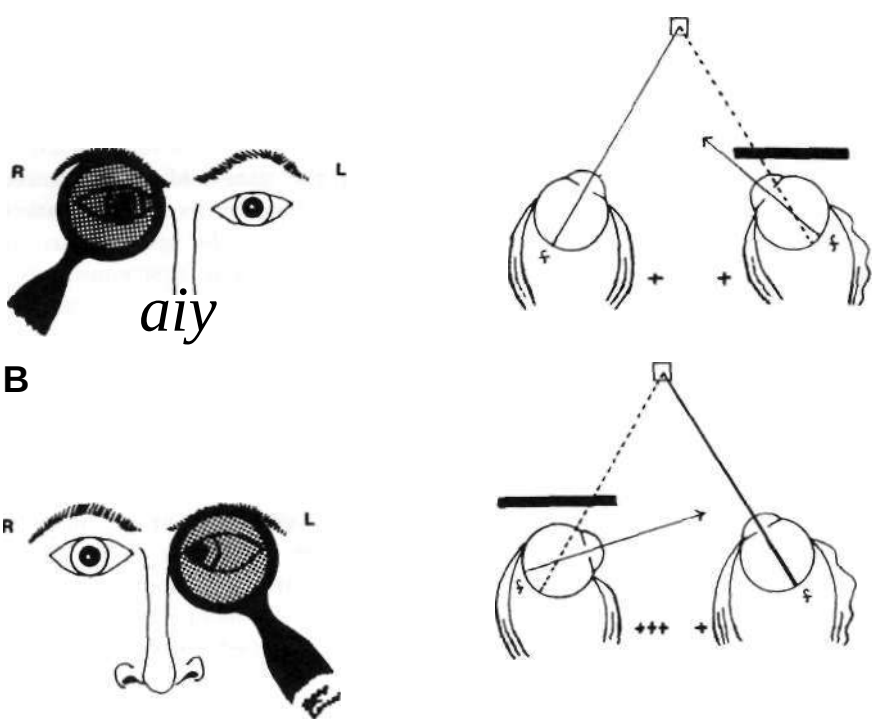

FIGURE 16.6 Primary and secondary deviation with palsy of the right lateral rectus muscle. (A) The right eye is covered with an occluder while the left eye fixates on the target. A small right esotropia (primary deviation) is demonstrated. (The opaque occludet is shown here to be partly transparent so the reader can observe the position of the covered eye.) (B) The left eye is covered while the paretic right eye fixates on the target. The right eye can fixate on the target despite the weak right lateral rectus muscle because that muscle is overdriven by the central nervous system. The normal left medial rectus muscle is also overdriven (Hcring's law of dual innervation), resulting in a large esotropia (secondary deviation). *f*= fovea.

Tabic 16.3: Rules for evaluating diplopia

1. *}\t'ad tilt:* When the weak extraocular muscle is unable to move the eye, the head moves the eye. Therefore the head tilts and turns in the direction of action of the weak muscle (sec Figure 16.9).
2. *The image from the nonfixing eye is the false image* and is displaced in the direction opposite the deviation; thus when the patient fixes with the nonparetic eye, the false image is displaced in the direction of action of the paretic muscle (sec Figure 16.5).
3. *The false image is the most peripheral image* and is displaced in the direction of action of the weak muscle, except when the patient fixes with the paretic eye. When the lateral rectus is paralyzed, the eyes are *esotropic* (crossed), but the images are uncrossed (see Figure 16.5A). The diplopia is worse at a distance and on looking to the side of the weak muscle. When I lie medial reel us is paralyzed, the eves are *exotropic* (wall-eyed), but the images are crossed (see Figure 16.5B). The diplopia is worse at near and on looking to the opposite side.
4. *The images are most widely separated when an attempt is made to look in the direction of the paretic muscle.*
5. *Secondary deviation* (the angle of ocular misalignment when the paretic eye is fixating) is always greater than primary deviation (when the good eye is fixating) (see Figure 16.6). Patients who fixate with the paretic eye may appear to have intracranial disease.
6. *Comitance:* With a comitant strabismus, the angle of ocular misalignment is relatively constant in all directions of gaze. With a *noncomitant (paralytic) strabismus,* the angle of misalignment varies with the direction of gaze.

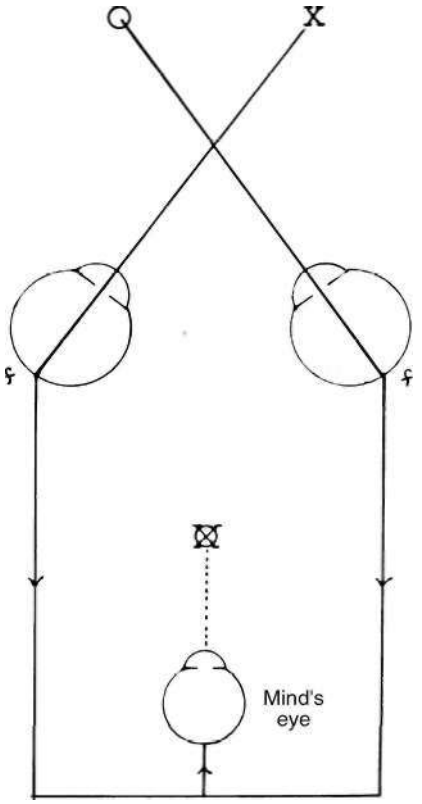

FIGURE 16.7 Visual confusion. Each fovea *(f)* views a different object, which is projected to the visual cortex by the cyclopean (mind's) eye and perceived in the same place at the same time, causing visual confusion (rare).

General Inspection

Ptosis that fatigues suggests myasthenia gravis. Ptosis associated with a dilated pupil suggests an oculomotor nerve palsy. Lid lag suggests thyroid orbitopathy or myotonia. Lid retraction suggests thyroid orbitopathy, aberrant rcinnervation after a third nerve palsy, a cyclic third nerve palsy (see Chapter 39), a dorsal midbrain lesion, hypokalemic periodic paralysis, or chronic corticosteroid use. Proptosis suggests an orbital lesion and, if associated with conjunctival injection and petiotbital swelling, an inflammatory disorder, such as orbital pseudotumor or lymphoma, dura! shunt fistula, or infection. Facial asymmetry suggests a superior oblique palsy **that** is congenita), contralatetal to the hemiatrophic side.

Head Posture

Because the weak extraocular muscle cannot move the eye fully, patients compensate by tilting or turning the head in the direction of action of the weak muscle. For example, with right lateral rectus palsy, the head is slightly turned to the right; then on attempted right gaze, the patient turns the head further to the right (Figure 16.9A). With a right superior oblique palsy, the head lilts forward and to the left (Figure 16.9B). The rule is as follows: The head turns or tilts in the direction of action of the weak muscle.

Sensory Visual Function

Visual acuity, color vision, and confrontation visual fields should be carefully checked in each eye, separately.

Stability of Fixation

Fixation and stability of the gaze-holding mechanism should be checked. This is done by having the patient look at a target and then observing for spontaneous eye movements, such as drift, microtremor, nystagmus, opsoclonus, ocular myokymia, ocular myoclonus, or saccadic intrusions.

Versions (Pursuit, Saccades, and Ocular Muscle Overaction)

Pursuit movements are tested by asking the patient to fixate on and follow (track) a moving tatget in all directions (see Figure 16.9A). This test determines the range of eye movement and provides an opportunity to observe for gaze-evoked nystagmus. If spontaneous primary-position nystagmus is present, the effects of the direction of gaze and convergence on the nystagmus may be determined. Pursuit movements should be smooth and

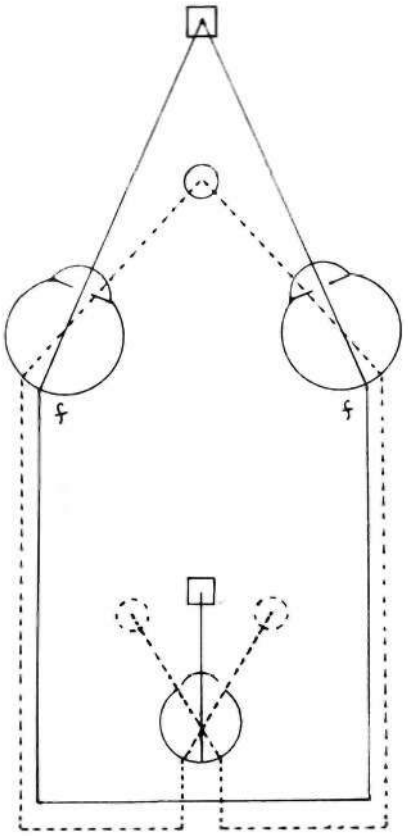

FIGURE 16.8 Physiological diplopia. The cyclopean eye views the target *(the square)* as a single object because each fovea *(f)* fixates it. The images of a nonfixated target *(the circle)* fall on n on corresponding points of each retina and so appears as double.

full. Cogwheel (saccadic) pursuit is a nonspecific finding and is normal in infants; when present in only one direction, however, it suggests a defect of the ipsilateral pursuit system (see Chapter 39).

Saccades (fast eye movements) are tested by asking the patient to look rapidly from one target to another (e.g., from the examiner's nose to a pen) while observing for a delay in initiating the movement (latency) as well as the movement's speed, accuracy, and conjugacy. An internuclear ophthalmoplegia is best detected by this method (see Chapter 39). If a specific muscle, particularly an oblique, is underacting or overacting, this can be observed in eccentric gaze before testing ductions in each eye separately, as shown in Figure 16.1OB. Assessment of disorders of conjugate (supranuclear) gaze is discussed in more detail in Chapter 39.

Convergence

Convergence is tested by asking patients to fixate on a target moving toward their nasion while observing the alignment of the eyes and for constriction of the pupils. Miosis confirms an appropriate effort, while its absence suggests less than optimal effort (see Chapter 39).

Tabic 16.4: Causes of vertical diplopia

Common causes
- Superior oblique palsy
- Dysthyroid orhitopathy (muscle infiltration)
- Myasthenia
- Skew deviation (brainstem, cerebellar, hydrocephalus)

Less common causes
- Orbital inflammation (myositis, pseudotumor)
- Orbital infiltration (lymphoma, metastases, amyloid)
- Primary orbital tumor
- Entrapment of the inferior rectus (blowout fracture}
- Third nerve palsy
- Superior division third nerve palsy
- Atypical third nerve (partial nuclear lesion)
- Aberrant third nerve rcinncrvation
- Brown's syndrome (congenital, acquired)
- Congenital exttaocular muscle fibrosis, or muscle absence
- Double elevator palsy (monocular elevator deficiency) is controversial in origin

Other causes
- Chronic progressive external ophthalmoplegia
- Fisher's syndrome
- Botulism
- Monocular supranuclear gaze palsy
- Verrical nystagmus (oscillopsia)
- Superior oblique myokymia
- Dissociated vertical deviation (divergence)
- Wernicke's encephalopathy
- Vertical one-and-a-half syndrome
- Monocular vertical diplopia (see Table 16.5)

Ductions

Ductions are tested monocularly by having the patient cover one eye and checking the range of movements of the other eye (see Figure I6.I0B). If ductions arc not full, the physician should check for restrictive limitation by moving the eye forcibly (see Forced Ductions, later in this chapter).

Ocular Alignment and Muscle Balance

Before determining ocular alignment, the examiner must first neutralize a head tilt or turn by placing the patient in

Table 16.5: Causes of monocular diplopia

- After surgery for long-standing tropia (eccentric fixation)
- Corneal disease, such as astigmatism, dry eye, or keratoconus
- Corrected long-standing tropia (eccentric fixation)
- Equipment failure (defective conract lens, ill-fitting bifocals in patient with dementia)
- Foteign body in aqueous or vitreous media
- Iris abnormalities (polycoria, trauma)
- I.ens: mulri-refractile (combined cortical and nuclear) cataracts, subluxation
- Monocular oscillopsia (nystagmus, superior oblique myokymia, eyelid twitching)
- Occipital cortex: migtaine, epilepsy, sttoke, tumor, trauma (palinopsia, polyopia)
- Psychogenic
- Retinal disease (rarely)

Tabic 16.6: Assessment of a patient with diplopia

History
- Define symptoms
- Effect of covering either eye?
- Horizontal or vertical separation of the images?
- Monocular?
- Effect of distance of target (worse at near or far}?
- Effect of gaze direction?
- Tilting ▷i oiii: image:

Observation
- Head tilt or turn? ("FAT scan")
- Ptosis (fatigue)?
- Pupil size?
- Proptosis?
- Spontaneous eye movements?

Examination
- Visual acuity (each eye separately)
- Versions (pursuit, saccades, and muscle overaction)
- Convergence (does miosis occur?)
- Ductions
- Ocular alignment (muscle balance) in the "forced primary position"
- Pupils
- Lids (examine palpebral fissures, levator function, fatigue)
- Vestibulo-ocular reflexes (doll's eyes)
- Bell's phenomenon
- I'I'KIII measurements
- Stereopsis ('Litmus stereo rest)
- Optokinetic nystagmus

General neurological examination
- Bruits
- Forced ductions
- Edrophonium (Tensilon) test

FAT= family album tomography—that is, review of old photographs for head tilt, pupil size, lids, ocular alignment, etc. For magnification, use ophthalmoscope or magnifying glass.

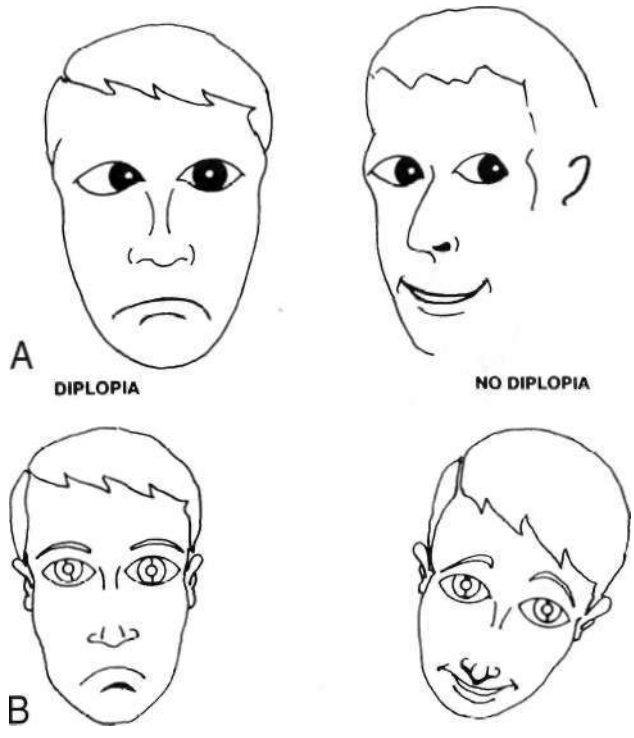

FIGURE 16.9 (A) Right lateral rectus palsy. A right esotropia is present in primary gaze; however, by turning the head to the right (in the direction of action of the weak right lateral rectus muscle), the patient can maintain both eyes on target (orthotropia), and thus have binocular single vision. (B) Acute right superior oblique muscle palsy. The right eye extorts (excycloduction) because of the unopposed action of the right inferior oblique muscle. By tilting the head to the left and forward (in the direction of action of the weak muscle), the right eye is passively intortcd while the left eye actively intorts to compensate and maintain binocular single vision. The head also tilts forward to compensate for the depressor action of the weak right superior oblique.

the "forced (or controlled) primary position"; otherwise, the misalignment may go undetected because of the compensating head posture. Subjective tests of ocular alignment include the red glass, Maddox rod, Lancaster red-green, and Hess screen.

In the red glass test, the patient views a penlight while a red filter or glass is placed, by convention, over the right eye. This allows easier identification of each image; the right eye views a red light and the left a white light. The addition of a green filter over the left eye, using red-green glasses, further simplifies the rest for younger or less cooperative patients. The target light is shown to the patient in the nine diagnostic positions of gaze (see Figure 16.10A). As the light moves into the field of action of a paretic muscle, the images separate. The patient is asked to signify where the images are most widely separated and to describe their relative positions. Interpretation of the results is summarized in Figure 16.11.

The Maddox rod uses the same principle as the red glass test but completely dissociates the images by changing the point of light seen through the rod, which is a scries of half cylinders, to a straight line perpendicular to the cylinders (Figure 16.12). This dissociation of images (a point of light and a line) breaks fusion, allowing detection of heterophorias as well as heterotropias. Cyclotorsion may be detected by asking if the image of the line is tilted (see Figure 16.15B). The Maddox rod can be positioned to produce a horizontal, vertical, or oblique line.

A further extension of these tests includes the Lancaster red-green and Hess screen tests, which use similar principles. Each eye views a different target (a red light through the red filter and a green light through the green filter). The relative positions of the targets are plotted on a grid screen and analyzed to determine the paretic muscle. These haploscopic tests are used mainly by ophthalmologists when quantitatively following patients with motility disorders.

The Hirschberg test, an objective method of determining ocular deviation in young or uncooperative patients, is performed by observing the point of reflection of a penlight held approximately 30 cm from the patient (Figure 16.13);

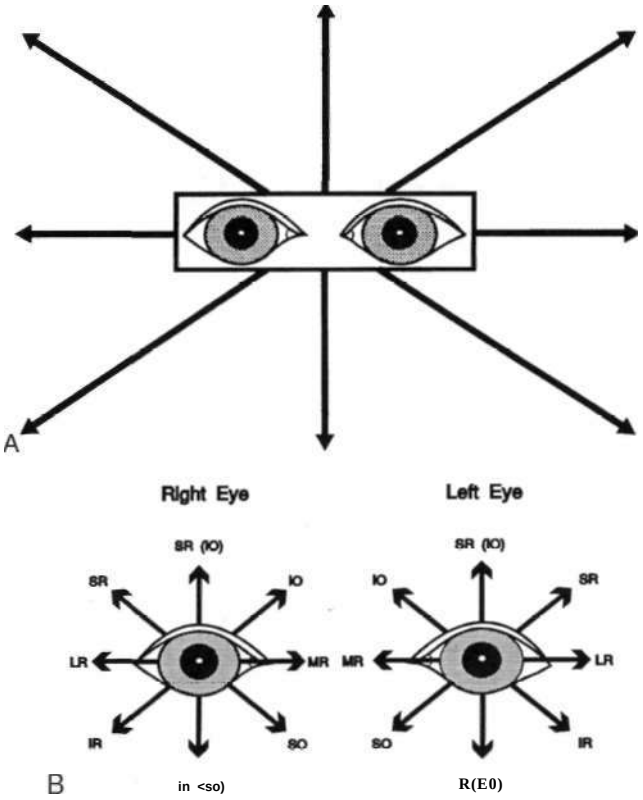

FIGURE 16.10 (A) The nine diagnostic positions of gaze, used for testing versions (saccades and pursuit). (B) Ductions, used to test the isolated action of each of the six muscles of each eye (assuming the other five muscles are functioning normally). Pure elevation (supraduction) and depression (iufraduction) of the eyes are predominantly functions of the superior (SR) and inferior (IR) rectus muscles, respectively, with some help from the oblique muscles. That is, the eyes are rotated directly upward primarily by the superior rectus, with some help from the inferior ohlique (IO). The eyes are rotated directly downward primarily by the inferior rectus, with some help from the superior oblique (SO). LR = lateral rectus; MR = medial rectus,

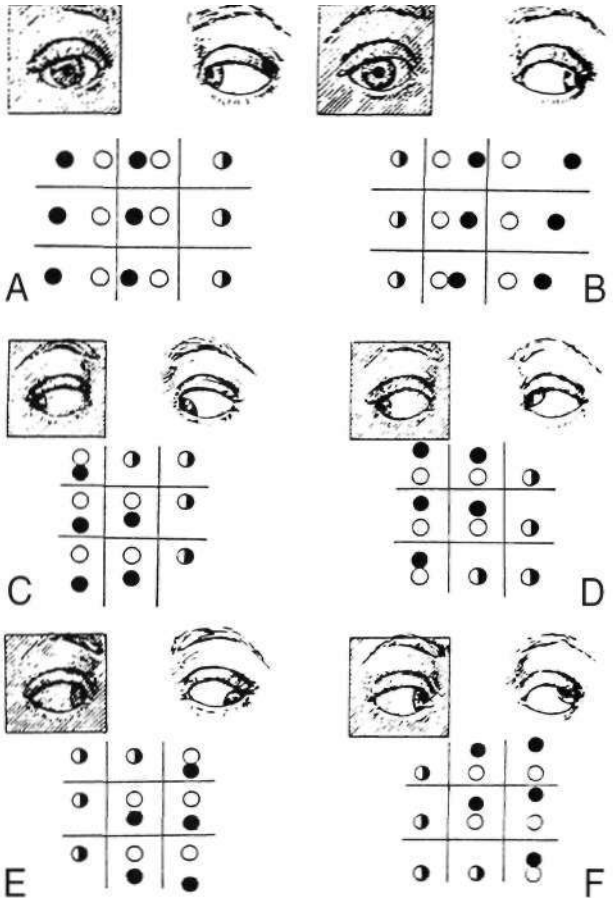

FIGURE 16,11 The red glass test. Diplopia fields for each muscle paralysis are shown. By convention, the red glass is placed over the right eye. The charts below each case are displayed as the subject, facing the examiner, indicates the position of the red (dark circle) and the white (white circle) images in the nine diagnostic positions of gaze. (A) Right lateral rectus palsy. (B) Right medial rectus palsy. (C) Right inferior rectus palsy. (D) Right superior rectus palsy. (E) Right superior oblique palsy. (F) Right inferior ohlique palsy. 1 mm of decentration is equal to 7 degrees of ocular deviation. One degree is equal to approximately two prism diopters. One prism diopter is the power required to deviate (diffract) a ray of light by 1 cm at a distance of 1 m (Figure 16.14).

The cover-uncover test is determined for both distance (6-m) and near (33-cm) vision. The patient is asked to fixate an object held at the appropriate distance. The left eye is covered while the patient maintains fixation on the target, If the right eye was fixating, it remains on target, but if the left eye was fixating, the right eye moves onto the target. If the uncovered right eye moves in (ad ducts), the pan cut has a right cxotropia; if it moves out, the deviation is an esotropia; if it moves down, a right hypertropia; if it moves up, .i left hypertropia. *The physician should always observe the uncovered eye.* The cover should be removed and the test repeated by covering the other eye. If the patient has a tropia, the physician must determine whether it is comitant or noncomitant by checking the degree of deviation in the nine diagnostic positions of gaze (see Figure 16,10A), With lateral rectus palsy, the esotropia increases on looking to the side ɨ>t the weak muscle and disappears on looking to the opposite side (see Figure 16.11A). Similarly, with a medial rectus weakness, the patient has an cxotropia that increases on looking in the direction of action of that muscle (see Figure 16.1 IB). Prisms are used, mainly by ophthalmologists, to measure the degree of ocular deviation (see Figure 16.14). If diplopia is due to breakdown of a long-standing (congenital) deviation, prism measurement can detect supranormal fusional amplitudes (large fusional reserve). If no manifest deviation of the visual axes is found using the cover-uncover rest, the patient is orthotropic. The physician should then perform the cross-cover test.

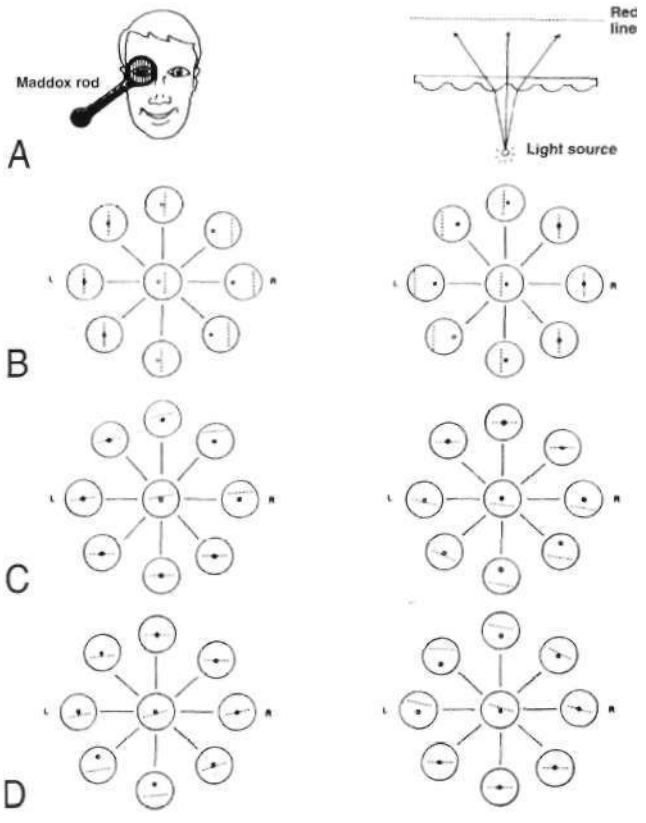

FIGURE 16.12 The Maddox rod test. (Unlike in Figure 16.11, the images are displayed as rhe patient perceives them.) (A) By convention, the right eye is covered by the Maddox rod, which may be adjusted so the patient sees a red line, at right angles to the cylinders, in the horizontal or vertical plane, as desired (red image seen by the right eye; light source seen by the left eye). (B) The Maddox rod is composed of a series of cylinders that diffract a point of light to form a line. (C) Right lateral rectus palsy. (D) Right medial rectus palsy.

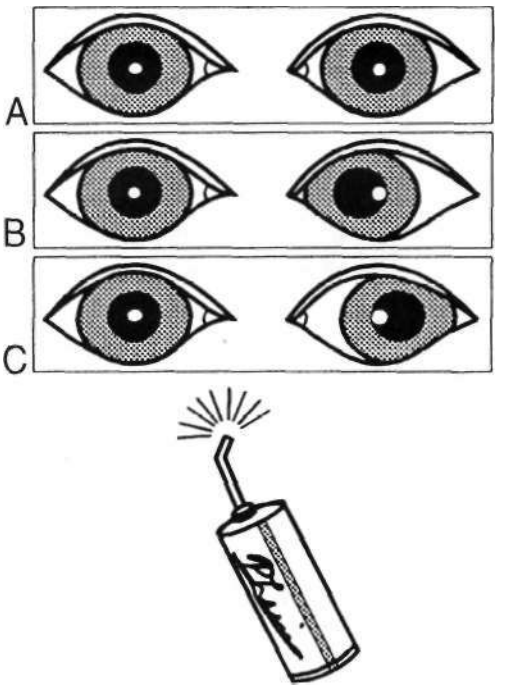

FIGURE 16.13 Hirschberg's method to estimate the amount of ocular deviation. The displacement of the corneal light reflex of the deviating eye varies with the amount of ocular misalignment. One millimeter is equivalent to approximately 7 degrees of ocular deviation, and 1 degree equals approximately 2 prism diopters. (A) No deviation (orthotropic). (B) Left esotropia. (C) Left exorropia.

During the cross-cover (alternate-cover) test, the patient is asked to fixate on a target, then one eye is covered for at least 4 seconds. The examiner should observe the uncovered eye. If the patient is orthotropic, the uncovered eye does not move, but the covered eye loses fixation and assumes its position of rest—latent deviation (heterophoria or phoria). In that case, when the covered eye is uncovered, it refixates by moving back; the uncovered eye is immediately covered and loses fixation. The cross-cover test prevents binocular viewing, and thus fovcal fusion, by always keeping one eye covered. Unlike the cover-uncover test, the cross-cover test detects heterophoria; most normal subjects are exophoric because of the alignment ot the orbits.

Fixation switch diplopia occurs in **patients with** long-standing strabismus who partially lose visual acuity in the fixating eye, usually as a result of a cataract or refractive-error. Such patients normally avoid double vision by ignoring the false image from the nonfixating eye, but a significant fall in acuity in the "good" eye forces them to fixate with the weak eye; this causes misalignment of the previously good eye and results in diplopia. Fixation switch **diplopia** can usually be treated successfully with appropriate optical management.

Dissociated vertical deviation (divergence) is an asymptomatic congenital anomaly that is usually discovered during the cover test. While the patient fixates **a** target, one eye is covered. The covered eye loses fixation and rises; the uncovered eye maintains fixation but may turn inward. This congenital ocular motility phenomenon is usually bilateral but frequently asymmetric; it is often associated with amblyopia, esotropia, and latent nystagmus (LN). Whether there ate an excessive number of axons decussating in the chiasm, as suggested by evoked potential studies, remains controversial. Dissociated vertical deviation has no other clinical significance.

Three-Step Test for Vertical Diplopia

Fight muscles arc involved in vertical eye movements: Four muscles arc elevarors and four arc depressors. The three-step test endeavors to determine if one particular paretic muscle is responsible for vertical diplopia (Figure 16.15). Using the cover-uncover test, which is objective, or one of the subjective tests, such as the red glass test, the physician can apply the three-step test. It is important to remember that the hypertrophic eye views the lower image.

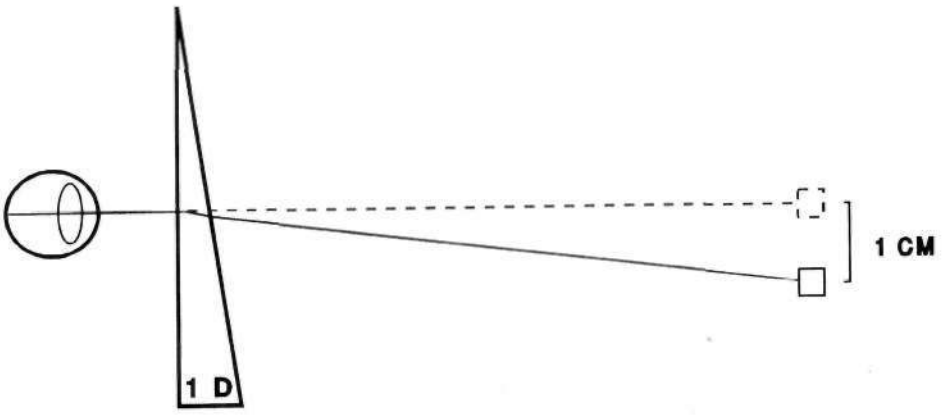

FIGURE 16.14 A prism with rhe power of I prism diopter (D) can defract a ray of light 1 cm at I meter.

Step 1 determines which eye is higher (hypertrophic) in primary position. The patient's head may have to he repositioned (forced primary position) because of a compensatory tilt. If the right eye is higher, the weak muscle is either one of the two depressors of the right eye (inferior rectus or superior oblique) or one of the two elevators of the left eye (superior rectus or inferior oblique).

Step 2 determines whether the hypertropia increases on left or right gaze. If it increases on left gaze, the weak muscle is cither rhe depressor in the right eye that acts best in adduction (i.e., the superior oblique) or the elevator in the left eye that acts best in abduction (i.e., the superior rectus), and vice versa.

Step 3 determines whethet the hypertropia changes when the head tilts to the left or right. If it increases on head tilt left, the weak muscle must be an intortor of the left eye (superior rectus); if it increases on head tilt right, the weak muscle must be an intortor of the right eye (superior oblique).

Two more optional steps can be introduced:

Step 4 (optional), using one of a number of techniques (such as the double Maddox rod, visual field blind spots, indirect ophthalmoscopy, or fundus photography), determines if ocular torsion is present. Establishing the degree and direction of ocular torsion, if any, can differentiate a skew deviation (see Chapter 39) from a true superior oblique palsy. Because the primary action of the superior oblique muscle is intorsion (sec Table 16.1), an acute palsy typically results in approximately 5 degrees of extorsion of the affected eye because of unopposed action of the ipsilateral inferior oblique muscle. If cither eye is intorted, a superior oblique palsy is not responsible, and the patient may have a skew deviation (Donahue et al. 1999).

Step 5 (optional) is helpful in the acute phase. If the deviation is greater on downgaze, the weak muscle is a depressor; if it is worse on upgaze, the weak muscle is likely to be an elevator. This fifth step is helpful only in the acute stage hecause, with time, the deviation becomes more comitant and may he misleading in a patient with a long-standing palsy, especially if the third step is omitted.

The examiner should he aware of the pitfalls of the three-step test, namely, where the rules break down. These include restrictive ocular myopathics (Table 16.7), long-standing strabismus, skew deviation (see Chapter *39),* and disorders involving more than one muscle.

The four fundamental features of the fourth cranial nerve are (1) it has the longest intracranial course, and is the thinnest of all the cranial nerves, and thus very susceptible to injury; (2) it is the only cranial nerve that exits the neuraxis dorsally; (3) its nucleus of origin is on the contralateral side of the neuraxis (the oculomotor subnucleus for the superior rectus is also on the opposite side); (4) the most common cause of isolated vertical diplopia is a fourth nerve (superior oblique) palsy. Lee et al. (1998) and Jaeohson (2002) comprehensively reviewed causes of superior oblique palsies.

Fatigability

Once the weak muscle is identified, the physician should determine whether it fatigues by testing its rapid (saccadic) action repetitively and its ability to sustain eccentric eye position without drift.

Forced Duct ions

If the weak muscle does not fatigue, the physician should determine whether it is restricted by performing forced ductions. The use of phenylephrine hydrochloride

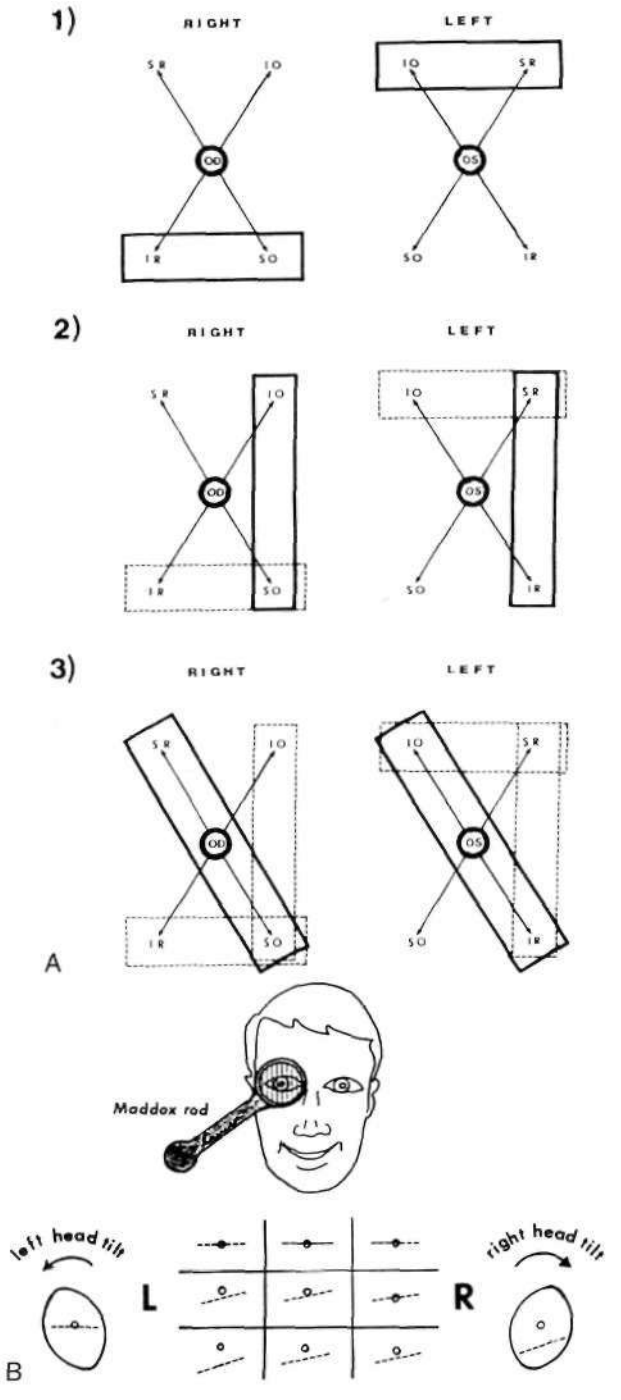

Table 16.7: Positive forced ductions (restrictive)

Acquired: superior oblique tendinitis, myositis, or injury
Brown's syndrome
Carotid-cavernous or dural shunt fistula
Congenital: superior oblique tendon sheath syndrome
Duane's syndrome
Entrapment (blowout fracture)
Extraocular muscle fibrosis (congenital, postoperative)
Long-standing muscle weakness
Orbital infiltration: myositis, lymphoma, metastasis, amyloidosis, cysticcrcosis, trichinosis
Thyroid ophthalmopathy

eye drops beforehand reduces the risk of subconjunctival hemorrhage. Although this test is in the realm of the ophthalmologist, it may be performed in the office using topical anesthesia and a cotton-tipped applicator, but great care must be taken to avoid injuring the cornea. The causes of restrictive myopathy are listed in Table 16.7; however, any cause of prolonged extraocular muscle paresis can result in contracture of its antagonist.

Signs Associated with Diplopia

Extraocular muscle or lid fatigue suggests myasthenia gravis, as does Cogan's lid twitch sign. Weakness of other muscles, such as the orbicularis oculi, othet facial muscles, neck flexors, or bulbar muscles, may he found in oculopharyngeal dystrophy and myasthenia gravis (see Chapters 28, 84, and 88). Narrowing of the palpebral fissure and retraction of the globe on adduction, associated with an abduction deficit, suggest Duane's retraction syndrome (Gutowski 2000).

Paradoxical elevation of the upper lid on attempted adduction or downgaze occurs with aberrant reinnervation of the third cranial nerve, which is virtually always a result of trauma or compression caused by tumor or aneurysm (see Chapter 77); the pupil may also constrict on attempted adduction or downgaze. Miosis accompanying apparent bilateral sixth nerve palsy occurs with spasm of the near reflex (see Chapter *S9).* Horner's syndrome, ophthalmoplegia, and impaired sensation in the distribution of the first division of the trigeminal nerve occur

FIGURE 16.15 Example of the three-step test in a patient with an acute right superior oblique palsy. (A) In a patient with hypcrtropia, one of eight muscles may be responsible for vertical ocular deviation. Identifying the higher eye eliminates four muscles. *(1)* With a right hypcrtropia, the weak muscle i-. either one of the two depressors of the right eye (IR or SO) or one of the two elevators of the left eye (IO or .SR) (enclosed by the solid line). (2) If the deviation (or displacement of images) is greater on left saw, one of the muscles acting in left gaze (enclosed by the solid line) must be responsible, in this case cither the depressor in the right eye (SO) or the elevator in the left eye (SR). (.?) If the deviation is greater on right head tilt, the incyclotortors of the right eye (SR and SO) or the exeyclotortors of the left eye (IR and 10) (enclosed) must be responsible, in this case, the right SO—that is, the muscle enclosed thtee times. If the deviation is greater on left head tilt, the left SR would be responsible. IO = inferior oblique; IR = inferior rectus; SO = superior oblique; SR = superior rectus. lii I he Maddux rod tci ul^pl.nvd ,is in Figure 1(S. I 2, as [he subject perceives the images) in a paiienl with a right superior oblique palsy shows vertical separation of the images that is worse in the direction of action of the weak muscle and demonstrates subjective tilting of the image from the right eye. When the head is tilted toward the left shoulder, the separation disappears, bur when the head is tilted to the right shoulder, to the side of the weak muscle, the separation is exacerbated (Biclschowsky's third step).

with superior orbital fissure and anterior cavernous sinus lesions. A third nerve palsy with pupillary involvement is most often caused by a compressive lesion; when this occurs acutely, a posterior communicating aneurysm is usually responsible.

Proptosis suggests an orbital lesion, such as thyroid disease (bilateral), inflammatory or infiltrative orbital disease (tumor, pseudotumor, or amyloidosis), or carotid-cavernous fistula, in which case it may be pulsatile. Ocular bruits, often heard by both patient and doctor, occur with carotid-cavernous or dural shunt fistulas. Other findings include entrapment (blowout fracture), which is a sign of periorbital and ocular injury, and nystagmus (see Chapter 39) seen with intcrnuclear ophthalmoplegia. Other cranial nerve deficits and various miscellaneous signs may be present. Ophthalmoplegia, ataxia, nystagmus, and confusion suggest Wernicke's encephalopathy. Pyramidal and spinothalamic signs with crossed hemiparcsis suggest brainstem syndromes (see Chapter 22). Facial pain, hearing loss, and ipsilateral lateral rectus weakness indicate Gradenigo's syndrome. Myotonia and retinitis pigmentosa suggest more widespread disorders.

Edrophonium (Tensilon) Test

The edrophonium test is discussed in detail in Chapter 84, but a few points are stressed here. The test must have an objective endpoint, such as ptosis, a tropia, or limited ductions; the physician must observe an objective change. The edrophonium test is negative when forced ductions are positive (restrictive myopathy) and is difficult to interpret when the patient has no objective signs of extraocular muscle weakness or ptosis,

Optokinetic Nystagmus

True optokinetic nystagmus (OKN) is a rhythmic involuntary conjugate ocular oscillation in response to a compelling full visual field stimulus, such as that produced by rotating an image of the environment around the patient or by turning the patient in a revolving chair. The oscillation is biphasic and consists of an initial slow phase provoked by, and in the direction of, the stimulus; this is followed by a fast, corrective, phase (see Chaprer 39). OKN in response to a pocket tape is a useful bedside test, but it evaluates only foveal pursuit and refixation saccades, which arc helpful in several circumstances. These circumstances are (1) detecting a subtle internuclear ophthalmoplegia; (2) provoking convergence-retract ion nysragmus, where the tape is moved downward in an attempt to induce upward saccades; (3) congenital nystagmus (CN), where the direction of the fast phase may be paradoxical—that is, in the direction of the slowly moving tape or drum; (4) patients feigning complete blindness or ophthalmoplegia; (5) homonymous hemianopia caused by a large, **deep**-seated parietotemporo-occipital lesion, where the OKN response is depressed or absent as the tape moves toward the side of the lesion.

A large mirror may be used to induce true optokinetic movements in patients with psychogenic ophthalmoplegia or psychogenic blindness. The examiner holds the mirror in front of rbi' patient, whose eyes *.ax* open, The minor is gently rocked so that the reflected environment (full visual field) moves. This compelling optokinetic stimulus forces reflex slow eye movements. The patient may close the eyes, look away, or converge in an attempt to avoid the reflex response. Care must be taken in diagnosing psychogenic disorders with this test in patients with supranuclear gaze palsies, ocular motor apraxia, or poor vision; those with "count-fingers" vision may still have an OKN response.

Vergence Disorders

Vergence disorders may cause diplopia (see Chapter 39).

Central Fusion Disruption

Central fusion disruption causes diplopia and is described in Chapter 39.

Acute Bilateral Ophthalmoplegia

The causes of acute bilateral ophthalmoplegia are outlined in Table 16.8.

Chronic Bilateral Ophthalmoplegia

The causes of chronic bilateral ophthalmoplegia are outlined in Table 16.9.

Treatment

Patching (occlusive) therapy is used mainly to eliminate one image during the acute phase. In children under age 6, each eye should be patched alternately to prevent developmental amblyopia. Such young patients should be followed by an experienced ophthalmologist. Adult patients may wear the patch over whichever eye is more comfortable, although some clinicians feel that alternating the patch reduces the incidence of contractures.

Prisms are helpful in eliminating double vision if the deviation is not too great. A reasonable range of binocular single vision may be achieved with prisms, provided the patient's expectations arc not too high and there is no significant cyclodeviation.

Botulinum toxin is used in patients with both comitant and noncomitant strabismus, with mixed success. It may be helpful in patients with acute abducens palsies, particularly if bilateral and traumatic in origin.

Extraocular muscle surgery can correct long-standing strabismus (comitant or noncomitant). Finally, orthoptic

exercises are of use in patients with convetgence insufficiency (see Chapter 39).

Related Disorders

Asthenopia (the visual concomitant of neurasthenia) is characterized by symptoms such as episodic blutring; watering; itching; diplopia; eyestrain; tiredness of the eyes or lids, especially after reading; sleepiness; and photophobia. Patients with this condition often exaggerate normal phenomena, such as physiologic diplopia, floaters, persistence of afterimages, and difficulty reading fine print. Their symptoms may he associated with accommodative insufficiency, headache, and other asthenic complaints. Care must be taken to exclude true refractive etrots, defective accommodation, convergence insufficiency, medication, dry eye syndrome, and diabetes mellitus (Waltz and Lavin 1993). Although asthenopia is usually psychogenic, a cause for isolated accommodative insufficiency, such as paneto-occipital stroke, may be found. Management includes a thorough examination, recognition of real abnormalities, and confident and authoritative reassurance.

Brainstem neoplasm
Chronic basal meningitis (infection, sarcoid, or carcinoma)
Congenita] extraocular muscle fibrosis
Dysthyroidism
Leigh disease
Multiple sclerosis
Myasthenia gravis
Myopathies (e.g., mitochondrial, fiber-type disproportion [see Table 39,2])
Nuclear, paranuclear, and supranuclear gaze palsies (see Chapter 39)
Vitamin t" deficiency

Occasionally, after extremely prolonged monotonous visual and vestibular stimulation, as in interstate or highway driving, interstate illusions (highway hallucinosis) may occur: The environment may appear to be sloping downward when in fact it is flat. This perception is somewhat similar to the prolonged sensation of movement after a long sea voyage (mal de debarquenient).

Micropsia, defined as the reduction in apparent size of an object of a given retinal angle, is the illusion of objects appearing smaller than normal. It can occur with optical aberrations, such as overcorrection of myopia with minus spherical lenses, retinal disorders (e.g., macular edema), and disorders of parietal region, such as stroke or, more commonly, migraine (the "Alice in Wonderland" syndrome). Convergence and accommodation are associated with micropsia to avoid a sense of enlargement as an object gets closer to the eye. Occasionally, a disturbance of convergence or accommodation, or both, can induce micropsia.

Monocular elevator deficiency (double elevator palsy) is discussed in Chapter 39.

Oscillopsia, an illusion of movement or oscillation of the environment, occurs with acquired nystagmus, superior oblique myokymia, other ocular oscillations, and disorders of the vestibulo-ocular reflex.

Polyopia, the perception of multiple images, is frequently optical and can be determined by the pinhole test, discussed under Diplopia, earlier in this chapter. Polyopia may also be caused by cortical lesions (see Table 16.5).

Palinopsia (or paliopia), the pathologic persistence or recurrence of visual images after the stimulus has been removed, may cause cerebral diplopia or polyopia. The images become more apparent and numerous when the target moves relative to the retina because it provokes multiple persistent afterimages (Figure 16.16). Sometimes patients describe the visual disturbance as trailing, vibrating, echoing, smearing, or ghosting of images. This visual perseveration occurs more frequently in patients with mild left homonymous visual field defects caused by right parieto-occipital lesions; it may he ictal and respond to anticonvulsant medication. It can also occur with metabolic

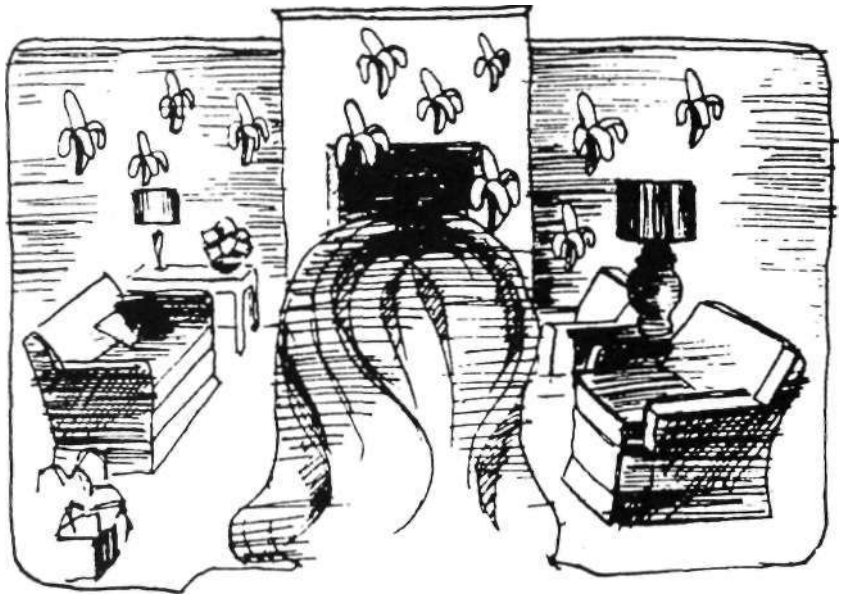

FIGURE 16.16 Palinopsia (cerebral poly opia). Visual images experienced by a patient moments after peeling a banana. (Reprinted with permission from Michel, E, N. & Troost, B. N. 1980, "Palinopsia: Cerebral local!'/.ation with computed tomography," *Neurology,* vol. 30, pp. 887-889.)

disorders, carbon monoxide poisoning, and a variety of drugs including domiphenc, interleukin-2, lysergic acid diethylamide, mescaline, nefazodonc, trazodone, and 3,4-methylenedioxymcthamphetamine (Ecstasy). Palinopsia can occur in patients with ocular or optic nerve disease and in apparently healthy people; occasionally, it may be associated with auditory perseveration (palinacusis) (Pomeranz and l.essell 2000).

Superior oblique myokymia is a small, rapid, monocular torsional-vertical oscillation (discussed under Superior Oblique Myokymia, later in this chapter).

Tortopia, the illusion of tilting or even inversion of the visual environment for a period of seconds to minutes, may occur in patients with posterior fossa disease, most commonly vertebrobasilar ischemia. Tortopia may be associated with headache, dizziness, vertigo, and double vision and is presumed to be due to dysfunction of the vestibulo-otohthic system or its central connections.

NYSTAGMUS

Nystagmus is an involuiitan hiphasic rhythmic ocular oscillation in which one or both phases are slow (Figure 16.17). The slow phase of jerk nystagmus is responsible for the initiation and generation of the nystagmus, whereas the fast (saccadic) phase is a corrective movement bringing the fovea back on target,

For clinical purposes, nystagmus may be divided into pendular and jerk forms. Either form may be horizontal or, less commonly, vertical. Jerk nystagmus is labeled conventionally by the direction of the fast phase and is divided into three types on the basis of the shape of the slow phase, detected by oculographic recordings (see Figure 16.17).

Mechanisms of Nystagmus

Nystagmus may result from dysfunction of the vestibular end organ, vestibular nerve, brainstem, cerebellum, or cerebral centers for ocular pursuit {see Chapter 39), Pendular nystagmus (see Figure 16.17A) is central (brainstem or cerebellum) in origin (Averbuch-Heller et al. 1995b), whereas jerk nystagmus may be either central or peripheral. Jerk nystagmus with a linear (constant-velocity) slow phase (see Figure 16.17B) is caused by peripheral vestibular dysfunction resulting in an imbalance in vestibular input to the brainstem gaze centers. When the slow phase has a decreasing velocity exponential (see Figure 16.17Q, the brainstem neural integrator (see Chapter 39) is at fault and is said to be leaky. The integrator is unable to

FIGURE 16.17 Oculographic diagrams of nystagmus waveforms. (A) Pendular (sinusoidal nystagmus). (B) Left-beating jerk nystagmus with a constant-velocity (linear) slow phase. (C) Left-beating jerk nystagmus with a decreasing (exponential) velocity slow phase. (D) Left-beating jerk nystagmus with an increasing (exponential) velocity slow phase.

maintain a constant output to the gaze center to hold the eyes in an eccentric position, resulting in gaze-paretic nystagmus. An increasing-velocity exponential slow phase (see Figure 16.17D) in the horizontal plane is central in origin and is the usual form of CN.

Clinical Evaluation

The physician should determine whether the nystagmus was present since birth or is acquired and whether there is a family history. CN is usually asymptomatic and rarely bothers the patient or causes oscillopsia (see Congenital Nystagmus below). Symptoms such as headache, diplopia, impaired vision, oscillopsia, vertigo, or other neurological abnormalities must be taken into account. Examination should include visual acuity, confrontation visual fields, pupil reflexes, observation for ocular albinism, and ophthalmoscopy. The latter may be used to detect subtle nystagmus not apparent to the naked eye. Ocular motility must also be assessed. The following features must be determined:

- Is the nystagmus present in primary position or only with eccentric gaze (gaze-evoked}?
- Is the nystagmus binocular and conjugate or is it dissociated?
- Is the waveform pendular or jerk? If jerk, whar is the direction of the fast phase?
- Is there a latent component (i.e., an increase in nystagmus intensity when one eye is covered)?
- Is there a torsional componenr?
- Is there spontaneous alteration of direction, as with periodic alternating nystagmus, which must be distinguished from rebound nystagmus (discussed later in the chapter) and which requires observation for some period?
- Is there a null zone (a direction of gaze where the nystagmus is minimal or absent)?
- Does convergence damp the nystagmus or change its direction?
- Is the nystagmus altered (accentuated or suppressed) by head positioning or posture or by head shaking (as in spasmus nutans)?
- What is the effect of optokinetic stimulation? In CN, the response is paradoxical, that is, the fast phase is in the direction of the slow-moving target.
- Are there associated rhythmic movements of other muscle groups, such as the face, tongue, ears, neck, palate (as in oculopalaral myoclonus), or limbs?

Nystagmus Syndromes

Table 16.10 summarizes the localizing value of nystagmus syndromes and non-nystagmus ocuiar oscillations.

Congenital Nystagmus

CN is usually present from birth but may not be noticed for the first few weeks, or occasionally even years, of life. It may be accompanied by severe visual impairment but is not the result of poor vision. Disorders, through genetic association, that are responsible for poor vision in patients with CN include achiasma (Jansionus et al. 2001), achromatopsia, albinism, amaurotic idiocy of Leber (Leber's congenital amaurosis), aniridia, congenital stationary night blindness, congenital cataracts, retinopathy of prematurity, optic nerve hypoplasia, and fovea! hypoplasia. Paradoxical pupil constriction in darkness, particularly in patients with poor vision, suggests an associated retinal or optic nerve disorder. Myopia, uncommon early in life, in infants with CN suggests a retinal disorder, such as congenital stationary night blindness, and high myopia suggests Leber's congenital amaurosis; such retinal disorders can be confirmed by electroretinography. CN is sometimes associated with head tirubation. CN may be familial and is inherited in an autosomal recessive, X-linked dominant or recessive pattern. Genetic defects identified in some families include a dominant form of CN linked to chromosome 6p12 (Kerrison etal. 1998), an X linked form ot CN with incomplete penetrance among female carriers associated with a defect on the long arm of the X chromosome (Kerrison et al. 2001), and a deletion in the OA1 gene (ocular albinism) in a family with X-linked CN associated with macular hypoplasia and ocular albinism (I'reising et al. 2001).

CN usually appears horizontal in most patients and may be either pendular or jerk in primary position. Pendular nystagmus often becomes jerk on lateral gaze. The horizontal oscillation may be accentuated during vertical tracking. However, oculography with 3-D scleral search coils demonstrates that many patients with CN have a torsional component, phase-locked with the horizontal component {Averbuch-Heller et al. 2002).

Patients with CN often have good vision unless there is an associated afferent defect (above). CN damps with convergence; latent super imposition *[Afi* increase in nys tagmus amplitude when one eye is covered) may be present. A null zone, where the nystagmus intensity is minimal, may be found; if this is to one side, the subject turns his head to improve vision. The head often oscillates as well. Both features—damping of nystagmus with convergence and a null zone—can be used in therapy by changing the direction of gaze with prisms or extraocular muscle surgery to improve head posture and visual acuity. Oculographic recordings (see Chapter 39) usually demonstrate cither a sinusoidal (see Figure 16.17A) or slow phase with an increasing exponential waveform (see Figure 16.17D). However, in the first few months of life the waveform of CN may be more variable, evolving into the more classic pattern as the child gets older.

Patients with CN do not experience oscillopsia (an illusory oscillation of the environment), unless a head

Table 16.10: Localizing value of nystagmus syndromes and n on -nystagmus ocular oscillations

Nystagmus syndromes	*Localization*
Downbeat nystagmus	Bilateral cervicomcdullary junction (flocculus) Floor of the fourth ventricle

injury, decompensated strabismus, or retinal degeneration causes a decline in vision, ocular motor function, or both; then, pnsms or strabismus surgery may correct such Lire-onset oscillopsia (Hertle et al. 2001a).

Rarely, CN may be pendular in the vertical plane or circumductory, in which the eyes move conjugately in a circular or cycloid pattern. Occasionally CN may be unilateral, occur later in the teens or adult life, or become symptomatic if changes in the internal or external environment alter fovcation stability and duration, causing oscillopsia. Less common patterns of CN, such as periodic alternating, upbeat, downbeat, and seesaw nystagmus (SSN), are discussed under those sections later in this chapter.

Because of considerable controversy classifying and defining nystagmus syndromes, particularly in infancy, the National Eye Institute sponsored a workshop to resolve such issues (CKMAS Working Group 2001).

Latent Nystagmus and Manifest Latent Nystagmus

LN and manifest LN (MLN) are both congenital forms of nysragmus.

LN occurs with monocular fixation, that is, when one eye is covered. The slow phase is directed toward the covered eye. The amplitude of the oscillations increases on abduction of the fixating eye. With MLN, the oscillation is present with both eyes open. However, only one eye is seeing; vision in the other is ignored or suppressed as a result of strabismus or amblyopia. The nystagmus waveform has a decreasing-velociry slow phase (sec Figure 16.16C), which differs from true CN. Some patients with LN can suppress it at will.

The pathogenesis of LN may be related to impaired development of binocular vision mechanisms. Under monocular viewing conditions, rhesus monkeys, deprived of binocular vision early in life, have poor nasal-to-temporal optokinetic responses. The pretectal nucleus of the optic tract (NOT) is necessary for generation of slow-phase eye movements in response to horizontal full-field visual motion. In normal monkeys, the NOT on each side is driven binocularly and responds well to visual stimuli presented to either eye. In monkeys with LN, each NOT is driven mainly by the conrralateral eye. Thus in the altered monkeys, when only one eye is viewing, one optic tract nucleus is stimulated, causing an imbalance between each NOT; this imbalance is believed to be responsible for LN (Kaminski and Leigh 1997). Interestingly, under monocular viewing conditions, patients with congenital esotropia have poor temporal-ro-nasal pursuit, and some have LN or MLN. Indeed, LN may be unmasked in dim light or by shining a bright light at the dominant eye, as when testing pupil reflexes, in esotropic patients.

Spasmus Nutans

Spasmus nutans is a transient, high-frequency, low-amplitude pendular nystagmus that occurs between the ages of 6 and 12 months and lasts approximately 2 years but

occasionally as long as 5 years. The direction of the oscillation may he horizontal, vertical, or torsional and is often dysconjugate, asymmetrical, even monocular, and variable. It may he associated with torticollis and tituhation (spasmus nutans triad}. The titubation (head nodding) has a lower frequency than the nystagmus and is thus not compensatory. Patients can improve vision by vigorously shaking the head, presumably to stimulate the vestibulo-ocular reflex and suppress or override the ocular oscillation. Some patients may have esotropia. Although spasmus nutans is a benign and transient disorder, it must be distinguished from acquired nystagmus caused by structural lesions involving the anterior visual pathways in approximately 2% of patients. In the latter situation, a careful ophthalmological examination reveals clinical evidence, such as impaired vision, a relative afferent pupillary defect, or optic atrophy. Retinal disorders may also masquerade as spasmus nutans; paradoxical pupil constriction in darkness is suggestive, but an electroretinogram is confirmatory.

Pendular Nystagmus

Pendular nystagmus (see Figure 16.17A) has a sinusoidal waveform and is usually horizontal. It may be either congenital or acquired. Large amplitude ("searching") pendular nystagmus is usually associated with poor vision as a result of afferent disorders such as optic atrophy. The most common cause of acquired pendular nystagmus is multiple sclerosis, followed by brainstem vascular disease involving the deep cerebellar nuclei or their efferent connections. Other disorders of myelin, including Cockayne's syndrome, Pelizaeus Mcrzbachcr disease, and toluene abuse can cause pendular nystagmus.

Barton and Cox (1993) found on magnetic resonance imaging (MR1) changes in the dorsal pontine tegmentum in their patients with pendular nystagmus, implicating the central tegmental tract, which is also affected in oeulopalatal myoclonus (discussed later in this section). Lopez et al. (1995) confirmed this by demonstrating a predominance of pontine lesions on MRI in patients with horizontal pendular nystagmus and a predominance of medullary lesions in those with torsional pendular nystagmus. The extent of involvement of the central tegmental tracts, the medial vestibular nuclei, the paramedian tracts, and the inferior olives led them to hypothesize that deafferentation of the inferior olive, by injury to the tracts projecting to it, is partly responsible for the rhythmic pendular oscillations. Disruption of preuuclear ocular motor pathways necessary for orthotropia (and conjugacy) must also be affected.

Convergent-divergent nystagmus, a rare variant of acquired pendular nystagmus, is dysconjugate and occurs in patients with demyelinating disease, brainstem stroke, Chiari malformations, cerebral Whipple's disease (see Oculomasticatory Myorhythmia, later in this chapter), and progressive ataxia (Averbuch-Hcllcr ct al. 1995a, 1995b). The eyes oscillate, mainly horizontally, in opposite directions simultaneously, although they sometimes form circular, elliptical, or oblique trajectories, depending on the phase relationship of the horizontal, vertical, and torsional vectors responsible for the oscillations,

Cyclovergcnt nystagmus (i.e., dysconjugate torsional nystagmus in which the upper poles of the eyes oscillate in opposite directions) was detected, by scleral search coil oculography, in a patient with progressive ataxia and palatal myoclonus (Averbuch-Hellei et al. 1995a). On rare occasions, cyclovergcnt nystagmus may be observed clinically.

Vertical pendular nystagmus closely resembles the vertical ocular oscillation associated with palatal myoclonus (the oculopalatal syndrome) (Dell'Osso and Daroff 1999a) and may be a form of the same disorder, which also results from lesions of the deep cerebellar nuclei and their connections.

Elliptical pendular nystagmus, with a larger vertical component and superimposed or interposed upbeat nystagmus, is characteristic of Pelizaeus-Merzbacher disease. This nystagmus can be difficult to discern with the naked eye. It is seen more easily with an ophthalmoscope, but oculography using scleral search coils may be necessary to detect it (Dell'Osso and Daroff 1999b).

Oculomasticatory Myorhythmia

Oculomasticatory myorhythmia, described in patients with Whipple's disease and, to date, pathognomonic of that disorder, consists of continuous rhythmic jaw contractions synchronous with dissociated pendular vergence oscillations. It may be associated with supranuclear vertical gaze palsy, altered mentation, somnolence, mild uveitis, or retinopathy (Knox et al. 1995). Myorhythmia of the face and arms is described in Hashimoto's encephalopathy (Erickson et al. 2002),

Pendular Pseudonystagmus

Patients with vestibular end organ damage and "essential" head tremor may develop pendular pseudonystagmus to compensate for an absent or defective vestibulo-ocular reflex (see Chapter 39). In the absence of a normal vestibulo-ocular reflex, head movements take the fovea off the target, causing blurred vision or oscillopsia. Eye movements, with longer latencies than normal vestibulo-ocular reflexes, are generated by alternative mechanisms (pursuit, cervico-ocular, and optokinetic movements) to maintain the fovea on target. This ocular oscillation, which is compensatory and not a sign of central nervous system disease, disappears when the patient's head is held still.

Gaze-Paretic Nystagmus

Gaze-paretic nystagmus, the most common type of nystagmus, is usually symmetrical and evoked by eccentric gaze to either side, but it is absent in the primary position,

It is also commonly present on vertical gaze with upward - beating nystagmus on upgaze and downward-heating nystagmus on downgaze. It may be asymmetrical with asymmetrical central nervous system disease or disorders such as myasthenia. It has a jerk waveform with the fast phase in the direction of gaze. Oculographic recordings show a decreasing exponential slow phase (see Figure 16.17C). Gaze-paretic nystagmus results from dysfunction of the neural integrator (see Chapter 39) and is commonly caused by alcohol or drug intoxication (anticonvulsants and tranquilizers). When it is caused by structural disease, it tends to be asymmetrical.

Vestibular Nystagmus

Vestibular nystagmus results from damage to the labyrinth, the vestibular nerve, the vestibular nuclei, or their connections in the brainstem or cerebellum. Vestibular nystagmus may be divided into central and peripheral forms on the basis of the associated features outlined in Chapter 18. Peripheral vestibular nystagmus, caused by dysfunction ot the vestibular end organ or nerve, has a linear slow phase (see Figure 16.17B), whereas with central lesions, the slow phase may be variable. Peripheral vestibular nystagmus is usually associated with severe vegetative symptoms, including nausea, vomiting, perspiration, and diarrhea; it may also be associated with hearing loss and tinnitus. On the other hand, with central vestibular nystagmus, vegetative symptoms are less severe, but other neurological features may be present, such as headache, dysconjugate gaze, and pyramidal tract signs (see Chapter 22).

Caloric-Induced Nystagmus

Caloric-induced nystagmus is discussed in Chapter 41.

Physiologic Nystagmus

Physiologic (endpoint) nystagmus is a jerk nystagmus observed on extreme lateral or upward gaze. If the bridge of the nose obstructs the view of the adducting eye, physiologic nystagmus may be dysconjugate because the amplitude is greater in the abducting eye. A torsional component is sometimes seen. Physiological nystagmus is distinguished from pathological nystagmus by its sym- • metry on right and left gaze and by the absence of other neurological features; it is not present when the angle of gaze is less than 30 degrees from primary position, Oculographic recordings primarily demonstrate a linear slow phase (see Figure 16.17B) and may detect transient small-amplitude rebound nystagmus.

Dysconjugate Nystagmus

Dysconjugate (dissociated) nystagmus occurs when the ocular oscillations are out of phase (different directions).

Tabic 16.11: Causes of monocular nysraj>mus

Acquired monocular blindness (nystagmus in blind eye)
Amblyopia
Brainstem infarction (thalamus and upper midbrain)
lctal nystagmus
Internuclear and pseudointernudear ophthalmoplegia
Multiple sclerosis
Nystagmus with monocular ophthalmoplegia
Nystagmus with one eye absent
Pseudonystagmus (lid fasciculations)
Spasmus nutans
Superior oblique myokymia

It is seen with internuclear ophthalmoplegia (see Chapter *3>9),* other brainstem lesions (see convergent-divergent nystagmus under Pendular Nystagmus, earlier in the chapter), and spasmus nutans. Monocular nystagmus is also dysconjugate and may be associated with amblyopia and other forms of vision loss (Table 16.11).

Monocular Nystagmus

Monocular nystagmus may be pendular or jerk and may also be horizontal, vertical, or oblique. Oculographic recordings may reveal small-amplitude oscillations in the fellow eye. Monocular nystagmus may occur in patients with amblyopia, strabismus, monocular blindness, spasmus nutans, internuclear ophthalmoplegia, multiple sclerosis, rarely with seizures, and of course when the other eye is completely ophthalmoplegic or absent.

The Heimann-fSielschowsky phenomenon is a rare form of monocular vertical pendular oscillation, with a frequency of 1-5 *Hz,* that occurs in an amblyopic eye or after acquired monocular vision loss, such as cataract. In the latter situation, it may be reversible after successful treatment of the underlying condition.

Superior oblique myokymia may be mistaken for a monocular torsional or vertical nystagmus (see Tabic 16.11).

Upbeat Nystagmus

Upbeat nystagmus is a spontaneous jerk nystagmus with the fast phase upward while the eyes are in primary position (Hirose et al. 1998). It is attributed to interruption of the anterior semicircular canal projections, which are responsible for the upward vestibulo-oculat teflex, causing downward drift of the eyes with corrective upward saccades. The amplitude and intensity of the nystagmus usually increase on upgaze. This finding strongly suggests bilateral paramedian lesions of the brainstem, usually at the pontomedullary or pontomesencephalic junctions, the paramedian tract neurons in the lower medulla, or midline cerebellum (vermis). Rarely, upbeat nystagmus may be congenital, or result from Wernicke's encephalopathy or intoxication with anticonvulsants, organophosphates,

lithium, nicotine, or thallium (personal observation). In infants, upbeat nystagmus may be a sign of anterior visual pathway disease, such as Leber's congenital amaurosis {see Chapter 40), optic nerve hypoplasia, aniridia, or cataracts, Small-amplitude upbear nystagmus may be seen in carriers of blue-cone monoehromatism, whereas affected patients may have intermittent pendular oblique nystagmus. If the intensity of upbeat nystagmus diminishes in downgaze, base-up prisms over both eyes may improve the oscillopsia; gabapentin may also be helpful.

Downbeat Nystagmus

Downbeat nystagmus is a spontaneous downward-beating jerk nystagmus present in primary position and is attributed to either (1) interruption of the posterior semicircular canal projections, which are responsible for the downward vcstibulo-oeular reflex, causing upward drift of the eyes with corrective downward saccades, or (2) impaired cerebellar inhibition of the vestibular circuits for upward eye movements, resulting in uninhibited upward drifts of the eyes with corrective downward saccades. The amplitude of the oscillation increases when the eyes arc deviated laterally, and slightly downward (Daroff sign). Downbeat nystagmus may he apparent only with changes in posture (positional downbeat nystagmus), particularly the head-hanging position. Downbeat nystagmus results from damage to either the commissural fibers between the vestibular nuclei in the floor of the fourth ventricle or bilateral damage to the flocculus that disinhibits the VOR in pitch and occurs frequently with structural lesions at the craniocervical junction (Table 16.12). A thorough investigation for such should be made; MRI of the foramen magnum region, in the sagittal plane, is the investigation of choice. Olson and Jacobson suggested that some cases of unexplained downbeat nystagmus are caused by radiographically occult infarctions {2001), The lesions that cause downbeat nystagmus are bilateral {Brandt and Dietrich 1995).

Causes of downbeat nystagmus are listed in Table 16.12.

The treatment of downbeat nystagmus involves correction of the underlying cause, when possible. When downbeat nystagmus damps on convergence, it may be treated successfully with base-out prisms, reducing the oscillopsia and improving the visual acuity; baclofen or clonazepam may also help.

Both upbeat and downbeat nystagmus may be altered in amplitude and direction by a variety of maneuvers, such as convergence, head tilting, and changes in posture.

Periodic Alternating Nystagmus

Periodic alternating nystagmus (PAN) is a horizontal jerk nystagmus in which the fast phase beats in one direction and then damps or stops for a few seconds before changing direction to the opposite side. During the short transition period, the nystagmus may beat vertically, A complete cycle takes approximately 3 minutes. PAN has the same clinical significance as downbeat nystagmus and may sometimes coexist. Attention should be focused at the craniocervical junction. PAN may also occur in Crcutzfeldt-Jakob disease.

When PAN is congenital, it may be associated with albinism. In one series of patients with congenital PAN, none had pure vertical oscillations, even during the transition period (Gradstcin ct al. 1997). Although not all patients with acquired PAN have vertical nystagmus during the transition period, its presence may distinguish acquired from congenital PAN {author's personal observation); this finding does not obviate further evaluation, when appropriate. Transient episodes of PAN were provoked by attacks of Meniere's disease in a patient with a hypoplastic cerebellum and an enlarged cistcrna magna (Chiu and Hain 2002). Episodic PAN may be a manifestation of a seizure {see ictal nystagmus below). An atypical form of paroxysmal alternating skew deviation and nystagmus has followed partial destruction of the inferior uvula and

  - Multiple sclerosis
  - Vertebrobasilar ischemia

adjacent pyramis during biopsy of a suspected brainstem glioma (Radtke et al. 2001).

Although the pathogenesis of PAN is speculative, lesions of the cerebellar nodulus in monkeys and humans have produced this unusual oscillation. Furthermore, instability in the velocity storage mechanism (see Chapter 39), hyperactive vestibular responses, and poor vestibular fixation suppression, also found in patients with PAN, are attributed to involvement of the nodulus and uvula. Instability in the velocity storage and cyclical firing between reciprocally connected inhibitory neurons may be responsible for generating PAN.

Treatment of PAN should be directed at correcting the cause, such as a Chiari malformation, when possible. Baclofen is usually effective in the acquired form of the disease; Dextroamphetamine has improved PAN in a patient who also had rod-cone dystrophy and strabismus (Hertleetal. 2001b).

Rebound Nystagmus

Rebound nystagmus is a horizontal gaze-evoked nystagmus in which the direction of the fast phase reverses with sustained lateral gaze or beats transiently in the opposite direction when the eyes return to primary position; the latter is occasionally a physiological finding. It is caused by dysfunction of the cerebellum or the perihypoglossal nuclei in the medulla. Occasionally, rebound nystagmus may be torsional.

Centripetal Nystagmus

Cerebellar dysfunction can cause a form of gaze-evoked nystagmus in which rhe fast phase beats toward primary position (i.e., centripetally), and the slow phase drifts peripherally toward an eccentric target. Centripetal nystagmus is similar to rebound nystagmus and may result from overcompensation by the cerebellar nodulus and uvula to adjust for a directional bias by temporarily moving the null zone during eccentric gaze. Centripetal nystagmus, in both the horizontal and vertical plane, may be associated with Creutzfeldt-Jakob disease.

Convergence-Evoked Nystagmus

Convergence-evoked nystagmus is an unusual ocular oscillation, usually pendular, induced by voluntary convergence (see convergent-divergent nystagmus under Pendular Nystagmus, earlier in the chapter). The movements may be conjugate or dissociated. This condition may be congenital or acquired, such as in patients with multiple sclerosis (Barton et al. 1999). A jerk form has been associated with a Chiari I malformation. Convergence-evoked vertical nystagmus (upbeat more common than downbeat) also occurs. Convergence-evoked nystagmus should be distinguished from voluntary nystagmus and from convergence retraction nystagmus (sec Non-Nystagmus Ocular Oscillations, later in this chapter).

Seesaw Nystagmus

SSN is a spectacular ocular oscillation in which one eye rises and intorts as the other eye falls and extorts. The waveform appears pendular. The oscillations usually become faster and smaller on upgaze but slower and larger on downgaze; they may cease in darkness. Disordered control of the normal ocular counter-rolling reflex (see Chapter 40) may be responsible. Bitemporal hemianopia, as a result of acquired chiasmal defects, or impaired central vision plays a significant role in generating SSN. Disruption of retinal error signals, necessary for vestibulo-ocular reflex adaptation, which are normally conveyed to the inferior olive by the chiasmal crossing fibers, results in an unstable visuovestibular environment. Fixation and pursuit feedback accentuate this instability, causing synchronous oscillations of floccular Purkinje's cells, which relay to the nodulus, and result in SSN. This mechanism may also be the basis for the ocular oscillations of oculopalatal myoclonus. The observations of SSN and CN in achiasmatic humans and achiasmatic Belgian sheepdogs support this hypothesis (Dell'Osso and Daroff 1998). Significantly, the onset of both SSN and oculopalatal myoclonus may be delayed after central nervous system lesions.

SSN occurs with lesions in the region of the mesodiencephalic junction, particularly the zona incerta and the interstitial nucleus of Cajal. Congenital SSN may be associated with a superimposed horizontal pendular nystagmus; some patients with congenital SSN may be achiasmatic or have septo-optic dysplasia. Acquired SSN may be associated with suprasellar tumors, Joubert's syndrome, and Leigh's disease, particularly the jerk form described below. Acquired SSN may be accompanied by a bitemporal hemianopia as a result of trauma, an expanding lesion in the third ventricular region, or severe loss of centra] vision caused by disorders such as choroiditis, cone-rod dystrophy, and vitreous hemorrhage (Dell'Osso and Daroff 1998).

Transient (latent) SSN may occur for a few seconds after a blink, perhaps because of loss of fixation, in patients with chiasmal region lesions,

If SSN damps with convergence, base-out prisms may be helpful. Baclofen may also improve SSN.

A jerk-waveform hcmi-SSN occurs with unilateral mesodiencephalic lesions, presumably due to selective unilateral inactivation of the torsional eye-velocity integraror in the interstitial nucleus of Cajal (see Chapter 39). During the fast (jerk) phases, the upper poles of the eyes rotate toward the side of the lesion. In hemi-jerk SSN caused by lateral medullary lesions, the fast phases jerk away from the side of the lesion. In both situations, the torsional component is always conjugate. With mesodiencephalic lesions, the

vertical component is always disjunctive {the eyes oscillate in opposite directions with the intorting eye rising and the extorting eye falling), but with medullary lesions it may be either conjugate {usually upward) or disjunctive. Other features of brainstem dysfunction may be necessary to localize the lesion.

Torsional (Rotary} Nystagmus

In torsional nystagmus (TN), the eye oscillates in a pure rotary or plane. TN may be present in primary position or with either head positioning or gaze deviation. It is usually the result of lesions in the central vestibular pathways. Pure TN occurs only with central vestibular dysfunction, whereas mixed torsional-linear nystagmus may occur with peripheral vestibular disease. When the waveform of torsional nystagmus is pendular (i.e., torsional pendular nystagmus), the lesion is usually in the medulla (Lopez et at. 1995). Skew deviation frequently coexists with torsional nystagmus (see Chapter *39).*

Torsional nystagmus with a jerk waveform, similar to jerk SSN, may be evoked by vertical pursuit eye movement and during fixation suppression of the vertical vestibulo-ocular reflex in patients with lesions of the middle cerebellar peduncle. The direction of the fast phase changes with direction- it is usually toward the side of the lesion on downward pursuit and away from the side of the lesion on upward pursuit (FitzGibbon et al. 1996).

Ictal Nystagmus

lctal nystagmus often accompanies adversive seizures and beats to the side opposite the focus, lctal nystagmus may be associated with transient pupillary dilation of either the abducting or adducting eye (Masjuan et al. 1997). Pupillary oscillations synchronous with the nystagmus may rarely occur. Nystagmus as the only motor manifestation of a seizure is rare; there are reports, however, of isolated ictal nystagmus, such as occurs in patients with vivid ictal visual hallucinations. Monocular nystagmus, associated with ipsilateral hemianopic visual hallucinations, in a binocular patient can occur as the only manifestation of a partial seizure caused by a focal discharge in the contralateral medial occipital lobe (Grant et al. 2002). It is difficult to draw any conclusion, clinically, regarding the location of the seizure discharge in these patients because seizure foci have been in occipital, parietal, temporal, and frontal areas. The nystagmus is usually horizontal, but there are occasional reports of vertical nystagmus, mainly in comatose patients. Periodic eye movements in comatose patients should alert the physician to the possibility of status cpilepticus; indeed, PAN associated with periodic alternating gaze deviation and periodic alternating head rotation may be a manifestation of a seizure (Moster and Schnayder 1998).

Brun's Nystagmus

Brun's nystagmus occurs in patients with large cerebellopontine angle tumors. The nystagmus is bilateral but asymmetrical with a jerk waveform. It is characterized by large-amplitude, low frequency oscillations on gaze toward the side of the lesion but small-amplitude, high-frequency oscillations on gaze to the other side. The ipsilateral large-amplitude (coarse) nystagmus has an exponentially decreasing-velocity slow phase attributed to compression of the brainstem neural integrator, which includes the ipsilateral medial vestibular nucleus (see Chapter 39). The contralateral small-amplitude, high-frequency nystagmus has a linear slow phase attributed to ipsilateral vestibular dysfunction (see Figure 16.17). Occasionally, an anterior inferior cerebellar artery territory stroke can cause Brun's nystagmus (author's personal observation).

Episodic Nystagmus

Episodic nystagmus is associated with a disorder in which the patient has paroxysmal episodes of vertigo, ataxia, and nystagmus lasting up to 24 hours. The nystagmus may be torsional, vertical, or dissociated. The frequency of attacks varies from once a day to only a few times per year. Such periodic ataxia occurs in patients with hereditary inborn errors of metabolism, in an autosomal dominant form without any detectable metabolic defect (channelopathy), and in patients with basilar migraine or multiple sclerosis. Accta/olaniiile may alleviate or prevent attacks in the familial form (see Chapter 78).

],id Nystagmus

I,id nystagmus, characterized by rhythmic jerking movements of the upper eyelids, occurs in the following situations: (1) synchronous with vertical ocular nystagmus; (2) synchronous with the fast phase of gaze-evoked horizontal nystagmus in some patients with the lateral medullary syndrome; (3) evoked by horizontal gaze in some patients with midbrain tumors; and (4) during voluntary convergence in some patients with brainstem or cerebellar disease (Dell'Osso and Daroff 1997a).

Nystagmus Treatment

Visual acuity should be corrected where necessary (Table 16.13), With the exception of CN, in which prisms, surgery, and contact lenses are helpful, the treatment of other forms of nystagmus is discouraging. Prisms are occasionally helpful in acquired nystagmus. Various pharmacological agents, including benzodiazepines, baclofen, isoniazid, trihexyphenidyl, tetrabennzine, prochlorper azine, carbamazepine, L-dopa, alcohol, and carisoprodol, have been tried. There has been some success treating

Tabic 16.13: Treatment of nystagmus and non-nystagmus oscillations (treat underlying cause where possible)

Nystagmus syndrome	*Treatment*
Congenital nystagmus	Prisms Contact lenses Extra ocular muscle surgery Kestenbaum-Anderson procedure Tenotomy (experimental)
Acquired pendular nystagmus	Trihexyphenidyl, benztropine, gabapentin, memantine, valproate, diethylpropion hydrochloride
Convergence-evoked horizontal nystagmus	Base-in prisms
Downbeat nystagmus	Base-out prisms (if nystagmus damps with convergence) Base-down prisms over both eyes if intensity of nystagmus diminishes in upgaze Baclofen, clonazepam, gabapentin, scopolamine, 3,4-diaminopyridine
PAN	
Congenital	Dextroamphetamine, Baclofen (?), 5-HT
Acquired	Baclofen, Dilantin
Upbeat nystagmus	Base-up prisms over both eyes if intensity of nystagmus diminishes in downgazc Gabapentin
Ocular myoclonus	Chronically patch one eye Baclofen, carbamazepine, cerulein, clonazepam, gabapentin, scopolamine, trihexyphenidyl, valproate,
Seesaw nystagmus	Baclofen, clonazepam, base-out prisms
Ictal nystagmus	Anti-epileptic drugs
Episodic nystagmus	
Episodic ataxia!	Acetazol amide
Episodic ataxia-2	Acetazolamide
Oculomasticatory myorhythmia	Antibiotics for Whipple's disease
Non-nystagmus ocular oscillations	*Treatment*
Opsoclonus	Steroids, clonazepam, ondansetron, if paraneoplastic protein A immunoabsorption
Superior oblique myokymia	Gabapentin, oxcarbazepine, other AEDs, topical beta-blockers, sumatriptan—transient effect (Quisling and Donahue, in press), base-down prism over the affected eye, muscle/tendon surgery, microvascular decompression
Ocular neuromyotonia (see Chapter 39)	Carbamazepine
Microflutter	Propranolol, verapamil
Square wave jerks (see Chapter 39)	Valproate (Traccis et al. 1997)
Square wave oscillations (see Chapter 39)	Valproate (Traccis ct al. 1997)

acquired pendular and downbeat nystagmus with the central muscarinic antagonists benztropine and scopolamine. Gabapentin, memantine, and valproate may be effective in acquired pendular nystagmus; clonazepam, baclofen, 3,4-diaminopyridine, and gabapentin may be helpful in downbeat nystagmus (Averbuch-I Idler et al. 1997; Strupp et al. 2003), as is gabapentin in upbeat nystagmus. Otherwise, with the exceptions of clonazepam and baclofen for acquired PAN and upbeat and downbeat nystagmus, and trihexyphenidyl for the pendular nystagmus of multiple sclerosis, there has been little success. For an extensive review, see Leigh et al. (1994) and Stahl et al. (2002).

NON-NYSTAGMUS OCULAR OSCILLATIONS

Voluntary Nystagmus

Voluntary nystagmus is not true nystagmus but, rather, ocular flutter under voluntary control. It consists of a series of fast (saccadic) back-to-back eye movements, without any interval or slow phase (Figure 16.18A). The oscillation is usually horizontal but may be vertical, torsional, or, rarely, cycloid (author's personal observation). The ability to induce flutter voluntarily tends to be familial. Subjects usually converge to initiate the oscillation but are unable to sustain it for longer than 30 seconds. Occasionally, patients use this ability to feign acquired illness, but the phenomenon should be easily recognized.

Ocular Flutter

Ocular flutter (see Figure 16.18A) occurs with brainstem or cerebellar disease and consists of horizontal conjugate back-to-back saccades that occur spontaneously, in intermittent bursts. It is aggravated by attempts at fixation. Occasionally, it is triggered by a change in posture. Ocular flutter results from loss of pause cell inhibition of the burst neurons in the paramedian pontine reticular formation (PPRF) (see Chapter 39) caused by cither injury to die I'PRl (Schon et al. 2001) or to the cerebellar neurons that

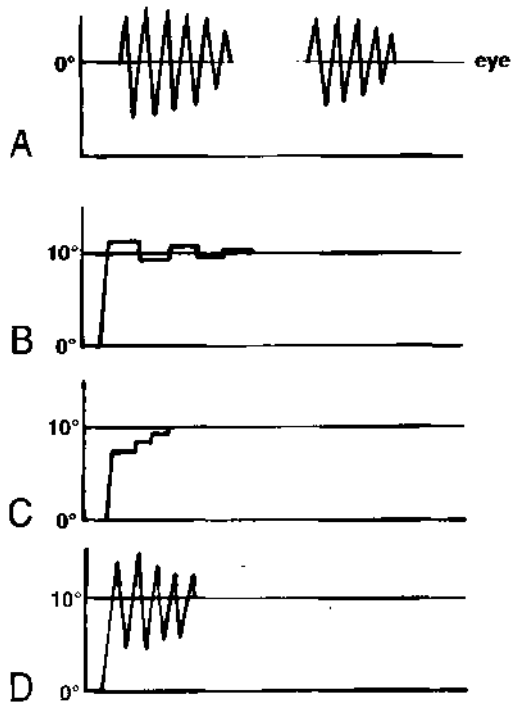

FIGURE 16.18 (A) Spontaneous ocular flutter in primary position. (B) Overshoot dysmetria (hypermetria). (C) Undershoot dysmetria (hypomctria). (D) Flutter dysmetria exacerbated by refixation of 1-10 degrees.

influence the pause cells, or both. Flutter is often associated with ocular dysmetria and may progress to opsoclonus.

Microsaccadic Ocular Flutter

Microsaccadic ocular flutter, or microflutter, is a rare symptomatic ocular oscillation requiring magnification for detection (Dell'Osso and Daroff 1999b). Patients complain of episodes of "shimmering" vision. It has been associated with cerebellar degeneration and multiple sclerosis bur in some patients may be a variant of voluntary nystagmus. Microflutter may respond to propranolol or verapamil in individual patients (Leigh and Zee 1999).

Opsoclonus

Opsoclonus is a spontaneous, chaotic, multivector saccadic eye movement disotder that is virtually always conjugate. Opsoclonus is aggravated by attempts at fixation and may be associated with myoclonic jerks of the limbs and cerebellar ataxia (dancing eyes-dancing feet syndrome). It is caused by dysfunction of the pause cells in the pons (see Chapter 39) as a result of cerebellar or brainstem disease. The most common causes (Table 16,14) include viral or postviral encephalitis and toxic, metabolic, and

Table 16.14A: Causes of opsoclonus

Acquired immunodeficiency syndrome-related brainstem encephalitis or lymphoma
Adults: carcinoma (thiamine-responsive)
Biotin-responsivc multiple carboxylase deficiency
Children: neuroblastoma (corticotropin-responsive)
Drugs (amitriptyline, chlordecone, cocaine, dichlorodiphcnyltriehloroethane, haloperidol, phencyclidine, phenytoin, diazepam, thallium, toluene, vidarabine)
Encephalitis (viral, pyogenic)
Hashimoto's encephalopathy
Hydrocephalus
Hyperosmolar coma
Lipidoses
Multiple sclerosis
Paraneoplastic
Pontine hemorrhage
Postencephalitic
Thalamic glioma
Thalamic hemorrhage
Transient phenomenon in healthy neonates

paraneoplastic disorders. The paraneoplastic opsoclonus-myoclonus-cerebellar syndrome that is a manifestation of neuroblastoma (7%), found in children, may be responsive to adrenocorticotropic hormone. In adults, opsoclonus may accompany paraneoplastic parenchymal cerebellar degeneration as a result of a remote carcinoma or lymphoma. Opsoclonus may also occur in hyperosmolar states and with many drugs at toxic levels. The efficacy of immunotherapy in adults with paraneoplastic syndromes is difficult to assess because of spontaneous fluctuations and remissions. However, in addition to treatment of the underlying neoplasm, early and aggressive immunotherapy, including the use of immunoadsorption therapy with plasma exchange through a protein A column (Cher et al. 1995), may be effective in opsoclonus. Responsiveness probably depends on the degree of the inflammatory component rather than the neuronal loss. Opsoclonus may occasionally respond to thiamine or clonazepam.

Tabic 16.14B: Age-related likely causes and features of opsoclonus

Neonates	Parainfectious Paraneoplastic (neuroblastoma in chest or abdomen)
Fight months to three years	Neural crest tumor or regressed neural crest tumor
Greater than three years	Regressed neural crest tumor
Children with opsoclonus	Good prognosis for tumor Poor prognosis for ocular movements (Respond to ACTH)
Adults	Paraneoplastic (breast, ovary) (May respond to protein A immunoa bso rption)

Ocular Dysmetria

Ocular dysmetria occurs with rcfixation saccades that overshoot (see Figure 16.18B) the target and often oscillate before coming to rest (see Figure 16.18C). It results from cerebellar dysfunction (dorsal vermis and fastigial nuclei). There is an intersaccadic latency of approximately 200 milliseconds (Leigh and Zee 1999).

Flutter Dysmetria

Flutter dysmetria occurs immediately after the patient rcfixates on a target; the eye then briefly oscillates without intersaccadic intervals across the line of the target for a few cycles (see Figure 16.18D). Both flutter and opsoclonus result from dysfunction of the pause cells in the paramedian pontine reticular formation, which tonically suppresses the burst cells (see Chapter 39). The pause cells have input from the cerebellum; thus cerebellar or brainstem dysfunction may result in flutter or opsoclonus.

Convergence Retraction Nystagmus

Convergence retraction nystagmus is not a true nystagmus but a rapid dysmetric horizontal eye movement induced by attempted upward saccades. It occurs as part of the dorsal midbrain (Parinaud's) syndrome. Clinically, rapid convergence with synchronous retraction of both globes caused by simultaneous co-contraction of the extraocular muscles is followed by a slow divergent movement. Less commonly, if lateral rectus innervation is dominant, a rapid divergent movement occurs initially.

Ocular Bobbing

Ocular bobbmg is a rapid downward movement of both eyes followed by a slow drift back to primary position. The oscillation recurs between 2 and 15 times per minute and is found in patients, usually comatose, with severe central pontine destruction and horizontal gaze palsies (Table 16.15). In atypical bobbing, horizontal eye movements arc spared.

With *reverse bobbmg.*, the initial fast phase is upward, followed by a slow downward drift, whereas with *inverse bobbing (dipping),* the initial deviation is a slow downward movement followed by a rapid return to primary position. The latter two phenomena occur in patients with severe metabolic disorders or structural damage involving the inesodiencephalic region. Reverse dipping, a slow upward movement followed by a fast downward movement, was described in an obtunded patient with a seizure disorder and chronic meningitis. Bobbing may also be dysconjugatc (see Table 16.15).

V-parte in pretectal pseu do bobbing, a higher-frequency, more rapid downward convergent movement with a slower-than-normal return toward primary position, occurs with acute obstructive hydrocephalus and is an indication of urgent decompression.

Some patients may have more than one type of bobbing.

Ocular Myoclonus (Oculopalatal Tremor)

Ocular myoclonus is a vertical pendular oscillation, with a frequency of approximately 160 Hz, usually associated with similar oscillations of the soft palate (palatal tremor) and, sometimes, other muscles of the branchial origin (Leigh and Zee 1999). The latter condition, referred to as the oculopalatal syndrome, occurs after brainstem

Tabic 16.15: Ocular bobbing

7 ype	*Movement*	*Cause*
Ocular bobbing (atypical bobbing, horizontal eye movements preserved)	hast down; slow upward return to primary position	Severe central pontine destruction, central pontine myelinolysis, encephalitis, extra-axial pontine compression (usually a cerebellar hematoma), organophosphate poisoning
Reverse bobbing	Fast up; slow downward return to primary position	Usually nonlocali/ing encephalopathy: anoxia, metabolic encephalopathy, head injury, poststatus cpilcpticus
Dipping (inverse bobbing)	Slow down; fast upward return to primary position	Anoxic, metabolic, and toxic encephalopathies, poststatus cpilcpticus
Reverse dipping	Slow up; fast downward return to primary position	Cryptococcal meningitis or obtundation (in an acquired immunodeficiency syndrome patient), pontine stroke
V-pattern pretectal pseudobobbing	Fast downward convergent movements at higher frequency than typical bobbing; slower than normal return to primary position	Acute obstructive hydrocephalus

infarction, particularly of the pons, involving the central tegmental tract. Following a latency of months, hypertrophy of the inferior olives develops and the myoclonus begins. The association of a facial nerve palsy and the one-and-a-half syndrome (see Chapter 39} may predict the development of oculopalatal myoclonus, probably because of the proximity of the central tegmental tract to the facial nerve (Wolin et al. 1996). Oculopalatal myoclonus also is reported to occur spontaneously in association with progressive ataxia, with a fourth ventricular tumor, and hydrocephalus following subarachnoid hemorrhage (Eggenberger et al. 2001). Dysfunction of the cerebellar nuclei or their connections (Guillain-Mollaret's triangle) and disruption of retinal error signals relayed to the inferior olive may be responsible for oculopalatal myoclonus, which is confined to the muscles of branchial origin. Patients may get some relief from anticonvulsants such as carbamazepine, clonazepam, and valproic acid and agents such as trihexyphenidyl HCl and cerulein, or by chronically patching one eye.

Superior Oblique Myokymia

Superior oblique myokymia is a paroxysmal, rapid, small-amplitude monocular torsional-vertical oscillation caused by contraction of the superior oblique muscle predominantly on the right side (Yousry et al. 2002). Patients may complain of monocular blurring, torsional or vertical oseillopsi.t, torsional or vertical diplopia, or twitching ot the eye. Oculography using magnetic search coils (see Chapter 39) has demonstrated both phasic and tonic contractions of in torsi on, depression, and to a much lesser extent, abduction of the superior oblique muscle (Leigh and Zee 1999). MRI demonstrated that the affected superior oblique muscle was smaller in some patients, suggesting antecedent injury to the fourth nerve (Mehta and Demer 1994); this hypothesis is supported by an MRI finding of neurovascular compression of the fourth nerve at its root exit zone (Hashimoto et al. 2001; Yousry et al. 2002).

Superior oblique myokymia may be difficult to detect with the unaided eye and is more easily detected with a direct ophthalmoscope. It may be precipitated by activating the superior oblique muscle when the patient looks down in the direction of action of that muscle or tilts the head toward the affected eye. Superior oblique myokymia has a relapsing-remitting course in otherwise normal, healthy adults. It has been reported with adrenoleukodystrophy, lead poisoning, cerebellar astrocytoma, a dural arteriovenous fistula, and microvascular compression (Samii et al. 1995; Hashimoto et al. 2001; Yousry et al. 2002).

Superior oblique myokymia may respond dramatically to carbamazepine or gabapentin (Tomsak et al 2002). Propranolol in low dosage, amitriptyline, baclofen, phenytoin, benzodiazepines, and topical beta blockers (used for glaucoma) may also be helpful. A base-down prism in front of the affected eye may alleviate the patient's symptoms, avoid potential side effects of long-term medication, and avoid superior oblique muscle or tendon surgery, which some advocate when the disorder is prolonged. Disabling superior oblique myokymia may respond to microvascular decompression of the trochlear nerve at is root exit (Samii et al. 1995; Scharwey et al. 2000) and one patient artained transient relief with repeated use of sumatriptan, (Quisling and Donahue in press); the researchers suggesred the vasospastic effects of sumatriptan were responsible.

Table 16.16; Saccadic oscillations (see Chapter *39)*

Flutter (voluntary, involuntary)
Flutter dysmetria
Microsaceadic flutter (variant of voluntary flutter?)
Opsoclonus
Macro square wave jerks (now designated square wave pulses)
Ocular bobbing, reverse and inverse bobbing, dipping, and reverse dipping
Superior oblique myokymia
Convergence-re traction nystagmus
Abduction nystagmus with internuclear ophthalmoplegia
Tic-like ocular myoclonic jerks (eye tics)

Saccadic Lateropulsion

See Chapter *39* for a discussion of saccadic lateropulsion.

Saccadic Intrusions and Oscillations

Saccadic intrusions, such as square wave jerks (see Chapter 39), are brief, unwanted, nonrepetitive saccadic interruptions of fixation (Table 16.16). Other intrusions are saccadic pulses (stepless saccades), which interrupt fixation and arc followed by a slow drift back on target (glissade); double saccadic pulses (fragment of flutter); and dynamic overshoots. Macrosaccadic oscillations, macro square wave jerks (Dell'Osso and Daroff 1999b), are saccadic oscillations that are discussed in Chapter 39.

Chapter 17
Pupillary and Eyelid Abnormalities

Terry A. Cox and Robert B. Daroff

ABNORMALITIES OF **THE** PUPILS

Clinical Presentation

The medical history of a patient rarely begins with the statement "I have unequal pupils." In fact, most patients with anisocoria {unequal pupils) first hear of it from a doctor, friend, or relative. Those who notice anisocoria themselves may confuse the diagnostician by giving a misleading account of the duration of the condition. Occasionally, a patient has visual dysfunction caused solely by abnormal pupillary size. Photophobia and slow dark adaptation occur when a fixed, dilated pupil fails to protect the retina from increased illumination. Less often, a complaint of poot night vision (or dim daytime vision) may atise in patients with small, poorly reactive pupils; this symptom is caused by pupils not dilating normally, which decreases the light-gathering power of the eye in conditions of dim illumination.

Because pupillaty disorders usually present as an abnotmality on physical examination father than a visual complaint, the following discussion is based on the various ways that abnormal pupils can be described by the clinician. Terms used include *anisocoria, poorly reactive pupils, light-near dissociation, pupillary irregularity,* and *hippus* (pupillary unrest); many pupillary disorders can be included in several of these categories. In her two-volume text, Loewcnfeld *(1999)* provides detailed discussions of all aspects of every pupillary abnormality. Thompson and Miller (1998) give a more succinct presentation.

Anisocoria

Many unilateral and bilatctal disorders affecting the iris or its innervation present as anisocotia, but there are only a few categories to consider in evaluating this sign: local disease of the eye, parasympathetic defects (affecting the third nerve or pupillary sphincter), sympathetic defects (affecting the ins dilator muscle or its innervation), and simple anisocoria.

A number of local conditions affecting the iris can cause unequal pupils. Blunt trauma to the eye can damage the pupillary sphincter, causing mydriasis with poor pupillary constriction to both light and near stimuli. Immediately after injury, the pupil may be smaller than normal, but after a few minutes, the pupil becomes dilated and poorly reactive. This course of events may simulate uncal herniation,

Acute inflammatory disease of the eye (iritis) can cause mild pupillary constriction. If inflammation petsists, adhesions between the iris and the anterior lens capsule may lead to pupillary irregularity and immobility. Usually, the inflamed eye is red and the patient has a great deal of photophobia. However, some chronic forms of iritis, such as sarcoid, can cause iris adhesions without these manifestations.

Ischemia of the iris can cause mydriasis and poor pupillary reactivity. Two situations in which ischemia occurs are acute angle-closure glaucoma and ocular ischemic syndrome; in both disorders, associated symptoms include poor vision and pain.

Syphilis causes a number of pupillary disorders, the best known being Argyll-Robertson pupils (see later discussion). A more common pupillary finding in syphilis, however, is anisocoria associated with degeneration of iris stroma.

Some rare forms of iris degeneration, such as essential iris atrophy and Fuchs' hetetochromic iridocyclitis, cause pupillary dilation, often with irregularity of the pupillary outline.

Causes of patasympathctic defects include oculomotor (third) nerve palsy, tonic pupils, and phatmacological mydriasis. Third cranial nerve palsies are discussed in Chapter 76. Usually, pupillary involvement in third ctanial nerve palsies is accompanied by paresis of other extraocular muscles; isolated pupillary dilation occurs most commonly in the setting of early uncal herniation.

Tonic pupils are characterized by light-near dissociation with slow redilation of the pupil after prolonged near effort. This condition is caused most often by Holmcs-Adic

(or Adie's) syndrome (Thompson and Miller 1998), a henign condition that usually affects only one eye. Holmes-Adie syndrome affects younger adults most often, and women are more commonly affected than men. Loss of one or more deep tendon reflexes occurs in 90% of cases. The site of ocular pathology is the ciliary ganglion, and the associated loss of accommodation often causes difficulties with reading. Tonicity of accommodation can cause periocular pain and headaches in some patients. The affected pupil tends to become smaller as time passes, and it may even be the smaller pupil when the patient first presents. Other causes of tonic pupil include orbital trauma, herpes zoster ophthalmicus, syphilis, temporal arteritis, and various peripheral neuropathies.

Pharmacological mydriasis usually occurs after accidental or intentional instillation of atropinic agents. Accidental mydriasis usually occurs by hand-eye contact in individuals who have contact with the agents; examples include use of a scopolamine skin patch for motion sickness and administration of eyedrops to a family member with eye disease. Pharmacologically dilated pupils tend to be larger than the dilated pupil of third cranial nerve palsy. Sympathomimetic agents, such as phenylephrine, cause mydriasis that is less extensive and prolonged than that caused by parasympathomimetic agents.

Sympathetic denervation causes pupillary miosis and ipsilateral ptosis (Horner's syndrome). Acutely, conjunctival vessels may he dilated, mimicking "pink eye."

Simple (physiologic, essential) anisocori.i occurs in approximately 20% of the normal population. Usually, the difference in pupil size is small—rarely more than 0.6 millimeters. The amount of anisocoria may differ in a given individual at different times. Pharmacological testing (Digre 1998) or pupillography may be necessary to confirm the diagnosis.

Episodic Anisocoria

Anisocoria may be intermittent. Simple anisocoria can vary from week to week and occasionally from hour to hour. A rare condition known as *tadpole pupils* results from intermittent spasms of segments of the pupillary dilator muscle; often, these patients have an underlying Horner's syndrome. A related phenomenon is oculosympathetic spasm associated with lesions of the cervical spinal cord.

In benign episodic unilateral mydriasis, episodes of pupillary dilation last from minutes to a few days (Jacobson 1995). Some patients have typical migraine headaches during the episodes, but most patients have only monocular visual blurring or no symptoms at all. The frequency of episodes varies from a few per week to one every few years. Some patients appear to have parasympathetic insufficiency and others sympathetic hyperactivity of the pupil, but no other neurological problems develop.

Cyclic oculomotor palsy is a rare condition in which periodic oculomotor spasms occur in a patient with third cranial nerve palsy. During the spasms, the eyelid rises, the exotropic eye moves to the midline, and the pupil constricts. In some cases, the spasms are limited to the pupil. Intermittent spasm of portions of the pupillary sphincter may occur in traumatic third cranial nerve paralysis and with aberrant oculomotor regeneration. Unilateral pupillary dilation and other pupillary signs can occur during seizures.

Poorly Reactive Puprfs without Anisocoria

Large pupils that arc poorly reactive but roughly equal in diameter can occur with hypothalamic and midbrain lesions, syphilis, botulism, the Miller Fisher variant of the Guillain-Barre syndrome, and autonomic neuropathy, Toxic and pharmacological causes should also be considered. Occasionally, bilateral mydriasis can be congenital. Anxious teenagers and young adults often have latge, poorly reactive pupils.

Small, poorly reactive pupils, often combined with simple anisocoria, are common in the aging individual (sometimes prematurely so). Other acquired causes of this finding include syphilis, diabetes, and long-standing Holmes-Adic pupils. Patients with glaucoma using drops containing pilocarpine have small pupils that do not react to light or near stimuli. Congenital miosis can be caused by Marfan syndrome or congenital rubella infection, but this may also be an isolated finding.

Light-Near Dissociation

The term *tight-near dissociation* refers to pupils that have marked diminution of constriction to light, with a much better constriction to near stimuli. When the pupils are large, the differential diagnosis includes syphilis, tonic pupils, pretectal lesions (Wilhelm et al. 2002), and bilateral afferent pupillary defects (e.g., from bilateral optic atrophy). Small pupils with light-near dissociation can occur in patients with syphilis (Argyll-Robertson pupils), long-standing Holmes-Adie pupils, and diabetic neuropathy. In some patients with aberrant regeneration of the oculomotor nerve, the pupil constricts poorly to light and much better with eye movements such as adduction; this disorder could be mistaken for true light-near dissociation.

Irregular Pupils

Irregular pupils are usually caused by local iris disease. Conditions mentioned earlier that cause pupillary irregularity include syphilis, ischemia, posterior synechiae (adhesions of iris to lens), traumatic iridoplegia, degenerative disease of the iris, and Holmes-Adie syndrome. Infiltration of the iris by tumor or amyloid can also cause irregular pupils. Oval or eccentric pupils (corectopia) may occur with midbrain disease and increased intracranial pressure.

Hippus (Pupillary Unrest)

In most individuals with reactive pupils, shining a lighr in the eyes elicits spontaneous conjugate oscillations in pupillary diameter. These movements are probably a result of changes in retinal illumination induced by pupillary movements (the pupil constricts, causing the light to appear dimmer; then it dilates, causing the lighr to appear brighter; then ir constricts, and so on), but oscillation in midbrain activity may play a role. Changes in the level of central nervous system alertness also cause the pupil to change size; somnolent individuals have large-amplitude, low-frequency oscillations in pupillary diameter just before they fall asleep.

Afferent Pupillary Defects

Pupillary defects caused by diseases of the afferent visual system arc discussed in Chapter 40.

Examination

Figure 17.1 provides a systematic approach to the evaluation of the patient with anisocoria. first, the pupillary response to light should he checked. Isolated Horner's syndrome affects pupil dilation only, sparing the light response, and anisocoria is less apparent in bright light. Simple anisocoria also tends to be less apparent in bright

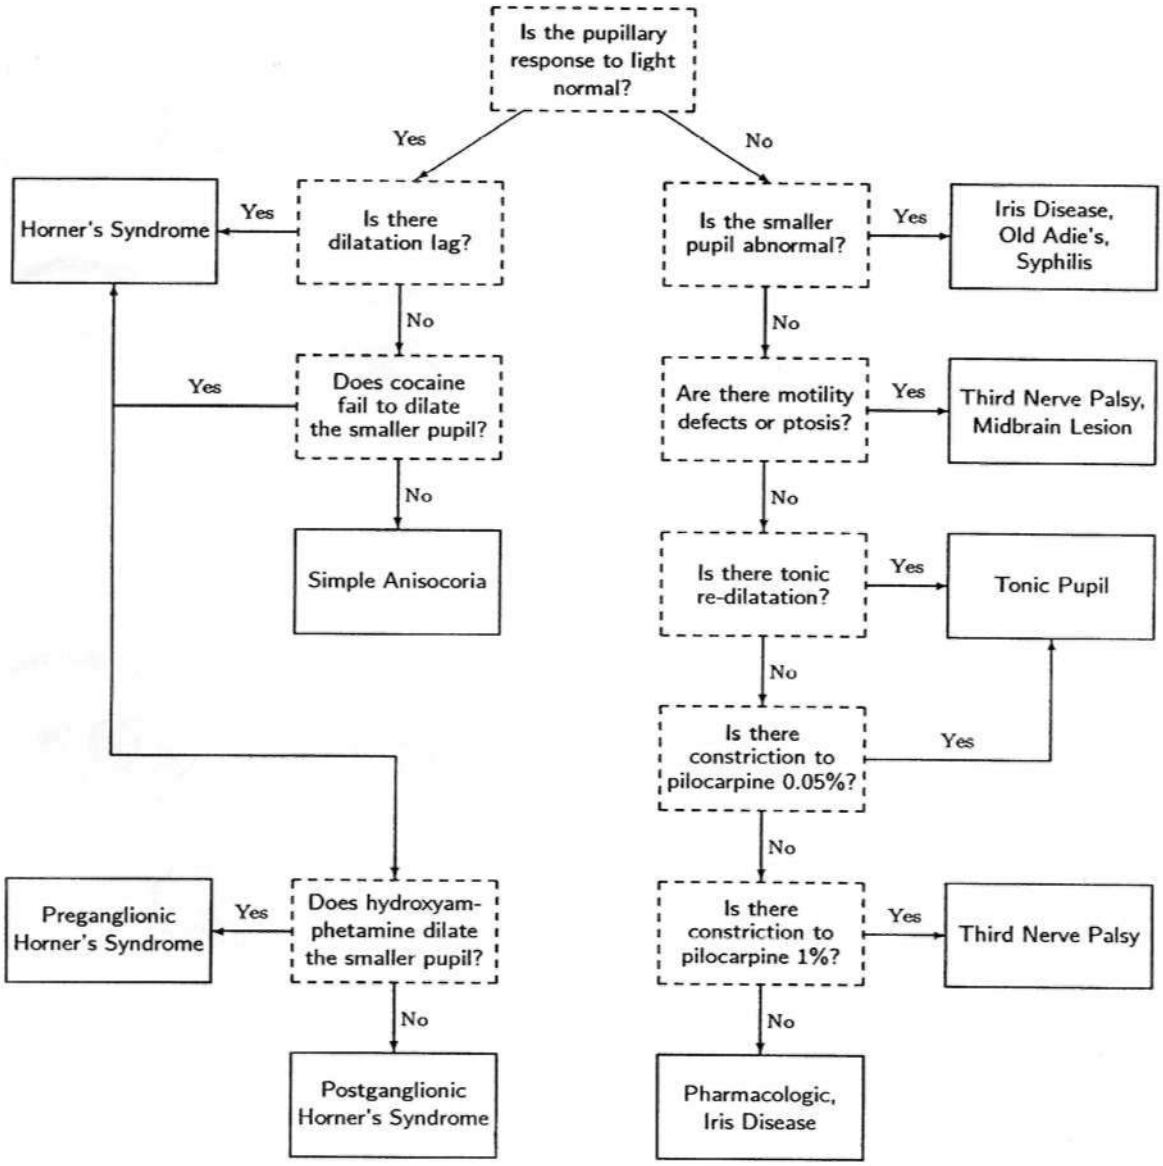

FIGURE 17.1 Flowchart for evaluation of anisocoria.

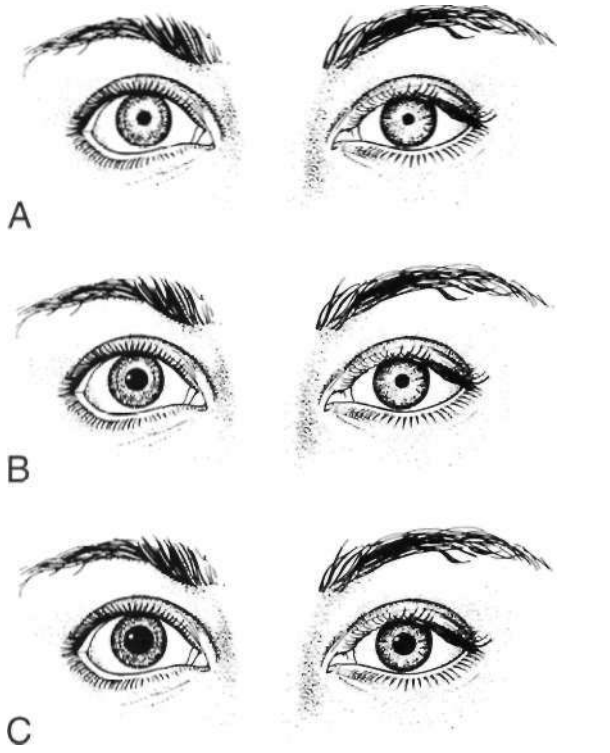

FIGURE 17,2 Homer's syndrome, left eye. (A) Room light. Mild upper lid ptosis and lower lid elevation, simulating enophthalmos. (B) Five seconds after lights off. Anisoeoria increases. (C) Fifteen seconds after lij-hts off. I)ilation las; manifested by more .nmocorui in middle than in bottom.

light. When the light response is abnormal, the iris sphincter on rhat side is defective. In this case, the differential diagnosis includes third cranial nerve palsy, traumatic iridoplegia, and pharmacological mydriasis. Table 41.1 provides a simple method for recording the examination.

If Horner's syndrome is a consideration, the pupils should be examined for dilation lag. The small pupil of Horner's syndrome dilates more slowly in darkness than the normal pupil. Therefore anisoeoria is maximal in these patients 3-5 seconds after the **lights** are turned off, compared to anisoeoria 15 seconds later (Figure 17.2). This sign is often difficult to elicit, particularly in brown-eyed individuals, because a certain amount of illumination of the pupils is necessary for the examiner to see. If there is any question about this finding, pharmacological testing should be done (Digre 1998).

If the pupillary response to light is poor, the reactivity to near should be assessed. If there is a near response, look for tonic redilation, a sign rhat establishes the diagnosis of tonic pupil. If a patient with a large unilateral tonic pupil has tonic redilation, the defective pupil can actually be transiently smaller than normal afrer near effort (Figure 17.3). Poor constriction to both light and near usually implies a local iris problem, parasympathetic defects, or midbrain disease; however, borh aging and anxiety may be causal.

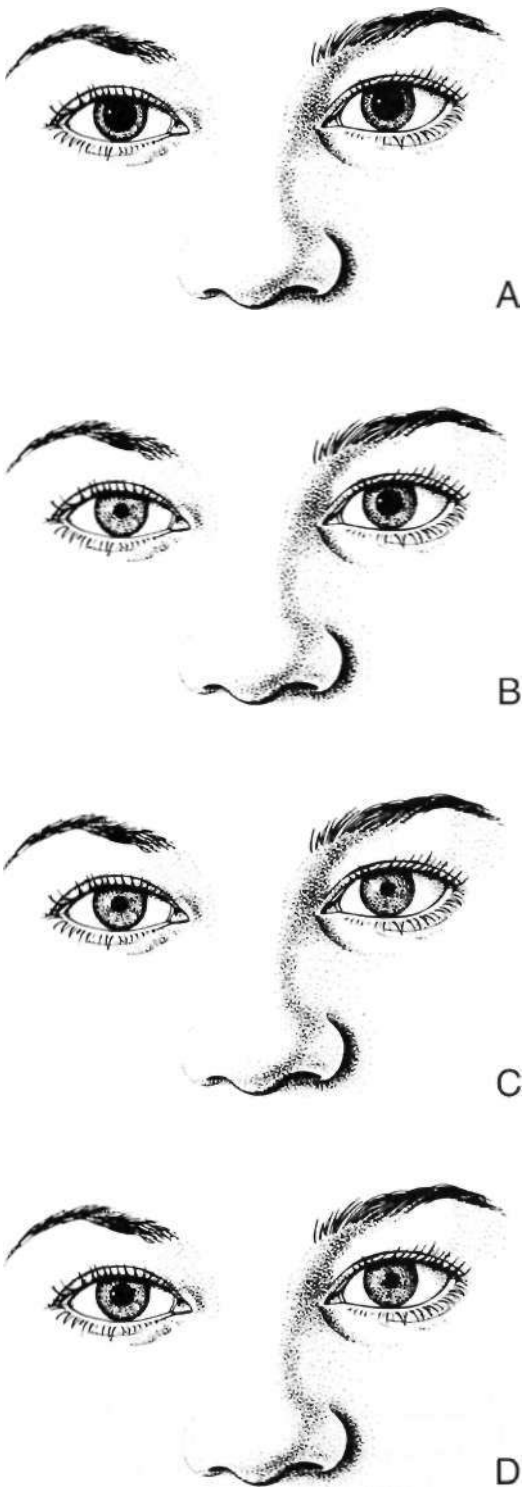

FIGURE 17,3 Tonic pupil, left eye. (A) Darkness. Anisoeoria is minimal. (B) Bright light. (C) Near, showing light-near dissociation. (D) A few seconds after return of gaze to a distant target, Tonicity of redilation on the affected side has caused transient reversal of anisoeoria.

After initial categorization of the pupil defect, the examination proceeds with evaluation of visual function, eyelid position, ocular motility, and the ocular fundus.

Light-near dissociation that is caused by visual sensory deficits can be diagnosed by testing visual acuity and visual fields (confrontation techniques are adequate) and looking for optic atrophy or other fundus abnormalities.

Both acute glaucoma and the ocular ischemic syndrome cause poor vision. Signs of acute glaucoma include corneal edema, ocular injection, and a pupil that is mid-dilated and unrcactive. The ocular ischemia syndrome arises in patients with marked stenosis of an internal carotid artery or narrowing of both internal and external carotid arteries on one side; associated eye findings include retinal neovascularization, rubeosis iridis, mild iritis, ocular hypotony, and corneal edema. Rubeosis iridis, a fine vascular network on the surface of the iris, is caused by diabetes, retinal vein occlusion, and other conditions associated with prolonged ocular ischemia.

Unilateral loss of accommodation often occurs in patients with parasympathetic denervation or pharmacological mydriasis; an eye with poor accommodation has greatly reduced near vision compared with distance vision.

Patients with Horner's syndrome have ipsilatcral ptosis, but this finding is not completely reliable. The combined prevalence of simple anisocoria and mechanical ptosis (congenital or senile) is such that a small pupil and ptosis do not always imply sympathetic denervation.

Generally, a third cranial nerve palsy can be diagnosed by associated findings of ptosis and limited ocular motility. Pretectal and other midbrain diseases that affect pupillary pathways cause abnormalities of ocular motility, such as upgazc palsy and convergence-retraction nystagmus. Irregular pupils caused by midbrain disease can be diagnosed by the associated neurological findings.

Assessment of deep tendon reflexes helps to establish the diagnosis of Holmes-Adie syndrome, and examination of the neck, brachial plexus function, and facial sweating pattern helps to localize the lesion in Horner's syndrome.

Investigations

Further evaluation of pupillary abnormalities begins with examination using the slit-lamp biomicroscopc or the ophthalmoscope with high plus lens. The Holmes-Adie pupil usually has segmental constriction to light, characterized by asymmetric contraction of the pupillary circumference. Similar segmental constrictions can be seen with eye movements in some patients with aberrant oculomotor regeneration. Eyes with traumatic iridoplcgia often have tears at the pupillary margin. Iris transillumination defects are usually seen in eyes with the small pupils of congenital rubella or Marfan syndrome, as well as in eyes affected by syphilis. Posterior synechiac can be seen only with **the slit** lamp. Ischemic eyes usually have rubeosis of the iris. Neurologists without access to a slit lamp can diagnose tonic pupils by using dilute pilocarpine as described later in this section.

Instillation of various drugs is often necessary to establish the cause of anisocoria (Loewenfeld 1999; Thompson and Miller 1998). Cocaine acts by blocking reuptake of notcpinephrinc; in a 44-10% solution, cocaine dilates the normal pupil of simple anisocoria but not the sympathetically denervated pupil of Horner's syndrome. Hydroxyamphetamine 1% acts by releasing norepinephrine from the presynaptic terminal and can be used for pharmacological localization of Horner's syndrome. When the lesion causing sympathetic denervation affects the postsynaptic pathway originating in the superior cervical ganglion, the nerve terminal degenerates, and norepinephrine is not available for release. More proximal lesions leave this neuron intact. Therefore hydroxyampheramine dilates normal pupils and those with preganglionic sympathetic lesions but not those with postganglionic sympathetic lesions. However, hydroxyamphetamine may dilate pupils with acute postganglionic lesions for the first week after onset. Hydroxyamphetamine eyedrops are no longer marketed in the United States but are obtainable from Leiter's Park Avenue Pharmacy, 1756 Park Avenue, San Jose, CA 95126 (www.lcitenx.com; phone SO0-2M2-6773).

Pilocarpine in a 0.05% solution is roo dilute to cause pupillary constriction, except in eyes with tonic pupils, where there is denervation suprasensitivity. Pilocarpine 0.05% is not commercially available and must be prepared from stronger solutions, diluted with normal saline without preservative. Pilocarpine in a 1% solution causes marked pupillary constriction in normal individuals and in those with third cranial nerve palsies but not in pharmacologic mydriasis. Eyes with local iris disease may or may not constrict in response to pilocarpine in a 1% solution, depending on the severity of involvement of the pupillary sphincter.

Examining old photographs of the patient (with a magnifying glass or ophthalmoscope) can help to establish the length of time that a pupillary abnormality has been present. Horner's syndrome that has been present for years has a better prognosis (less likely to be secondary to a serious condition) than Horner's syndrome that began in the past month, regardless of the localization. Old photographs may also help in establishing the diagnosis of episodic anisocoria.

Laboratory studies for tertiary syphilis (the fluorescent treponemal antibody absorption test or the microhemagglutination assay for *Treponema pallidum)* should be performed for any patient with bilateral tonic pupils, poorly reactive or irregular pupils, or pupils with light-near dissociation, if the cause is uncertain. Because of the high frequency of false-negative results, the serum Venereal Disease Research Laboratory test should not be used for detecting tertiary disease in these cases.

Almost all stable pupillary conditions will have been diagnosed by this point in the investigation. Further workup depends on the specific diagnosis. Preganglionic Horner's syndrome may require a chest radiograph, computed tomography of the brachial plexus, or magnetic resonance imaging of the head and cervical spine (Nagy et al. 1997), depending on associated findings. Postganglionic Horner's syndrome of recent onset may require investigation for carotid dissection. Episodic conditions may not be well characterized after the initial examination. In these cases, either performing follow-up office evaluations or having the patient take pupil photographs at home is necessary.

ABNORMALITIES OF THE EYELIDS

Clinical Presentation

Lid abnormalities present as ptosis, lid retraction, insufficient eyelid closure, or excessive lid closure. Ptosis causes symptoms when the lid or lashes intrude on the visual axis; more often, the drooping lid is perceived as a cosmetic defect. Lid retraction usually causes no symptoms. Insufficient lid closure may result in exposure keratitis, causing the patient to complain of eye pain and blurred vision. Blepharospasm or inappropriate levator inhibition {apraxia of lid opening) may cause a functional disability equivalent to severe bilateral vision loss. Sibony and Evinger (1998) provide an excellent, comprehensive review of the conditions discussed here.

Ptosis

Congenital ptosis can be caused by abnormalities of the levator muscle or its innervation and can be either unilateral or bilateral. Muscular abnormalities include congenital maldevelopment and neonatal myasthenia. Congenital abnormalities of innervation include trigeminal-levator synkinesis (the Marcus Gunn's jaw-winking phenomenon), Duanc's syndrome, third cranial nerve palsies, and Horner's syndrome. Trigeminal-levator synkinesis causes unilateral ptosis that varies in degree with movements of the jaw. This congenital condition can usually be diagnosed soon after birth: The affected infant has a drooping upper eyelid that twitches upward during bottle feeding or nursing. In older people, lid movements occur with opening the mouth, moving the jaw from side to side, or clenching the teeth. Duanc's syndrome consists of paresis of abduction, adduction, or both, associated with ptosis and globe retraction on attempted adduction, In this congenital condition, the third cranial nerve innervates the lateral rectus muscle, and the abducens nerve is absent.

One common cause of acquired ptosis is dehiscence of the levator aponeurosis. This condition occurs most often as an aging change (senile ptosis), but trauma can also be responsible, as in lid manipulation associated with contact lens wear. Ptosis can also occur when a contact lens becomes embedded in the conjunctiva of the upper lid. Other local lid diseases causing ptosis include inflammatory conditions, such as chalazion or giant papillary conjunctivitis, and infiltrative conditions, such as amyloidosis or lymphoma.

Myopathic causes of acquired ptosis include myasthenia, botulism, myotonic dystrophy, and chronic progressive external ophthalmoplegia (CPEO). In these cases, the associated systemic and ocular findings usually help the physician make the diagnosis. Myasthenia is the most common cause of acquired, isolated, painless, monocular ptosis.

Neuropathic causes of ptosis include Horner's syndrome, oculomotor paresis, Guillain-Barrc syndrome, midbrain lesions, and facial paresis. Ptosis and a number of other eyelid abnormalities can be caused by diseases affecting the cerebral hemispheres (Averbuch-Heller et al. 2002) (Table 17.1).

Pseudoptosis can be caused by blepharospasm, apraxia of lid opening, dcrmatochalasis, or contralateral lid retraction. The term *dcrmatochalasis* refers to redundancy of the skin of the eyelids, often associated with prolapse of orbital fat; treatment is surgical (blcpharoplasty).

Table 17,1: Lid abnormalities associated with cerebral hemisphere lesions

Lid abnormality	*Pathological findings*
Unilateral ptosis	Contralateral hemisphere lesions; contralateral and ipsilateral hemisphere lesions
Bilateral ptosis	Bilateral frontal lobe lesions; unilateral and bilateral hemisphere lesions
Impairment of voluntary lid opening and closure	Dominant hemisphere or bilateral hemisphere lesions or basal ganglia disease
Impairment of voluntary and reflex lid opening (apraxia of lid opening)	Basal ganglia disease; bilateral hemisphere lesions; nondominant cerebral lesion
Difficulty maintaining lid closure (motor impersistenee)	Nondominant hemisphere or bilateral hemisphere lesions
Difficulty maintaining lid opening (reflex blepharospasm)	Nondominant hemisphere or bilateral hemisphere lesions

M., Picone, C. M., et al. "Apraxia of eyelid opening secondary to right hemisphere infarction," *Ann Neurol,* vol. 25, pp. 622-624.

Lower lid elevation may accompany upper lid ptosis. Elevation of the lower lid occurs in enophthalmos (e.g., from orbital blowout fractures). The lower lid contains sympathetically innervated smooth (Midler's) muscle, and in Horner's syndrome, this muscle is paretic, causing lid elevation that mimics enophthalmos. Other causes of lower lid elevation are local edema, excessive lid closure (see Excessive Lid Closure, later in this chapter), and factitious ptosis.

Voluntary mimicking of ptosis by contraction of the orbicularis oculi causes lowering of the eyebrows and elevation and wrinkling of the lower lids.

Lid Retraction

Although elevated upper eyelids may be a normal variant, lid retraction is most commonly caused by hyperthyroidism or Graves* ophthalmopathy. It also occurs with increased adrenergic tone, as in very anxious patients.

In patients with thyroid disease, upper (and often lower) lid retraction may be present when the patient looks either straight ahead or down, and lid lag can be elicited by having the eyes pursue a target moving down (von Graefe's sign). Normally, the upper lid stays at the upper corneal limbus as the eyes move down; any visible sclera between lid and limbus during this movement is evidence of lid lag.

Patients with unilateral ptosis (e.g., from myasthenia) may have lid retraction on the opposite side. When the ptotic lid is raised manually, the retracted lid falls. Generally, these patients have contraction of forehead muscles as well. Patients with aberrant regeneration of the third cranial nerve often have retraction of the eyelid with depression or adduction of the eye (pseudo-von Graefe's sign). In patients with trigeminal-levator synkinesis, the affected lid may elevate with jaw movements so that the palpebral fissure is transiently wider than normal. Upper lid retraction occasionally occurs as part of Parinaud's dorsal midbrain syndrome (Collier's sign). Usually, there are also difficulties with conjugate upgaze, slow saccades upward, and vertical diplopia (see Chapter 22). Upper lid retraction may also occur in hepatic disease (Summerskill's sign) and Guillain-Barre syndrome. In Horner's syndrome, the smooth muscle of the upper lid often develops denervation supersensitivity. In stressful situations, circulating catecholamines can cause transient lid retraction on the affected side. Failure of levator inhibition (spastic eyelids) may occur with brainstem disease; in these patients, the eyes may remain open during sleep.

Lower lid retraction may be congenital, but more often it is a sign of proptosis. Lower lid retraction can also be caused by conditions that contract or displace the lid, including lower lid tumor or chalazion, trauma with scarring, and aging (senile ectropion). The lower lid may appear to be spuriously retracted in three situations: (1) when the contralateral lower lid is elevated (as in Horner's syndrome), (2) when the globe is elevated in conditions that cause hypertropia, such as fourth cranial nerve palsy, and (3) when the lower lid is weak from myasthenia or seventh cranial nerve palsy.

Insufficient Lid Closure

Poor eyelid closure does not usually pose a diagnostic dilemma but can cause serious ocular damage. Failure of the lids to cover the cornea during sleep, blinks, or forced eyelid closure results in exposure keratitis-—corneal epithelial defects, eye pain, and conjunctival injection—with the risk of corneal ulceration or scarring.

Insufficient closure of the eye can result from marked proptosis, but the more usual cause is weakness of the orbicularis oculi muscle. Such weakness can result from myasthenia, CPEO, myotonic dystrophy, or seventh cranial nerve palsy.

Another cause of insufficient lid closure with the threat of corneal damage is a reduced rate of blinking. This sign occurs frequently in patients with Parkinson's disease or progressive supranuclear palsy. In these disorders, blinks tend to be incomplete as well. Most normal blinks result in complete coverage of the cornea by the upper lid; incomplete or partial blinks cover only the superior cornea. Some normal individuals tend to have incomplete blinks, which are generally asymptomatic unless they try to wear contact lenses.

Excessive Lid Closure

The most common causes of excessive lid closure are blepharospasm, apraxia of lid opening, hemifacial spasm, myokymia, and myotonia. Blepharospasm consists of uncontrolled bilateral contraction of the orbicularis oculi causing eyelid closure (Figure 17.4). Ocular causes of photophobia and secondary blepharospasm include conjunctival disorders (dry eyes), cornea) disease (abrasion, keratitis), uveitis, and pupillary dilation (e.g., after an eye examination). When the condition is bilateral, with no associated ocular or neurological abnormalities, the diagnosis is benign essential blepharospasm, which is a focal dystonia. When there arc dystonic movements of the lower

FIGURE 17,4 Blepharospasm. Bilateral contraction of the orbicularis oculi.

face, jaw, tongue, or neck, the designation is otomandibular dystonia with blepharospasm (Meige's syndrome), a segmental dystonia. In Parkinson's disease and other disorders of the basal ganglia, the condition is called *central blepharospasm.* When orbicularis contraction occurs only with lid manipulation or other stimulation, the term *reflex blepharospasm* is sometimes used; this finding has been reported in patients with lesions of the cerebral hemispheres and in one family with no other neurological disorder. Most patients with parkinsonism have reflex blepharospasm, and all types of blepharospasm are made worse by lid manipulation or conditions causing photophobia. Factitious (voluntary) blepharospasm is rare.

The term *apraxia of lid opening* (Boghcn 1997) is used to describe inappropriate inhibition of the levator palpcbrac muscle that occurs in some patients with central nervous system disorders or bilateral or noudominant cerebral lesions or in association with benign essential blepharospasm. Rare patients have an isolated i.-dopa-responsive syndrome.

Hemifacial spasm is characterized by paroxysmal, involuntary, synchronous contraction of all muscles innervated by the facial nerve on one side (Figure 17.5) (see Chapters 76 and 77). Occasionally, the condition is bilateral; in these cases, the paroxysms on each side are asynchronous.

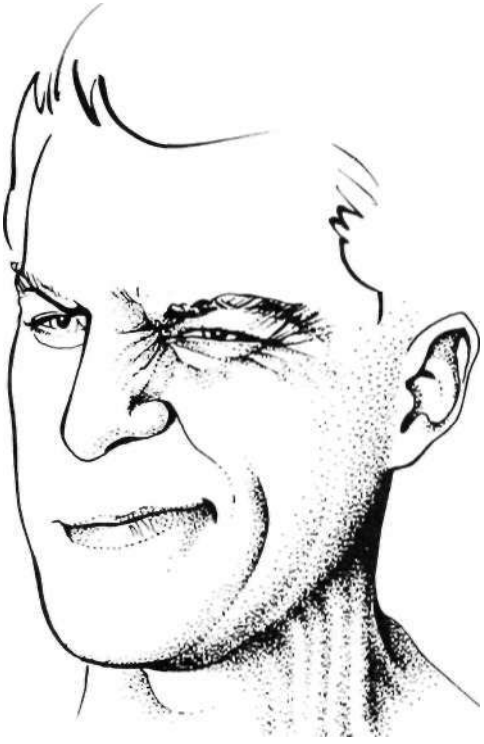

FIGURE 17.5 Hemifacial spasm. Synchronous contraction of muscles innervated by the left facial nerve, including platysma. Ohm, tilt- nrbimhns omii musdi's .ire involved ;is illuMr.ned. but with less obvious contraction of other facial muscles.

Involuntary twitches of portions of the orbicularis muscle (orbicularis myokymia, "live flesh") are common in normal individuals. These generally affect the lower eyelid; some patients describe oscillopsia when the twitches arc strong enough to move the globe. In facial myokymia, these muscular contractions involve other facial muscles. Occasionally, facial myokymia is associated with spastic paretic hemifacial contracture, a condition characterized by tonic contraction of facial muscles on one side with associated weakness of the same muscles. Facial myokymia may be unilateral or bilateral. This sign indicates brainstem disease; the most common causes are multiple sclerosis and brainstem neoplasm (usually gliomas), but Guillain-Barrc syndrome and extra-axial neoplasms may be causal.

Myotonia of lid closure may occur in myotonic dystrophy, hypothyroidism, and hyperkaiemic (and more rarely, hypokalemic) familial periodic paralysis.

Examination

Steps in the examination of the eyelids are summarized in Table 17.2. First, the eyelids and face should be observed and inspected and the blink rate measured. At rest, the upper eyelid normally covers the upper 1-2 mm of the cornea (Figure 17.6) and the upper border of the lower lid normally just touches the lower border of the cornea. In an eye with mild upper lid retraction (Figure 17.7), the lid just touches the upper limbus of the cornea, or sclera is visible between the cornea and the upper lid margin (superior scleral show). With lower lid retraction, sclera is visible between the cornea and the lower lid margin (inferior scleral show). Patients with factitious (voluntary) ptosis have some contraction of both upper and lower lid orbicularis; the contraction of the lower orbicularis raises the eyelid and wrinkles the skin near the lid margin. Patients with bilateral ptosis often have associated frontalis

Tabic 17.2: Clinical examination of the eyelids

Observe for at least 1 minute
Look for proptosis and enophthalmos
Assess lid position in different gaze directions
Observe gentle and forceful lid closure
Examine for pupillary and ocular motor abnormalities

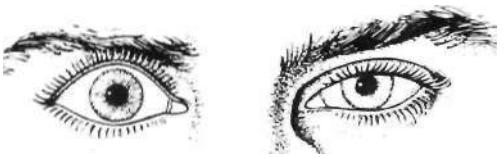

FIGURE 17.7 Lid retraction of the right eye and ptosis of the left upper iid.

contraction that elevates the eyebrows. Inspection of the lids is important to detect scarring or swelling caused by trauma, tumor, or inflammation; lid changes from these causes are usually not difficult to detect. Normally, the blink rate during conversation is at least 18 per minute. Patients with parkinsonism and related disotders often have a greatly reduced rate of normal blinks. Subtle seventh cranial nerve weakness may be manifested by incomplete spontaneous blinks on the affected side. In patients with excessive lid closure, the clinician should determine whether other facial muscles are involved, whether the contractions are synchronous in several facial muscle groups, and whether the problem is unilateral or bilateral. In hemifacial spasm, the facial muscle contractions are synchronous. In blepharospasm, the orbicularis contractions are bilateral and synchronous. Myokymic contractions involve smaller muscle groups and are not synchronous. Facial synkinesis after seventh cranial nerve paralysis can be evaluated by inspecting the lower face during spontaneous blinks; synkinetic mentalis, orbicularis oris, or platysma contractions are most common.

Proptosis (exophthalmos) can be evaluated by inspecting globe position with respect to the orbital rim by looking tangentially across the orbital margin from above, from below, or laterally.

The next step in the evaluation is to assess lid position in different gaze directions. Lid retraction on downgaze suggests lid lag or aberrant regeneration of the third cranial nerve. The latter condition also causes lid retraction on adduction. Ptosis on adduction occurs in Duane's syndrome. There are a variety of lid findings in myasthenia. Ptosis often worsens with sustained upgaze; after looking down, the patient's ptosis often improves. When the eyes return to the primary position after looking down for several seconds, the eyelids often demonstrate transient elevation before settling down to the previous ptotic position (Cogan's lid-twitch sign). Occasionally, several twitches occur before the lids stabilize. Transient elevation alone is not specific for myasthenia, but the twitches are virtually diagnostic of disease of the neuromuscular junction, such as myasthenia or botulism.

The next step is to observe both gentle and forceful lid closure. Fatigue of gentle lid closure occurs in myasthenia and can be demonstrated by asking the patient to close the eyes gently, as in sleep; after a few seconds, the lids may open slightly. Poor lid closure is the rule in facial weakness from disorders such as facial nerve paralysis and CPFO.

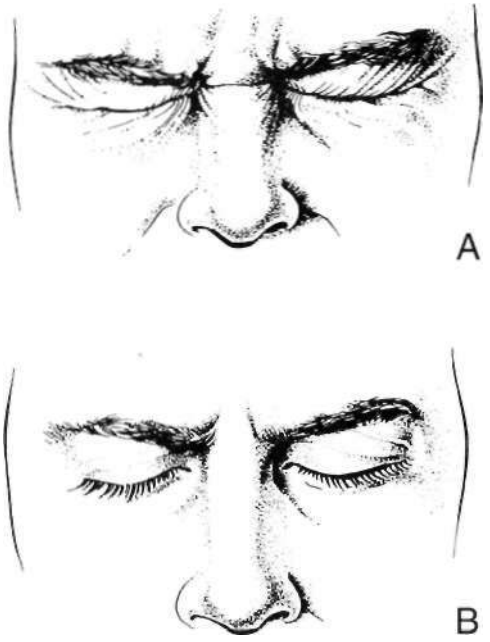

FIGURE 17.8 Forceful eyelid closure. (A) Normal forced eyelid closure. (B) Weak eyelid closure. The lashes remain visible.

Weak orbicularis function can also be assessed by asking patients to close their eyes forcefully (Figure 17.8). With forced eyelid closure, the eyelashes are normally buried by folds of skin; with even mild facial paresis, the lashes are more exposed. Forced lid closure with rapid reopening is an excellent technique for evaluating myokymia, hemifacial spasm, apraxia of lid opening, and blepharospasm, conditions that are often worsened by this maneuver.

Patients with apraxia of lid opening contract their forehead and elevate their brows when asked to open their eyes after forced lid closure, but their eyes remain closed (Figure 17.9). Patients with blepharospasm have persistent orbicularis contraction after being asked to open their eyes.

The next step is to look for abnormalities of the pupil and ocular motility, suggesting Horner's syndrome, third

FIGURE 17.9 Apraxia of lid opening. F.levated eyebrows and forehead contraction with persistent eyelid closure.

crania! nerve palsy, muscle disease, or congenital anomalies of innervation. Trigeminal-levator synkinesis can involve either external or internal pterygoid muscles. When the external pterygoid is involved, the eyelid rises with mouth opening or movement ot the jaw to the opposite side. With internal pterygoid involvement, the lid elevates with clenching of the teeth. Babies with this congenital condition have movements of the involved eyelid when they suck.

In patients with eyelid disturbances associated with more generalized disease, the neurological examination provides essential diagnostic information.

Investigations

Ophthalmologics! examination should be done in most patients with lid abnormalities. It should include exophthalmometry and tonometry in primary position and upgaze {an increase in intraocular pressure by 5 millimeters or more in upgaze suggests dysthyroid orbitopathy; low pressures occur in myotonic dystrophy). Slit-lamp examination for the lens opacities of myotonic dystrophy should also be performed, along with ophthalmoscopy to detect the pigmentary degeneration of the retina seen in some cases of CPEO and myotonic dystrophy. Cardiac evaluation of patients with CPEO is important because of associated heart block. Quantitative orbital echography is a sensitive test for detecting dysthyroid orbitopathy. Computed tomographic scanning of the orbit is the most useful test for evaluation of proptosis and enophthalmos. Magnetic resonance imaging of the head should be done in patients with blepharospasm, hemifacial spasm, and facial myokymia. Laboratory tests to consider include acetylcholine receptor antibodies and thyroid function studies.

The edrophonium test is essential in the diagnosis of myasthenia, but two other noninvasive procedures may be useful (Kubis ct al. 2000). The ice test consists of assessing changes in lid position before and after applying ice to the closed eye for 2 minutes. The sleep test consists of having the patient rest (or sleep) with closed eyes in a quiet room for 30 minutes and then assessing ocular motility and lid position immediately after the eyes are opened. Myasrhcnic ptosis is usually improved after cither of these tests.

Chapter 18
Dizziness and Vertigo

B. Todd Troost

Dizziness, vertigo, and disequilibration are common complainrs in patients referred for neurological evaluation. Because the entire physical examination and all diagnostic test results may be normal, the diagnosis depends primarily on the history. Vestibular tests (described in Chapter 41) rarely provide an exact diagnosis; they should be used as confirmatory measures in an attempt to document abnormality in the peripheral or central vestibular system.

SYMPTOMS AND SIGNS

Vertigo, strictly defined, refers to a hallucination of movement. Although some patients do experience a definite sense of environmental spin or self-rotation, the majority do not present solely with true vertigo as defined. The most common complaint is of *dizziness,* a term that represents a wide tange of symptoms (Table **18.1).** The first attempt should be to elicit an exact description of what the patient is experiencing. Is it a spinning sensation that could be characterized as vertigo, pointing to the peripheral vestibular apparatus? Is it a sensation of falling without rotation? Is it a sensation of unsteadiness or imbalance? Is there a particular direction in which the patient tends to fall? When the patient's complaint is actually of incoordination or clumsiness, the possibility of cerebellar dysfunction or peripheral neuropathy is raised. When the description is of lightheadedness or a swimming head, one thinks of pre syncope or syncope and would, perhaps, favor a consideration of systemic factors, including vasodepressor syncope, postural hypotension, or cardiac dysrhythmia (see Chapter 2).

After trying to define the true qualitative nature of the symptom complex, the neurologist must proceed to a consideration of temporal factors. Is the patient's experience continuous? Are there episodes of severe symptomatology with symptom-free intervals? If the symptoms ,irc episodic, do they occur only when the patient is upright?

Patients often have a great deal of difficulty describing their symptoms. Initially, it is paramount that patients provide their own description before the physician biases the outcome by suggesting desctiptive phrases. Often, patients who are asked to describe their symptoms without using the word *dizziness* cannot further characterize the symptoms but revert to descriptions such as "I'm just dizzy all the time."

The signs that accompany vertigo and dizziness depend primarily on the cause. When the cause is an acute peripheral vestibulopathy, the patient probably has a nystagmus with a fast phase beating away from the side of the involved car. The patient may tend to fall toward the side of the involved ear during a Romberg test and to past-point (i.e., overshoot when attempting to point at an object with the eyes closed) in a similar direction. If the symptom is really lightheadedness and the cause is postural hypotension, the drop in blood pressure should be documented on examination. Central neurological causes of dizziness are almost always accompanied by other signs of central nervous system (CNS) dysfunction, such as gaze-evoked nystagmus, facial weakness, other cranial nerve abnormalities, ataxia, hemisensory loss, or even paralysis.

If the cause is anxiety, the examiner may observe other signs of nervousness, such as tremulousness or hyperventilation.

ELUCIDATING THE HISTORY

In addition to determining whether the symptom complex is episodic, the history must define factors such as duration, length of symptoms, and any associated symptoms, such as

Tabic 18.1: Symptoms encompassed by the term *dizziness*

Blurring vision	Listing	Staggering
Bouncing	Moving	Swaying
Disorientation	Oscillating	Swimming
falling	Passing out	Tilting
Fainting	Poor equilibrium	Twisting
Floating	Rocking	Unsteadiness
Imbalance	Rolling	Vertigo
Lightheadedness	Spinning	Weaving

tinnitus, hearing loss, double vision, slurred speech, numbness, or weakness. A history of episodic discquilibration accompanied by diplopia, slurred speech, perioral numbness, dimming of vision, and occasional drop attacks suggests transient vertebrobasilar episodes. Are there associated symptoms, such as headache, and have they occurred before? If the patient has experienced severe episodes of imbalance in early life, followed by pulsating occipital or generalized headaches, the history is very suggestive of a basilar type of migraine. Did the dizziness follow head trauma, a systemic illness accompanied by aminoglycoside antibiotic therapy, or a mild upper respiratory tract infection? Episodic positional vertigo after head trauma is suggestive of cupulolithiasis {see Post-Traumatic Vertigo, later in this chapter). Did the symptom complex occur after ear surgery or infection, deep-sea diving, or a concussive blow to the ear? Such a history, with or without hearing loss, suggests a perilymph fistula.

In many large clinics dealing with balance disorders, a significant number of patients experience anxiety. If the symptom of disequilibrationor dizziness is of long duration, it is often difficult to tell whether the symptom complex is the result of anxiety or depression or the anxiety or depression is secondary to the dizziness. I believe that very few (<207o) patients with a clear movement sensation (vertigo) have a symptom complex caused solely by anxiety. One should be able to make a positive diagnosis of chronic-anxiety disorder based on other symptomatology and historical information. There usually is a history of previous episodes of serious depression or anxiety attacks (Baloh 1995).

Migrainous vertigo was reviewed by Neuhauser et al. (2001), who proposed new criteria for the definition of both probable and definite migrainous vertigo, finding that migraine is more common in dizziness clinic patients than in orthopedic controls and that patients who carry the diagnosis did not fill International Headache Society (1HS) criteria for migraine with aura- or basilar-type migraine (see Chapter 25). Physicians should ask for migrainous symptoms in patients with vertigo to determine whether they have migrainous vertigo and might be treated with antimigraine medication. Neurologists and neuro-otologists follow a large number of patients with chronic vertiginous sensations who remain undiagnosed. Such patients complain of constant or intermittent discquilibration, often aggravated by position change, as well as by visual stimuli, such as moving traffic, patterned wallpaper, striped rugs or curtains, or passing food displays in supermarkets. Many of these patients have become agoraphobic; they hesitate to leave their homes and particularly fear driving a car because of passing other automobiles. Some of these people have had a single attack of acute peripheral vestibulopathy but have never made appropriate central compensation or adapted to their peripheral abnormality. Although mechanisms for compensation remain unclear, most patients, particularly those younger than 30 years, rapidly recover from an acute peripheral vestibulopathy. Elderly patients or patients with a previously existing brainstem or cerebellar abnormality rarely make adequate compensation for an acute peripheral vestibulopathy. Such patients continue to complain of severe disequilibration. Symptoms may be exacerbated by various visual inputs. These dizzy patients have chronic symptoms and often consult more than one physician. They often have completely normal examination and vestibular test results.

Figures 18.1 and 18.2 illustrate what might happen after an acute peripheral vestibular abnormality. Figure 18.1 shows a different afferent input to the two peripheral end organs during the act of normal head turning. The stylized drawing is not meant to represent true anatomy but the concept of asymmetrical afferent input. The right panel of Figure 18.1 suggests that when there is a unilateral injury to one peripheral vestibular end organ, the result may be asymmetrical input to the CNS. This could be interpreted centrally as a sensation of turning or vertigo. In Figure 18.2, there has been, as a result of CNS plasticity, some attempt to compensate for an injured peripheral vestibular system. In this situation, there may still be a difference in afferent input, but adjustments have been made so that the patient no longer experiences a sensation of vertigo and no nystagmus is present. In some individuals, as shown in the right panel of Figure 18.2, there is either lessened or no ability to compensate for peripheral abnormality. One possible explanation for this is a congenital inability to make CNS compensation. Other explanations include (1) an acquired central inability to compensate because of a CNS lesion, as from multiple sclerosis or previous posterior circulation stroke; (2) *a* fluctuating peripheral vestibular problem, such as might occur in Meniere's disease; (3) relative physical inactivity without much afferent input; and (4) a peripheral vestibular apparatus providing inaccurate, though nonfluctuating, afferent information. Careful history taking may reveal childhood meningitis, a remote head injury, or particular susceptibility to motion sickness in childhood. An explicit search during the history should be made to define these possibilities.

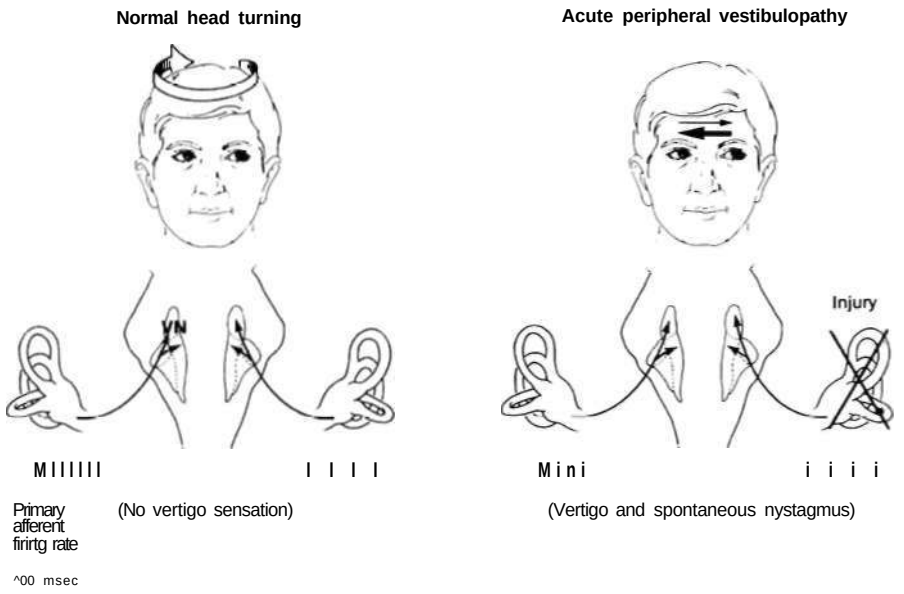

FIGURE 18.1 (A) Vestibular afferent input during normal horizontal head rotation to the right. Increased firing rate from right peripheral vestibular apparatus. Ocular deviation shows slow-phase deviation to the left. (VN = vestibular nuclei.) (B) Acute left peripheral vestibulopathy with resultant acute vertiginous sensation simulating head rotation to the right. Slow-phase ocular deviation to the left *{small arrow)* and fast phase of nystagmus to the right *[bold arrow)* and away from the side of the peripheral vestibular injury.

DIFFERENTIAL. DIAGNOSIS

Because ongoing or episodic conditions accompanied by vertigo, unsteadiness, or presyncope are produced by multiple and often subtle causes, a significant number of patients cannot be readily diagnosed. A major differential diagnostic classification includes broad categories, such as (1) peripheral vestibulopathy, (2) central neurological disorders, and (3) systemic conditions. There is some ambiguity in the term *central,* which otolaryngologists may use to include causes that are central, or proximal, to the vestibular end organ and therefore include the vestibular portion ot the eighth nerve. Neurologists, however, consider conditions that affect the vestibular nerve (e.g., tumors) peripheral in location because they are extra-axial. Because masses or neoplasms can enlarge to involve other structures in the cerebellopontine angle, particularly the brainstem, conditions that affect the eighth nerve are discussed in the central category.

Peripheral Causes of Vertigo

Peripheral causes of vertigo result from dysfunction of vestibular end organs (semicircular canals, utricle, and saccule) (Table 18.2).

Peripheral Vestibulopathy

Peripheral vestibulopathy has been described as *vestibular neuronitis, labyrinthitis,* or *viral neurolabyrinthitis.* Such terms imply an inflammatory mechanism, which is unproved. *Vestibular neuronitis,* strictly speaking, is characterized by single or recurrent sudden episodes of

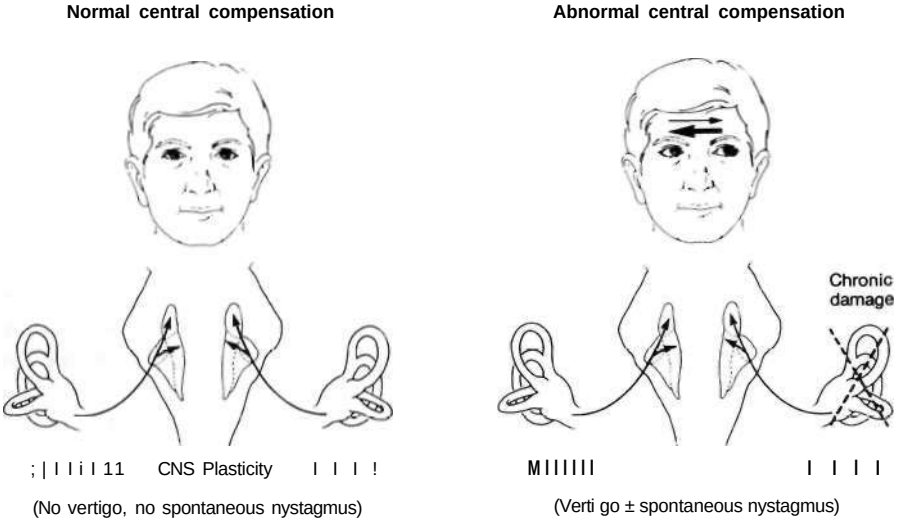

FIGURE 18.2 (A) Normal adaptation for prior left peripheral vestibulopathy. Despite a reduced firing rate from the left side, the central nervous system has compensated for the disparity and there is no nystagmus or vertigo. (B) Abnormal compensation for prior left peripheral vestibulopathy. The patient continues ro experience vertiginous sensations and may have nystagmus with a fast phase to the right *(bold arrow).*

Tabic 18.2: Peripheral causes of vertigo*

1. Peripheral vestibulopathy (includes labyrinthitis, vestibular neuronitis, and acute and recurrent peripheral vestibulopathy)
2. Benign positional vertigo (includes benign positional nystagmus, benign paroxysmal vertigo)
3. Post-traumatic vertigo
4. Vcstibulotoxic, drug-induced verrigo
5. Meniere's disease
6. Other focal peripheral diseases (includes local bacterial infection, degeneration of hair cells, genetic anomalies of labyrinth, cupulolithiasis, rumor of eighth nerve, otosclerosis, fistula of labyrinth, and, rarely, focal ischemia)

"Hearing loss is often present.

true vertigo lasting from hours to days and often associated initially with vomiting. When the condition is associated with hearing loss, the entire labyrinth is assumed to be involved, and the term *labyrinthitis* is used. Despite this technical distinction, many neuro-otologists, otologists, and neurologists use the terms *vestibular neuronitis* and *labyrinthitis* interchangeably, whether or not auditory symptoms are present. In such patients, the vertiginous sensation may be provoked by head movement but not necessarily by a particular head position.

Whether isolated viral involvemenr of the vestibular nerves is a cause of acute or episodic vertigo is controversial. Many prefer the term *acute* or *recurrent peripheral vestibulopathy.* In the acute phase, most patients presenr with sudden severe vertigo, nausea, and vomiting without any hearing disturbance or facial weakness. The acute symptoms usually resolve in a few days to a week but may recur in weeks or months. If true vertigo is part of the symptom complex, the condition is most likely to be associated with some disorder of the peripheral end organ. However, patienrs with either acute peripheral vestibulopathy or more commonly recurrent attacks may experience only a sensation of lightheadedness or floating or a feeling of "walking on tennis balls." Even if the patient has had hundreds of episodes, it is important to try to determine whether any of them were associated with spinning vertigo. With time, the nature of the patient's symptom complex may change, even with peripheral vestibulopathy, from vertiginous sensations to those of pure unsteadiness or disequilibration.

Epidemic and seasonal outbreaks of acute vertigo have suggested an infectious origin caused by viral disease, but this remains largely unproved. Viral labyrinthitis can also be part of a systemic viral infection, such as mumps, measles, infectious mononucleosis, or upper respiratory tract viral infections. Isolated viral infections of the labyrinth are also believed to cause the sudden onset of hearing loss, vertigo, or both, m children and adults. Otitic herpes zoster is an infection characterized by pain in the ear, followed in 1-10 days by a vesicular eruption in the external ear. When the seventh and eighth nerves are affected, there is a combination of facial weakness, heating loss, and vertigo known as the *Ramsay Hunt syndrome.* Whenever vertigo is associated with severe ear pain or facial pain, one must consider this possibility. A dyscsthetic area of skin may precede, by many days, the appearance of the skin eruption (see Chapter 76).

Benign Paroxysmal Positional Vertigo

Benign paroxysmal positional (or "positioning") verrigo (BPPV) is a symptom complex suggesting benign peripheral (end-organ) disease (Furman and Cass 1999). It is a major cause of vertigo. Historical factors that should lead to the consideration of BPPV include the following: (1) symptoms associated with certain head positions, (2) episodic rotational vertigo of brief duration, (3) antecedent episode of severe rotary vertigo with or without nausea and vomiting, associated with an upper respiratory tract infection that suggests prior viral neurolabyrinthitis, (4) history of head trauma before attacks of vertigo, (5) most severe symptomarology early in the day, with lessening symptoms as the day progresses, and (6) relative absence of spontaneous symptoms without head movement or position change. These symptoms, differentiated from central neurological symptoms, arc outlined in Table 18.3. The signs and symptoms of benign positional vertigo are transient and rarely last longer than 40 seconds. They usually occur when a certain position is assumed, such as lying down or turning in bed. Depending on whether the symptom (vertigo) or sign (nysragmus) is being emphasized, this condition can be called *benign paroxysmal positional nystagmus* or *BPPV.* Physical examination findings include (1) vertical rotary benign positional paroxysmal nystagmus produced by provocative maneuvers (Figure 18.3), (2) latency to onset of symptoms once precipitating head position is achieved, (3) short-duration nystagmus (3-30 seconds), and (4) adaptation of nystagmus and symptoms (i.e., disappearance with repeated maneuvers). The finding of rhe typical nystagmus on assumption of certain head positions is considered the most important physical finding in making the diagnosis of BPPV (Figure 18.4).

Post-Traumatic Vertigo

Post-traumatic vertigo immediately follows head trauma in most cases. It implies end-organ damage in the absence of other CNS signs and may be related to fracture of the temporal bone. The interval between injury and onset of symptoms can, however, be days or even weeks. The mechanism for the delay of symptoms is uncertain but may be hemorrhage into the labyrinth, with later development of serous labyrinthitis. Another mechanism for delayed post-traumatic positional vertigo is cupulolithiasis, in which the calcateous deposits (otoconia) of a damaged organ of the labyrinth are displaced to a sensitive region of the posterior canal, making it more susceptible to stimulation in certain head positions. Another possible mechanism

Table 18.3: Characteristics of peripheral versus central positional vertigo

Symjitinii iir s/yj;	*Peripheral*	*Central*
Latency (time to onset of vertigo or nystagmus)	0-40 sec (mean 7.8*)	No latency; begins immediately
Duration	<1 min	Symptoms may persist (signs and symptoms of single episode)
Fatigability (habituation) (lessening signs and symptoms with repetition of provocative maneuver)	Yes	No
Nystagmus direction	Direction fixed, torsional, up, upper pole of eyes toward ground	Direction changing, variable
intensity of signs and symptoms	Severe vertigo, marked nystagmus, nausea	Usually mild vertigo, less intense nystagmus, rare nausea
Reproducibility	inconsistent	More consistent

* According to Baloh, R. W,, Honrubia, V., & Jacobson, K. 1987, "Benign positional vertigo: Clinical and oculographic features in 240 cases," *Neurology,* vol. 37, pp. 371-378.

is the presence of freely moving pathological densities in the endolymph of the semicircular canal. This is known as the *canalitb theory* (Brandt, Steddcn, and Daroff 1994). In post-traumatic vertigo, the symptoms may be those of general peripheral vestibulopathy or benign positional vertigo. The prognosis is usually good, with symptoms gradually resolving within weeks to months. Disabling persistent positional vertigo that is untesponsive to medical therapy does occur, however. Most patients respond to exercise therapy, as described in Chapter 41 (Figure 18.5).

Drug Toxicity

Patients with dizziness produced by vestibulotoxic drugs are presumed or documented to have petsistent injury to the peripheral end organ. Among the agents causing such end-organ injury are the aminoglycosides. Streptomycin and gentamicin have their greatest effect on the vestibular end organ; kanamycin, tobramycin, and neomycin cause more damage to the auditory end organ (Minor 1998; Troost and Waller 1998). Patients usually report

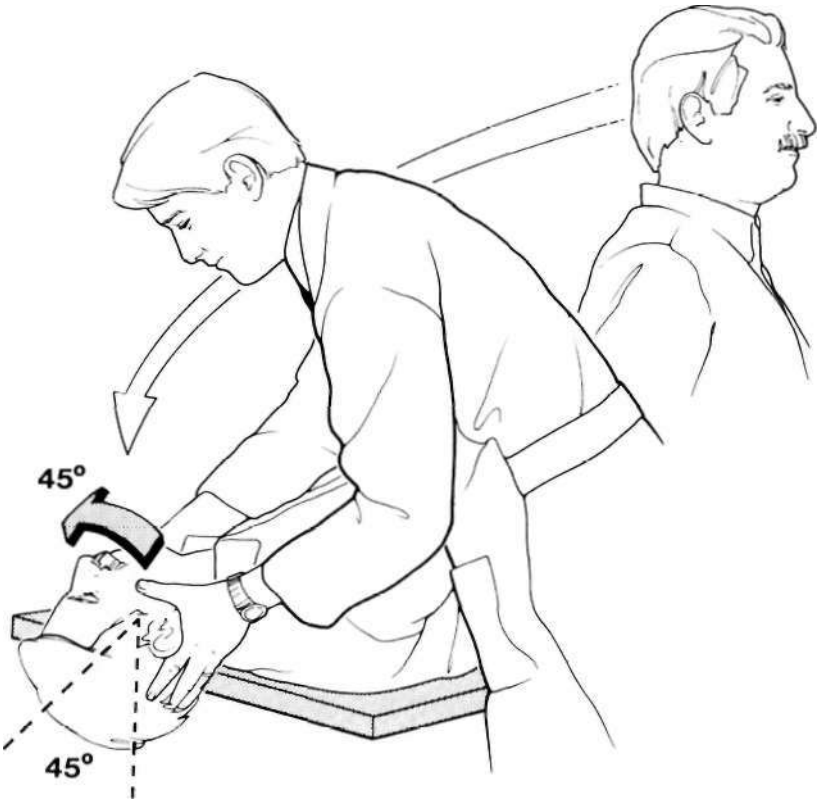

FIGURE 18.3 Provocative maneuvers for positional vertigo and nystagmus. The patient is abruptly moved from a seated position to one with the head hanging 45 degrees below the horizontal plane and rotated 45 degrees to one side. The patient is then observed for positional nystagmus. The maneuvers are repeated with the head straight back and turned to the other side.

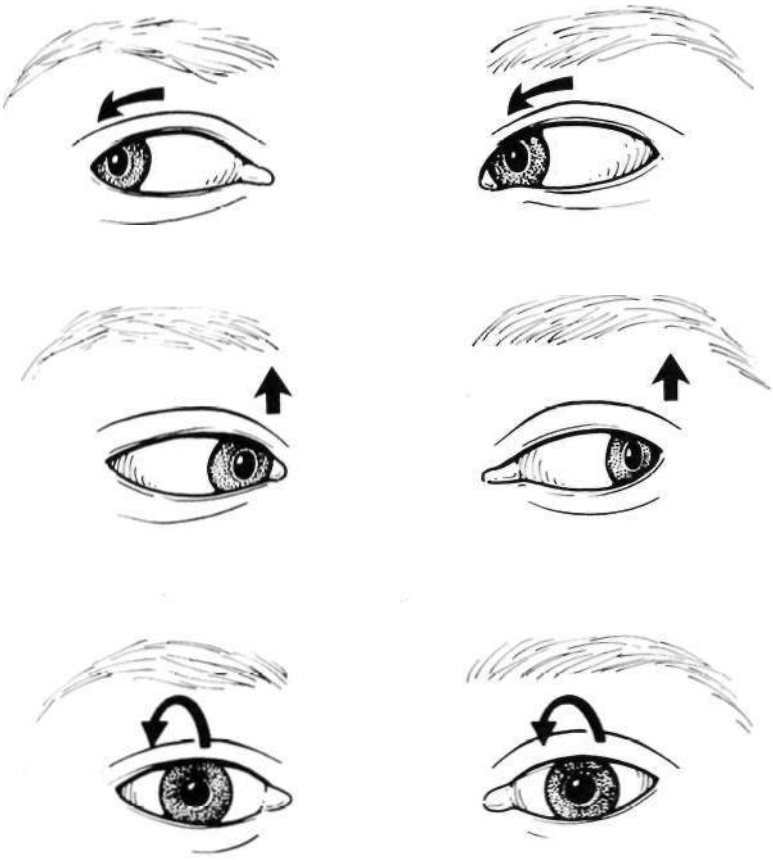

FIGURE 18.4 In benign paroxysmal positional vertigo, the nystagmus fast phase is horizontal-rotary directed toward the lower ear (A). The nystagmus fast phase is upward toward the tore-head when gaze is directed to the upper car (B). With the eyes in the central orbital position, the nystagmus fast phase is vertical upward and rotary toward the lower ear (C).

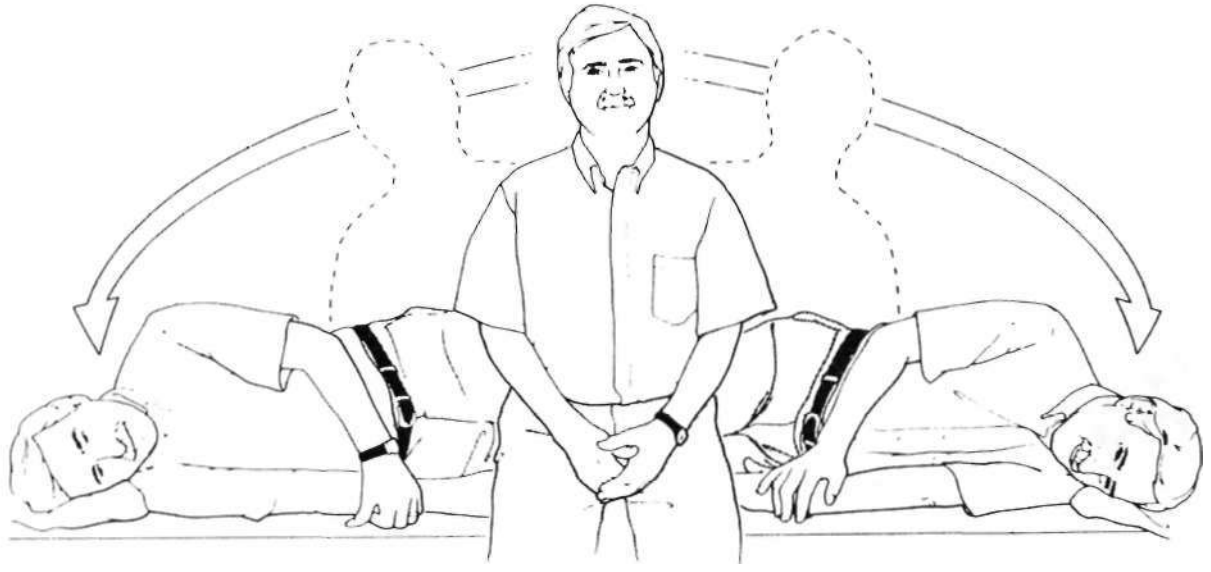

FIGURE 18.5 Exercise therapy. The patient begins in the seated position and then leans rapidly to the side, placing the head on the bed or table. The patient remains there until the vertigo subsides and then returns to the seated upright position, remaining there until all symptoms subside. The maneuver is repeated toward the opposite side, completing one full repetition. Ten to twenty repetitions should be performed three times a day.

Tabic 18.4: Systemic causes of vertigo and dizziness

t. Drugs (including anticonvulsants, hypnotics, antihypertensives, alcohol, analgesics, tranquilizers)
2. Hypotension, presyncopc (including primary cardiac causes and postural hypotension from a wide variety of causes)
3. infectious diseases (including syphilis, viral and other bacterial meningitides, and systemic infection)
4. Endocrine diseases (including diabetes and hypothyroidism)
5. Vasculitis (including collagen vascular disease, giant ceil arteritis, and drug-induced vasculitis)
6. Other systemic conditions [including hematological disorders [polycythemia, anemia, and dysproteinemia], sarcoidosis, granulomatous disease, and systemic toxins)

progressive unsteadiness, particularly when visual input is diminished, as happens at night or in a darkened room. Vestibular testing documents a progressive bilateral loss of vestibular function. The aminoglycosides are concentrated in the endolymph and petilymph, so the hair cells are exposed to high concentrations of the drugs. Extreme caution should be used in patients with even mild renal disease because most of these agents are primarily eliminated by the kidney. This type of end-organ toxicity should be contrasted with that produced by the large group of drugs with widespread reversible CNS and peripheral nervous system effects (Table 18.4); these drugs cause transient disequilibration, which subsides with cessation of the medication.

Meniere's Disease

Meniere's disease is characterized by attacks of severe vertigo and vomiting, tinnitus, fluctuating hearing loss, ill-described aural sensations of fullness and pressure, and spontaneous recovery in hours to days. Usually, the patient develops a sensation of fullness and pressure associated with decreased hearing and tinnitus in a single ear. This is followed by severe vertigo, which reaches peak intensity within minutes and slowly subsides over hours, with a persistent sense of disequilibration for days after an acute episode. Occasionally, severe attacks cause sudden falls to the ground. Consciousness is not lost in such episodes, although awareness of surroundings may be altered by the intensity of the accompanying vertigo nausea. The most consistent pathological finding in Meniere's disease is an increase in the volume of the endolymphatic fluid and distention of the canals, hence the term *endolymphatic hydrops* (Saced 1998). Although some specific causes, such as bacterial, viral, and syphilitic infections, may lead to the same pathological changes and symptoms, most cases are idiopathic.

Other Peripheral Vestibular Conditions

Many other disorders affect the peripheral labyrinth, including acute and chronic otitis media, hereditary degenerative disorders of the end organ, and local tumors. Conditions such as a vertebrobasilar transient ischemic attack (TIA) or focal ischemic stroke of the end organ, particularly in an elderly patient, are often cited as a cause of vertigo. Such isolated involvement is difficult to document, and vertebrobasilar insufficiency is unusual without associated brainstem symptoms and signs,

Central Causes of Vertigo

Central pathological causes of vertigo result from dysfunction of the vestibular portion of the eighth nerve, the vestibular nuclei within the brainstem, and their central connections (Table 18.5}. Neural connections with the central vestibular nuclei include the vestibular portions of the cerebellum (primarily the cerebellar flocculus, nodulus, and uvula).

Normal people experience physiological vertiginous sensations when visual and vestibular inputs are in conflict (such as in motion sickness or watching motion pictute automobile chase scenes), or when they are exposed to heights while standing on a ledge.

Central pathological causes of vertigo are less common than either peripheral or systemic causes, the vertiginous symptoms are usually less prominent, and additional neurological signs are usually present on examination (Froehling et al. 1994).

Brainstem Ischemia and Infarction

Vertigo, including brief episodes of isolated vertigo, can be caused by posterior circulatory disturbances (Baloh 2002), The posterior circulation supplies blood to the brainstem, cerebellum, and peripheral vestibular apparatus, in addition to other structures. In general, brainstem TIAs should be accompanied by neurological symptoms or signs, in addition to vertigo or dizziness, for a clear diagnosis to be entertained, but isolated episodes of vertigo lasting many minutes may be due to posterior circulation dysfunction.

Table 18.5; Central neurological causes of vertigo*

1. Brainstem ischemia and infarction
2. Demyelinatmg disease: multiple sclerosis, postinfectious demyelination, remote effect of carcinoma
3. Cerebellopontine angle tumor: acoustic neuroma, meningioma, cholesteatoma, metastatic tumor, etc.
4. Cranial neuropathy: focal involvement of eighth nerve or in association with systemic disorders
5. Intrinsic brainstem lesions (tumor, arteriovenous malformation)
6. Other posterior fossa lesions (primarily other intrinsic or extra-axial masses of the posterior fossa, such as hematoma, metastatic tumor, and cerebellar infarction)
7. Seizure disorders (rare)
8. Heredofamilial disorders (such as spinocerebellar degeneration) (Ohetal. 2001)

"Hearing loss is rare except in the condition listed in no, 3.

The usual TIA symptoms include transient clumsiness, weakness, loss of vision, diplopia, perioral numbness, ataxia, drop attack, and dysarthria (Chapter 57a). Common signs include disorders of motor function, such as weakness, clumsiness, or paralysis. A crossed detect (i.e., a motor or sensory deficit on one side of the face and the opposite side of the body) is good evidence of brainstem dysfunction. If the occipital lobes are the site of ischemia, transient vision loss in the form of complete blindness or partial homonymous hemianopia occurs. Ataxia, imbalance, unsteadiness, or disequilibrium, not necessarily associated with spinning vertigo, may occur because of labyrinthine or cerebellar ischemia.

Sudden hearing loss with dizziness may be due to infarction in the distribution of the internal auditory artery. In isolation, this symptom complex is uncommon in elderly patients with atherosclerotic vertebrobasilar disease and is more suggestive of diseases affecting small- and intermediate-diameter arteries, such as syphilis, systemic lupus erythematosus, or periarteritis nodosa. In the atherosclerotic patient, such symptoms usually accompany other signs of brainstem or cerebellar dysfunction, which allow a more certain diagnosis. If actual brainstem infarction occurs, neurological signs are often present on examination. Such signs include nystagmus of the central type, hyperreflexia, internuclear ophthalmoplegia, homonymous visual field defects, dysarthria, and ataxia.

Severe vcttigo, mimicking labyrinthine disease, may be an early symptom of acute cerebellar infarction. To differentiate this condition from labyrinthine disease, particular attention is directed to the type of nystagmus that is present. Acute peripheral vestibulopathy usually causes unidirectional nystagmus, with the fast phase in the opposite direction. This is similar to the mnemonic COWS (cold, opposite—warm, same) for the direction of the nystagmus fast phase during thermal irrigation of the ear. The fast phase is away from the side of the cold water irrigation. Cold water mimics a peripheral destructive lesion of the labyrinth, and almost all lesions are destructive. Therefore with a peripheral labyrinthine disturbance, the nystagmus fast phase is in the opposite direction or away from the involved ear. The nystagmus increases during gaze in the direction of the fast phase (Alexander's law) or contralateral to the peripheral vestibulopathy. Swaying or falling occurs toward the side of the lesion (opposite the nystagmus fast phase). The nystagmus is unidirectional and remains horizontal on upward gaze.

By contrast, with incipient cerebellar infarction, the sway or fall is ipsilateral to the lesion, and the nystagmus may be variable in direction but is most prominent ipsilateral to the lesion. In other words, with central lesions the fast phase of the nystagmus is in the direction of gaze (direction-changing nystagmus) but becomes more prominent when gaze is directed ipsilateral to the lesion (Oas and Baloh 1992). Other ocular motor findings are often present in brainstem disease; such conditions as limitation of vertical gaze, upbeat or downbeat nystagmus, or dysconjugate nystagmus are often present (see Chapter 16). However, in certain syndromes of the posterior circulation, the initial presentation can mimic acute vestibulopathy, particularly the syndrome of the anterior cerebellar artery {Oas and li.iluh 1992) and the syndrome of the distal posterior interior cerebellar artery.

Cerebellopontine Angle Tumors

Tumors of the cerebellopontine angle rarely present solely with episodic vertigo. The most common tumor in this location results from a proliferation of the Schwann cells (schwannoma). Most of these tumors arise on the vestibular portion of the eighth nerve within the internal auditory-canal. They progressively enlarge, deforming the internal auditory meatus and compressing adjacent neural structures, such as the acoustic portion of the eighth nerve, facial nerve, trigeminal nerve, brainstem, and cerebellum.

The most common symptoms associated with eighth nerve tumors are progressive hearing loss and tinnitus. Vertigo occurs in approximately 20%, but a symptom of imbalance or disequilibration is more common, approaching 50%.

Cranial Neuropathy

Multiple or isolated cranial neuropathies occur in focal or systemic disease, including vasculitis, granulomatous disease, and meningeal carcinomatosis. Often, however, the cause is elusive. Evidence of systemic involvement is elicited by history, physical examination, and laboratory evaluation. Cogan's syndrome may be considered with cranial neuropathies and is characterized by nonsyphilitic keratitis associated with vertigo, tinnitus, ataxia, nystagmus, rapidly progressive deafness, and systemic involvement,

Posterior Fossa Lesions

Posterior fossa lesions in various locations are unusual causes of isolated vertigo. The symptoms are usually positional vertigo of the central type (see Table 18.3).

Brainstem and cerebellar disease cause a variety of types of nystagmus that sometimes present as a complaint of oscillopsia—an illusion of environmental movement characterized by bouncing or jiggling of objects. Although oscillopsia is a common complaint with significant bilateral labyrinthine abnormality, the presence of vertical oscillopsia indicates upbeat or downbeat nystagmus (see Chapter 16). These nystagmus types are reliable indicators of CNS abnormality (Troost and Waller 1997).

Seizure Disorders

Seizure disorders, especially temporal lobe epilepsy, are rare causes of dizziness or vertigo. The history almost always

re VIM Is additional symptoms, such as loss of awareness, automatic behavior, or generalized seizure activity after an aura of vertigo. I lowever, some epileptics with psychomotor seizures have isolated auras of the symptoms listed in Table 18.1.

Systemic Causes of Vertigo

Systemic causes are discussed as a separate category to include more widespread conditions that secondarily affeci peripheral or central vestibular structures, or both, to produce vertigo (see Table 18.4).

Drugs

Side effects of drug ingestion often cause dizziness in the broadest definition of the term. Vestibulotoxic drugs, as previously described, can produce true vertigo. The dizziness produced by other drugs is more a sense of weakness, disequilibration, or "fuzzy hcadedness." The agents listed in Table 18.4 are among the most common offenders. Every attempt should be made to determine the type and quantity of medication being taken by the dizzy patient. Frequently, the elimination or reduction of medication, such as a mild tranquilizer, produces a clear improvement. However, the dizzy patient with a systemic condition will have been treated with a variety of medications that may add to disequilibration or dizziness.

Hypotension

The multiple causes of presyncope or postural hypotension are often responsible for complaints of vertigo or dizziness (see Chapter 2). Presyncope is often described as lightheadedness and is actually a common mechanism for dizziness or even vertiginous sensations. Postural hypotension is a common side effect of antihypertensive agents, diuretics, and dopaminergic agents.

Endocrine Disorders

Among the endocrinopathies that cause disorders of equilibration are diabetes and hypothyroidism. The mechanism in diabetes is probably an accompanying autonomic neuropathy and orthostatic hypotension. Though much less common as a specific cause, hypothyroidism should be considered when the symptoms of vertigo remain undiagnosed. The remaining systemic conditions (listed in Table 18.4) rarely present with isolated vertigo.

Multiple Afferent Sensory Loss

The vestibular system functions to provide (1) spatial orientation at rest or during acceleration, (2) visual fixation during head or body movement (the vestibulo-ocular reflex fVOR|), and (3) feedback control of muscle tone to maintain posture. These functions and their control mechanisms arc interconnected in a complex fashion. Thus the symptoms of episodic vertigo may reflect disturbances in more than one system. The combination of multiple sensory deficits can produce disorientation or disequilibration that is interpreted as dizziness or vertigo. This often occurs in the elderly, in whom vision (cataracts), hearing (presbycusis), and proprioception (peripheral neuropathy) may all be impaired. Presbylibrium, or imbalance resulting from aging, may be due to a selective progressive deterioration of the peripheral vestibular apparatus or a combination of sensory deficits.

Even a young, healthy person is easily confused by afferent sensory information, as exemplified by the sensation of spinning or true vertigo experienced during full-field optokinetic stimulation. Almost every individual, while quietly seated, experiences a compelling illusion of rotation while viewing a moving environment of optokinetic stripes (the circular vection illusion). Thus patients with abnormalities of peripheral or central vestibular mechanisms experience periods of disorientation while viewing a moving patterned environment or experience vertigo during vehicular travel.

An age-related degeneration of vestibular receptors, analogous to presbycusis, contributes to vertigo. Although most younger patients readily compensate for unilateral peripheral vestibular damage, older patients usually cannot because of bilateral peripheral vestibular dysfunction or a separate central abnormality that decreases their ability to compensate.

Dizziness in Childhood

The most common causes of vertigo and dizziness in childhood and infancy are similar to those in the adult: acute peripheral vestibulopathy, trauma, and infection. Vertigo after air travel is more common in children than in adults because of the frequency of accompanying middle ear infection and effusion. Migtaine is a significant cause of episodic dizziness or vertigo in childhood and should be considered even when the symptoms of headache are absent.

Benign paroxysmal vertigo in childhood is thought by some to be a variety of vestibular neuronitis and by others to be a migraine variant. Although an attack may be unaccompanied by loss of consciousness, children may fall during its course and often indicate a sensation of spinning. The episodes may last minutes to hours or recur for many weeks or even months, gradually decreasing in severity. The preservation of consciousness during an attack distinguishes the condition from temporal lobe seizures with a vestibular component and from vcstibulogenic epilepsy, in which an attack is triggered by labyrinthine stimulation. Congenital anomalies of the inner ear and brainstem, vascular disease, and tumor are rare causes in childhood.

EXAMINATION OF **THE** DIZZY PATIENT

General Examination

Every patient with a disorder of equilibration or true vertigo should have a screening general physical examination. In particular, patients who exhibit symptoms suggesting presyncope or actual syncope must have particular attention paid to theit cardiovascular system and blood pressure on standing (see Chapter 2). One should also evaluate the musculoskeletal system because abnormalities adversely affect balance. Attention should also focus on systemic conditions that could give rise to a general feeling of malaise or weakness, which the patient may intetpret as a disorder of balance.

Neurological Examination

The neurological examination should be specifically determined by the patient's history (see Chapter 1). In patients with cleat episodic vertigo, the neurological examination usually shows no abnormalities, with the exception of the ocular motor findings to be described. However, when the patient's symptom complex is more vaguely defined and includes disequilibration or unsteadiness, examination of the motor system, reflexes, sensation, and cerebellar function may uncovet abnormalities.

All patients with undiagnosed disorders of equilibration, however described, should have a complete neurological examination. The vatious parts of the neurological examination are described here only briefly, with each part followed by a suggestion of which entities might be discovered.

Mental Status Examination

Signs of diffuse alterations in consciousness may suggest overmedieation, metabolic encephalopathy, or an acquired dementing process. Focal disturbances in intellectual function, such as a subtle aphasia, may lead to the consideration of either a mu hi-infarction state (multi-infarct dementia) with accompanying brainstem infarctions or an intracranial mass lesion,

Cranial Nerve Examination

Alterations in visual sensory function may be a primary or exacerbating cause of disequilibration. Even the recent addi[ion of a new refractive correction, particularly lenses for presbyopia, may be an added or primary cause of imbalance. Visual field defects, such as unsuspected bitemporal or homonymous field defects from tumors or infarcts, may cause patients to tun into objects or feel disoriented in space. The presence of papilledema or absent venous pulsations on funduscopy should be an immediate clue to raised intracranial pressure. Altctcd corneal sensation may be the clue to a previously unsuspected cerebellopontine angle mass. Tuning fotk tests (see Chaptet 19) may confirm the patient's complaint of hearing loss and should lead to audiologic assessment. Abnormalities on examination of cranial nerves IX-XII raise the differenrial diagnosis of multiple cranial neuropathies, such as collagen vascular disease, tumors of the base of the skull, and nasopharyngeal carcinoma.

Ocular Motor Examination

The presence of spontaneous or induced nystagmus is of crucial importance in making a diagnosis of peripheral, central, or systemic causes of imbalance. The patient should be evaluated for the ptesence of strabismus because this may be a relatively nonspecific cause of dizziness and intermittent diplopia. Some types of nystagmus that are of particular importance are described (sec Directed Neuro-Otological Examination, latet in this chapter). Failute of vertical gaze, particularly in a downward direction, may be the first sign of disequilibration caused by progressive supranuclear palsy. The presence of asymmetrical slowing of the adducting eye may be a subtle but important clue to the presence of brainstem multiple sclerosis, brainstem infarction, or mass lesion of the posterior fossa.

Motor System Examination

Motor sysrem examination may reveal focal or diffuse weakness indicative of CNS or neuromuscular disorders. A subtle hemiparesis may be the true cause of the patient's balance complaint. Diffuse hyper-rcflexia may reflect cerebral or spinal cord dysfunction and, in combination with cerebellar abnormality, may lead to the diagnosis of a spinocctcbellar degeneration (sec Chapter 78).

Sensory Examination

Sensory examination may reveal a significant peripheral neuropathy, leading to a diagnosis of diabetes or toxic neuropathy. Selective loss of proprioception and vibration may indicate that the patient has vitamin B deficiency ot early tabes dorsalis. Such patients may be relatively steady during the Romberg test with eyes open but rapidly lose balance and fall in any direction when visual compensation is eliminated by eye closure. Patients with symptomatic petiphetal vestibulopathy tend to fall towatd the side of the abnormality during eye closure with the head directed straight ahead.

Cerebellar System Examination

Clear limb or body ataxia should be an immediate clue to a CNS abnormality as the cause of the patient's imbalance. Unsteadiness during Romberg testing with eyes open and only slight exaggeration on eye closure indicates a cerebellar abnormality. It is usually accompanied by a definite

abnormality during gait testing or even difficulty maintaining balance while seated. Unilateral limb ataxia is almost always an indicator of focal posterior fossa abnormality, such as infarct, dcmyelination, abscess, or tumor.

Directed Neuro-Otohgical Examination

A directed neuro-otological examination should be performed, particularly when there are abnormalities of the auditory, ocular motor, and vestibular systems. Audiometric testing is discussed in Chapter 19. During the neurological examination, there may be subtle signs of peripheral vestibular dysfunction indicated by nystagmus. During the funduscopic examination, particular attention should be paid to the movement of the optic disc. A rhythmic, subtle, horizontal slow and fast component is commonly present in patients with new peripheral vestibular dysfunction. For example, with the patient staring at a dimly lit target in the distance, the presence of a slow ocular drift to the left and a fast phase to the right of the optic disc should indicate to the examiner that the patient has a subtle left-beating nystagmus in the primary position. This indicates a right peripheral vestibular abnormality. Vertical drifts of the optic disc seen during funduscopy may signify the presence of vertical nystagmus, thus directing the examiner to search for the presence of nystagmus during upward, downward, and oblique gaze.

The need to determine the presence of any type of nystagmus during the directed neuro-otological examination cannot be overemphasized; all too often thete is unnecessary dependence on the results of clectrony stag mographic testing. The directed neuro-otological examination should include an otoscopic examination of the external auditory canal and the tympanic membrane. The presence of a retracted or scarred eardrum may be the clue to prior middle ear infection. The presence of a blue mass behind the tympanic membrane points to a glomus jugulare tumor.

The patient should be tested for balance during standing, walking, and turning and for the presence of past-pointing—that is, a tendency for the repetitively elevated and lowered outstretched fingers to drifr in one direction. Past-pointing is a clear indication of tonic imbalance in the vestibular system.

The physician **may also** clinically test for the presence of an intact VOR and may observe whether the patient is able to maintain steady ocular fixation during funduscopic examination as the head is gently rotated from side to side (Sharpe and Barber 1993). The patient with an intact VOR can still maintain fixation on distant objects during head turning. The absence of this ability produces an apparent nystagmus, most easily observed during funduscopic examination, which is good evidence for a defective VOR. A different test of vestibulo-ocular control is for the patient to fixate on his or her own moving rhumb while rotating his or her head in the same direction. During this maneuver, the patient must suppress the VOR to permit combined head and eye tracking. The loss of this ability may be a subtle clue to cerebellar system dysfunction. The patient may also be examined for the presence of nystagmus when visual fixation is reduced by the wearing of Frenzel glasses, which blur the patient's vision and magnify the eyes, thereby allowing the examiner to observe previously undetected nystagmus.

INVESTIGATIONS

Screening Tests

Patients with undiagnosed vertigo should have metabolic screening tests, including blood cell count, electrolytes, glucose, erythrocyte sedimentation rate, thyroid function testing, and possibly a rheumatologic battery. Many physicians involved in the evaluation of dizzy patients also perform lipid screens for the presence of hypercholesterolemia or increased triglycerides. The laboratory investigation, like the physical examination, is directed particularly by the patient's history. If **there** is a history of presyncope or syncope, the patient must have a cardiac evaluation, to include at least an electrocardiogram and rhythm strip. A more suggestive history would lead to use of 24-hour Holter monitoring or an event monitor, during which the patient wears a battery-powered apparatus that can be activated when symptoms occur. This device then records the cardiac rhythm. The presence of auditory symptoms requires audiometric tests, as described in Chapter 19. Multiple or recurrent cranial neuropathy leads to a variety of screening tests for collagen vascular disease or basal skull or meningitic processes.

Vestibular Tests

Vestibular testing may be divided into categoties such as standard electronystagmographic testing, specific ocular motor testing, rotational tests, and posturography. Each test is reviewed briefly in Chapter 41.

DIAGNOSTIC FORMULATIONS

Symptoms, findings, and the results of investigations that would lead to a tentative diagnosis in each of the **major** categories of vestibular disorders are briefly discussed here.

Peripheral Vestibulopathy

A patient who complains of episodic spinning vertigo, with or without auditory symptoms, whose neurological examination shows no abnormalities, and who has evidence of reduced vestibular function in one ear on caloric testing

Table 18.6: Differential diagnosis of dizziness attacks

Hiiii-le	*Recurrent*	*Chronic disequilibration*
Acute peripheral vestibulopathy	Peripheral vestibulopathy	Uncompensated peripheral vestibulopathy
Trauma	Benign positional paroxysmal vertigo	Cerebellopontine tumor
Perilymph fistula	Meniere's disease	Multiple sclerosis
Air travel	Vertebrobasilar ischemia	Brainstem infarct
Ramsay Hunt syndrome	Migraine	Drugs
Syncope and presyncope	Complex partial seizure	Ototoxicity
	Familial periodic ataxia	Chronic otomastoiditis
		Autonomic neuropathy
		Multiple sensory deficits
		Arteritis
		Cogan's syndrome

should initially be placed in this diagnostic category. Such patients often respond to vestibular suppressant medication early in the course and, thereafter, to vestibular exercises. Peripheral vestibulopathy of idiopathic, infectious, or post-traumatic origin is one of the most common causes of a single attack of vertigo (Table 18.6).

Central Vestibular Disorders

Patients with central vestibular disorders usually have vague descriptions of their symptomatology; they rarely describe true spinning vertigo or symptoms evoked by position change (but see Table 18.3), and they have abnormalities, such as nystagmus or hyperreflexia, on physical examination. These patients are candidates for additional neurological diagnostic investigations. If a history of alteration of consciousness is present, the neurologist may consider a rare presentation of temporal lobe seizures and perform an electroencephalogram and magnetic resonance imaging. The presence of progressive hearing loss or central auditory findings during audiometric testing leads to suspicion of a cerebellopontine angle tumor and the appropriate neuroradiology investigations. When faced with a patient with chronic vestibular symptoms (even including episodic imbalance) and failure to respond to medical therapy, however, one should carry out a neuroradiologic investigation, even in the presence of a completely normal neurological examination. Such patients may have unsuspected multiple cerebral and brainstem infarctions or may be experiencing the late-life onset of multiple sclerosis. Central vestibular disorders, including uncompensated peripheral vestibulopathy, are among the most common causes of chronic dizziness. There is considerable overlap in the conditions causing single recurrent or chronic attacks of dizziness (see Table f 8.6).

Systemic Conditions

Alteration in vestibular function may be suspected in patients who are taking multiple drugs to lessen their vertiginous symptoms. In fact, the drugs often initially used to treat such patients, such as benzodiazepines, may later give rise to systemic effects, including imbalance. The patient's symptoms are usually vague but often present as symptoms of disequilibration or imbalance rather than dizziness. The description of lightheadedness particularly suggests this category of disease and may prompt a more detailed search for postural hypotension occurring minutes after rising or a search for cardiac arrhythmia. Such patients deserve a complete metabolic workup and often consultation with other specialists. Syncope and presyncope are listed as a cause of a single attack of dizziness, but recurrent episodes are common.

Chapter 19
Hearing Loss and Tinnitus without Dizziness or Vertigo

B$_t$ Todd Troost and Lisa C. Arguello

The diagnosis and management of patients with hearing disorders are the responsibility of a variety of specialists, including the audiologist, the otolaryngologist, and, occasionally, the neurologist. Each may view the problem from a different perspective, but all should work in concert to provide the best possible care. Most neurologists' knowledge of hearing disorders is fragmentary. This chapter provides basic information for understanding the approach to a patient with hearing loss or tinnitus.

HEARING LOSS

In the assessment of hearing impairment, one must remember that dysfunction of the auditory system may be a manifestation of a systemic and possibly life-threatening disorder. Therefore, the examiner must elicit a history of complaints referable to other systems. The examination of the patient, the complaints, and the preliminary audiologic findings determine how inclusive the examination must be and what subsequent tests must be ordered. Be aware that audiologic tests do not always provide an exact diagnosis, Audiologic test data should be used with the neurological, otoneurological, and radiological information for the maximum diagnostic accuracy.

Types of Hearing Loss

Hearing loss can result from a lesion anywhere in the auditory system (Nadol 1993). An abnormality in the outer or middle ear creates a conductive loss of hearing because of inefficient transmission of sound to the inner car system. When the loss of hearing is due to pathology in the cochlea or is along the eighth cranial nerve from the inner ear to the brainstem, the loss is referred to as a *sensorineural* hearing loss. Patients may exhibit both conductive and sensorineural loss, which is known as *mixed* hearing loss. Central hearing loss (or central auditory dysfunction) is present when a lesion exists in the central auditory pathway beyond the eighth cranial nerve, such as the cochlear nucleus in the pons or the primary or association auditory cortex of the temporal lobe.

In addition to these organic types of hearing loss, one should consider functional hearing loss when a patient claims to have a loss but discrepancies in objective test measures or behavior suggest that the loss does not exist, at least to the degree claimed.

Auditory Neuropathy

Individuals with auditory neuropathy (AN), also known as *auditory dyssyncbrotty,* is increasingly recognized (Sininger and Starr 2001). Identification of AN is now readily available by the use of otoacoustic emissions (OAEs) in the test battery. A typical presentation of a patient with AN is that of a variable bilateral hearing loss with test findings as follows:

1. Presence of OAEs that indicate normal outer hair cell function.
2. Presence of cochlear microphonics on auditory brainstem responses. These findings would be consistent with functioning outer hair cells. The cochlear microphonic is differentiated from a neural response by performing one test run with what is termed a *condensation click* and then performing a second test run with what is termed a *rarefaction click* (Sininger and Starr 2001). Hair cell response will reverse with the change in click polarity, whereas the standard neural response is not affected by the change.
3. Absent or elevated acoustic reflexes. Most often children with AN will have speech/language delays and require remediation by a speech pathologist. The patient's own speech will sometimes sound distorted but will not have the typical distortions seen with sensorineural impairment. Noisy backgrounds are particularly difficult with AN because speech is already

distorted. Treatment varies with some functional improvement over time, but those with progressive hearing loss are candidates for cochlear implantation or the use of frequency modulation (FM) systems. **"The** mechanisms underlying AN could be sensory, dendritic, or axonic in nature. Possible sites could include the inner hair cells, the synaptic juncture between the inner hait cells and the auditory nerve, or the auditory nerve itself" (Hood 2002).

AN is an important consideration for neurologists because 25-30% occur in association with hereditary sensory motor neuropathies or spinocerebellar degenerations (Table 19.1).

Examination. A number of audiologic tests provide differential information on the function of the auditory system, and various tests arc grouped to form test battcties. One such grouping can be used to differentiate conductive from sensorineural impairments and may futther help in localizing a sensorineural loss to either the cochlea or the eighth cranial nerve. Other tests ate used to examine auditory deficits of the central auditory sysrem. Still anothct set of tests is designed to detect functional or nonorganic hearing disorders. Although the results from these batteries may be helpful in establishing a diagnosis, differential auditoty measures cannot be used to establish the disease process. The findings from any audiologic study must be integtatcd with the histoty, physical examination, and laboratory tests.

Basic Office Examination of Hearing. Whether or not **the** patient's complaint is one of hearing loss, a basic assessment of auditory function should be part of the neurological examination. The external ear should be inspected with an otoscope to determine the patency of the external ear canal and the integtity of the tympanic membrane. If the external canal is occluded by cerumen, simple tests of heating may be invalidated. Assuming thete is no cerumen in rhe external ear canal, the tympanic membrane should be inspected. The neurologist shouid be able to tecognize an inflamed, bulging, or scarred drum and should note whether there is perforation of rhe tympanic membrane; blood behind the eardrum; or a pulsating blue mass, which may indicate a glomus jugulare tumor. An excellent desctiption of tympanic membrane findings may be found in modern texts of otology {Hughes and Pensak 1997).

The office examination of hearing loss may include tuning fork rests of air and bone conduction. Tuning forks at a frequency of 256 Hz or 128 Hz should not be used because the vibrations they produce by bone conduction may be mistaken for sound; the 512-Hz fork is the lowest useful ftequency. Two standard timing fork tests ate the Weber and the Rinne tests.

Weber Test. The Weber test is based on the principle that signal transmitted by bone conduction is localized to the ear with the greatest conductive deficit or the ear opposite to the one with a M::IMH nn.uial loss, 1 lie test can determine the type of hearing impairment when the two cars arc affected to different degrees. The stem of a vibrating tuning fork is placed on the skull in the midline, and the patient is asked to indicate in which ear the sound is heard. The usual location described is for placement on the forehead, but better locations are the nasal bones or teeth when a stronger bone conduction stimulus is tequircd. In unilateral hearing losses, lateralization to the poorer hearing car indicates an clement of conductive impairment in that ear. lateralization to the better hearing ear suggests a sensorineural problem in the opposite ear.

Rinne Test. The Rinne test is probably the most commonly used tuning fork test, but the name is usually mispronounced; the originatot was Gentian, not French, and the accent is on the first syllable. The Rinne test compares a patient's hearing sensitivity by bone conduction versus air conduction. A person with normal hearing or sensorineural impairment perceives the air-conducted sound as loudet than or the same volume as bone-conducted sound. Proper placement of the tuning fork in each situation is important. When testing by bone conduction, the stem of the fork should be placed firmly on the mastoid, as near to the posterosuperior edge of the ear canal as possible. The stem should not touch the auricle of the external canal, which should be held to the side by the examiner's fingers. Touching the external ear itself could give false results because of vibration of the auricle. When testing by air conduction, the fork is held approximately 2.5 cm lateral to the ttagus. In the Rinne test, when the conduction mechanism is normal in an ear (i.e., in

individuals with normal hearing and with sensorineural hearing impairment), air conduction is heard better than bone conduction because it is a more efficient means of sound transmission. This finding is termed a *positive Rinrte.* Bone conduction is heard better than air conduction when there is a deficit in the conduction mechanism (a *negative Rinne).* When tested by bone conduction, patients should remove their eyeglasses because the earpieces can interfere with proper placement of the tuning fork or give inappropriate conduction or vibratory information. Although tuning fork tests allow the examiner to screen for a conductive versus a sensorineural loss, they do not evaluate the degree of impairment or the effects of that impairment on speech understanding.

Audio logic Assessment. An a ud io I og ic a ss ess m en t com - priscs pure-tone air and bone conduction testing, speech reception threshold, and word recognition measures. The threshold is defined as the lowest intensity, measured in decibels, at which an individual can detect a pure-tone or speech signal. Pure-tone air thresholds arc established for frequencies of 250-8000 Hz. Bone conduction thresholds are measured from 250-4000 Hz. This frequency range is important to the detection and understanding of the speech signal. Hearing is considered normal when threshold sensitivity is 0-25 dB for frequencies of 250-8000 Hz (Figure 19.1). Responses greater than 25 dB are classified by degree as mild, moderate, moderately severe, severe, and profound (Figure 19.2). Responses at 500 Hz, 1000 Hz, and 2000 Hz are averaged to compute the pure-tone average.

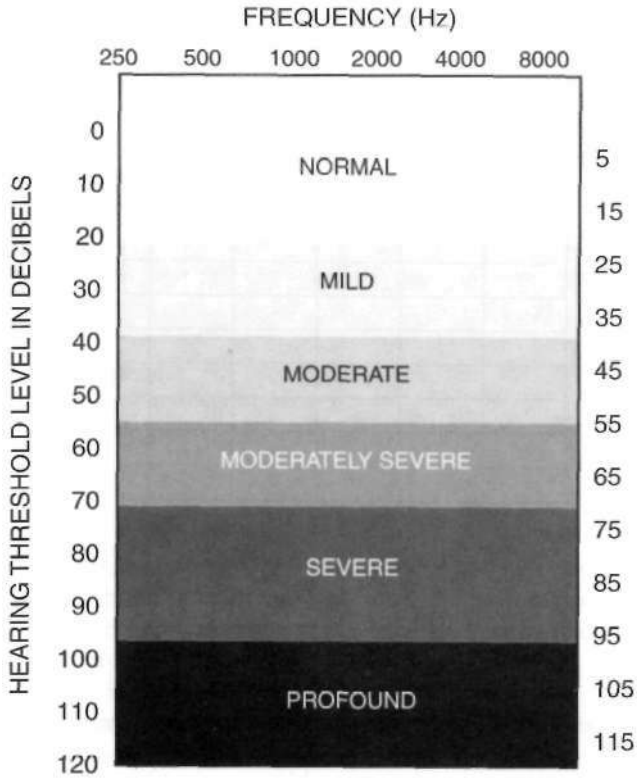

FIGURE 19.2 Classification of degree of hearing loss. (Reprinted with permission from American Spin-li I alienage I tearing Association. 1990, "Guidelines For audiometric symbols," *ASHA* vol. 32, suppl. 2, pp. 25-30.)

In the measurement of bone conduction thresholds, pure-tone signals are transmitted via a bone oscillator, usually placed on the mastoid. This signal directly stimulates the cochlea, bypassing the external and middle ear. The presence of decreased air conduction threshold and normal sensitivity of bone conduction suggests abnormality in the external ear or middle car system (conductive hearing loss) (Figure 19.3),

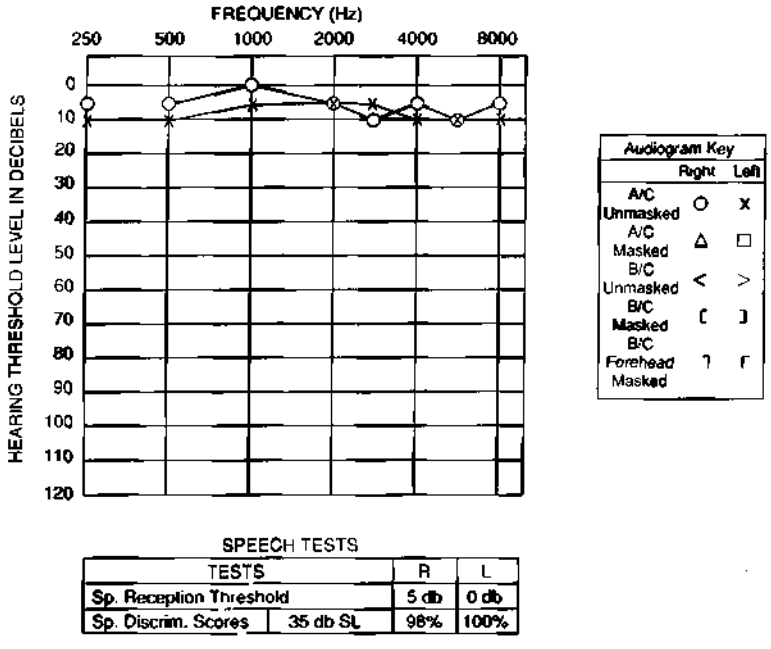

FIGURE 19.1 Normal hearing sensitivity.

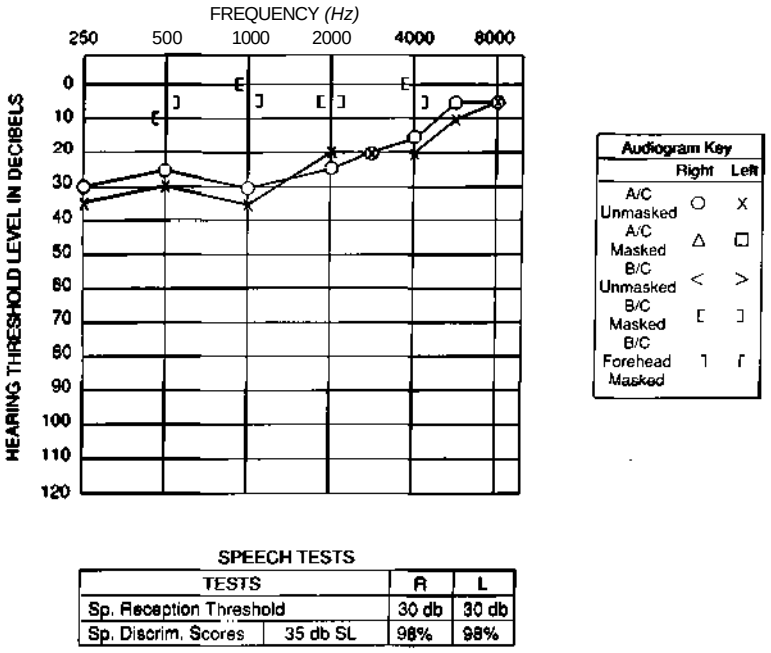

SPEECH TESTS

TESTS		R	L
Sp. Reception Threshold		30 db	30 db
Sp. Discrim. Scores	35 db SL	96%	98%

FIGURE 19.3 Pure-tone air and bone conduction (B/C) findings for a conductive hearing loss. (A/C = air conduction; SL = sound level.)

The speech reception threshold is the lowest intensity at which an equally weighted, two-syllable word is understood approximately 50% of the time. The pure-tone average and speech reception threshold should be within 7 dB of each other. Comparing the speech reception threshold and the pure-tone average serves as a check on the validity of the pure-tone thresholds. Large discrepancies between these measures may suggest a functional or nonorganic hearing loss.

Word recognition is used to assess an individual's ability to understand a speech signal. Most commonly, a phonetically balanced word list of 50 one-syllable words is presented to the patient at a sup rath res ho Id level. The patient's score is represented as the number of words correct. Generally, word recognition ability decreases proportionately with an increase of hearing impairment. However, there is an exception in conductive hearing loss in which word recognition ability remains relatively good because the inner ear system is normal. Poor word recognition ability in the presence of relatively good hearing sensitivity may suggest retrocochlear pathology, such as acoustic neuroma, and should be aggressively pursued by the clinician. A more detailed discussion of audiologic tests is provided in Chapter 41.

Immittance Test Battery. Tympanometry, static acoustic immittance, and acoustic reflex threshold measures make up the acoustic immittance test battery. Static acoustic immittance measures the contribution of the middle ear to the immittance of the auditory system. This measure is most useful for the detection of even small perforations of the tympanic membrane. It may also assess the patency of tympanostomy tubes. Tympanometry is a measure of middle ear mobility when air pressure in the external canal is varied. Results are graphically represented with pressure along the X-axis and compliance along the Y-axis. Normal tympanograni measurements have a pressure peak point of ±100 mm H_20.

Static compliance refers to the ease of flow of acoustic energy through the middle ear. Compliance measures are obtained at +200 mm H_20 {first point of compliance, or CI) and again at the point the tympanic membrane is most compliant (second point of compliance, or C2). The point at which the tympanic membrane is most compliant allows maximal transmission of energy through the middle ear cavity. Compliance of the tympanic membrane is derived by subtracting CI from C2. Values less than 0.25 cm^3 of equivalent volume indicate a stiff or noncompliant middle ear system. Values greater than 2.0 cm^3 suggest an overly compliant system. Abnormalities associated with reduced mobility of the tympanic membrane in middle ear structures include otitis media, otosclerosis, and large cholesteatomas. Ossicular chain discontinuity is the most common cause of excessive tympanic membrane mobility. Examples of tympanometry are shown in Figure 19,4, Extremely high equivalent middle ear volume and low static compliance suggest a nonintact tympanic membrane from a perforation or previously placed tympanostomy tube.

The acoustic reflex threshold is the lowest intensity of a pure-tone stimulus needed to elicit a contraction of the stapedius and tensor tympani muscles (sec Chapter 41). The introduction of an intense sound into the ear canal results in a temporary increase in middle ear impedance. This phenomenon occurs bilaterally, but it is typically measured in one ear at a time. Contralateral reflexes are measured by stimulating one ear and measuring the reflex from the other. Ipsilatcral reflexes are measured by stimulating and recording from rhe same ear. Reflexes occur between 70- and 100-dB sound pressure level in normal ears.

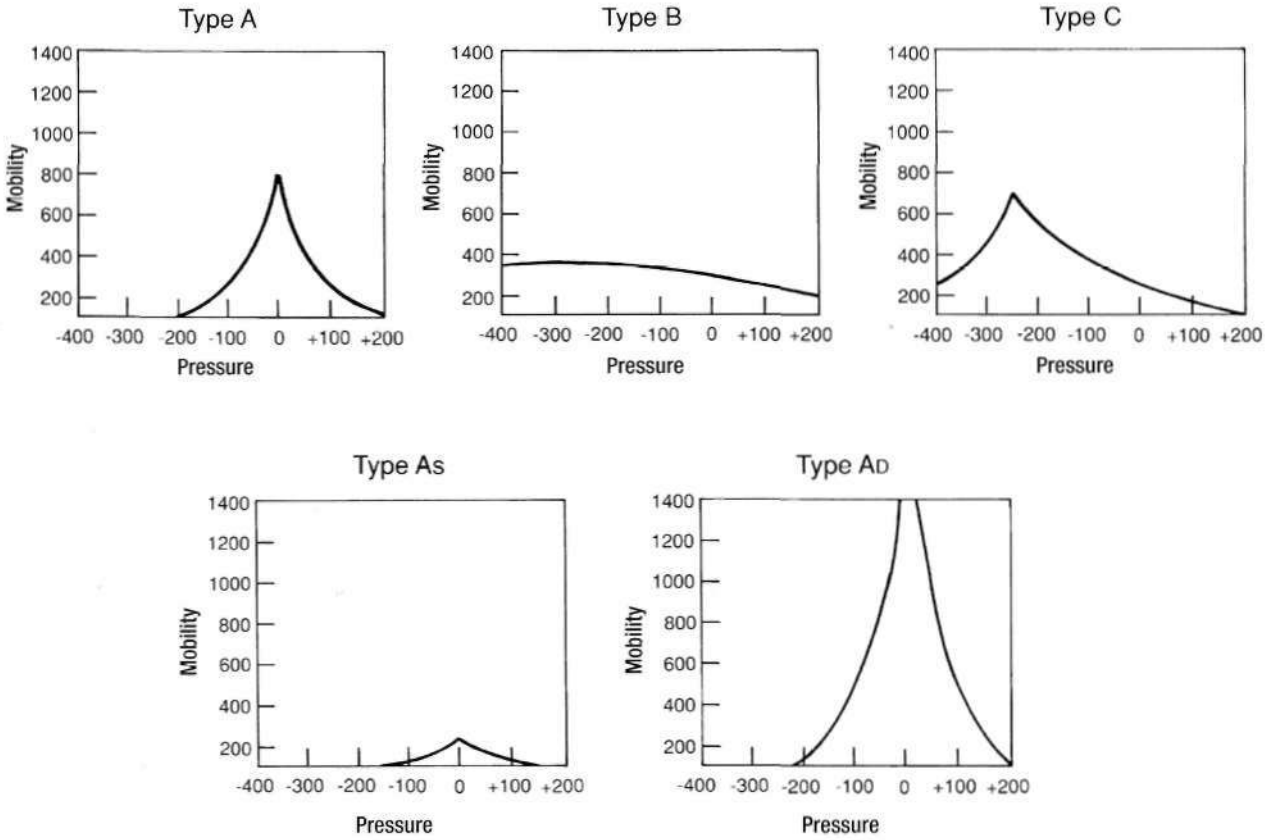

FIGURE 19.4 Tympanometry classifications: Type A represents normal middle ear function. Type A curves have normal mobility and pressures and are typically seen with normal hearing and sensorineural hearing loss with normally functioning middle car systems. Type B represents restricted tympanic membrane mobility. Type B curves have little or no point of maximum mobility and reduced compliance. This curve is typical of a stiff middle ear system, as seen in otitis media and sometimes with cholcstoma. Type C represents significant negative pressure in the middle ear cavity. Type C curves have normal mobility and negative pressure at the point of maximum mobility (negative pressure is considered significant for treatment with greater than -200 mm H^O). Type As represents normal middle ear pressure hut reduced mobility, suggesting limited mobility of the tympanic membrane and middle ear structure. commonly seen in fixation of the ossicular chain. Type An represents normal middle car pressure bur hypermobility. This pattern indicates a flaccid tympanic membrane due to disarticulation of the ossicular chain or scarring of the eardrum.

Middle ear abnormalities or significant sensorineural hearing losses may elevate or obliterate the acoustic reflexes. Retrocochlcar pathology and facial nerve disorders may also affect contralateral and ipsilatcral acoustic reflexes (see Table 41.1).

Ear Reflexes. Because the seventh cranial nerve innervates the stapedial muscle, the acoustic reflex is sometimes helpful in detecting the location of a seventh cranial nerve lesion. If the abnormality of the facial nerve is proximal to the stapedial branch of the facial nerve, facial paralysis results and the acoustic reflex is elevated or absent with ipsilateral and contralateral stimulation by probe on the affected side. If the facial nerve abnormality is distal to the stapedial branch of the facial nerve, facial palsy results, but the acoustic reflexes are normal.

Some neurologists and otolaryngologists monitor acoustic reflexes in patients with Bell's palsy. The reflex is absent at the onset of Bell's palsy and gradually returns as the Bell's palsy improves. There is usually a return of acoustic reflexes several days before the return of any facial nerve function.

Otoacoustic Emissions. OAEs are sounds produced by the outer hair cells of the cochlea in response to an acoustic stimulus. The outer hair cells in the cochlea are not just passive receptors, they actively respond to enhance or amplify incoming sound vibrations from the middle car. A sensitive microphone in the external canal can pick up **the** outer hair cell response. The two most clinically useful types of OAEs are transient evoked OAEs (TEOAEs) and distortion-product OAEs (DPOAEs) (Lonsbury-Martin ct al. 1995).

TEOAEs are almost always present in cars when hearing is better than 30 dB and the middle ear is normal. Significant negative middle ear pressure, wax, fluid, or other middle ear pathology can adversely affect or even eliminate the OAE response. A sensory hearing loss worse than 35 dB does not have a TEOAE because the outer hair cells in the cochlea are damaged. A loss greater than 45-55 dB docs not have a

DPOAE for the same reason. OAEs are most useful as an objective screening tool for infants or children who cannot be tested by traditional audiometry.

Conductive Hearing Loss

Conductive hearing losses occur with pathology in the outer or middle car. Bone conduction thresholds arc normal, but air conduction results suggest a decrease in hearing sensitivity. The patient with a conductive hearing loss tends to have approximately the same loss of sensitivity for sounds of all frequencies. Sometimes hearing is better for the higher frequencies than it is for the lower ones, and occasionally the reverse may be true, but the loss pattern is usually relatively flat across the frequencies (see Figure 19.3). Another symptom of conductive loss is that speech discrimination is relatively unimpaired.

Conductive pathologies affect the tympanogram in various ways (see Figure 19.4). With conductive hearing loss, acoustic reflexes are almost always elevated or absent, and OAEs are usually absent. Frequently, the patient with a conductive loss of hearing complains of tinnitus, which may be localized in one ear, in both ears, or unlegalized in the head. The tinnitus tends to be of relatively low pitch.

Sensorineural Loss

Sensorineural loss occurs with pathology in the inner ear or along the nerve pathway from the inner ear to the brainstem. Hearing loss from cochlear disorders alone is rermed *sensory loss.* There is some disagreement among audiologists, neurologists, and otologists over what is a *retrococblear* problem and what is a *central* problem. For the purposes of this discussion, we define *retrococblear* as an abnormality between the cochlea and the brainstem.

The term *sensorineural* includes both cochlear and retrocochlcar disorders. A pure sensorineural impairment exists when the sound-conducting mechanism (outer and middle ear) is normal in every respect but a disorder is present in the cochlea or auditory nerve. Sensorineural impairment can be congenital or acquired. Congenital sensorineural hearing loss may result from hereditary factors that cause underdevelopment or early degeneration in the auditory nerve, from viral infections in utero, or from birth trauma. Acquired sensorineural hearing loss may be caused by noise exposure, acoustic tumor, head injury, infection, toxic drug effects, vascular disease, autoimmune inner ear disease, or presbycusis.

The patient with a sensorineural impairment may speak with excessive loudness of voice in situations in which a loud voice is inappropriate. The configuration of the audiogram demonstrating a sensorineural hearing loss may vary significantly and in some instances may suggest the cause of the loss. Many people with sensorineural losses experience a hearing loss only in the high frequencies. These individuals have no difficulty understanding speech at normal intensities in a quiet environment because their low-frequency hearing is unimpaired. They do experience difficulty in understanding speech in a noisy environment. Generally, the low frequencies are defined as rhe range of 250-750 llz, middle frequencies as 1000-2000 Hz, and high frequencies as 300O-K0O0 Hz on rhe standard audiogram.

Loudness recruitment is usually associated with sensory loss of cochlear origin, which constitutes the majority of sensorineural losses. Recruitment is an abnormally rapid growth of loudness with an increase in intensity. The recruiting patient with sensory loss cannot hear low-intensity sounds and may just barely hear sounds of moderate intensity, but recruitment may cause louder sounds to be perceived as uncomfortably loud. There is a narrow range between the point of detection of sound and that where sound is uncomfortable.

The patient with sensorineural hearing loss is subject to tinnitus (usually a constant ringing or buzzing), which may be localized in either ear or both ears. In general, the pitch of tinnitus tends to be higher in sensorineural impairment than in conductive impairment.

In sensorineural loss, the audiometric Weber test is expected to lateralize to the better ear. Audiometrically, sensorineural loss is characrerized by overlapping air and hone conduction Thresholds. The tympanogram is typically normal, and acoustic reflexes may be present, elevated, or absent (Chapter 41), With cochlear hearing losses, the degree of hearing loss and recruitment plays a large role in the ability to elicit a reflux. If the patient's hearing loss is less than 60 dB, a reflex can be seen. As the hearing loss increases above this level, a measurable reflex response becomes less and less likely. *Reflex decay* refers to the ability of the facial nerve to sustain a contraction of the stapedial muscles for 10 seconds. Reflex decay is negative with cochlear pathology. TEOAEs are typically present in cochlear pathology if the hearing thresholds are between 0 and 20 dB of hearing loss (dBHL) and are sometimes present when the thresholds range from 20 to 30 dBHL. DPOAEs arc usually present if the hearing threshold is between 0 and *iS* dBHL and are sometimes present when the thresholds are 30-50 dBHL. The audiometric findings for a typical sensorineural hearing loss are displayed in Figure 19.5.

Contrary to a commonly held misconception, individuals with sensorineural hearing loss may be helped by the use of hearing aids. An array of technologies are available for persons with different degrees and configurations of hearing loss. Digital hearing aid technology provides a broader, clearer auditory signal than traditional hearing aids, which merely amplify the sound. Many digital and some programmable hearing aids use multimicrophone Technology. Hearing aid users are now often able to use different computerized programs in their hearing aid, depending on the nature of the acoustic environment.

Other technology includes implantable hearing aids for individuals with severe sensorineural hearing loss. There

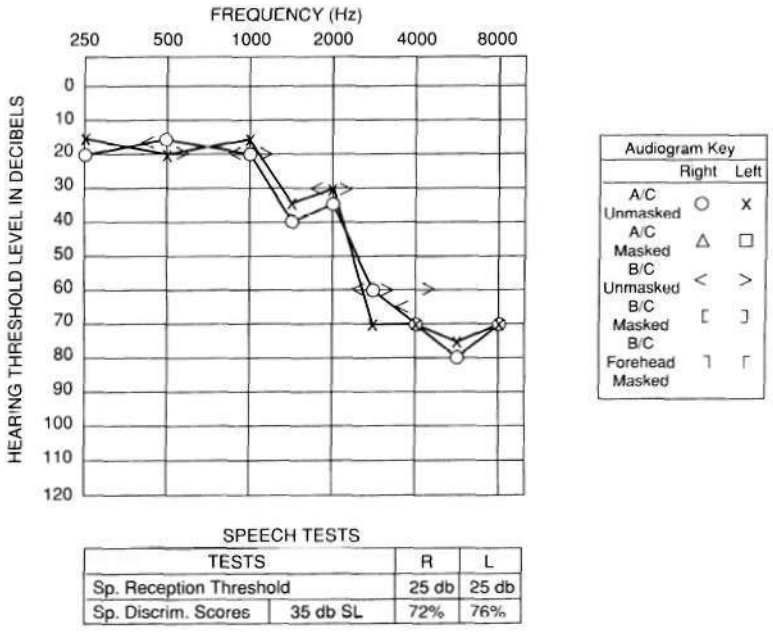

FIGURE 19.5 Pure-tone air and bone conduction (B/C) findings for a sensorineural hearing loss. (A/C = air conduction; SL = sound level.)

are bone-anchored hearing aids for individuals with conductive hearing loss. Frequency-transposition hearing aids are used for those with little or no mid- to high-frequency hearing. Cochlear implants are available for those with severe to profound bilateral hearing loss with extremely poor word recognition.

Mixed Loss

A mixed hearing loss consists of a conductive and a sensorineural component in the same ear. The patient's behavior has attributes of both conductive and sensorineural disorders. Causes of mixed hearing loss may be any combination of the conditions described earlier for conductive and sensorineural hearing loss. The conductive component of the mixed hearing loss may be corrected by successful treatment, but the sensorineural component is not reversible. Examples of successful treatment include tympanostomy tubes for fluid accumulation or stapedectomy for otosclerosis. The pure-tone audiometric pattern for a mixed hearing loss is displayed in Figure 19.6. With a mixed loss, both air and bone conduction thresholds are elevated, but bone conduction thresholds are better than air conduction thresholds. The difference between the two thresholds is referred to as the *air-bone gap* and represents the amount of conductive loss.

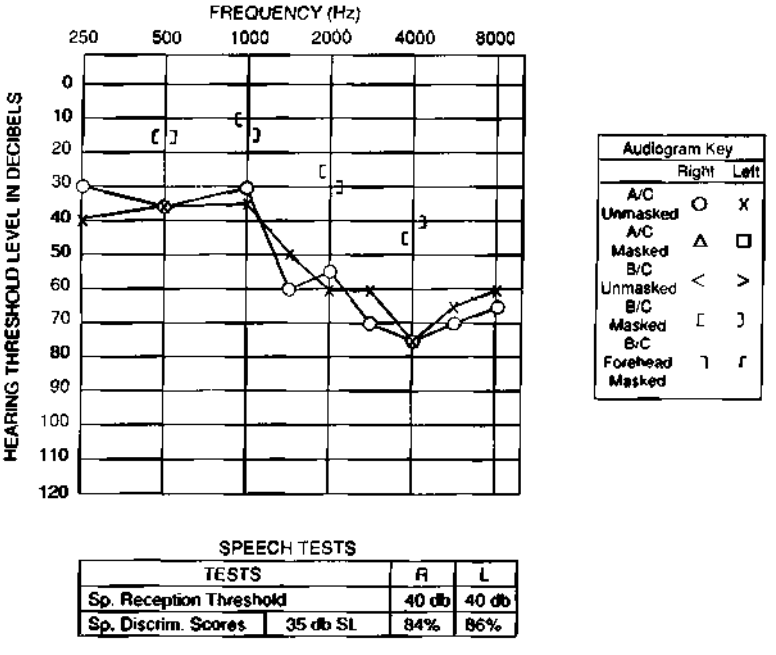

FIGURE 19.6 Pure-tone air and bone conduction (B/C) findings for mixed hearing loss. (A/C = air conduction; SL = sound level.)

Sensory Vctsus Neural Lesions

The problems of differentiating cochlear dysfunction from eighth cranial nerve lesions have received major emphasis. The neurologist's interest in sensorineural hearing loss pertains to the possibility of a cerebellopontine angle tumor. Although many referrals for audiometric evaluation are made for this reason, even the more sophisticated special auditory tests cannot determine the specific pathology underlying the disorder. Similarly, magnetic resonance imaging may locate the presence of an abnormality (Fitzgerald and Mark 1998), hut it does not necessarily define the nature of the pathology. Audiometric tests, however, highlight patterns of auditory behavior that are generally associated with cochlear or neural involvement.

Routine pure-tone and speech testing can yield valuable information on the site of lesion during the initial phase of the differential audiologic study. For example, a pure-tone configuration that often occurs in patients with a presumptive diagnosis of Meniere's disease (a cochlear disorder) is a unilateral hearing loss most pronounced in the low frequencies. In sharp contrast, patients with eighth cranial nerve lesions often have a unilateral hearing impairment most evident in the high frequencies and with poor speech discrimination. Although such generalizations may describe a substantial number of cases falling into these two categories, numerous exceptions are encountered.

OAEs may prove helpful in differentiating sensory from neural lesions, OAEs test the prcncural function of the auditory system. The presence of a TEOAE with hearing loss greater than 30-35 dB suggests an intact cochlea and therefore a retrocochlear cause. Caution must be used in interptetation, however, when a tumor reaches such a size that it impinges on the cochlear blood supply, thereby affecting the emission response. Thus absence of OAEs does not necessarily signify that the loss is purely cochlear. Acoustic reflexes are usually elevated or absent with pathology of the eighth cranial nerve if the hearing loss is 30 dB or worse. In contrast, a cochlear hearing loss of 60 dB or less usually has a reflex. Reflex decay is usually present with eighth cranial nerve involvement. If there is an intra-axial brainstem tumor or lesion, the ipsilateral reflexes are usually present and the contralateral reflexes absent. If a brainstem tumor or lesion above the level of the pons is present, the reflexes are usually normal.

Central Auditory Disorders

Lesions within the central auditory system are difficult to detect or localize. Indeed, many central auditory dysfunctions cannot be demonstrated by conventional audiologic measurements. Total removal of one hemisphere of the brain in humans docs not result in any major change of auditory sensitivity in either ear. Measures such as acoustic reflex testing, acoustic reflex decay, and speech discrimination at high intensity levels must be used to distinguish between eighth cranial nerve, extra-axial, and intra-axial brainstem dysfunction. The auditory evoked response and, particularly, magnetic resonance imaging (sec Chapter 41) are very useful in making such a differentiation.

TINNITUS

Ear noise and head noise are the most common complaints presented to audiologists and otolaryngologists, and often to the neurologist. As much as .32% of the adult population has tinnitus, with 20% rating their condition as severe. Tinnitus may be considered a significant symptom when its intensity so overrides normal environmental sounds that it invades consciousness. The patient experiencing tinnitus may describe the sound as ringing, roaring, hissing, whistling, chirping, rustling, clicking, or buzzing. Although most patients report the presence of tinnitus as constant, others report it as intermittent, fluctuating, or pulsating. Tinnitus may be perceived as a high- or a low-pitched tone, a band of muse, or some combination of such sounds,

The perceived loudness of tinnitus in any patient may be sufficiently intense to be disquieting. Most patients with sensorineural hearing loss report tinnitus as a high-frequency tone, but tinnitus associated with conductive hearing loss tends to be low in frequency. In sensorineural loss, the pitch of the tinnitus is usually located in the region of maximal hearing loss. However, knowledge of the pitch of the tinnitus is of little diagnostic benefit other than allowing for the gross distinction between conductive versus neural pathology.

Most patients with tinnitus have concomitant hearing loss, which may be either conductive or sensorineural. No more than 8% of patients with tinnitus have audiometrically normal hearing sensitivity. Tinnitus may precede or follow the onset of a loss in hearing, or the two may occur simultaneously.

Tinnitus is a symptom of an underlying disease or specific lesion when it is perceived above the intensity levels of environmental sounds. Tinnitus may be an early symptom of a tumor in the internal auditory meatus or in the cerebellopontine angle, a glomus tumor, or a vascular abnormality in the temporal hone or skull. Because tinnitus may be a characteristic symptom of a number of disorders, a complete medical and audiological evaluation of the patient with tinnitus is an important initial step in the management process.

Classification

Subjective tinnitus is an auditory sensation heard only by the patient. It may he present in one or both ears or localized within the head. For most patients, tinnitus is a subjective sensation. Although this type of tinnitus can

result from a lesion involving the external ear canal, tympanic membrane, ossicles, cochlea, auditory nerve, brainstem, or cortex, the most common cause is cochlear disease. Tinnitus associated with Meniere's disease is often low pitched and continuous and is described as a hollow seashell sound or very loud roaring. Tinnitus with otosclerosis is also low pitched, is described as a buzzing or roaring sound, and may be continuous or intermittent. Continuous bilateral high-pitched tinnitus often accompanies chronic noise-induced hearing loss, presbycusis, and hearing loss due to ototoxic drugs. A number of drugs, such as aminoglycosides, quinidinc, salicylates, indomethacin, catbamazepine, propranolol, i.-dopa, aminophyllinc, and caffeine, may produce tinnitus with or without associated hearing loss.

Objective tinnitus is less common than subjective tinnitus. It is perceived by the examiner and the patient. Objective tinnitus may be vascular (an arteriovenous malformation or fistula) or mechanical in origin. Objective mechanical tinnitus is due to abnormal muscular contraction of the nasopharynx or middle ear, as may occur in palatal myoclonus. Objective tinnitus of vascular origin may also be a referred bruit from stenosis in the carotid or vertebrobasilar system.

Tinnitus may be classified as mild, moderate, or severe. Mild tinnitus is usually noticed only in quiet environments or at bedtime. It is usually not very disturbing, and the patient can easily be distracted from the tinnitus by other stimuli. Moderate tinnitus is more intense and is constantly present; the patient is conscious of the tinnitus when attempting to concentrate or when trying to sleep. Severe tinnitus may disable individuals to the extent ih.it thov cannot concentrate on anything other than the tinnitus itself,

Evaluation and Management

The complete evaluation of the patient with tinnitus should be approached from a multidisciplinary perspective (Ruth and Hamill-Ruth 2001). The patient with tinnitus, regardless of location, type, or severity, must first have a thorough otological and audiological examination. If there arc accompanying symptoms, a complete neurological examination may be appropriate. The patient with an isolated symptom of a persistent, unexplained tinnitus should receive follow-up examinations at definite intervals when initial medical, otologic, and neurological studies reveal no evidence of disease.

Otologic management is indicated when a specific otologic cause for the tinnitus is identified. When a specific lesion or disease process is not identifiable, there is no effective surgery or medical therapy for tinnitus.

Research on the effectiveness of pharmacologic therapy for tinnitus involves medications, such as carbamazepine, and intravenous lidocaine or barbiturates. There are potentially serious side effects that limit their usefulness. AntianMctv drugs such as diazepam and alprazolam, in low doses, or antidepressants such as amitriptyline may prove effective in tinnitus management.

Masking

The use of masking as a management tool in the treatment of the patient with tinnitus has met with mixed success over the years. Tinnitus maskers are designed to provide relief to the patient with tinnitus by introducing an external masking sound into the affected ear or ears, thereby minimizing or eliminating the perception of the tinnitus. The actual efficacy of tinnitus maskers is probably less than 30%. A hearing aid may be beneficial by addressing the primary bearing problem and providing relief to some individuals with tinnitus by masking the tinnitus itself.

Biofeedback

Many patients with tinnitus have high levels of anxiety, tension, or other symptoms of chronic stress. There is a significant correlation between tinnitus and tension. Biofeedback may be effective in the relief of tinnitus or the associated annoyance produced by it.

Counseling

The need for effective counseling is an important aspect of tinnitus management. Many patients are frightened by the presence of tinnitus and need a clear explanation of the disorder, coupled with firm reassurance from both the neurologist and the audiologist.

Chapter 20
Disturbances of Taste and Smell

Pasquale F. Finelli and Robert G. Mair

Taste and smell rely on chemical stimuli to excite their receptors—hence the designation *chcmosensory system.* The two senses arc closely relared: Their combination produces the sensation of flavor, and dysfunction in one is often perceived as an abnormality in the other. Disorders of the chemosensory system, though common, may he ignored by the patient as insignificant or downplayed by the physician who views testing as imprecise, time consuming, and cumbersome. Nevertheless, accurate diagnosis is essential because these disorders may herald a serious illness or affect the patient's life in areas of nutrition, satisfaction in eating, personal hygiene, and livelihood {as in the case of chefs, food handlers, and perfumers). They also pose the dangers inherent in the inability to recognize spoiled food or the presence of natutal gas and smoke.

SMELL (OLFACTION)

Pathophysiology

In humans, there are two well-characterized nasal chemosensory systems: the free nerve endings of the trigeminal nerve and the sensory receptors of the olfactory system. A vomeronasal organ is located along the anterior portion of the nasal septum about 1 mm above the nasal floor (Meredith 2001), but little is known about the organ's function in humans. The free nerve endings of the trigeminal system innervate the walls of the nasal passages and respond nonselectively to a large variety of volatile chemical substances. Human psychophysical studies indicate that stimulation of the trigeminal nerve contributes the sensation of general nasal irritability that is provoked by high concentrations of most odorants. Olfactory receptors respond to chemical stimuli at lower concentrations and with greater selectivity than the trigeminal endings do and are responsible for distinguishing among odorous substances. In cases of total anosmia, the capacity to distinguish odors is lost, but the response to nasal irritation is generally preserved. Thus cases of malingering occasionally can be exposed by comparing responses to odorants that differ in their propensity to stimulate trigeminal nerve endings.

The olfactory receptor cell is a bipolar sensory neuron having a dendritic knob extending into the mucous lining of the nasal cavity and a thin unmyelinated axon that travels in bundles through the cribriform plate into the olfactory bulb (Figure 20.1). The dendritic knobs bear cilia, wherein odorant transduction occurs. The receptor neurons have a limited life span, averaging 30 days, and are replaced by newly formed cells that differentiate as they migrate from the basement membrane toward the surface of the sensory epithelium. The plasticity of the receptor neuron is clinically important fot two reasons: (1) Treatments that affect cell division (radiation, antiproliferative agents) can disrupt olfactory receptor function by interfering with the replacement of degenerate neurons, and (2) under some circumstances, receptor function can be restored by tissue regeneration. Ciliary regrowth occurs within days, but months are required for neural regeneration.

The axons of the first cranial (olfactory) nerve terminate within the glomeruli of the olfactory bulb, where they form synaptic contacts with inter neurons that have processes restricted to the bulb and with output neurons (mitral and internal tufted cells) that contribute axons to the lateral olfactory tract. The olfactory nerve is potentially important as a pathway for environmental toxins or viruses to enter the brain. The olfactory bulb provides a direct pathway from the periphery to important cholinergic and adrenergic systems implicated in the etiology of dementing diseases.

Axons of the olfactory tract terminate in primitive cortical areas, including piriform cortex and adjacent areas of uncus, hippocampal gyrus, amygdaloid complex, and entorhinal cortex. These and other areas of the frontal cortex and cingulate gyrus, not previously associated with processing olfactory information, are activated by olfactory stimuli on functional magnetic resonance imaging (fMRI) (Levy et al. 1997). Patients with hypos mi a who are exposed

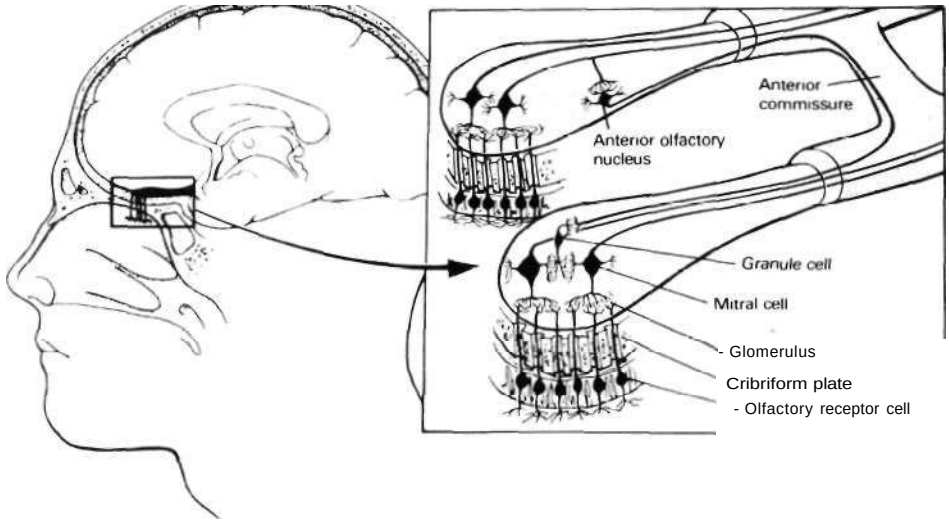

FIGURE 20.1 Olfactory nerve and bulb connections. Within the glomerulus, the olfactory receptor neuron terminals make synaptic contacts onto the dendritic branches of the mitral cells. Deep within these layers are the granule cells, whose main dendrites make synaptic contact with the secondary dendrites of the mitral cells. The mitral cells project axonal branches to the anterior olfactory nucleus, which is made up of cells in the posterior olfactory bulb. The pyramidal cells of the anterior olfactory nucleus project their main axons, after passing through the anterior commissure, to synapse with the granule cells in the contralateral olfactory bulb. The output of the bulb is earned by the axons of the mitral cells via the olfactory tract and the olfactory striae to the primary olfactory cortex. (Adapted with permission from Otroson, D. 1983, *Physiology of the Nervous System,* Oxford University Press, Oxford, England.)

to olfactory stimuli exhibit significantly less brain activation on fMRI than individuals with normal smell acuity. After theophylline treatment in patients with hyposmia, there is increased brain activation on fMRI in response to odors (Levy et al. 1998). Also, olfactory stimulation increases cerebral blood flow in the region of the piriform cortex. Temporal lobectomies affecting the piriform cortex disrupt odor identification, as measured by the University of Pennsylvania Smell Identification Test (UPS1T), and impair odor recognition memory while sparing the ability to detect odorants (Jones-Gotman et al. 1997). In humans, olfactory auras may represent activation of the uncus or amygdala by seizures.

Clinical Evaluation of Smell

Olfactory discrimination can be disrupted by (1) nasal obstructions that prevent volatile substances from reaching the receptor epithelium (transport olfactory loss), (2) impairment of receptor or olfactory nerve function (sensory olfactory loss}, and (3) pathologic processes affecting central pathways from the bulb to the primary olfactory cortex, medial dorsal thalamic nucleus, and orbitofrontal neocortex (neural olfactory loss). The second and third processes are designated *neurogenic.*

A primary objective in assessing impaired sense of smell is to distinguish an intranasal from a neurogenic cause. Transport olfactory loss can be produced by viral upper respiratory tract infection, rhinitis, sinusitis, polyps, neoplasms, and abnormalities in mucus secretion. There is loss of or decreased ability to detect odors (anosmia or hyposmia), distortions of normal smells (parosmia or dysosmia), increased sensitivity to some or all odorants (hyperosmia), or impaired ability to discriminate among different odors. Sensory olfactory loss produces similar symptoms and is caused by direct olfactory nerve damage (closed-head injury, viral infection, toxic substances) or impairment of normal receptor cell turnover (radiation or antiproliferative drug therapy). Neural olfactory loss can impair discrimination without producing anosmia,

Unilateral loss of smell is not recognized by the patient and, when found on examination, can be a useful sign of a focal neurogenic lesion. Such patients, or those complaining of loss of smell, should be asked about a history of head trauma, recent upper respiratory tract infection, drug use (both prescribed and abused), systemic illness, occupational exposure to toxins, dental procedures and prostheses, smoking and alcohol history, seizure disorder, radiation therapy, and pending litigation (loss of smell is a compensable disorder). System review should include headache, vision changes, nosebleeds, nasal obstruction, menstrual history, decline in intellectual capacity, and psychiatric disturbances, including mood changes, such as depression. Physical examination, in addition to taste and smell testing, should evaluate the ears, nose, mouth, oronasopharynx, and cranial nerves (specifically, decreased visual acuity, impaired color vision, papilledema, optic atrophy, and ocular motility abnormality). Mental status evaluation for evidence of dementia and depression is important.

In clinical practice, examination of odor discrimination or identification is sufficient to screen for deficits in

transport, sensory, and neural olfactory functions. Traditionally, the sense of smell is tested by having the patient sniff a familiar odoriferous substance (small bottle of coffee, oil of cloves, oil of peppermint) held in turn beneath each nostril while the other is occluded by a finger. Suggestion is minimized by having the patient keep the eyes closed and indicating that the bottle may or may not have something in it. If the patient detects an odor, he or she is then asked to identify the smell. Appreciation of an odor, despite the inability to name it, excludes anosmia. Hysterical patients may demonstrate unilateral anosmia on the side of an alleged neurological deficit. A malingerer can be detected by testing with ammonia, which stimulates the trigeminal nerve; if the patient denies noticing the stimulus, it is likely that the anosmia is false.

The UPSIT, which uses microencapsulated odorants (the so-called *scratch-and-snifftest),* consists of 40 odorants with a forced choice of one of four alternative responses for each item. The UPSIT is practical, easily administered, and reliable and is able to identify patients with a wide variety of olfactory disorders, including total and partial anosmia and malingering.

The extent of the laboratory investigation depends on the history and physical examination. If no obvious cause can be identified, appropriate studies for an underlying systemic illness should include complete blood cell count, routine blood chemistries, serum vitamin B_{125} thyroid function tests, glucose, syphilis serology, imaging examination of the skull and sinuses, and an electroencephalogram. A formal otorhinolaryngologic evaluation is essential to exclude local nasal disorders. If a cause is still not evident and the condition persists, magnetic resonance imaging (MRI) of the head and paranasal sinuses is needed.

Disease Entities

The causes of smell disturbances are diverse (Table 20.1), but nasal and paranasal sinus disease disorders that follow upper respiratory tract infections, head trauma, and idiopathic conditions account for more than 85% of the total (Table 20.2). The high frequency of nasal and parasinus disease causing anosmia and hyposmia underscores the need for thorough otorhinolaryngologic evaluation. Although intracranial causes (excluding head trauma and intracranial surgery) are rarely responsible for loss of smell, they result in the greatest morbidity if not diagnosed.

Olfactory Groove Meningioma

Anosmia may be the first symptom of an olfactory groove meningioma. In one scries of *19* patients with an olfactory groove meningioma in whom smell could be tested, anosmia was bilateral in 26 and unilateral in 3, Although most such patients mentioned this complaint to a physician, anosmia alone was never the cause of subsequent diagnosis in this series. The most egregious error in dealing with a chemosensory disturbance is the failure to capitalize on the symptom of anosmia as the sole or principal feature of an olfactory groove meningioma. This diagnosable and treatable condition, if not detected, frequently enlarges and causes seizures, vision loss, and dementia. Headache is present in most patients. The importance of imaging studies in this condition cannot be overemphasized. MRI should he performed in all patients in whom loss of sense of smell cannot be explained by head injury, other disease, or surgical procedure of the olfactory region. Viral infection should he a diagnosis of exclusion for patients with permanent anosmia.

Head Trauma

Loss of smell from head trauma may result from damage to the olfactory nerve as it enters **the** skull at the cribriform plate of the ethmoid bone, damage to the olfactory bulb, and possibly cerebral cortical injury. Shearing forces, fracture of the anterior fossa, and direct contusion are the mechanisms most commonly responsible. Most such injuries are to the occipital or frontal areas and are associated with motor vehicle accidents. The frequency of smell dysfunction after head trauma is 10% to 20% and is proportional to the severity of the injury. Anosmia and hyposmia after head injury may be unilateral or bilateral, transient or permanent, and with or without fracture at the base of the skull in the anterior fossa. MRI changes are present in 88% of patients, predominantly in the olfactory bulbs and tracts of the inferior frontal lobes (Yousem et al. 1996b). Recovery of smell occurs in up to 30-40% of patients after the head injury but is unlikely if the loss of smell persists for more than 1 year after injury.

Aging

Olfactory changes due to aging include reduced sensitivity, intensity, identification, and discrimination. These may relate to problems at the receptor or neuronal level, to associated disease states, to pharmacologic agents, and to changes in hormonal and neurotransmitter levels. Age-related deficits can alter food choices and subsequently exacerbate disease states and impair nutritional status and immunity. Use of flavor-enhanced food can help to maintain appetite and food enjoyment (Schiffman 1997).

Other Causes

Impaired odor detection and discrimination occur in Parkinson's disease (PD) and Alzheimer's disease. Patients with Korsakoff's psychosis retain a normal capacity to detect odors presented at threshold concentrations and yet exhibit a consistent inability to discriminate between odorants or to perform the UPSIT. Similarly, surgical

removal of the parts of the orbitofrontal cortex that receive projections from medial dorsal thalamic nucleus produces a comparable deficit. In patients with PD, there is no correlation between degree of olfactory impairment and age, duration of disease, disease severity, cognitive impairment, and dopaminergic or cholinergic treatment. Hyposmia in asymptomatic relatives of patients with PD suggests subclinical dopamine dysfunction (Bcrendse et al. 2001). Normal olfactory function in progressive supranuclear palsy and benign essential tremor supports the distinctness of these disorders from PD, Other studies in PD demonstrate abnormal olfactory evoked potentials and Lewy bodies on pathologic examination of the olfactory bulb, particularly in the anterior olfactory nucleus. As with idiopathic PD, familial PD is also associated with olfactory impairment, and [his heritable detect occurs independent of the parkinsonian phenotype (Markopoulou et al. 1997). Significant neurofibrillary tangle formation and cell loss in the anterior olfactory nuclei occur in Alzheimer's disease, along with reduced choline acety[transferase activity in the olfactory tubercle. Olfactory impairment is also present in other neurodegenerative conditions, such as motor neuron disease, Lewy body disease, Huntington's chorea, granulomatous angiitis of the central nervous system, idiopathic midline granuloma, Wolfram's syndrome, and hypogonadotropic hypogonadism {Kallmann's syndrome).

Source: Adapted with permission from Deems, D. A., Doty, R. L., Settle, R. G., et al. 1991, "Smell and taste disorders: A study of 750 patients from the University of Pennsylvania Smell and Taste Center," *Arch Otolaryngol Head Neck Surg,* vol. 117, pp. 519-528.

In patients with reduced or no sense of smell since birth, there is absence or hypoplasia of olfactory bulbs and tracts on MRI; thus congenital anosmia or hypoplasia may be an olfactory bulb-olfactory tract phenomenon rather than a cerebral process (Yousem et al. 1996a).

Olfactory dysfunction, reported in almost 40% of patients with multiple sclerosis, correlated with the number of demyelinating plaques on MRI involving areas of olfaction in the inferior frontal and temporal lobe regions (Doty et al. 1997), An increased sense of smell, *hyperosmia,* is uncommon and may occur with depression and exposure to toxic vapors.

Parosmia, the distortion of normal smell, may reflect an intracranial disease, such as a temporal lobe seizure or a tumor, olfactory bulb injury from rrauma, depression, or a local nasopharyngeal condition, such as sinusitis. Approximately 75% of patients with parosmia have associated hyposmia or anosmia.

Olfactory hallucinations occur in association with Alzheimer's disease, depression, schizophrenia, alcohol withdrawal, and uncinare seizures. In seizures, the olfactory auras are characteristically unpleasant or foul and rarely, if ever, appear as isolated epileptic events. One study, however, showed the olfactory sensation was unpleasant in only 7 of 13 patients; tumor was the most common etiology (10/13 patients), most likely involving the amygdala, with mesial temporal sclerosis a rare cause (Acharya V, Acharya J, and I.udcrs 1998). Cigarette smoking, a variety of drugs (both prescribed and recreational), radiation therapy, and hemodialysis, as well as environmental and industrial toxins, cause disturbances of smell (sec Table 20,2). Abnormalities of taste and smell may be an early manifestation of temporal arteritis.

TASTE

In humans, the gustatory system is responsible for the perception of sweet, salty, bitter, and sour. Disturbances of taste arc far less common than disturbances of smell. Although patients with chemosensory disorders often have complaints that food no longer has any taste, most such patients have olfactory dysfunction with normal taste. Disorders of taste are characterized as absence of taste (ageusia), diminished sensitivity (hypogeusia), increased sensitivity to some or all taste qualities (hypcrgeusia), distortion of normal taste (dysgeusia or parageusia), and gustatory hallucinations.

Pathophysiology

Gustatory receptor cells are clustered in taste buds, which are located in the papillae on the surface of the tongue and, to a lesser extent, at the back of the mouth and pharynx. Taste buds are innervated by sensory fibers of the chorda tympani and greater superficial petrosal bundles of the facial nerve, the glossopharyngeal nerve, and the superior laryngeal branch of the vagus nerve. Receptor cells have a limited life span and undergo constant replacement. Unlike the olfactory system, taste receptor cells lack axons; thus their replacement does not involve regenerative processes within the nervous system.

Taste afferent fibers from the anterior two thirds of the tongue course through the lingual nerve, a branch of the trigeminal nerve, which they leave via the chorda tympani to join the facial nerve as the nervus intermedius with cell bodies in the geniculare ganglion. The posterior one third of the tongue, pharynx, and soft palate are subserved by taste fibers in the glossopharyngeal nerve; the cell bodies lie in the nodose ganglion. Gustatory nerve fibers from the facial, glossopharyngeal, and vagus nerves terminate in the brainstem in the ipsilareral nucleus of the solitary tract. The central pathway from this nucleus projects via the parvocellular division of the ventral posterior medial nucleus and then via the posterior limb of the internal capsule to the frontal operculum and the anterior insular cortex. Studies of cerebral blood flow in humans (Small et al. 1997) and single-unit activity in monkeys indicate a secondary gustatory area in caudal orbitofrontal cortex. Damage to these central pathways may explain why temporal lobectomies affect the ability to recognize tastes without affecting taste detection. There may be an alternative or accessory taste pathway through the trigeminal nerve. This is supported by abnormal electrogustometric detection thresholds in patients with trigeminal neuralgia and trigeminal sensory neuropathy, with a further moderate but significant threshold increase after surgical treatment.

Gustatory responses depend on the adaptive state of the tongue. For example, if the tongue is exposed (i.e., adapted) to a variety of substances, water itself becomes capable of evoking tastes (the so-called *water taste).* This phenomenon has important clinical implications in conditions associated with changes in the rate of flow or composition of saliva.

These can be affected by food or drug consumption; diseases affecting salivary secretions, such as cystic fibrosis, Sjogren's syndrome, Cushing's disease, or Addison's disease; destruction of salivary tissue by irradiation; or periodontal conditions that add gustatory stimulants to the fluid bathing the tongue. In all cases of dysgeusia or parageusia, it is important to rule our conditions affecting salivary fluids before considering less common causes ot altered taste perception.

Clinical Evaluation of Taste

Patients presenting with a disturbance of taste should be asked about any associated disorder of smell; any pre-existing medical conditions and their treatment, such as ear infection, ear surgery, Bell's palsy, significant head injury, or tracheal intubation; recent upper respiratory tract illness; dental procedures or prostheses; and a detailed drug history.

In addition to a physical examination and testing of taste and smell, special attention should be paid to the oral cavity for evidence of infection, inflammation, degeneration, and masses, as well as atrophy and dryness of tongue, gums, dentition, and surrounding mucous membranes. Specific investigations are ordered to identify suspected causative considerations suggested by the clinical features. If no local cause is suggested, patients with taste abnormalities, particularly unilateral, should have audiologic evaluation and imaging studies to include the middle ear.

The sense of taste can be tested with natural stimuli, such as aqueous solutions of sugar, sodium chloride, acetic acid, and quinine, or with electrical stimulation of the tongue (clectrogustometry). A cotton applicator is used to rub the aqueous solution gently on one quadrant of the protruded tongue. The patient should not talk but should identify the perceived taste by pointing to cards printed with the words *sweet, salt, sour,* and *bitter.* The mouth is rinsed with water between tests. Elecrrogtistometry is the evaluation of taste by applying graded electrical currents to the tongue to produce a sensation described as sour or metallic. In normal subjects, the two sides of the tongue have similar thresholds for electrical stimulation, rarely differing by more than 25%. The technique has the advantages of simplicity, speed, and case of quantification and is capable of providing a reliable objective recording of the gustatory detection threshold.

Disease Entities

Although the cause of most cases of hypogeusia is unknown, the two most common are nasal disorders and a prior respiratory tract infection. Disturbances of taste may result from local disorders involving the tongue, taste buds, or both and from damage to neural pathways in the peripheral or central nervous system.

Drugs, Physical Agents, and Aging

Heavy smoking, particularly of pipe tobacco, and pharmaceutical agents, especially antirheumatic drugs, antiproliferative drugs, and drugs with sulfhydryl groups, such as penicillamine and captopril, are frequent causes of taste dysfunction (Table 20.3). Calcium-channel blockers, such as nifedipine and diltiazem, as well as antifungal agents, smokeless tobacco, anticonvulsants, and sumatriptan nasal spray may cause abnormalities of taste. Other local causes, in part related to drying of the mouth (xerostomia), include Sjogren's syndrome, radiation therapy, and pandysautonomia; these illustrate the important role saliva plays in taste perception. In the elderly, the taste threshold is more than twice as high as that of the general population, and drugs and disease states may further decrease taste (Schiffman 1997). Loss of taste may be the initial symptom of primary amyloidosis and is reported with variant Creutzfeldt-Jakob disease and ciguatera fish poisoning.

Belt's Palsy (See Chapter 76)

Although Bell's palsy is frequently associated with ipsllateral loss of taste over the anterior two thirds of the tongue, the patient usually does not recognize the loss. Loss of taste with facial palsy indicates involvement of the nervus intermedins portion of the facial nerve and localizes the lesion to the region between the pons and the point where the chorda tympani joins the facial nerve in the facial canal, distal to the geniculate ganglion. Recovery of taste within the first 14 days of onset of Bell's palsy is usually associated with complete recovery from paralysis. Impairment of taste for more than 2 weeks suggests a poor prognosis for the rapid return ol facial movement.

Trauma

The chorda tympani is particularly vulnerable to injury in its course through the middle ear on the medial superior surface of the tympanic membrane between the malleus and the incus. Isolated involvement of the chorda rympani is rare but can occur with middle ear lesions, such as cholesteatoma, otitis media, ear surgery (including tympanoplasty, stapedectomy, and mastoidectomy), and head trauma. Injury to preganglionic parasympathetic fibers within the chorda tympani, with loss of salivary secretion, may contribute to long-term impairment of taste even if taste fibers regenerate.

Injury to the lingual nerve (a branch of the mandibular division of the trigeminal nerve) causes loss of both general somatic sensation, resulting in numbness, and special visceral sensation, with taste loss over the anterior two

Tabic 20.3: Drugs affecting taste and smell

Classification	*Drug*
Amebic ides and anthelmintics	Metronidazole, niridazole
Anesthetics, local	Ben^ocaine, procaine hydrochloride (Novocain), and others, cocaine hydrochloride, tetracaine hydrochloride
Antilipemic	Clofibrate
Anti coagulants	Phenindione
Anticonvulsants	Lamotrigine
Antihistamines	Chlorpheniramine maleate
Antimicrobial agents	Amphotericin B, ampicillin, cefamandole, griseofulvin, ethambutol hydrochloride, lincomycin, protease inhibitors, sulfasalazine, sulfortes, streptomycin, terbinafine, tetracyclines, tyrothricin
Antiproliferative, including immunosuppressive agents	Doxorubicin and methotrexate, azathioprine, earmustine, vincristine sulfate
Antirheumatic, analgesic-antipyretic, anti-inflammatory agents	Allopurinol, colchicine, gold, levamisole, o-penicillamine, phenylbutazone, 5-thiopyriodoxine
Antiseptics	Hexetidinc
Antithyroid agents	Catbimazole, methimazole, methylthiouracil, propylthiouracil, thiouraeil
Agents for dental hygiene	Sodium lauryl sulfate (toothpaste)
Calcium-channel blockers	Nifedipine, diltiazem
Diuretics and antihypertensive agents	Captopril, diazoxide, ethacrynic acid
Hypoglycemic drugs	Glipizide, phenformin, and derivatives
Muscle relaxants and drugs for treatment of Parkinson's disease	Baclofen, chlormezanone, L-dopn
Opiates	Codeine, hydromorphone hydrochloride, morphine
Psycho pharmacologic, including antiepileptic, dtugs	Carbamazepine, lithium carbonate, phenytom, psilocyhin, trifluoperazine
Sympathomimetic drugs	Amphetamines, phenmetrazinc thcoclatc and fenhutrazate hydrochloride (combined)
Vasodilators	Oxyfedrine, bamifylline hydrochloride
Others	Germine monoacctatc, hydroquinone, idoxuridinc, ironsorbitex, vitamin D, industrial chemicals (including insecticides), smokeless tobacco, sumatriptan nasal spray

thirds of the tongue. This nerve may be injured as a result of jaw trauma and wounds, but most cases are iatrogenic due to laryngoscopy, difficult orotracheal intubation, and removal of wisdom teeth.

Head Injury

Taste disorders after head injury are rare and, when present, arc almost always due to disturbance of smell. They may be central or peripheral in origin. The frequency of ageusia after head injury is approximately 0.5%, with approximately 6% of all patients with post-traumatic anosmia also having ageusia. Recovery from ageusia is much more likely than from anosmia and usually occurs in most over a period of a few weeks to a few months.

Areas of brainstem damage that can cause taste disturbance include the tractus solitarius and its nucleus (ipsilateral ageusia) and the pontine tegmentum, involving both gustatory lemnisci (bilateral ageusia). Ipsilateral hypogeusia may follow pontine hemorrhage or infarcts involving the tegmentum. Ageusia may occur after bilateral thalamotomy. Unilateral thalamic or parietal lobe lesions may cause contralateral impairment of taste sensation. Gustatory hallucinations occur much less frequently than olfactory hallucinations hut may occur with similar structural lesions and with psychosis.

Dysgeusia is commonly experienced in association with dental problems, presence of dental prosthesis, poor oral hygiene, recent upper respiratory tracr infection, aging, depression, and psychotic conditions. Dysgeusia with facial numbness may occur with dissecting aneurysms of the carotid artery, possibly related to an alteration in blood supply to the seventh cranial nerve or branches of the chorda tympani,

Other Causes

Impaired raste may follow a focal disturbance of anatomic structures subserving taste, including jugular foramen tumors and more diffuse processes, such as idiopathic midline granuloma, high-altitude sickness, and diabetes mellitus. Hcmiagcusia can accompany vascular and demyelinating processes of the brainstem. Increased sensitivity to taste (hypergeusia) is uncommon and is reported in

association with cerebellar glioma, the mechanism of which is unclear.

Chapter 21
Cranial and Facial Pain

J. D. Bartleson, David F. Black, and Jerry W. Swanson

Headache is a common symptom with a high prevalence in most epidemiological studies of Western populations (Rasmussen and Lipton 2000). Headache is one of the 10 most common reasons for outpatient physician visits in the United States. Patients typically present with head and facial pain because the discomfort is severe, intetferes with work or other activities, or raises concerns about a serious underlying cause.

The diagnosis of a painful cephalic condition depends on three elements: the history, neurological and general examinations, and appropriate investigations.

HISTORY

The diagnostic advice offcted by the late Dr. A. L, Sahs is useful also for rhe patient with headache: "If you have 30 minutes to see a patient, spend 29 on history, one on the examination."

The method of taking a histoty for headache or facial pain is usually straightforward. Nevertheless, several specific aspects need to be addressed. The scheme of questions listed in Table 21.1 can be useful tor nhnnning a pertinent history. The discussion that follows illustrates some responses and theit implications.

It is usually helpful to begin by asking the patient to describe the pain or, alternatively, simply by asking what kind of help the patient seeks. This approach allows patients to relax and to say what they had planned to say previously. Usually, the patient continues to speak fot only a few minutes if not interrupted (Langcwitz et al. 2002). Once the patient has had an opportunity to speak, directed but open-ended questions (see Table 21.1) can be asked. The questions typically contain the word *headache,* although *facial pain* could easily be substituted, if appropriate.

Types of Headaches

Many individuals, especially those with a long-standing problem, have more than one rype of headache. It is valuable to establish this information at the beginning of the interview so each type of pain can be carefully delineated. For instance, some patients have frequent or persistent headaches that are punctuated occasionally by migraine headaches. Other patienrs have clearly separated migraine and tension-type headaches (formerly called *muscle contraction* or *tension headaches).* A patient with a chronic headache disorder may also develop a new headache that is a manifestation of a new different condition.

Onset of Headaches

A headache disorder of many years' duration, with little change, is almost always of benign origin. Migraine headaches often begin in childhood or early adulthood. A headache of recent onset obviously has many possible causes, including the new onset of either a benign or a more serious condirion. An increasingly severe headache raises rhe possibility of an expanding intracranial lesion. A new headache in an older patient suggests an intracranial lesion

Tabic 21.1: Questions for obtaining the history of headache

How many types of headaches occur?
When and how did the headaches begin?
If the headaches are episodic, what is their frequency and periodicity?
How long does it take for the headaches to reach maximal intensity, and how long do they last?
When do the headaches tend to occur, and what factors precipitate a headache?
Where does the pain start, and how does it evolve?
What is the quality and the severity of the pain?
Is the pain pulsatile (throbbing)?
Are there symptoms dun herald the onset or that accompany the headaches?
Does anything aggravate the pain?
What measures tend to reduce the pain?
Is then- ;i family history of headaches?
What prior evaluation has the patient undergone?
What medications have been used to treat the headaches?
What ideas does the patient have about the headaches?
How disabling are the headaches?
Why is the patient seeking help now?
Are there other medical or neurological problems?

(e.g., subdural hematoma) or giant cell (temporal or cranial) arteritis. Headaches of instantaneous onset suggest an intracranial hemorrhage, usually in the subarachnoid space, but also may be caused by cerebral venous sinus thrombosis, spontaneous cerebrospinal fluid (CSF) leaks, pituitary apoplexy, and severe hypertension (Dodick 2002). Occasionally, mass lesions, such as third ventricular tumors and posterior fossa or cervicomedullary tumors, can produce intermittent acute headaches if there is interference with CSF circulation.

Frequency and Periodicity of Episodic Headaches

Migraine may be episodic or chronic. Chronic migraine (formerly referred to as *transformed migraine)* usually occurs in individuals with a history of episodic migraine headaches. Episodic migraine may become chronic with or without medication overuse.

Episodic cluster headaches typically occur daily for several weeks or months and are followed by a long, headache-free interval, although chronic cluster headaches may occur daily for years. A related disorder, chronic paroxysmal hemicrania, occurs multiple times per day, often for years. A chronic daily headache without migrainous or autonomic features is likely to be a chronic tension-type headache. If there is no regular periodicity, it is useful to inquire about the longest and shortest periods of freedom between headaches. Asking the patient to monitor headache frequency, intensity, and medication use on a "headache calendar" often provides very helpful information.

Peak and Duration of Headaches

Migraine usually peaks within 1-2 hours of onset and usually lasts 6 to 36 hours. Cluster headache is typically maximal immediately if the patient awakens with the headache in progress or peaks within a few minutes if it begins during wakefulness. Cluster headaches characteristically last 45-120 minutes but occasionally last a few hours. Headaches similar to cluster headaches but lasting only about 15 minutes several times a day are typical of chronic or episodic paroxysmal hemicrania. "Ice-pick" head pains (idiopathic stabbing pain) are momentary, lasting only seconds. Tension-type headaches commonly build up over hours and may last days to years. These headaches may include some migraine features and were formerly called a *mixed* or *tension-vascular* headache but more appropriately fall under the rubric of chronic migraine. A new sudden, severe headache that is maximal at onset suggests intracranial hemorrhage, cerebral venous sinus thrombosis, or pituitary apoplexy. A chronic, continuous, unilateral headache of moderate severity with superimposed attacks of more intense pains that are associated with autonomic features suggests the diagnosis of hemicrania continua, an indomethacin-rcsponsive syndrome (Goadsby and Lipton 1997). Occipital neuralgia and trigeminal neuralgia manifest as brief shocklike pains, sometimes occurring in a crescendo pattern over a period of seconds to minutes. Occasionally, a duller pain in the same nerve distribution persists longer. Short-lasting unilateral neuralgiform headache with conjunctival injection and tearing (SUNCT) is a rare syndrome manifested by paroxysms of retro-orbital pain lasting seconds but with 3-100 episodes per day and the associated autonomic symptoms for which it is named.

Time and Occurrence and Precipitating Factors

Cluster headaches often awaken patients from a sound sleep and have a tendency to occur at the same time each day in a given person. Hypnic headaches typically affect elderly patients, regularly awakening the patient at a particular time of night. Unlike cluster headaches, they are typically diffuse and not associated with autonomic phenomena (Raskin 1997). Migraine can occur at any time during the day or night but usually begins in the morning, A headache of recent onset that disturbs sleep or is worse on waking may be caused by increased intracranial pressure. Tension-type headaches are typically present during much of the day and are often more severe late in the day. Obstructive sleep apnea may be accompanied by the chronic occurrence of headaches on awakening.

Patients with chronic, recurrent headaches often can recognize factors that trigger an attack. Migraine headaches may be precipitated by bright light, menstruation,

weather changes, caffeine withdrawal, sleeping longer or less than usual, and ingested substances, such as alcohol. Trauma, emotional or physical, may be an important causative factor in the pathogenesis of headache.

If bending, lifting, coughing, or Valsalva's maneuver produces a headache, an intracranial lesion, especially involving the posterior fossa, must be considered; however, most exertional and cough headaches are benign. Intermittent headaches that are precipitated by assuming the upright position and promptly relieved by lying down are characteristic ot a CST leak. If no Iiisrorv exists of a lumbar puncture, head trauma, or neurosurgical procedure, a spontaneous leak may be the cause. Alcohol is often a potent precipitant of cluster headaches.

Headache occurring during sexual activity, especially during or shortly after orgasm, may be of benign origin, especially if a headache has occurred on multiple occasions previously. A single headache in this circumstance, however, may be caused by a subarachnoid hemorrhage.

Lancinating face pain triggered by facial or intraoral stimuli occurs with trigeminal neuralgia. Glossopharyngeal neuralgia is most commonly triggered by chewing, swallowing, and talking, although cutaneous trigger zones in and about the ear are occasionally present.

Location and Evolution

Asking the patient to delineate the location of the pain with a finger is often helpful. Trigeminal neuralgia is confined to one or more branches of the trigeminal nerve. The patient may be able to localize one or more trigger points over the face or in the mouth and then outline the spread of the pain. Pain in the throat may be related to a local process or glossopharyngeal neuralgia. Pain in the lower portion of the face and neck can be produced sometimes by either a cluster or a migraine variant—a so-called *lower half headache.* Carotid dissection commonly presents with neck, face, and head pain ipsilateral to the dissection; this should be considered in any patient with pain of recent onset in these locations.

Migraine is most often unilateral, commonly in the frontotemporal region, but it may be generalized or may evolve from a unilateral location to become generalized. Cluster headaches are virtually always unilateral during an attack and are typically centered in, behind, or about the eye. At different times (different clusters), some patients do experience cluster headaches that have switched sides from a prior cluster.

A typical tension-type headache is generalized, although it may originate across the nuchal muscles only to spread and perhaps predominate in the frontal or occipital regions. When pain is localized to an eye, the intraoral region, or the ear, local processes involving these structures must be considered. Otalgia may be caused by a process involving the tonsillar fossa and the posterior tongue. Unilateral facial pain when chronic often does not have an underlying lesion. Occasionally, though, facial pain may be a symptom of nonmetastatic lung cancer (Eross et al. 2003).

Quality and Severity

Although it is often difficult for the patient to describe the quality of the pain, this information may be useful. It may be helpful to ask the patient to grade the severity of pain on a scale of 1 to 10. Migraine often has a pulsating quality that may be superimposed on a more continuous pain. Cluster headache is characteristically severe, boring, and steady and is often described as similar to a "hot poker." SUNCT produces moderately severe pain in the orbital or temporal region and may be described as stabbing or pulsatile. Tension-type headaches are usually described as a feeling of fullness, tightness, or pressure, or as being like a cap, band, or vise. Headaches caused by meningeal irritation, whether related to infectious meningitis or to a hemorrhage, are typically severe. Trigeminal neuralgia is severe, brief, and stabbing, occurring up to several times per minute; a milder ache may occur between paroxysms of pain. Pain caused by glossopharyngeal neuralgia is similar in character to that of trigeminal neuralgia.

Premonitory Symptoms, Aura, and Accompanying Symptoms

Leading questions may be necessary. Some patients have premonitory symptoms that precede a headache attack by hours. These can include psychological changes, such as depression, euphoria, and irritability, or more somatic symptoms, such as constipation, diarrhea, abnormal hunger, fluid retention, or increased urination. The term *aura* refers to focal cerebral symptoms associated with a migraine attack. These symptoms most commonly last 20-30 minutes and precede the headache. At other times, the aura may continue into the headache phase or arise during the headache phase. Visual symptoms are the most common kind of cerebral dysfunction and may consist of either positive or negative phenomena or a mixture of both. Other hemispheric symptoms, such as weakness, somatosensory disturbances (usually paresthesias), or language dysfunction, may precede the headache. Aura symptoms usually have a gradual onset and spread over minutes. If more than one symptom occurs (e.g., visual and somatosensory), the onsets are usually staggered and not simultaneous. The slow spread is a helpful feature to differentiate these from focal neurological symptoms caused by cerebral ischemia. Symptoms of brainstem origin, such as vertigo, dysarthria, ataxia, quadriparesis, diplopia, and loss of

consciousness, accompany basilar migraine. Nausea, vomiting, photophobia, phonophobia, and osmophobia characteristically accompany migraine attacks. In addition, lacrimation, rhinorrhea, and nasal congestion accompany migraine headache in many patients and should not be confused with a headache of sinus origin (Cady and Schreiher 2002).

Ipsilateral miosis and ptosis (oculosympathetic paresis or Horner's syndrome), lacrimation, conjunctival injection, and nasal stuffiness commonly accompany cluster headache. Sweating and facial flushing on the side of the pain have been described but are uncommon. Facial swelling, usually periorbital in location, may develop with repeated attacks. Shorter lived attacks occurring multiple times per day with similar autonomic features suggest a diagnosis of episodic or chronic paroxysmal hemicrania, an indomethacin-responsive syndrome (Goadsby and Lipton 1997). An oculosympathetic paresis is also a common feature associated with ipsilateral interna! carotid artery dissection. In the setting of acute transient or persistent monocular blindness, giant cell arteritis and carotid dissection should be considered.

Temporomandibular joint dysfunction often is characterized by jaw pain precipitated by movement of the jaw, clenching of the teeth, reduction in the range of jaw movement, joint clicking, and tenderness over the joint.

Headache accompanied by fever suggests an infectious cause. Persistent or progressive diffuse or focal central nervous system symptoms, including seizures, suggest a structural cause for a headache. Purulent or bloody nasal discharge suggests an acute sinus cause for the headaches. Likewise, a red eye raises the possibility of an ocular process, such as infection or acute glaucoma. A history of polymyalgia rheumatica, jaw claudication, or tenderness of the scalp and superficial arteries in an elderly person suggests the possibility of giant cell arteritis. Transient visual obscurations, tinnitus, diplopia, and the finding of papilledema may be associated with increased intracranial pressure from any cause, particularly idiopathic intracranial hypertension {pseudotumor cerebri).

An important principle is that symptoms that accompany a headache can be key in accurate diagnosis.

Aggravating Factors

The worsening of headache as a result of a cough or jolt suggests an intracranial element to the pain, whereas aggravation by torsion of the neck may indicate a musculoskeletal component. Sufferers of cluster headaches tend to endure their pain in an agitated state, pacing and moving about, whereas patients with migraines prefer to lie still. Precipitation or marked aggravation of headache in the upright position suggests intracranial hypotension.

Mitigating Factors

Rest, especially sleep and avoidance of light and noise tends to provide relief to the migraineur. Massage or heat may ameliorate the pain associated with a tension-type headache. Local application of pressure over the affected eye or ipsilateral temporal artery, and local application of heat or cold, or rarely short-lasting intense physical activity may alleviate the pain of cluster headache. Headache caused by intracranial hypotension typically is relieved or markedly benefited by recumbency.

Family History of Headaches

Migraine is often an inherited disorder, and a family history of migraine or "sick headaches" should he sought. Tension-type headaches are also frequently familial. Cluster headache is familial in a minority of cases (approximately 7%). Familial hemiplegic migraine is a rare, autosomal dominant variant of migraine with aura, wherein the migraine attack includes hemiparesis lasting minutes to weeks.

Prior Evaluation

The patient should be asked about prior consultations and testing for the headaches. If appropriate, the records and imaging study films can be obtained for review.

Prior Medications

Response to medications should be sought, including those used to treat individual headache attacks and those used prophylactically. The dose, route of delivery, dosage schedule, and duration of treatment should be established. This information also provides an opportunity to determine whether medications such as ergot preparations and analgesics have been overused. It also establishes whether prophylactic medications were optimized. A history of the use of caffeine-containing substances also should be elicited, because they may cause or aggravate headaches.

Disability

The assessment of head ache-re I a ted disability is important. A baseline determination with follow-up assessments is useful when judging the effects of treatment and can be useful in guiding headache therapy. In addition, disability can be useful in guiding the headache therapy (Upton et al. 2000). The Migraine Disability Assessment Scale (MIDAS) is an example of a useful, validated clinical tool (Stewart et al. 2001).

Patient Concerns

Headache pain can produce significant fear and anxiety regarding serious disease. The patient should be allowed to articulate any concerns so each aspect can be appropriately addressed by the physician.

Reason for Seeking Help

The question of why the patient is seeking help may be irrelevant if the problem is of recent onset. If the problem is chronic, however, it can be useful to inquire why the patient has come for aid at this point.

Other Medical or Neurological Problems

A history of past or current medical and neurological conditions and history of trauma, operations, and medication allergies should be obtained. Additionally, a history of the use of other medications and dietary supplements unrelated to the headaches should be obtained.

EXAMINATION

In the patient with headache, the physical examination often shows no abnormalities. However, findings on examination may yield important clues about the underlying cause. Even when the results of the examination are normal, both the physician and the patient gain confidence that nothing has been overlooked.

Although, strictly speaking, the history and the examination are separate parts of the evaluation, in practice the examination begins the moment the physician encounters the patient. Careful observation helps determine whether the patient has physical illness, appears anxious or depressed, and whether the patient's history is reliable. For instance, with respect to reliability, a patient who is unable to give a reasonably coherent history is suspected of having an abnormal mental status.

It is important to perform a neurological examination, including examination of the mental status, gait, cranial nerves, motor system, and sensory system, as discussed in Chapter 1. A neurovascular examination also should be performed.

The skull and cervical spine should be examined. The skull should be palpated for lumps and local tenderness. There may be tenderness over inflamed sinuses. Thickened, tender, irregular temporal arteries with an associated reduction in pulse suggest giant cell arteritis. Occasionally, other scalp lesions may be present that point to a cause for head pain. In tension-type headaches, the scalp muscles may be tender.

A short neck or low hairline suggests basilar invagination or an Arnold-Chiari malformation. In an infant, separation of the sutures suggests increased intracranial pressure, most commonly caused by hydrocephalus. Measuring the head circumference is always worthwhile in a child.

The cervical spine also should be tested for tenderness and mobility. Nuchal rigidity on passive neck flexion and Kernig's sign are evidence of meningeal irritation.

Vital signs, especially blood pressure and pulse, always should be assessed. If there is a question of fever, temperature should be measured. The body habitus should be noted. This observation may be relevant especially in young women with headache possibly related to pseudotumor cerebri, who are almost always obese. The general examination also includes auscultation of the heart and lungs, palpation of the abdomen, and examination of the skin.

Differential Diagnosis

In most cases, the history and examination are all that are needed to make a diagnosis, especially in the patient with a chronic headache. Migraine, tension-type headaches, and cluster headaches usually can be diagnosed with a high degree of certainty, particularly if the headaches have been recurrent over a long period and the examination is normal. In this case, it may be possible to proceed directly to management.

In some situations, however, the diagnosis is uncertain. These situations specifically raise concerns of a serious organic cause for rhe headaches. Headaches that are progressive are a worrisome indication of a possible intracranial process. A new headache of abrupt onset always raises concern about an intracranial process, especially hemorrhage and sometimes a mass lesion. Headaches that interfere with sleep, though sometimes benign, must be considered to have a potential serious cause. Headaches precipitated by exertion, change of position, cough, sneeze, or strain may be benign, although again they raise the possibility of an intracranial lesion, especially in the posterior fossa. Systemic symptoms, such as weight loss, fever, or those associated with another known systemic disease, such as malignancy or human immunodeficiency virus infection, should be investigated with care. Headaches that are associated with neurological symptoms, except those that are typical for migraine, should raise concern. Unexplained findings on neurological examination and a history of seizures should prompt additional evaluation.

The investigations used to evaluate a patient with headaches can include almost all of the tests used in neurology and neurosurgery, as well as various medical tests. Selection of the appropriate studies depends on the formulation after the history and examination. Indiscriminate use of batteries of tests is unwarranted.

Neuroimaging Tests

Computed Tomographics! Scanning and Magnetic Resonance Imaging

Computed tomographic (CT) scanning and magnetic resonance imaging (MRI) are extremely useful tests in the evaluation of patients with headache. Tumors, hematomas, cerebral infarctions, abscesses, hydrocephalus, and many meningeal processes can be identified with CT scanning and MRI. Abnormalities of the skull base, pituitary gland craniocervical junction, and white matter are better seen with MRI. The cost of an MRI study is severalfold that of a CT scan, but MRI is safer because x-rays are not used to generate the image and the enhancing agent used with MRI {gadolinium) is safer than the iodinated contrast used with CT. CT can detect acute subarachnoid hemorrhage if sufficient bleeding has occurred. If the CT scan is normal and the history is suggestive of recent subarachnoid hemorrhage, a lumbar puncture should be performed. CT scanning can be helpful for evaluating abnormalities of the skull, orbit, sinuses, facial bones, and the cervical spine. Changes associated with intracranial hypotension are best shown with MRI (Mokri 2001). The cervical spinal cord and exiting nerve roots and the craniocervical junction are much better shown with MRI.

Magnetic resonance angiography (MRA) is a noninvasive method that can demonstrate intracranial and extracranial vascular occlusive disease including large vessel dissection, intracranial arteriovenous malformations, and aneurysms. Intracranial venous sinus thrombosis is best diagnosed with magnetic resonance venography.

Evidence-based guidelines for neuroimaging of patients with nonacute headache {Frishberg et al. 2000) found MRI to be more sensitive in finding white matter lesions and developmental venous anomalies than CT.

For the acute onset of headache, CT is the optimal imaging study; in patients with subacute and chtonic headache, MRI is likely to reveal more, but many of rhe abnormalities will be incidental.

Plain X-ray Films of the Skull, Sinuses, and Cervical Spine

Plain x-ray films of the skull arc unnecessary in the routine evaluation of patients with headache but can he obtained if there has been acute head trauma or if there is an unusual bony abnormality on physical examination. Although plain x-ray films of the sinuses can show infection, hemorrhage, or tumor, CT scanning and MRI provide greatet definition. The role of the cervical spine in the cause of headaches remains uncertain, but occipitonuchal pain may result from degenerative disc and joint disease of the mid- and upper cervical spine. Rheumatoid arthritis can lead to craniocervical junction instability and pain. Tomographic films may be needed to show bony changes in the upper cervical spine and craniocervical junction. Flexion and extension, odontoid, and pillar views of the cervical spine can help to exclude ligamentous damage and fractures in patients with a history of head and neck injury. Congenital abnormalities of the cervical spine, such as the Klippel-Feil syndrome, may be associated with other disorders such as an Arnold-Chiari malformation.

Other Imaging Studies

Panoramic x-ray examination, MRI, or CT of the temporomandibular joints may be helpful in selected patients. The presence of temporomandibular joint disease should not be taken as proof that a patient's headaches arc related. Dental x-ray films are useful if dental-origin pain is suspected.

Cerebral Angiography

Cerebral angiography is rarely needed in the initial investigation of headache. It can be helpful in confirming vascular disease including arterial dissections, arteriovenous malformations, intracranial aneurysms, and the presence of central nervous system vasculitis.

Radioisotope and Computed Tomographic Studies for Cerebrospinal Fluid Leaks

Isotope cisternography can be helpful in determining the presence and location of a spontaneous, post-trail ma tic, or postoperative CSF leak. Alternatively, CT scanning ol the spine after instillation of contrast into the lumbar spinal fluid can be used to identify the location of CSF leaks.

Cerebrospinal Fluid Tests

CSF examination is used to diagnose or exclude meningitis, encephalitis, subarachnoid hemorrhage, and leptomeningeal cancer and lymphoma and is required to confirm increased or decreased intracranial pressure. Measurement of the opening CSF pressure should be performed in all cases,

Electroencephalography

Electroencephalography is not useful in the investigation of headache unless the patient also has a history of seizures, syncope, or episodes of altered awareness (Quality Standards Subcommittee of the American Academy of Neurology 1995).

General Medical Tests

A few blood tests are important in the investigation of headache. Detetmining the erythrocyte sedimentation rate

is essential in the evaluation of giant cell arteritis. Although a normal value does not exclude this condition, it greatly reduces the likelihood (see Chapter 75), Episodic headaches associated with unusual behavior ot impairment of consciousness may suggest an insulinoma. A diagnosis of insulinoma is supported by elevated insulin and C-peptide levels in the face of a low or relatively low fasting glucose level. Levels of carboxyhemoglobin can be measured in patients complaining of early morning headaches during the winter when home heating is used, especially when several members of the same household are affected. Estimation of blood alcohol levels and drug screening may be helpful in certain patients. Sensitive thyroid-stimulating hormone and serum thyroxine levels should be measured in patients with chronic headache because hypothyroidism may present with headaches. Urine concentrations of mctancphtines and free catecholamines should be measured if a pheochromocytoma is suspected.

Special Examinations and Consultations

Perimetry is helpful in the delineation of visual field defects. Tonometry is necessary to document elevated intraocular pressure in glaucoma, hut unless the eye is red or the cornea is cloudy, glaucoma is an unlikely cause of head or even eye pain. These tests are routinely done by ophthalmologists, who also have the equipment and expertise to perform slit-lamp examinations and other specialized examinations.

If pain of dental or temporomandibular joint origin is suspected, a dentist or oral surgeon skilled in the detection and trearment of these disorders should be consulted.

Diagnosis of tumors of the sinuses, nasopharynx, and neck, as well as inflammation of the sinuses, is aided by the expertise of an otorhinolaryngologist.

Temporal artery biopsy is performed to confirm or exclude giant cell arteritis (see Chapters 55A and 75).

In some selected cases (e.g., headaches as a manifestation of a chronic pain disorder with or without a history of drug abuse), psychiatric consultation may be helpful for diagnosis and management.

Further Observation

Sometimes, a definitive diagnosis cannot be reached after history taking, examination, and investigation. In such cases, further observation, perhaps coupled with a trial of therapy, usually reveals the diagnosis.

Chapter 22
Brainstem Syndromes

Michael Wall

Other chapters in this hook that deal with symptoms emphasize history as the starting point for generating a differential diagnosis. The differential diagnosis is then tefined during the examination. This chaptet calls for a different approach. When the neurologist evaluates a patient with a brainstem disorder, often the most effective method of diagnosis is to organize the differential diagnosis around the objective physical findings, particularly in patients with an altered mental status, such as coma. The symptoms are still integrated in the approach, but the physical findings take centct stage.

Organization around physical findings is efficient because very specific neurological localization, which limits the diagnostic alternatives, is often possible. The long tracts of the nervous system traverse the entire brainstem in the longitudinal (rostrocaudal) plane. Cranial nerve nuclei and their respective cranial nerves originate and exit at distinct levels of the brainstem. This allows for exquisite localization of function based on the findings of the neurological examination,

The chapter begins with a discussion of the brainstem ocular motor syndromes followed by miscellaneous brainstem, brainstem stroke, diencephalic, and thalamic syndromes.

OCULAR MOTOR SYNDROMES

Combined Vertical Gaze Ophthalmoplegia

Combined vertical gaze ophthalmoplegia is defined as paresis of both upward and downward gaze. Vertical gaze ophthalmoplegia is an example of a brainstem syndrome in which the objective physical findings dictate the diagnostic approach to the problem. Symptoms of vertical gaze ophthalmoplegia, when ptesent, are relatively nonspecific and usually occur in patients who have difficulty looking down, as when reading, eating from a table, and walking down a flight of stairs. In addition, symptoms may be unobtainable because of mental status changes caused by dysfunction of the reticular formation that lies adjacent to the vettical gaze generator in the rostral midbrain (see Chapter 39),

The neutological examination discloses associated signs of the disorders listed in the differential diagnosis (Table 22.1). Coma may be associated with reticular system involvement. Long-ttact signs and loss of pupillary reflexes are commonly associated. The syndrome of combined vertical gaze ophthalmoplegia is diagnosed when the ocular findings occur in isolation from long-tract signs.

With combined vertical gaze ophthalmoplegia, there is loss of vertical saccades and pursuit. This gaze limitation may be overcome by the oculocephalic (doll's head or doll's eye) maneuver, which tests the vestibulo-oculat reflex (VOR; see Chapter 39). It is demonstrated by having the patient focus on an object, rotating the patient's head, and looking for a conjugate eye movement in the opposite direction. Bell's phenomenon (reflex movement of the eyes up and out in response to forced eye closure) is often absent. Skew deviation (vertical malalignment of the eyes) may occur. Absence of convergence and loss of pupillary reactions to light are common.

The location of the lesion of combined vertical gaze ophthalmoplegia is the rostral interstitial nucleus of the medial longitudinal fasciculus (riMLF) for loss of vertical pursuit and saccades (Leigh and Zee 1999).

Table 22.1: Differential diagnosis of combined vertical gaze ophthalmoplegia

- Stroke
  - Ischemic
  - Hemorrhagic
- Progressive supranuclear palsy
- Corticobasal ganglionic degeneration
- Arteriovenous malformation
- Multiple sclerosis
- Thalamic and mesencephalic tumors
- Whipple's disease
- Syphilis
- Vasculitis (e.g., systemic lupus erythematosus)
- Metabolic disorders
  - Lipid storage diseases
  - Wilson's disease
  - Kern icterus
  - Wernicke's encephalopathy

Table 22.1 lists the disorders involving the rostral mesodiencephalic region (differential diagnosis) that cause combined vertical gaze ophthalmoplegia (see Chapter 39). The most common causes of isolated combined vertical gaze ophthalmoplegia are stroke and progressive supranuclear palsy (PSP). Cortical-basal ganglionic degeneration has similar ocular motility findings to PSP, but they are less severe. Whereas the supranuclear vertical gaze ophthalmoplegia may be prominent early in the course of PSP, obvious vertical and horizontal gaze restriction is usually a late finding in cortical-basal ganglionic degeneration (Rottach et ah 1996).

The diagnostic formulation varies with the age of the patient. Isolated combined vertical gaze ophthalmoplegia is usually due to infarction of the rostral dorsal midbrain (Bogousslavsky et al, 1994). When onset is gradual instead of abrupt or the patient is young, other disorders should be considered (see Table 22.1). In the elderly, PSP (see Chapter 77) is likely if the onset is gradual. PSP can be mimicked by the treatable Whipple's disease (Averbuch-Heller et ah 1999).

For Whipple's disease, the movement disorder oculomasticatory myorhythmia is pathognomonic. Laboratory investigations used to evaluate combined vertical gaze ophthalmoplegia include computed tomographic (CT) scan or, preferably, magnetic resonance imaging (MRI). Care should be taken not to overlook lesions inferior to the floor of the third ventricle. Lumbar puncture, syphilis serology, erythrocyte sedimentation rate, and an antinuclear antibody test complete the evaluation when the cause is not obvious. One should consider small bowel biopsy if Whipple's disease is a possible diagnosis. A polymerase chain reaction (PCR) assay of small bowel biopsy, cerebrospinal fluid (CSF), or other tissues for the 16S ribosomal ribonucleic acid (RNA) gene of *Tropberyma whippleii* appears to have both sensitivity and specificity for the diagnosis of Whipple's disease (Lee 2002).

Upgaze Paresis (Dorsal Midbrain or Parinaud's Syndrome)

Another brainstem syndrome that often occurs without symptoms is the dorsal midbrain syndrome. When symptoms do occur, the patient has difficulty looking up and may have blurry distant vision caused by accommodative spasm.

Tin- trtnid of findings in the dorsal midbrain syndrome are (1) loss of upgaze, which is usually supranuclear (loss of pursuit and saccades with preservation of the VOR); (2) normal-to-large pupils with light-near dissociation (loss of the light reaction with preservation of pupilloconstriction in response to a near target) or pupillary areflexia; (3) convergence-retraction nystagmus, in which the eyes make convergent and retracting oscillations after an upward saccade; and (4) lid retraction,

The location of the lesion causing the upgaze paresis of the dorsal midbrain syndrome is the posterior commissure and its inrersririal nucleus (Leigh and Zee 1999). The presence of the full syndrome implies a lesion of the dorsal midbrain (including the posterior commissure), a bilateral lesion of the pretectal region, or a large unilateral tegmental lesion.

The differential diagnosis is listed in Table 22,2. Other than the mild upgaze limitation that occurs with age, the most common cause of loss of upgaze is a tumor of the pineal region. The next most common causes are stroke and trauma. The upgaze palsy portion of the syndrome can be mimicked by (1) double elevator palsy; (2) PSP; (3) orbital causes, such as thyroid ophthalmopathy and bilateral Brown's superior oblique tendon sheath syndrome; (4) pseudo-dorsal midbrain syndrome, secondary to myasthenia gravis, or the Cuillain-Barre syndrome; and (5) congenital upgaze limitation. Forced ductions

Table 22.2: Differential diagnosis of dorsal midbrain syndrome

- Pineal tumors
- Stroke
  - Ischemic cerebrovascular disease
  - Thalamic hemorrhage
- I r;nini:I
- Hydrocephalus
- Multiple sclerosis
- Transtentorial herniation
- Congenital aqueductal stenosis
- Metastatic tumors
- Infections
  - Encephalitis
  - Cysticercosis
- Midbrain arteriovenous malformation
- Stereotactic midbrain surgery
- Metabolic disorders
  - Lipid storage disease
  - Wilson's disease
  - Kern icterus
  - Wernicke's encephalopathy

(see Chapter 16) may be performed by grasping anesthetized sclera with forceps and moving the globe through its range of motion. The presence of restriction of movement with forced ductions implies a lesion within the orbit, as distinct from a midbrain lesion.

The diagnostic formulation of the dorsal midbrain syndrome varies with age. In children and adolescents, pineal region tumors are usually the cause. In young and middle-aged adults, the disorder is uncommon, and the cause may be trauma, multiple sclerosis, or arteriovenous malformation. In the elderly, stroke and PSP are rhc most common causes.

The laboratory investigation needed to evaluate dorsal midbrain syndrome is MRi. If no tumor is present and an infectious or inflammatory cause is suspected, a lumbar punctute should be performed.

Downgaze Paresis

Isolated downgaze paresis is uncommon. Symptoms, when they occur, are difficulty in reading, eating, and walking down staits.

Neurological examination reveals loss of downward pursuit and saccades, although occasionally pursuit may be spared. The vertical oculocephalic maneuver may be normal or may disclose gaze limitation. Convergence may be lost, and gaze-evoked upbeat nystagmus may be present on upwatd gaze. In young patients, one should evaluate forced ductions for evidence of congenital downgaze limitation.

The site of the lesion for isolated downgaze paresis is bilateral involvement of the lateral portions of the riMLF. The differential diagnosis is ischemic stroke, PSP, and Whipple's disease. Laboratory investigations to support the clinical diagnosis include CT or preferably MRI. Lesions may be detected in the rostral mesodiencephalic junction inferior to the floor of the third ventricle.

The diagnostic formulation of isolated downgaze limitation is uncomplicated. When acute in onset, it is usually due to ischemic cerebrovascular disease. In an elderly patient with a progressive course, PSP should be considered.

In ternu clear Ophthalmoplegia

Internuclear ophthalmoplegia (INO) is characterized by paresis of adduction of one eye, with horizontal nystagmus in the contralateral eye when it is abducted. It is due to a lesion of the MLF ipsilateral to the side of the adduction weakness.

Surprisingly, most patients with INO have no symptoms. The symptoms that may be associated with INO are diplopia, oscillopsia of one of the two images, and blurred vision. When diplopia is present, it is due to medial rectus paresis (horizontal diplopia) ot skew deviation (vertical diplopia).

The MLF carries information for vertical pursuit and the vertical VOR. Consequently, other associated findings with MLF lesions are abnormal vertical smooth pursuit and impaired reflex vertical eye movements (doll's eye maneuver, Bell's phenomenon). Voluntary vertical eye movements (pursuit and saccades) are unaffected, daze-evoked vertical nystagmus, usually on upgaze, and skew deviation may be present. Skew deviation is a pure vertical ocular deviation that is not due to a cranial nerve palsy, orbital lesion, or strabismus but to disturbed suptanuclcar input to the third and fourth cranial nerve nuclei. It is thought to be due to unilateral damage to the otolith-oculat pathways or the pathways mediating the VOR. The topic is discussed further in Chapter 39.

INO may occur as a false localizing sign. Cases of brainstem compression due to subdural hematoma with transtentorial herniation and cerebellar masses may cause INO. Myasthenia gravis and the Guillain-Barre syndrome may also simulate INO.

The differential diagnosis is varied. Kxamination can differentiate a lesion of the MLF from a partial third cranial nerve palsy, myasthenia gravis, strabismus, or thyroid ophthalmopathy. The common causes of INO are stroke (including vertebral artery dissection) in older age-groups (Eggenberger et al. 2002) and multiple sclerosis in the young.

Laboratory investigations are performed to elucidate the cause including MRI. An edrophonium (Tensilon) test should be performed to evaluate for myasthenia gravis unless there are associated signs of obligatory brainstem dysfunction.

The diagnostic formulation for INO first necessitates accurate localization of the lesion. Limitation of adduction is initially formulated simply as an adduction deficit. It may be due to (1) a lesion of the midbrain or third cranial nerve disrupting innervation, (2) a disorder of the neuromuscular junction (myasthenia gravis), or (3) a lesion directly involving the medial rectus muscle.

Horizontal Gaze Paresis

Although there are no common symptoms of horizontal gaze paresis, this condition seldom occurs in isolation. Patients may complain of inability to see or to look to the side. Because supranuclear gaze pareses are conjugate by definition, diplopia does not occur.

On examination, with unilateral isolated involvement of the paramedian pontine reticular formation (PPRF), there is loss of ipsilateral saccades and pursuit. However, full horizontal eye movements are demonstrated with the oculocephalic maneuver.

Lesions of the sixth cranial nerve nucleus cause horizontal gaze paresis with inability of the oculocephalic maneuver to overcome the gaze limitation. Although there is usually an associated ipsilateral peripheral facial palsy

from involvement of the fascicle of the seventh cranial nerve coursing over the sixth cranial nerve nucleus, cases of isolated horizontal gaze paresis caused by sixth nerve nuclear lesions have been reported (Miller et al. 2002). With bilateral lesions, there is loss or limitation of horizontal saccades and (usually) pursuit in both directions. Gaze-paretic nystagmus may be present. In the acute phase, transient vertical gaze paresis and vertical nystagmus or upgaze paresis can occur. In the chronic phase, vertical eye movements are full, although there may be nystagmus on upgaze.

The location of the lesion for horizontal gaze paresis is the frontopontine tract, mesencephalic reticular formation, PPRF, and sixth cranial nerve nucleus. The explanation of gaze palsy occurring with a nuclear lesion is given in Syndromes Involving Ocular Motor Nuclei, later in this chapter.

The differentia] diagnosis is varied. As with other ocular motility disorders, myasthenia gravis may cause gaze limitation that simulates a central nervous system (CNS) lesion. The diagnostic formulation varies with age, rapidity of onset, and associated clinical findings. For patients with an acute onset whose age is older than 50 years, cerebrovascular disease, ischemic or hemorrhagic, is a likely cause. With a subacute onset before age 50 years, one should consider multiple sclerosis. Congenital cases are usually due to Mobius' syndrome. Systemic lupus erythematosus, syphilis, and Wernicke's encephalopathy should be considered for any acquired cases.

Laboratory investigations for horizontal gaze paresis include MRI. If there are no obligatory signs of CNS dysfunction, myasthenia gravis needs to be considered.

Global Paralysis of Gaze

The common symptoms of the global paralysis of gaze arc inability to look voluntarily (saccades and pursuit) in any direction. Global paralysis of gaze rarely occurs in isolation, however, and signs and symptoms of involvement of other local structures are usually present.

The location of the lesion is the frontopontine tract for saccades, and the parieto-occipito-pontinc tract for pursuit, where they converge at the subthalamic and upper midbrain level.

The differential diagnosis for total ophthalmoplegia is given in Table 22.3. The common causes for this presentation arc diseases outside the CNS, such as Guillain-Barre syndrome, myasthenia gravis, and chronic progressive external ophthalmoplegia (CPEO); for intra-axial lesions, consider stroke, Wernicke's encephalopathy, and PSP.

The diagnostic formulation is usually concerned with extra-axial (cranial nerve, neuromuscular junction, or muscle) pathology, because isolated complete ophthalmoplegia is rarely caused by a brainstem lesion. Myasthenia gravis (sometimes in combination with thyroid ophthalmopathy) and Guillain-Barre syndrome are much more likely possibilities if the onset is subacute. If the presentation is long-standing, slowly progressive, and accompanied by eyelid ptosis, the CPF.O syndromes, such as Kearns-Sayre syndrome, should be considered. In these extra-axial disorders, oculocephalic reflexes do not overcome the gaze limitations. PSP is a diagnostic possibility in the elderly, whereas Wernicke's encephalopathy should be considered in alcoholics and nutritionally deprived patients, Whipple's disease can also cause this rare clinical presentation.

Table 22,3: Differential diagnosis of total ophthalmoplegia

Oculomotor a praxis
Guillain-Barre syndrome
Myasthenia gravis
Thyroid ophthalmopathy (especially in combination with myasthenia gravis)
Chronic progressive external ophthalmoplegia syndromes
Wilson's disease
Pituitary apoplexy
Botulism
Tetanus
Progressive supranuclear palsy
Anticonvulsant intoxication
Wernicke's encephalopathy
Acute bilateral pontine or mesodieneephalic lesions

Laboratory investigations for patients with global paralysis of gaze should include MRI. An edrophonium test is performed when myasthenia gravis is suspected. When botulism is suspected, elecrtomyography with repetitive stimulation and serum assay for botulinum toxin should be performed.

One-and-a-Half **Syndrome**

The one-and-a-half syndrome is characterized by a gaze palsy when looking toward the side of the lesion, together with INO on looking away from the lesion. The common symptoms are diplopia, oscillopsia (the illusion that objects or scenes are oscillating), and blurred vision. Associated findings arc skew deviation and gaze-evoked nystagmus on upgaze or lateral gaze, and less commonly on downgaze. Acutely, in the primary position there may be exotropia (one eye deviated outward). There may also be limitation of upgaze, saccadic vertical pursuit, and loss of convergence.

The location of the lesion is the PPRF or sixth cranial nerve nucleus with extension to involve the intemuclear fibers crossing from the contralateral sixth cranial nerve nucleus, which causes the INO.

The differential diagnosis is multiple sclerosis, stroke (Kataoka et al. 1997), arteriovenous malformation, or tumor of the lower pons. A pseudo-one-and-a-half syndrome may occur with myasthenia gravis or the Giiill.lm-l'.urc syndrome. The diagnostic formulation tor

the one-and-a-half syndrome is similar to that for INO. Before age 50 years, the wusc is usually multiple sclerosis; after age 50 years, it is usually cerebrovascular disease.

Laboratory investigations for the one-and-a-half syndrome are MRI and if indicated lumbar puncture.

SYNDROMES INVOLVING OCULAR MOTOR NUCLEI

Patients with lesions of the third or sixth cranial nerve nucleus not only present with accompanying long-tract signs but also show different ocular motility disturbances than with lesions of the third or sixth cranial nerve.

Third Cranial Nerve Nucleus

The common symptoms of nuclear third cranial nerve palsies are diplopia and eyelid ptosis.

The signs present on the side of the lesion are weakness of the inferior and medial recti and the inferior oblique muscles. Upgaze limitation is present in both eyes because the superior rectus subnucleus is conttalateral, and the axons cross within the nuclear complex. In addition, eyelid ptosis and dilated, unreactive pupils may be present on both sides because the levator subnucleus and Edinger-Westphal nuclei arc bilaterally represented.

To localize a lesion to the third cranial nerve nucleus, both eyes must have some involvement because of the bilateral representation. The superior rectus and levator of the eyelid, however, are bilaterally represented and thus cannot demonstrate single muscle involvement. In addition, because the medial rectus subnucleus is in the most ventral portion of the nucleus, and all the dorsal subnuclei send axons through it, single muscle involvement of the medial rectus may not be possible. The eyelid levator subnucleus may be spared, because it is located at the dorsocaudal periphery of the nuclear complex.

The differential diagnosis is stroke (either ischemic or hemorrhagic), metastatic tumor, and multiple sclerosis. Of these diagnoses, only ischemic stroke is common. Disorders that simulate nuclear third cranial nerve palsy are myasthenia gravis, CPEO, thyroid ophthalmopathy, and the Guillain-Barre syndrome.

The laboratory investigation for this syndrome is MRI, which usually demonstrates the ischemic cerebrovascular lesion. Once the proper localization has been made, the diagnostic formulation is straightforward.

Sixth Cranial Nerve Nucleus

The sixth cranial nerve nucleus has two populations of neurons. The abducens motor neurons terminate on the ipsilatetal lateral rectus muscle. Internuclear neurons cross at the level of the sixth cranial nerve nucleus, join the MLF, and terminate on the medial rectus subnucleus of the third cranial nerve. Therefore a lesion of the sixth cranial nerve nucleus causes ipsilateral gaze palsy.

Patients with isolated horizontal gaze paresis are usually asymptomatic. If they do have symptoms, they complain of difficulty looking to one side. On examination, there is conjugate horizontal gaze paresis not overcome by an oculocephalic maneuver or caloric stimulation. This occurs because the fibers mediating this response, the VOR, synapse in the sixth cranial nerve nucleus. A peripheral seventh cranial nerve palsy invariably accompanies a lesion of the sixth cranial nerve nucleus. The differential diagnosis is stroke (Miller et al. 2002), Wernicke's encephalopathy, multiple sclerosis, and a tumor of the pontomcdullary junction.

Laboratory investigations for evaluating a lesion of the sixth cranial nerve nucleus are MRI, possibly lumbar puncture, and an edrophonium test to evaluate for myasthenia gravis if there are none of the long-tract signs obligatory for intra-axial disease.

OTHER BRAINSTEM AND ASSOCIATED SYNDROMES

Diencephalic Syndrome (Russell's Syndrome)

The common symptoms of diencephalic syndrome are emaciation with increased appetite, euphoria, vomiting, and excessive sweating (Pcrilongo et al. 1997). Patients may also have an alert appearance with motor hyperactivity. Most cases occur in children younger than 3 years.

The differential diagnosis at this stage is hyperthyroidism, diabetes mellitus, a tumor in the region of fourth ventricle, vein of Galen malformation, and a hypothalamic tumor. Most patients appear pale despite lack of anemia. Ophthalmological findings include optic atrophy and less commonly nystagmus.

Laboratory investigations for diencephalic syndrome may show an elevated serum growth hormone level that is incompletely suppressed by hyperglycemia. MRI usually demonstrates a hypothalamic mass lesion. Malignant cells may be present in the CSF, which are diagnostic. The CSF may also contain human chorionic gonadotropin in cases of germinomas. A lumbar puncture should not be performed if neuroimaging studies demonstrate a mass effect.

Thalamic Syndrome

Thalamic syndrome was first described by Dejerine and Roussy in 1906. The common symptoms of this syndrome are pain (thalamic pain), numbness, and hemisi'nsory loss. The pain may be spontaneous or evoked by any form of stimulation. It often has a disagreeable and lasting quality.

Patients may also complain of a distorted sense of taste. Right thalamic lesions appear to predominate.

On examination, there is marked hemianesthesia, which may be dissociated; that is, pain and temperature or light touch and vibration sense may be separately lost. There is usually proprioceptive loss, often with astereognosis. A transitory hemiparesis sometimes occurs.

The location of the lesion for this type of pain is usually the ventroposterolateral nucleus of the thalamus. In addition to the thalamus, thalamic-type pain can occur with lesions of the parietal lobe, medial lemniscus, and dorsolateral medulla (MacGowan et a I. 1997),

The differential diagnosis is stroke or tumor. The diagnostic formulation depends on the rate of onset of symptoms, associated signs, and neuroimaging studies. The apoplectic onset of symptoms implicates cerebrovascular disease. Gradual onset with progressive worsening of symptoms and signs is characteristic of brain tumor, Neuroimaging studies should confirm the clinical impression. The imaging modality of choice is MRI.

Tectal Deafness

The symptoms associated with tectal deafness are bilateral deafness associated with other related CNS symptoms, such as poor coordination, weakness, or vertigo. The differential diagnosis of the deafness is conduction-type hearing loss, cochlear disorders, bilateral eighth cranial nerve lesions, tectal deafness, and pure word deafness (sec Chapter 19).

On examination, there is deafness that usually spares pure tones. Pure word deafness with lesions of the inferior eolliculi has been reported (Vitte et a I. 2002). Other brainstem signs, including the dorsal midbrain syndrome, are often associated. The location of the lesion is the inferior eolliculi, with the most common causes being a tumor of the brainstem, cerebellum, or pineal region, trauma, and stroke.

The diagnostic formulation for hearing loss caused by lesions rostral to the cochlear nuclei is the presence of hearing loss characterized by sparing of pure tone, with marked deterioration when background noise distortion or competing messages are added. In addition, signs of damage to adjacent nervous system structures are present. Neuroimaging studies may confirm the diagnosis.

The pertinent laboratory investigations include MRI and an audiogram. Tests that reveal CNS auditory loss are distorted speech audiometry, dichotic auditory testing, and auditory brainstem-cvoked responses, although the latter may be normal (Vitte et al. 2002).

Foramen Magnum Syndrome

Foramen magnum syndrome is characterized by upper motor neuron-type weakness and sensory loss in any modality below rhe head. Detecting this syndrome is important, because it is often caused by benign tumors, such as meningiomas or fibromas, which may be removed completely when detected early in their course. Its only manifestations may be those of a high spinal cord syndrome {see Chapter 27).

The common, initial symptoms are typically neck stiffness and pain, which may radiate into the shoulder. Occipital headache also may be an early symptom. Other common symptoms are weakness of the upper or lower extremities, numbness (most commonly of hands or arms}, clumsiness, and a gait disturbance.

The differential diagnosis at this stage is cervical spondylosis, syringomyelia, multiple sclerosis, transverse myelitis, atlantoaxial subluxation, Chiari malformation, and foramen magnum or upper cervical cord tumor.

On examination, hemiparesis or quadriparesis and sensory loss are common. The loss of sensation may involve all modalities. It may be dissociated and capelike or occurring in a C2 distribution. Some patients have a hemisensory pattern below the cranium or involvement of only the lower extremities. Pseudoathctosis resulting from loss of joint position sense may be an early sign. Atrophy of muscles of the upper extremities may occur at levels well below the lesion (e.g., intrinsic muscles of the hands). Electric shock-like sensations radiating down the spine, which may be transmitted into the extremities, may occur with neck flexion (Lhermitte's sign). This finding occurs with lesions of the posterior columns, most commonly multiple sclerosis. Lower cranial nerve patsies are less common. The presence of downbeat nystagmus in primary position or lateral gaze strongly suggests a lesion of the cranioccrvical junction. This sign may be missed unless the eyelids are manually elevated and the nystagmus is sought when the patient gazes laterally and slightly downward.

The differential diagnosis at this stage is a foramen magnum or upper cervical cord tumor. The tumor type is usually meningioma, neurofibroma, glioma, or metastasis. Cervical spondylosis, multiple sclerosis, syringobulbia, and the Chiari malformation (often accompanied by a syrinx) are other diagnostic considerations. The definitive laboratory investigation for evaluation of the foramen magnum syndrome is MRI.

Patients with foramen magnum tumors may have a relapsing-remitting course that simulates multiple sclerosis. Because many of these tumors are meningiomas, one slit HI Id lv alert for patients at. risk. Meningiomas occur with increased frequency in women in their childbcaring years and increase in size during pregnancy. Cervical spondylosis is usually associated with a related radiculopathy and is not accompanied by downbeat nystagmus or lower crania] nerve abnormalities. Diagnosis requires a high index of suspicion early in the patient's course. Foramen magnum tumors are known to present difficult diagnostic problems because signs may be minimal despite a large tumor.

Syringobulbia

Syringobulbia is a disorder of the lower brainstem caused by progressive enlargement of a fluid-filled cavity that involves the medulla and almost invariably the spinal cord (syringomyelia). The symptoms and signs are primarily those of a disorder of the central spinal cord region (see Syringomyelia in Chapter 79; also sec Chaprct *66).*

The common symptoms of syringobulbia and syringomyelia arc painless burns, hand numbness, neck and arm pain, leg stiffness, and headache together with oscillopsia, diplopia, or vertigo. On examination, there are signs of lower brainstem dysfunction. Lower motor neuron signs of the ninth through twelfth cranial nerves may be present. Nystagmus, if present, is hotizontal, vertical, or rotatory. Signs of a spinal cord lesion characteristically coexist. In the upper extremities, there may be dissociated anesthesia of an upper limb or forequartet (i.e., loss of pain and temperature sensation with sparing of other modalities). The sensory loss may also be in a hemisensory distribution. Absent or decreased deep tendon reflexes in the upper extremities are the rule.

Spastic patapatesis, usually asymmettic, may occur. Loss of facial sensation can occur in an onionskin pattern emanating from the corner of the mouth. Charcot's (neuropathic) joints and trophic skin disorders can appear in long-standing cases. Horner's syndrome and bowel and bladder disturbances are other occasional findings.

The lesion is located in a rostrocaudal longitudinal cavity from the medulla into the spinal cord. The cavity is usually located near the fourth ventricle or central canal of the spinal cotd. The definitive laboratoty investigation fot syringobulbia is MRl, the most reliable and sensitive test to demonsttate a syrinx.

The differential diagnosis is intrinsic central cord and lowet brainstem lesion (syrinx, tumor, or trauma) and compressive foramen magnum syndrome caused by a tumor. Less likely causes are multiple sclerosis and spinal arachnoiditis.

The diagnostic formulation for syringobulbia involves history, examination, and laboratory evaluation. It is usually a disease of young adults, with a peak incidence in the third and fourth decades. Painless burns and dissociated segmental anesthesia of the upper extremities are of major diagnostic significance. Multiple sclerosis requires the presence of other noncontiguous lesions, oligoclonal bands in the CSF, and characteristic MRl findings. Tumors usually produce a more rapid course. Williams (1993) reviewed the treatment.

BRAINSTEM ISCHEMIC STROKE. SYNDROMES

Caplan, Pesin, and Mohr (1992) found that vcrtcbtobasilar ischemic lesions often have a rostrocaudal or patchy localization (Figure 22.1}, rather than the simplified transverse localization that is usually schematized. In addition, all the patient's symptoms and signs may not be explainable in anatomical terms; thai is, clinicopathological correlation may not be precise.

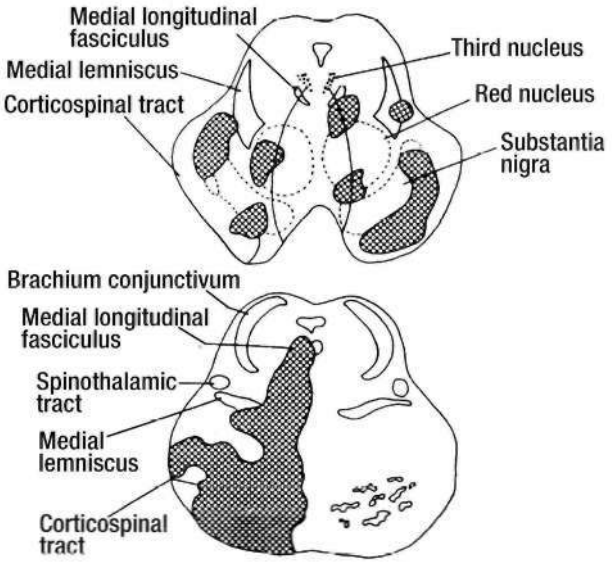

FIGURE 22.1 A postmortem examination of a patient of Kubik and Adams with embolism of the basilar artery. Note the rostrocaudal extension of the infarction along with its patchy nature. (Reprinted with permission from Kubik, C. S. *&c* Adams, 11. D. 1946, "Occlusion of the basilar artery: A clinical and pathological study," *P>rain,* vol. *69,* pp. 73-121.)

The cardinal manifestations of brainstem stroke are involvement of the long tracrs of the brainstem in combination with cranial nerve deficits. Crossed cranial nerve and motor or sensory long-tract deficits are characteristic. The cranial nerve palsy is ipsilatetal to the lesion and the long-tract signs are contralateral, hence the term *crossed.* Coma, ataxia, and vertigo, which ate common with vcrtcbtobasilar stroke, ate uncommon with internal carotid artery circulation stroke. INO, unreactive pupils, lower motor neuron cranial nerve impairment, and ocular skew deviation, when caused by stroke, occur only with posterior circulation lesions. The same is usually true fot nystagmus and most other ocular oscillations.

Another characteristic of vertebrobasilar ischemia is bilateral involvement of the long tracts. This can result in locked-in syndrome. This syndrome, usually caused by a lesion of the basis pontis, is characterized by quadriplegia with corticobulbar tract involvement and loss of the ability to produce speech. The reticular activating system is spared, and thus consciousness is preserved. Lye movements or blinking may be all that is left under voluntary control.

Anothet manifestation of bilateral lesions of the long tracrs is pseudobulbar palsy. The symptoms resemble those that occut with lesions of the medulla (bulb). However, cranial nerve nuclei have been disconnected from cortical input. This causes dysarthria, dysphagia, bilateral facial weakness, extremity weakness, and emotional lability.

A more descriptive term for this syndrome is *supranuclear bulbar palsy.*

Blindness occurs with bilateral posterior cerebral artery occlusion and concomitant occipital lobe infarction.

Ischemic stroke syndromes arc outlined in the following sections. These syndromes occur in isolation, as presented here, and in combination. The combinations can be medial, with lateral or often rostrocaudal extension.

Thalamic Stroke Syndromes

The blood supply of the thalamus is from the posterior cerebral, posterior communicating, basilar communicating (Figure 22,2), and anterior and posterior choroidal arteries. Thalamic stroke syndromes are listed in Table 22.4. They have been reviewed by Kumral et al. 2001,

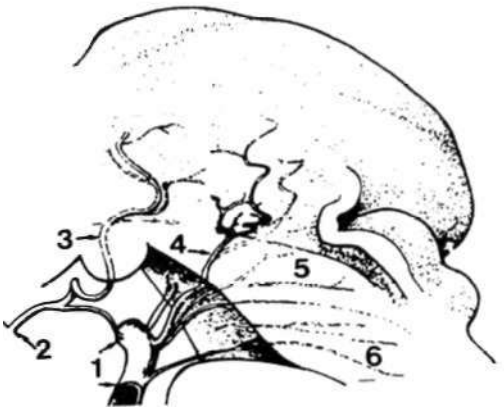

FIGURE 22.2 Branches of the basilar communicating artery as seen in a sagittal section of the brainstem. (1) Thalamic polar, (2) posterior communicating, (3) posterior th alamo subthalamic paramedian, (4) superior paramedian, (5) inferior paramedian, and (6) mesencephalic paramedian. (Reprinted with permission from Percheron, G. 1976, "Les arteres et territoires du thalamus humain: II. Arteres et territoires thalamiques paramedians de 1'artere basilare communicante," *Rev Neurol,* vol. 132, pp. 309-324.)

Midbrain Stroke Syndromes

Ischemia of the midbrain is characterized by long-tract signs combined with involvement of the third and fourth

Tabic 22.4: Ischemic stroke syndromes of the diencephalon

- Anterolateral
  - Common symptoms
    - Contralateral weakness, vision loss
    - Confusion
    - Disorientation
    - Language disturbance
  - Signs
    - Contralateral
      - I Icimparesis
      - Hemiataxia
      - Hemisensory loss
      - Homonymous hemianopia
    - Right-sided lesion: visuospatial abnormalities, hemincglect, nonverbal intellect affected
    - Left-sided lesion: disorientation, aphasia
  - Arterial territory involved: thalamic polar (tuberothalamie) artery (see Figures 22.2 and 22.3)
- Medial
  - Common symptoms
    - Disorientation and confusion
    - Coma with occlusion of mainstem variant
    - Visual blurring
  - Signs
    - Vertical gaze ophthalmoplegia
    - Loss of pupillary reflexes
    - Loss of convergence
    - Disorientation and confusion, stupor, coma, and various neuropsychiatry disturbances
  - Arterial territory involved: posterior tliaUunosLtbthahimic paramedian artery (thalamic paramedian or deep interpeduncular profundus artery [see Figures 22.2 and 22.3])
- Lateral and posterior internal capsule
  - Common symptoms
    - Contralateral
      - Hemiparesis
      - Numbness
      - Confusion
  - Signs
    - Contralateral
      - Hemiparesis
      - Diminished pain and temperature
      - Dysarthria
      - Homonymous hemianopia; characteristically with a tongue of visual field spared along the horizontal meridian (Figure 22.4]
    - Memory impairmenr
    - With right-sided lesions: visuoperceptual abnormalities
  - Arterial territory involved: anterior choroidal artery (see Figure 22.3)
- Posterolateral
  - Common symptoms
    - Contralateral
      - Weakness
      - Numbness
      - Vision loss
      - Neglect
      - Confusion
  - Signs
    - Contralateral
    - Loss of touch, pain, temperature, and vibration sense (common)
    - Hemiparesis in some
    - Hemiataxia
    - Homonymous hemianopia
    - Left hemispatial neglect
    - Poor attention span
  - Arterial territory involved: gcniculothalamic artery (see Figure 22.3)

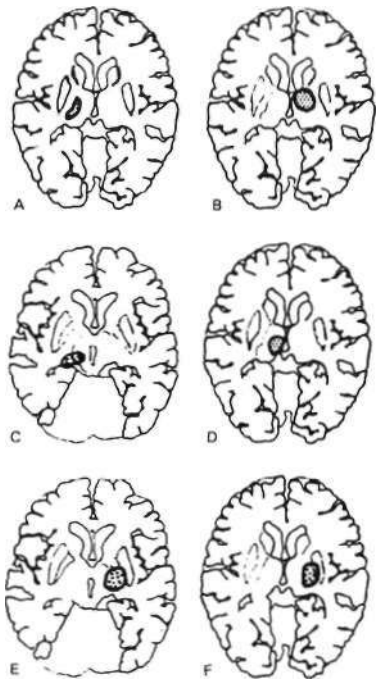

FIGURE 22.3 Schematic computed tomography sections showing the five arterial territories of the thalamus: (A) geniculothalamic (inferolateral) artery territory; (B) anterior thalamosubthalamic paramedian (tuberorhalamic} territory; (C) posterior choroidal territory; (D) posterior thalnmosubrhalamic paramedian territory; (E, F) anterior choroidal territory. (Modified with permission from Bogousslavsky, J,, Regti, F., & Uske, A. 1988, "Thalamic infarcts: Clinical syndromes, etiology and prognosis," *Neurology,* vol. 38, pp. 837-848.)

cranial nerves (Kumral et al. 2002b). Supratentorial (anterior circulation) stroke syndromes may present with midbrain signs when rostrocaudal deterioration occurs, causing transtentorial herniation. There are numerous classifications of the blood supply to the brainstem, and this is nowhere more apparent than in the midbrain.

Blood flows to the upper mesencephalon via perforating btanches of the basilar communicating artery. The basilar communicating artery (PI segment of the posterior cerebral artery or mesencephalic artery) connects the basilar artery with the posterior communicating artery. A simplified scheme used here divides the vasculat tctritories into median and lateral transverse regions.

The medial midbrain syndromes are characterized by an ipsilateral thitd cranial nerve palsy associated with a contralateral hemi paresis. Loss of the discriminative sensations (proprioception, vibration, and stereognosis) with involvement of the medial lemniscus may occur. The lateral syndromes are composed of contralateral loss of pain and temperature sensation and ipsilateral Horner's syndrome and loss of facial sensation. Ataxia may occur on either side. Ischemic stroke syndromes of the mesencephalon are outlined in Table 22.5, and the eponymic designations are given in Table 76.1.

Pontine Stroke Syndromes

The pons is supplied by numerous penetrating branches of the basilar artery. These arteries have little collateral supply; consequently, lacunar syndromes (see Chapter 57A) commonly occur (Table 22.6). These syndromes may be clinically indistinguishable from lacunar syndromes due to lesions of the interna! capsule. The medial syndromes are characterized by contralateral hemiparcsis and ipsilateral ataxia, 1NO, and conjugate horizontal gaze paresis.

The lateral syndromes arc distinguished by contralateral hemianesthesia and loss of discriminative sensation with ipsilateral Horner's syndrome, facial hemianesthesia, and ataxia. Ipsilatetal lower motor neuron-type facial paresis, sixth cranial nerve paresis, deafness, and vertigo occur with inferior pontine lesions.

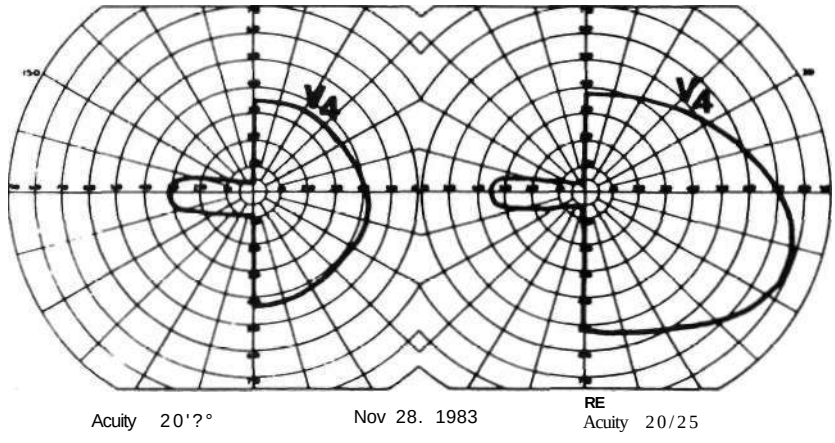

FIGURE 22.4 Typical homonymous hemianopia associated with anterior choroidal artery infarction. Notice the tongue of preserved vision along the horizontal meridian. This pattern is highly localizing to the lateral geniculate nucleus. (LE = left eye; RE = right eye.) (Reprinted with permission from Hclgason, C, Caplan, L., Goodwin, J., et al. 1986, "Anterior choroidal artery territory infarction: Report of cases and review," *Arch Neurol,* vol. 43, pp. 681686.)

Tabic 22.6: I sell emit stroke syndromes of the pons

- Superior medial pontine syndrome (Figure 22.7)
  - Common symptoms
    - Contralateral weakness
    - Clumsiness
  - Signs
    - On side of lesion
      - Ataxia
      - Internuclear ophthalmoplegia
      - Myoclonus of palate, pharynx, vocal cords
    - On side opposite lesion
      - Paralysis of face, arm, and leg
  - Arterial territory involved: median branches of the basilar artery
- Superior lateral pontine syndrome (see Figure 22.7)
  - Common symptoms
    - Clumsiness; ipsilateral
    - Contralateral numbness
    - Dizziness, nausea, vomiting
  - Signs
    - On side of lesion
      - Ataxia of limbs and gait, falling to side of lesion
      - Horner's syndrome
      - Facial hemianesthesia
      - Paresis of muscles of mastication
    - On side opposite lesion
      - Hemianesthesia (trigeminothalamic tract) impaired touch, vibration, and position sense
  - Arterial territory involved: superior cerebellar artery
- .Middle medial pontine syndrome (Figure 22.8)
  - Common symptoms
    - Contralateral hemiparesis
    - Ipsilateral clumsiness
  - Signs
    - On side of lesion
      - Ataxia of limbs
      - Conjugate gaze paresis toward the side of the lesion
      - Internuclear ophthalmoplegia
    - On side opposite lesion
      - Paresis of face, arm, and leg
    - With bilateral lesions, locked-in syndrome may occur
  - Arterial territory involved: median branches of the basilar artery
- Middle lateral pontine syndrome (sec Figure 22.8)
  - Common symptoms
    - Numbness
    - Clumsiness
    - Chewing difficulty
  - Signs
    - Contralateral
      - Hemisensory loss
    - Ipsilateral
      - Ataxia of limbs
      - Paralysis of muscles of mastication
      - Impaired pain sensation over side of face
      - Horner's syndrome
  - Arterial territory involved: long lateral branches of basilar artery
- Inferior medial pontine syndrome (Foville's syndrome) (Figure 22.9)
  - Common symptoms
    - Contralateral weakness and numbness
    - Facial weaknesses: ipsilateral
    - Diplopia
  - Signs
    - Contralateral
      - Paralysis of arm and leg
      - Impaired tactile and proprioceptive sense over half the body
      - Internuclear ophthalmoplegia
    - Ipsilateral
  - Paresis of conjugate gaze to side of lesion; to oeulocephalic maneuver also if the sixth cranial nerve nucleus is involved
    - One-and-a-half syndrome
    - Nystagmus
    - Diplopia on lateral gaze
    - Lower motor neuron—type facial palsy
  - Arterial territory involved: median branches of the basilar artery
- Inferior lateral pontine syndrome (anterior inferior cerebellar artery syndrome) (see Figure 22.9)
  - Common symptoms
    - Vertigo, nausea, vomiting
    - Oscillopsia
    - Deafness, tinnitus
    - Facial numbness
    - Dyscoordination
  - Signs
    - Contralateral
      - Impaired pain and thermal sense over half the body (may include the face)
    - Ipsilateral
      - Deafness
      - Facial paralysis
      - Ataxia
      - Impaired sensation over face
  - Arterial territory involved: anterior inferior cerebellar artery

Medullary Stroke Syndromes

Medial medullary ischemia can cause crossed hypoglossal hemiparesis syndrome (Table 22."). In addition, patients may have loss of discriminative-type sensation (position sense, graphesthesia, and stereognosis) when there is associated medial lemniscus involvement. Kumral et al. (2002a) have described four patterns of medial medullary stroke: (1) the most frequent classic crossed hypoglossal hemiparesis syndrome, (2) sensorimotor stroke without lingual palsy, (3) pure hemiparesis, and (4) bilateral medial medullary stroke.

Lateral medullary syndrome (Wallenberg's syndrome) is one of the most dramatic clinical presentations in neurology (see Table 22.7). Long-tract signs (i.e., contralateral loss of pain and temperature sensation over half the body, ipsilateral ataxia, and Horner's syndrome) are accompanied by involvement of the nuclei and fasciculi of cranial nerves V, VIII, IX, and X, Nystagmus is often present. The critical sign that distinguishes this from a lateral

Table 22.7: Ischemic stroke syndromes of the medulla

Medial medullary syndrome (Figure 22.10)
- Common symptoms
  - Contralateral weakness
  - Dysarthria
- Signs
  - Contralateral
    - Paralysis of arm and leg, sparing face
    - Impaired tactile, vibratory, and proprioceptive sense over half the body
  - Ipsilateral
    - Paralysis with atrophy (late) of hall the Longue
  - Primary-position upbeat nystagmus
- Arterial territory involved: occlusion of vertebral artery or branch of vertebral or lower basilar artery or anterior spinal artery

Lateral medullary syndrome (Wallenberg's syndrome) (see Figure 22.10)
- Common symptoms
  - Ipsilateral facial pain and numbness
  - Vertigo, nausea, and vomiting
  - Ipsilateral clumsiness
  - Diplopia, oscillopsia
  - Numbness ipsilateral or contralateral to lesion
  - Dysphagia, hoarseness
- Signs
  - Contralateral
    - Impaired pain sensation over half the body, sometimes including the face
  - Ipsilateral
    - Impaired sensation over half the face
    - Ataxia of limbs, falling to side of lesion
    - Horner's syndrome
    - Dysphagia, hoarseness, paralysis of vocal cords
    - Diminished gag reflex
    - Loss of taste
  - Other
    - Nystagmus
    - Primary-position rotatory
    - Gaze-evoked horizontal
    - Downbeating on lateral gaze
    - Ocular skew deviation
    - Hiccup
- Arterial territory involved: occlusion of any of five vessels may be responsible: vertebral; posterior inferior cerebellar; or superior, middle, or inferior lateral medullary arteries

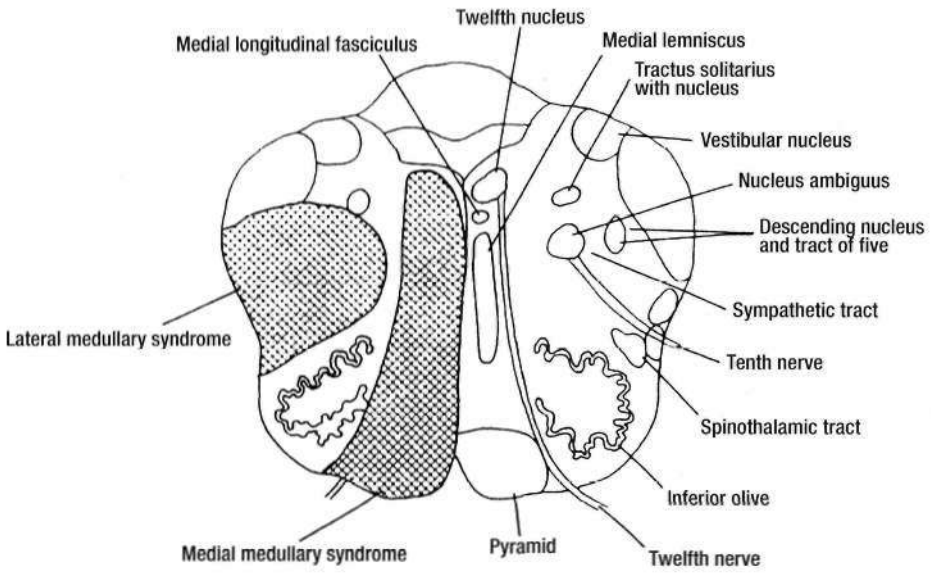

FIGURE 22.10 Cross section of medulla at the level of the inferior olivary complex showing the medial and the more common lateral territory involved with ischemic stroke in this brainstem site. (Reprinted with permission from Adams, R. D. & Victor, M. 1993, *Principles of Neurology*, 5th ed, McGraw-Hill, New York.)

pontine syndrome is involvement of the nucleus ambiguus or its fasciculus and consequent weakness of the ipsilatcral palate and vocal cord. (A more detailed discussion of stroke is found in Chapter 57A.)

Chapter 23
Ataxic Disorders

S. H. Subramony

The term *ataxia* is used by clinicians to denote a syndrome of imbalance and incoordination involving gait and limbs, as well as speech; it usually connotes a disorder involving the cerebellum or its connections (Middleton and Strick 1998). Ataxia can also result from disturbances of sensory input to the cerebellum, especially proprioceptive input. The clinical approach to patients with ataxia involves differentiating ataxia from other sources of imbalance and incoordination, distinguishing cerebellar from sensory ataxia, and designing an evaluation based on knowledge regarding various causes of ataxia and cerebellar disorders (Massaquoi and Hallett 2002). This chapter describes the clinical features of ataxia and outlines a basic approach to patients presenting with ataxia.

SYMPTOMS AND SIGNS OF ATAXIC DISORDERS

In the case of cerebellar diseases, a few general statements can be made. In lateralized lesions of the cerebellum, signs and symptoms occur ipsilateral to the lesion. Generalized cerebellar lesions give rise to symmetrical symptomatology. Acute cerebellar lesions often produce severe abnormalities early but may show remarkable recovery with time. Chronic progressive diseases of the cerebellum tend to cause a gradually declining balance with longer lasting effects. To some extent, signs and symptoms have a relation to the location of the lesions in the cerebellum (Fine, Ionita, and Lohr 2002). Thus vestibulocerebellar lesions cause disequilibrium and an ataxic gait. Lesions of the vermis, which is primarily a "spinocerebellar organ," cause truncal and gait ataxia with relative sparing of the limbs. Neocerebellar lesions (cerebellar hemispheres) produce more severe appendicular ataxia.

Symptoms in Patients with Ataxia

1. *Gait disturbances:* Patients with cerebellar and sensory ataxia often present with abnormalities of gait. The initial symptom may be a sense of insecurity while walking, especially when doing acts that require a bit more skill such as turning or balancing on a narrow ledge. Even before gait becomes abnormal, patients may note problems with specialized skills they have previously learned, such as skiing, bicycling, or climbing. Patients may report the sense of imbalance as dizziness, but the sensation is more like being on a boat rather than vertigo. Patients and family notice that the patient feels more secure with feet progressively apart. An increase in imbalance when visual cues are removed suggests a sensory component to the ataxia.
2. *Limb ataxia:* Ataxic diseases cause a variety of symptoms in the upper limbs, resulting from incoordination and tremor. Patients report clumsiness with activities such as writing, picking up small objects, and buttoning. Patients become slow in their movements in an attempt to be more accurate. These symptoms are one sided with lateralized lesions of the cerebellum.
3. *Truncal ataxia:* Midline cerebellar lesions cause truncal ataxia. Patients may experience head tremor and a truncal instability leading to oscillatory movement of the head and trunk while sitting or standing {tituhation). Because of associated hypotonia, they may need back support while sitting.
4. *Dysarthria and bulbar symptoms:* Ataxic diseases of cerebellar origin result in slurred speech and abnormalities of pitch and volume control. Dysphagia may result from incoordination of swallowing muscles.
5. *Visual symptoms:* Patients may experience blurriness or a sense of environmental movements as a result of ocular oscillations associated with cerebellar disease.
6. *Symptoms in sensory ataxia:* Patients with a sensory basis for ataxia usually do not experience dysarthria or visual symptoms. They may report other symptoms of peripheral nerve disease such as paresthesias and numbness.

Neurological Signs in Patients with Cerebellar Ataxia

Gordon Holmes (1922; 19.39) is often credited with the initial descriptions of cerebellar deficits, although certainly earlier works had reported on the effects of cerebellar lesions. Lesions of the cerebellum can cause deficits involving gait and stance, limb incoordination, muscle tone, speech, and oculomotor system. There is also recent interest in the possibility that the cerebellum may have some role in cognitive function.

1. *Stance and gait:* Patients with cerebellar disease experience an increase in body sway, initially when the feet are placed together. The trunk moves excessively in the sideways direction (latcropulsion). With more severe disease, patients experience the increased sway with even normal stance and learn that balance is better with feet apart. Healthy persons have a spread of feet during normal stance of usually less than 12 cm; patients with cerebellar disease tend to have a much larger spread of feet during quiet stance (Manto 2002). In the clinic, one can detect problems with balance even earlier by asking the patient to do a tandem stance or stand on one foot; normal adults can do these maneuvers for at least 30 seconds. The Romberg test is usually positive in patients with cerebellar ataxia, although this tends to be more prominent in patients with proprioceptive or vestibular lesions. Lastly, many patients experience rhythmic oscillations of the trunk and head known as titubation. Severe truncal ataxia can also result in inability to sit without back support. Gait can be tested by asking the palienl lo walk naturally down a straiglil path. Ataxic gait is characterized by a widened base and an irregular staggering appearance resembling alcoholic intoxication. Overall, the speed of movements is not severely impaired, although patients may deliberately slow down to keep their balance. The steps are irregular and the patient may lurch in unpredictable ways. Ataxic gait disturbance can be detected even earlier by testing tandem gait; patients with cerebellar lesions lose their ability to do heel-to-toe walking in a straight line.
2. *Limb incoordination:* A number of clinical tests have been designed to test limb incoordination and the presence of tremor usually associated with cerebellar lesions. The finger-to-nose test involves touching the tip of the nose with the tip of the index finger repeatedly after extending the arm. The finger-to-finger test is done by asking the patient to touch the examinct's finget repeatedly and rapidly as the examiner moves his or her finger to a different location. Action tremor can be examined by placing the arms in the outstretched position and asking the patient to point the index fingers at each other at about chest level separated by about 1 cm. Rapid alternating movements are examined by asking the patient to supinatc and pronatc the forearm in the unsupported position. This can also be done by having the patient clap one hand on the other (stationary) hand alternately with the palm and dorsum of the clapping **hand.** Rebound is examined by allowing the patient to flex the elbow against the examiner's hand and then abruptly removing the resistance and assessing the ability of the patient to arrest the sudden flexion movement. In the lower limbs, the heel-to-shin maneuver is done by having the patient bring the heel of the leg being tested to the opposite knee and then sliding it in a straight line down the anterior aspect of the tibia to the ankle. The foot should be nearly vertical while doing this. Having the patient rest the heel on the opposite knee for a period can elicit tremor in the leg. The toc-to-finger test is done by asking the patient to touch the examiner's finger repeatedly as the examiner moves the finget to a new position. Lower limb testing is best done in the supine position. These tests detect the following abnormalities in patients with ataxia:

   a. *Dysmetria:* This term refers to an error in the path of movement so that the desired target is either under-reached (hypometria) or over-reached (hypermetria). Dysmetria is evident in the finger-to-finger and toe-to-finger tests. Holmes thought of dysmetria as a disturbance of the rate, range, and force of movement. Dysmetria is often increased by adding a mass to the hand.
   b. *Intention (kinetic) tremor:* Oscillations of the limbs that show a characteristic increase in amplitude at the end of a voluntary movement intended to reach a target are typically seen with cerebellar lesions. The oscillations appeat to result from instability at the proximal, rather than the distal, portions of the limbs and are typically perpendicular to the axis of motion. In contrast, patients with essential tremor who do not have any other cerebellar signs may exhibit an cxaggctation of their tremor at the termination of a purposeful movement that is primarily in the distal portions of their limbs. The finger-to-nose and heel-to-shin maneuvers detect the kinetic tremor. Kinetic tremor is better evaluated when mass is added to the hand.
   c. *Action tremor:* Cerebellar lesions can give rise to a postural tremor initiated by keeping the arms outstretched or pointing the fingers steadily at each other. In the legs, maintaining one heel on the opposite knee can bring out such a tremor.
   d. *Other types of tremor:* Ataxic patients can exhibit an axial tremor involving the head and shoulders. Also, a severe tremor in the upper limbs that has both an intention and a postural component can appear in cerebellar outflow tract disease. This has been also

called a "rubral" tremor or "wing-beating" tremor. This cerebellar outflow tremor is often seen in multiple sclerosis, Wilson's disease, and midbrain strokes.

e. *Dysdiadochokinesis:* This term refers to irregularity of the rhythm and amplitude of rapid alternating movements. Simple tapping movements such as the index finger on the thumb crease or the feet on the floor can also detect the disturbance in rhythm (dysrhyth mokincsis).

f. *Decomposition of movements;* The characteristic jerkiness and the appearance that the movements are composed of their elemental components rather than a smooth finished product are referred to as *decomposition of movements.* This overall feature of ataxic movements can be conceptualized as being secondary to a combination of dysdiadochokinesis, dysmetria, and kinetic tremor,

3. *Abnormalities of muscle tone and strength;* Although hypotonia can occur with acute cerebellar lesions, this is not a major feature of most cerebellar diseases. The inability of patients to check forearm movement in the rebound test is often quoted to result from hypotonia but may have other explanations. Similarly, cerebellar lesions do not cause a loss of strength in the traditional sense, but many patients experience problems with sustaining a steady force during sustained hand use (isometrataxia) (Manto 2002).

4. *Oculomotor disturbances* (Martin and Corbett 2000): Routine eye movement examination can detect most of the signs of cerebellar disease. Fixation abnormalities are examined by asking the patient to maintain sustained gaze at the examiner's finger held about 2 feet in front. Then the patient is asked to follow the finger as it is moved slowly in all directions of gaze (pursuit). Eccentric gaze is maintained (at about 30-degree deviation) to check for nystagmus. Saccades are tested by having the patient shift gaze quickly between an eccentrically held finger and the examiner's nose in the middle. More sophistication can be brought to clinical examination by looking at the vestibulo-ocular reflex (VOR), with the patient in a rotary chair and looking at an object that moves with the chair. Rotating striped drum is used to examine for optokinetic nystagmus (OKN) and Frenzel goggles can be used to remove fixation.

   a. *Disorders of pursuit:* Pursuit movements include fixation (pursuit at 0 degree velocity). Small, 0.1-0.3-degrce square wave movements of the eyes are often seen even in normal persons during fixation. Square wave jerks exceeding 10 per minute are indicative of central nervous system (CNS) disease but arc not as specific for cerebellar ataxia as are large-amplitude square wave jerks. Square wave jerks larger than 10 degrees in amplitude are called *macrosquare wave jerks.* The square wave jerks are so called because in eye movement recordings they appear as 2 saccades in opposite directions separated by a short period of no movement, giving a "square" appearance to the waveform. Cerebellar disease also slows down pursuit movements, requiring catch-up saccades to keep up with a moving target. Such saccadic intrusions and intrusions of square wave jerks give a "ratchety" appearance to pursuit movement.

   b. *Disorders of saccades:* Saccade velocity is normal in cerebellar disease, but its accuracy is impaired so that both hypermetric and hypomctric saccades are seen. Such saccades are followed by a corrective saccade in the appropriate direction (Munoz 2002).

   c. *Other saccadic intrusions:* Ocular flutter differs from square wave jerks in that the back and forth horizontal saccades are not separated by an intcr-saccade interval. Opsoclonus is characterized by continuous saccades in all directions in a chaotic fashion. Both ocular flutter and opsoclonus are associated with cerebellar disease, especially paraneoplastic or postinfectious syndromes.

   d. *Nystagmus:* Gaze-evoked nystagmus is elicited when eccentric gaze is maintained at about 30 degrees from the midline. There arc repetitive drifts of the eyes toward midline followed by saccades to the eccentric position. The fast phase of the nystagmus is always to the side of the eccentric gaze. This nystagmus is usually seen in cerebellar disease. When typical gaze-evoked nystagmus fatigues and reverses direction after a few seconds, this is called *rebound nystagmus.* Rebound nystagmus may also appear as a transient nystagmus in the opposite direction when the eye is first returned to the midline. Rebound nystagmus is also seen in cerebellar disease. Downbeat nystagmus is characterized by a rapid phase in the down direction in primary position of the eyes. Such downbeat nystagmus becomes more prominent with downgaze or gaze to the side. Downbeat nystagmus is typically seen in abnormalities of cranio vertebral junction such as A mold-Chiari malformation but can also occur in some degenerative ataxias such as spinocerebellar ataxia type 6. Finally, upbeat primary position nystagmus can be seen in lesions ot the anterior vermis.

   e. VOR; In a rotary chair, normal individuals can suppress the VOR and keep their eyes on an object moving slowly with the chair. Patients with cerebellar disease cannot inhibit the VOR, so the eyes tend to drift away from the object and make catch-up saccades as the chair is rotated,

5. *Speech and bulbar function:* Speech is evaluated by listening to the spoken words and asking the patient

to speak a standard phrase. Speech in cerebellar disease is characterized by some slowness, slurring of the words, and a general inability to control process of articulation, leading to unnecessary hesitations and stops, omission of pauses when needed, and an accentuation of syllables when not needed Also, there is a moment to-moment variability in the volume and pitch conttol and inappropriate control of the breathing needed for speech, causing a scanning dysarthria. Mild dysphagia is not uncommon in cerebellar disease. In children, a form of "cerebellar mutism" has been described after posterior fossa surgery. This is transient and followed by more typical cerebellar dysarthria.

Cognitive function (Scmahmann 2002): A cerebellar cognitive affective syndrome has been described and includes defective executive function, visuospatial difficulties, mild language disturbances such as agrammatism, and behavioral changes including inappropriate behavior and attention deficits. Such cognitive deficits arc modest compared with the motor difficulties in these patients.

Neurological Signs in Patients with Sensory Ataxia

In this situation, the major basis of ataxia is defective proprioception. Patients can be shown to have impaired position and vibration sense and the deep tendon reflexes are often lost because of the afferent fiber pathology. The Romberg test is positive. Many "degenerative" ataxic syndromes combine features of cerebellar and proprioceptive deficits in a variable combination. This led Greenfield to classify ataxic disorders as spinal, cerebellar, or spinocerebellar in nature.

APPROACH TO PATIENTS WITH ATAXIA

The recognition of an ataxic basis to the gait and coordination problems a patient may have is usually easy (see Chapter *7H:* Disorders of the Cerebellum, including the Degenerative Ataxies). Other neural disorders that can give

Table 23.1: Acquired and genetic causes of ataxias

Acquired disorders causing ataxia	
Congenital	Ataxic cerebral palsy; other early insults
Vascular:	Ischemic strokes, hemorrhagic stroke, AV malformations
Infectious:	Acute cet'cbellins; postinfectious encephalomyelitis; cerebellar abscess; HIV; CJD
Toxic:	Alcohol; anticonvulsants; mercury; 5-FU; cytosine arabinoside
Neoplastic:	Gliomas, ependymomas, meningiomas; basal meningeal carcinomatosis
Immune:	Multiple sclerosis; paraneoplastic syndromes; anti-GAD, gluten ataxia
Deficiency:	Hypothyroidism, vitamin B^, vitamin Bi
Genetic disorders causing ataxia	
Recessive:	Friedreich's ataxia, AT, other DNA repair defects; metabolic errors
Dominant:	SCA type 1 through SCA type 23; episodic ataxias
linked	
Mitochondrial	NARP; MERRF; others including Kearns-Sayre syndrome and MELAS

AT = ata x la -te I a ng icctasi a; A V = atri o ven tri c u la r; CJ D = G reutz-Creut/feldr-Jakob disease; DNA = deoxyribonucleic acid; 5-FU = 5-fluorouracil; GAD = glutamate decarboxylase; HIV = human immunodeficiency virus; MELAS = mitochondrial, encephalopathy, lactic acidosis, and strokelike episodes; MF.RRF = myoclonus epilepsy and ragged red fibers; NARP = neuropathy, ataxia, and retinitis pigmentosa; SCA = spinocerebellar ataxia.

Tabic 23.2: Causes of ataxia related to age at onset

Age at onset	*Acquired*	*Genetic*
Infancy	Ataxic cerebral palsy, other intrauterine insults	Inherited congential ataxias such as Joubert's syndrome, Gillespie's syndrome
Childhood	Infections like acute cerebellitis, abscess; posterior fossa tumors like cerebellar gliomas, ependymomas, pontine glioma; vascular malformations; congential anomalies like Arnold-Chiari malformation; toxic such as anticonvulsants; immune related to neoplasms, especially opsoclonus-myoclonus	Ataxias related to "inborn errors of metabolism" such as the aminoacidurias, organic acidurias, Wilson's disease, etc.; Friedreich's ataxia; AT; ataxia with oculomotor apraxia; vitamin *E* deficiency syndromes; some dominant SCAs like SCA-7, SCA-13, and DRPLA, as well as episodic ataxia syndromes
Young adults	Infections such as abscesses, HIV; posterior fossa mass lesions such as meningiomas, gliomas; congenital anomalies including vascular malformations, Arnold-Chiari malformation; hypothyroidism; toxic such as anticonvulsants and alcohol; immune causes such as MS	Friedreich's ataxia; dominantly inherited SCAs such as SCA-1, SCA-2, MJD, SCA-7; inherited tumor syndromes such as von Hippel-I.andau syndrome
Older adults	Same as above plus idiopathic ("sporadic") ataxias; immune lesions such as paraneoplastic ataxias; anti-GAD and anti-gliadin antibodies	More benign SCAs such as SGA-6

AT = ataxia-telangiectasia; DRPLA = dentatorubral-pallidoluysian atrophy; HIV = human immunodeficiency virus; GAD = glutamate decarboxylase; MJD = Machado-Joseph disease; MS = multiple sclerosis; SCA = spinocerebellar ataxia.

Table 23.3: Causes of ataxia based on mode of onset and subsequent course

'ii-ui/iu	*Acquired diseases*	*Genetic diseases*
Episodic		Many "metabolic ataxias" of childhood; autosomal dominant episodic ataxia syndromes
Acute (hours to days)	Strokes, ischemic and hemorrhagic; MS; infections and parainfectious causes such as acute ccrcbcllitis and abscesses; toxic disorders	
Subacute (weeks to months)	Mass lesions such as gliomas, ependymomas, meningeal infiltrates; infections such as HIV and CJD; deficiency syndromes such as B_{12} and *B,;* hypothyroidism; immune causes such as paraneoplastic and anti-GAD/anri-gliadin; alcohol	
Chronic (years)	Some mass lesions such as meningiomas, cranio vertebra I junction anomalies; alcoholic; idiopathic cerebellar and "olivopontocerebellar" atrophies; MSA	Most genetic disorders such as FA, AT, and other recessive ataxias; all progressive SCA (dominant inheritance)

AT = ataxia-telangiectasia; CJD = Creutzfeldt-Jakob disease; FA = Friedreich's ataxia; CAD = glutamate decarboxylase; HIV : human immunodeficiency virus; MS = multiple sclerosis; MSA = multiple system atrophy; SCA — spinocerebellar ataxia.

rise to such problems with gait and dexterity, including nerve and muscle diseases, spinal cord diseases, and basal ganglia disorders, can usually be distinguished on the basis of physical signs alone.

Some patients with bilateral frontal lobe lesions may have a gait disorder superficially resembling ataxia (Bruns' ataxia or frontal ataxia}. However, limb and eye movement signs of cerebellar disease are absent and the gait is narrower based. Other gait disorders such as those associated with dystonia or chorea may also be occasionally mistaken for cerebellar ataxia.

The next task is to determine whether the ataxia is primarily cerebellar, primarily proprioceptive, ot a combination of both. Further diagnostic considerations and avenues for investigations and therapy arc dependent on arriving at a specific diagnosis (Table 23.1). This can be a daunting task, especially when the disease appears to be "degenerative" in naIlire (i.e., associated with cerebellar atrophy). As an example, the Online Mendelian Inheritance in Man Web site lists more than 400 genetic disorders alone in which ataxia can occur. In a patient with ataxia, many additional pieces of information may be useful in arriving at a diagnosis. These include the age at onset (Table 23.2); the tempo of disease (Table 23.3); whether the ataxia is predominantly spinal, spinocerebellar, cerebellar, or associated with spasticity (Tabic 23.4); the presence or absence of nonccrebellar neurological signs (Table 23.5); the occurrence of any distinctive systemic features (Table 23.6); and the nature of imaging abnormalities (Table 23.7).

Table 23.4; Ataxias that are primarily cerebellar, proprioceptive, and cerebellar, primarily proprioceptive and associated with spasticity

t <• rubellar araxias	
	Most of the acquired lesions in Table 23.1; dominant ataxias characterized by pure cerebellar ataxia
Proprioceptive-cerebellar ataxias	
	AT; SCA-2, MJD, SCA-4
Proprioceptive ataxias	
	FA; vitamin F. deficiency; acquired sensory ataxias such as those associated with paraneoplastic sensory ncuronopathy, Sjogren's syndrome, and diabetes
Spastic ataxias	
	SCA-1, MJD, SCA-7, some cases of FA

AT = ataxia-telangiectasia; FA = Friedreich's ataxia; MJD = Machado-Joseph disease; SCA — spinocerebellar ataxia.

Table 23,5: Systemic signs that may be useful in the differential diagnosis of ataxia

Systemic feature	*Possible diagnosis*
Short stature	Mitochondrial disease; early CNS insults
Hair loss	Hypothyroidism
Conjunctival telangiectasia	AT
(annuls	Marinesco-Sjogren syndrome
KF rings	Wilson's disease
Cervical lipoma	Mitochondrial disease
Abnormal ECG, echocardiogram	FA, mitochondrial disease
Organomegaly	Niemann-Pick disease, Gaucher's disease
Hypogonadism	Ataxia with hypogonadism (Holmes's ataxia)
Diabetes	FA
Spine and foot deformity	FA, AT
Hematological malignancy	AT
Sinopulmonary infections	AT
Tendon xanthomas	Cerebrotendinous xanthomatosis
High CK	AR ataxia with high CK and neuroparhy; mitochondrial
High uric acid	Partial HGPRT deficiency

AR = autosomal recessive; AT = ataxia-telangiectasia; CK = creatine kinase; CNS = central nervous system; ECG = electrocardiogram; FA = Friedreich's ataxia; HGPRT = hypoxanthine guanine phosphorihosyl transferase.

Table 23.6: Noncerebellar neurological signs or symptoms that may help in the differential diagnosis of ataxia

Neurological signs or symptoms	*Possible diagnosis*
Focal and laterali/ed brainstem deficits such as facial palsy, hemiparesis	Posterior circulation strokes, posterior fossa tumors, MS
Visual loss from optic atrophy or retinopathy	MS, FA, mitochondrial diseases, SCA-7
Papilledema, headache	Posterior fossa tumors or ataxia as a "false localizing" sign
Internuclear ophthalmoplegia	Posterior circulation strokes, MS, some SCAs
Gaze palsies	MS, strokes, SCAs 1, 2, 7, and MJD
Ptosis and ophthalmoplegia	Strokes, mitochondrial disease
Slow saccades and ocular apraxia	SCA-2, AT, SCA-7, recessive ataxia with oculomotor apraxia
Downbeat nystagmus	Aniokl-Clnari malformation, basilar invagination. SCA-<S and LA-2, lithium toxicity
Spasticity, UMN signs	Posterior circulation strokes, tumors/malformations compressing brainstem, MS, many SCAs, FA
Basal ganglia deficits	Many SCAs like MJD, SCA-2, SCA-1, and DRPLA; ataxic form of MSA; Wilson's disease, Fahr's disease, mitochondrial disease
Autonomic failure	Ataxic form of MSA
Proprioceptive loss	Bi2 deficiency, other sensory ataxias, FA
Epilepsy	Ataxia associated with anticonvulsants, some idiopathic ataxias, SCA-IO, DRPLA
Myoclonus	Mitochondrial disease, Unverricht-Lundbotg disease, DRPLA, and SCA-7 of childhood onset, sialidosis, ceroid lipofuscinosis, "idiopathic" ("Ramsay Hunt syndrome")
Cognitive decline	Alcohol related, MS, CJD, HIV, DRPLA, SCAs at endstage

CJD = Creutzfeldt-Jakob disease; DRPLA = dentatorubral-pallidoluysian atrophy; F,A = episodic ataxia; FA = Friedreich's ataxia; HIV = human immunodeficiency virus; MJD — Machado-Joseph disease; MS = multiple sclerosis; MSA = multiple system atrophy; SCA = spinocerebellar atrophy; UMN = upper motor neuron.

Table 23.7: Brain imaging abnormalities that can serve to differentiate the ataxias

MRl abnormality	*Possible diagnostic considerations*
Mass in cerebellum/posterior fossa	Tumors such as gliomas, posterior fossa meningiomas, abscess
Abnormal cranio vertebral junction	Arnold-Chiari malformation, basilar invagination
Infarcts, vascular malformations	Ischemic lesions; vascular malformations
Signal density changes in the cerebellum	MS, acute cerehellitis
Pure cerebellar atrophy	Inherited ataxias such as SCA-6, SCA-5, and others; idiopathic cortical cerebellar atrophy; other acquired atrophic cerebellar diseases such as hypothyroidism, toxic diseases, autoimmune ataxias
Pontocerebellar atrophy	Common inherited ataxias such as SCA-1, SCA-2, MJD; sporadic olivopontocerebellar atrophy; "ataxic" form of MSA
Cervical cord atrophy	"Spinal" forms of ataxia such as FA and vitamin E deficiency
White matter changes	Leukodystrophies presenting with ataxia, MS

FA = Friedreich's ataxia; MJD = Machado-Joseph disease; MR] = magnetic resonance imaging; MS = multiple sclerosis; MSA = multiple system atrophy; SCA = spinocerebellar atrophy

Chapter 24
Movement Disorders: Diagnosis and Assessment

Joseph Jankovic and Anthony E. Lang

The term *movement disorders* often is used synonymously with *basal ganglia* or *extrapyramidal diseases,* but neither of those terms adequately encompasses all the disorders included under the broad umbrella of movement disorders. Movement disorders are neurological motor disorders manifested by slowness or poverty of movement {bradykinesia or hypokinesia, such as that seen in parkinsonian disorders} at one end of the spectrum and abnormal involuntary movements (hyperkinesias) such as tremor, dystonia, athetosis, chorea, ballism, tics, myoclonus, restless legs syndrome, stereotypies, akathisias, and other dyskinesias at the other. Although motor dysfunctions resulting from upper and lower motor neuron, spinal cord, peripheral nerve, and muscle diseases usually are not classified as movement disorders, abnormalities in muscle tone {e.g., rigidity, spasticity, and stiff man syndrome), incoordination (cerebellar ataxia; Chapters 23 and 78), and complex disorders of execution of movement denoted by the term *apraxia* (Chapter 10) arc now included among movement disorders.

Abnormal movements are a clinical sign for which there are many possible causes. In most fields of neurology, the recommended clinical approach to movement disorders is to determine where in the nervous system the disease process is located and what that process could be. When dealing with movement disorders, however, the first step is to define the most appropriate broad movement disorder class, based on knowledge and recognition of phenomenology. Some abnormal movements may appear to be bizarre and therefore difficult to categorize. Despite attempts at uniformity in definition, classification errors are common. Inaccurate categorization occasionally has resulted in clinical, generic, and epidemiological misinformation becoming embedded in the literature. Video documentation is very useful in clarifying the phenomenology, thereby minimizing the risk of misdiagnosis.

Many movement disorders have no known or established cause. These disorders, sometimes called essential or idiopathic, are now best classified as primary and should be distinguished from those that arc secondary to identifiable diseases. In the following sections, historical and clinical features are emphasized that help the clinician make this distinction. Family history, including the ethnic origin (e.g., Ashkenazi Jewish} and parental consanguinity, often is helpful in arriving at a diagnosis. It is crucial to recognize-that the symptoms in other family members may be different from those in the patient because of variability of gene expression and penetrance. For example, some family members of patients with primary dystonia may have dystonic features, whereas others may have predominantly tremor. Additional problems that may hamper the acquisition of an adequate family history include adoption, uncertain paternity, and even the deliberate withholding of important family information. Denial of positive family history is particularly common in patients with Fluntington's disease and the genetic ataxias. An adult-onset disorder may not have been evident in a family member who died at an early age. It is particularly important to exclude Wilson's disease because of the specific therapy available and its universally fatal outcome if left untreated (Svetel etal, 2001}.

A history of birth and early developmental abnormalities also must be obtained, especially emphasizing the possibility of anoxia or kernictcrus. A history of encephalitis must be sought. Certain drugs and toxins have a strong potential for causing movement disorders, particularly drugs that block dopamine receptors. These include antipsychotic drugs; certain antiemetic drugs and other drugs used for various gastrointestinal disorders such as metoclopramide, prochlorperazine, and promethazine; calcium channel blockers such as cinnarizine and flunarizine; central nervous system (CNS) stimulants such as methylphenidate and cocaine; and dopaminergic drugs such as levodopa.

Besides documenting the movement disorder, neurological examination should search for additional findings that would help indicate the secondary nature of the problem. General physical examination must be thorough. An extremely important component of the examination is a corneal evaluation, including slit-lamp examination, to exclude the presence of a Kayser-Fleischer ring, characteristic of Wilson's disease (Plate 24.1). The nature and extent of laboratory investigations depend on the clinical suspicions. Without clues from the history and physical examination, however, very few specific or special investigations assist in diagnosing these patients.

PARKINSONISM

The initial feature of many basa! ganglia diseases is slowness of movement (bradykincsia) and paucity or absence of movement (akinesias), often associated with rigidity and ttemor (Jankovic 2003). Some authors have used the term *hypokinesia* to describe a reduction in amplitude of movement. Many parkinsonian symptoms are explained by the combination of slowness and poverty of movement and increase in muscle tone. The term *parkinsonism* is used to describe a syndrome manifested by a combination of the following six cardinal features: (1) tremor at rest, (2) rigidity, (3) bradykincsia, (4) loss of postural reflexes, (5) flexed posture, and (6) freezing (motor blocks). A combination of these signs is used to clinically define definite, probable, and possible parkinsonism. Diagnosis of definite parkinsonism requires **that at** least two of these features must be present, with one of them being resting tremor or rigidity; probable parkinsonism consists of resting tremor or rigidity alone; and possible parkinsonism includes at least two of the remaining four features. The four major characteristics of parkinsonism—tremor, rigidity, akinesia, and postural disturbances {forming the acronym TRAP)—account for most of the clinical abnormalities described here.

The most common cause of idiopathic parkinsonism (akinetic-rigid syndrome) is Parkinson's disease (PD). As a resulr of advances in genetics, many forms of idiopathic parkinsonism have been found to result from mutations in specific genes, such as those coding fot cc-synuclein or the Parkin protein. Whereas some of the gene mutations (e.g., *a-synuclein* gene) are very rare causes of parkinsonism, *Parkin* gene mutations account for up to 50% of all patients with early-onset parkinsonism. Because PD is defined as idiopathic parkinsonism, the notion of multiple Parkinson's diseases should be considered to draw attention to the different genetic causes of idiopathic parkinsonism, Besides genetic causes, there are many other causes of pure parkinsonism and of parkinsonism combined with other neurological deficits (parkinsonism-plus syndromes) (Table 24.1).

Motor Abnormalities

Early in the course of the disease, many patients with parkinsonism are unaware of any motor deficit. Often, the patient's spouse comments on a reduction in facial expression (often misinterpreted as depression), a reduction in arm swing while walking, and a slowing of activities of daily living, most notably dressing, feeding, and walking. The patient may then become aware of a reduction in manual dexterity, with slowness and clumsiness interfering with activities. PD often is asymmetrical, especially early in **the** course. A painful shoulder is one of the most common early symptoms of incipient unilateral rigidity and bradykinesia. This symptom, probably related to decreased arm swing and secondary joint changes or shoulder muscle rigidity, often is misdiagnosed as bursitis, arthritis, or rotator cuff disorders. All recreational and work tasks, household chores, and self-care functions eventually become impaired. Handwriting often becomes slower and smaller (micrographia), with speed and size decreasing as the task continues. Eventually, the writing may become illegible. Use of eating utensils becomes difficult, chewing is laborious, and choking while swallowing may occur. If the latter is an early and prominent complaint, one must consider bulbar involvement in one of the parkinsonism-plus syndromes, such as progressive supranuclear palsy (PSP) and multiple system atrophy (MSA; Thomas and Jankovic 2003b; Table 24.2). Dressing tasks, such as fastening small buttons or getting arms into sleeves, often are difficult. Hygiene becomes impaired. As with most other tasks, disability is greater if the dominant arm is more affected (e.g., shaving, brushing teeth, and other repetitive movements usually arc affected the most).

Speech becomes slurred and loses its volume (hypophonia), as a result of which patients are often asked to repeat themselves. A large number of additional speech disturbances may occur, including stuttering and palilalia (involuntary repetition of a phrase with increasing rapidity). Early pronounced voice changes often indicate a diagnosis other than PD (e.g., palilalia is more commonly a feature of PSP and MSA). Another problem related to impairment of bulbar function is excessive salivation and drooling. Initially, this may occur only at night, but later it

Tabic 24.1: Classification of parkinsonism

1. Primary (idiopathic) parkinsonism
   - Parkinson's disease
   - Juvenile parkinsonism

II. Multisystem degenerations ("parkinsonism plus")
   - Progressive supranuclear palsy
   - Multiple system atrophy
     - Striatonigral degeneration
     - Olivopontocerebellar atrophy
     - Shy-Drager syndrome
   - Lytico-Bodig or parkinsonism-dementia-ALS complex of Guam
   - Corticobasal degeneration
   - Progressive pallidal atrophy
   - Parkinsonism-demcnria complex
   - Pallidopyramidal disease

III. Heredodegencrative parkinsonism
   - Hcreditaty juvenile dystonia-parkinsonism (autosomal recessive *Parkin* mutation)
   - Do pa-responsive dystonia
   - Autosomal dominant Lewy body disease
   - Huntington's disease
   - Wilson's disease
   - Hereditary ceruloplasmin deficiency
   - Pantothenate kinase associated neurodegencration, also known as ncurodegeneration with brain iron accumulation, and Hallervotden-Spatz disease
   - Olivopontocerebellar and spinocerebellar atrophies including Macliado-Joseph disease
   - Familial amyotrophy-dementia-parkinsonism
   - Disinhibition-dementia-parkinsonism-amyotrophy complex
   - Gerstmann-Straussler-Scheinker disease
   - Familial progressive subcortical gliosis
   - I.ubag (X-linked dystonia-parkinsonism)
   - Familial basal ganglia calcification
   - Mitochondrial cytopathies with striatal necrosis
   - Ceroid lipofuscinosis
   - Familial parkinsonism with peripheral neuropathy
   - Parkinsonian-pyramidal syndrome
   - Neuroacanthocytosis
   - Hereditary hemochromatosis

IV. Secondary (acquired, symptomatic) patkinsonism
   - Infectious: postencephalitic, acquired immunodeficiency syndrome, subacute sclerosing panencephalitis, Crcutzfeldt-Jakob disease, prion diseases
   - Drugs: dopamine receptor blocking drugs (antipsychotic, antiemetic drugs), rcscrpine, tetrabenazine, a-mcthyldopa, lithium, fhtnarizine, cinnarizine
   - Toxins: MPTP, carbon monoxide, manganese, mercury, carbon disulfide, cyanide, methanol, ethanol
   - Vascular: multi-infarct, Binswangcr's disease
   - Trauma: pugilistic encephalopathy
   - Other: parathyroid abnormalities, hypothyroidism, hepatocerebral degeneration, brain tumor, paraneoplastic, normal-pressure hydrocephalus, nonco m mu n ica ti ng h y d rocephaluSj sy ri ngomescneep ha I i a, hemiatrophy - h em i p a rk i nso nism, peripherally induced tremor and parkinsonism, and psychogenic

CBD = corticobasal degeneration; DLB = dementia with Lewy bodies; OPCA = olivopontocerebellar atrophy (the cerebellar form of sporadic multiple system atrophy); I'D = Parkinson's disease; PDACG = parkinsonism-dementia-amyottophic lateral sclerosis complex of Guam; PSP = progressive supranuclear palsy; SDS = Shy-Drager syndrome; SND = sttiatonigral degeneration.

Source: Modified from Jankovic, J. 1995b, "Treatment of parkinsonian syndromes," in *Treatment of Movement Disorders,* ed R. Kurlan, J.B. Lippincorr, Philadelphia, 95-114.

can be present throughout the day, at times necessitating the constant use of a tissue or handkerchief.

Getting in and out of a chair or car and climbing in and out of the bathtub cause problems; patients often switch to showering. Many patients interpret these difficulties as resulting from "weakness." Generalized loss of energy and easy fatigability arc also common complaints. "Walking becomes slowed and shuffling, with flexion of the knees and narrow base. When involvement is asymmetrical, one leg may drag behind the other. Stride then becomes shortened, and turns include multiple steps (turning en bloc). Later, patients may note a tendency to advance more and more rapidly with shorter and shorter steps (festination), at times seemingly propelled forward with a secondary inadequate attempt to maintain the center of gravity over the legs. When this occurs, a nearby wall or an unobstructed fall may be the only method of stopping. Alternatively, the feet may seem to become glued to the floor, the so-called freezing phenomenon or motor block. Early on, this is appreciated when the patient initiates walking (start hesitation), is turning (especially in an enclosed space), or attempts to walk through an enclosed area, such as a doorway (an elevator door is a common precipitant). When combined with poor postural stability, prominent freezing results in the tendency to fall forward or to the side while turning. Later, impaired postural reflexes may cause falls without a propulsive or freezing precipitant. The early occurrence of falls suggests a diagnosis of PSP or other parkinsonian disorder besides PD. Turning over in bed and adjusting the bedclothes often become difficult. Patients may have to sit up first and then turn, and later the spouse may have to help roll the person over or adjust position for comfort.

Cognitive, Autonomic, and Sensory Abnormalities

The complaints of patients with parkinsonism are not limited to the motor system (see Table 24.2). Dementia may be seen in a variety of parkinsonism syndromes (see Chapters 72 and 77), Depression also is a common problem, and patients often lose their assertiveness and become withdrawn, more passive, and less motivated to socialize. The term *bradyphrenia* has been used to describe the slowness of thought processes and inattentiveness that are often seen.

Complaints related to autonomic dysfunction arc also common. In all parkinsonian syndromes, constipation is a common complaint and may become severe. However, fecal incontinence is not seen in PD unless the motor disability is such that the patient cannot maneuver to the bathroom or dementia is superimposed. Bladder complaints, such as frequency, nocturia, and the sensation of incomplete bladder emptying, may occur. A mild to moderate degree of orthostatic hypotension is common in parkinsonian disorders, and antiparkinsonian drugs often aggravate the problem (see Chapter 77). If the autonomic features, particularly erectile dysfunction, sphincter problems, and orthostatic lightheadedness, occur early or become the dominant feature, one must consider the possibility of MSA (see Chapter 77). Besides impotence with early loss of nocturnal or morning erections and inability to maintain erection during intercourse, the other symptom that may precede the onset of motor problems associated with MSA is a sleep disorder, such as sleep apnea or REM sleep behavior disorder,

Visual complaints usually are not a prominent feature, with the following specific exceptions. In PD, diplopia may occur during reading secondary to impaired convergence. Other parkinsonian disorders, particularly PSP and the olivopontocerebellar atrophies, sometimes have visual complaints (see Chapter 78). Oculogyric crises, which are sudden episodes of involuntary ocular deviation (most often up and to the side) in the absence of neuroleptic drug exposure, arc virtually pathognomonic of parkinsonism after encephalitis lethargica, although they may be seen in rare neuromctabolic disorders as well. Sensory loss is not part of parkinsonism, although patients with PD may have poorly explained positive sensory complaints, such as numbness and tingling, aching, and painful sensations, which are sometimes quite disabling.

Although a variety of neurophysiology] and computer-based methods have been proposed to quantitate the severity of the various parkinsonian symptoms and signs, most studies rely on clinical rating scales, particularly the Unified PD Rating Scale (UPDRS), Hoehn-Yahr Stages, and Schwab-England Scale of activities of daily living (Table 24,3). The historical section of the UPDRS can be self-administered and reliably completed by nondemented patients. In some clinical research studies the UPDRS is supplemented by a more objective timed test such as the Purdue pegboard test and movement and reaction times. Many scales, such as the PD questionnaire 39 (PDQ-39) and the PD quality of life questionnaire (PDQL), attempt to assrss the overall qualm <t lite.

Onset and Course

As in other movement disorders, the age of onset of a parkinsonian syndrome is clearly important in considering a differential diagnosis. Although the majority of patients arc adults, parkinsonism can be seen in childhood (see fable 24.1 j. I'D usually lias a slow onset and very gradual progression. Generally, patients with early-onset PD and those with tremor-dominant form tend to progress at a slower rate and arc less likely to have an associated cognitive decline than those with postural instability and the gait difficulty form of PD. Other disorders (such as those caused by toxins, cerebral anoxia, or infarction) may present abruptly or progress more rapidly (resulting in so-called malignant parkinsonism) and may even improve spontaneously (as in those caused by drugs, multiple infarcts, and certain forms of encephalitis).

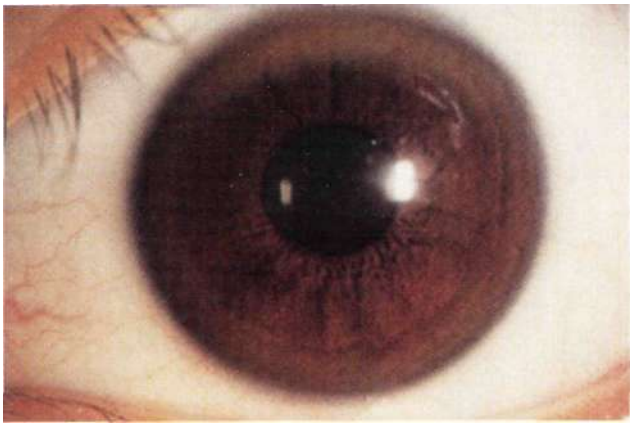

PLATE 24,1 Kayser-Fleischer ring. Note the golden-brown full-circumference ring thickest and most readily seen between the 11 o'clock and 1 o'clock positions of the cornea.

Tabic 24.3: Unified PD Rating Scale (UPDRS) definitions of 0-4

Mentation, behavior, and mood

1. Mentation
   0 = None.
   1 = Mild. Consistent forgetfulness with partial recollection of events and no other difficulties.
   2 = Moderate memory loss, with disorientation and moderate difficulty handling complex problems. Mild but definite impairment of function at home with need of occasional prompting.
   3 = Severe memory loss with disorientation to time and often place. Severe impairment in handling problems.
   4 — Severe memory loss with orientation preserved to person only. Unable to make judgments or solve problems. Needs much help with personal care. Cannot be left alone at all.
2. Thought disorder (caused by dementia or drug intoxication)
   0 = None.
   1 = Vivid dreaming.
   2 = "Bemgn" hallucinations with insight retained.
   3 — Occasional to frequent hallucinations or delusions, without insight, could interfere with daily activities.
   4 = Persistent hallucinations, delusions, or florid psychosis. Not able to care for self.
3. Depression
   0 = Not present.
   1 = Periods of sadness or guilt greater than normal, never sustained for days or weeks.
   2 = Sustaincd depression (1 week or more).
   3 = Sustained depression with vegetative symptoms (insomnia, anorexia, weight loss, loss of interest).
   4 = Sustained depression with vegetative symptoms and suicidal thoughts or intent.
4. Motivation and initiative
   0 = Normal.
   1 = Less assertive than usual; more passive.
   2 = Loss of initiative or disinterest in elective (nonroutine) activities.
   3 = Loss of initiative ot disinterest in day-to-day (routine) activities.
   4 = Withdrawn, complete loss of motivation.

Activities of daily living

5. Speech
   0 = Normal.
   1 = Mildly affected. No difficulty being understood.
   2 = Moderately affected. Sometimes asked to repeat statements.
   3 = Severely affected. Frequently asked to repeat statements.
   4 = Unintelligible most of the time.
6. Salivation
   0 = Normal.
   1 = Slight but definite excess of saliva in mouth; may have nighttime drooling.
   2 — Moderately excessive saliva with some drooling.
   3 = Marked excess of saliva with some drooling.
   4 = Markcd drooling, needs constant tissue or handkerchief.
7. Swallowing
   0 = Normal.
   1 = Rare choking.
   2 = Occasional choking.
   3 = Needs soft food.
   4 — Needs nasogastric tube or gastrotomy feeding.
8. *H.* Handwriting
   0 = Normal.
   1 = Slightly slow or small.
   2 — Moderately slow or small; all words are legible.
   3 = Severely affected; not all words are legible.
   4 = The majority of words are not legible.
9. Cutting food
   0 = Norma I.
   1 = Somewhat slow and clumsy, but no help needed.
   2 = Can cut most food, although clumsy and slow, some help needed.
   3 = Food must be cut by someone but can still feed slowly.
   4 = Needs to be fed.
10. Dressing
   0 = Normal.
   1 = Somewhat slow but no help needed.
   2 = Occasional assistance with buttoning, getting arms in sleeves.
   3 = Considerable help needed bur can do some things alone.
   4 = Helpless.
11. Hygiene
   0 = Normal.
   1 = Somewhat slow but no help needed.
   2 = Needs help to shower or bathe; or very slow in hygienic care.
   3 = Needs assistance for washing, brushing teeth, combing hair, going to bathroom.
   4 = Foley catheter or other mechanical aids.
12. Turning in bed
   0 = Normal.
   1 = Somewhat slow and clumsy but no help needed.
   2 = Can turn alone or adjust sheets, but with great difficulty.
   3 = Can initiate but not turn or adjust sheets alone.
   4 = Helpless.
13. Falling
   0 = Normal.
   1 = Rare falling.
   2 — Occasionally falls, less than once per day.
   3 = Falls an average of once daily.
   4 = Falls more than once daily.
14. Freezing
   0 = None.
   1 = Rare freezing when walking; may have start hesitation.
   2 = Occasional freezing when walking.
   3 = Frequent freezing. Occasionally falls from freezing.
   4 = Frequent falls from freezing.
15. Walking
   0 = Normal.
   1 = Mild difficulty. May not swing arms ot may tend to drag leg.
   2 = Moderate difficulty but needs little or no assistance,
   3 = Severe disturbance of walking, needs assistance.
   4 = Cannot walk at all, even with assistance.
16. Tremor
   0 = Absent.
   1 = Slight and infrequently present.
   2 = Moderate, bothersome to patient.
   i — Severe, interferes with many activities.
   4 = Marked, interferes with most activities.

Continued

Table 24.3: Unified PD Rating Scale (UPDRS) definitions of *0-4* scale—cnnr'd

17. Sensory symptoms
    I) • - \(HH'.
    1 = Occasionally has numbness, tingling, or mild aching.
    2 — Frequently has numbness, tingling, or aching, not distressing.
    3 = Frequent painful sensations.
    4 = Excruciating pain.

Motor examination

18. Speech
    0 = Normal.
    1 = Slight loss of expression, diction, or volume.
    2 — Monotone, slurred but understandable; moderately impaired.
    3 = Marked impairment, difficult to understand,
    4 — Unintelligible,
19. Facial expression
    0 = Normal.
    1 = Minimal hypomimia, could be normal ("poker face").
    2 = Slight but definitely abnormal diminution of facial expression.
    3 = Moderate hypomimia, lips parted some of the time.
    4 = Masked or fixed facies with severe or complete loss of facial expression, lips parted 1/4 inch or more.
20. Tremor at rest
    0 = Absent.
    1= Slight and infrequently present.
    2 = Mild in amplitude and persistent. Or moderate in amplitude but only intermittently present.
    3 = Moderate in amplitude and present most of the time.
    4 = Marked in amplitude and present most of the time.
21. Action tremor
    0 = Absent.
    1 -• Slight; present with action.
    2 = Moderate in amplitude; present with action.
    3 = Moderate in amplitude, with posture holdings as well as action,
    4 = Marked in amplitude, interferes with feeding.
22. Rigidity (judged on passive movement of major points with patient telaxed in sitting position; cogwheeling to be ignored)
    0 = Absent.
    1 = Slight or detectable only when activated by mirror or other movements.
    1 — Mild to moderate.
    3 = Marked, but full range of motion easily achieved.
    4 = Severe, range of motion achieved with difficulty.
23. Finger taps (patient taps thumb with index finger in rapid succession with widest amplitude possible, each hand separately)
    0 = Normal.
    1 = Mild slowing or reduction in amplitude.
    2 = Moderately impaired. Definite and early fatiguing. May have occasional arrests in movement.
    3 = Severely impaired. Frequent hesitation in initiating movements or arrests in ongoing movement.
    4 = Can barely perform the task.
24. Hand movements (patient opens and closes hands in rapid succession with widest amplitude possible, each hand separately)
    0 = Normal.
    1 = Mild slowing or reduction in amplitude.
    2 = Moderately impaired. Definite and early fatiguing. May have occasional arrests in movement.
    3 —Severely **impaired. Ireijiienr hesitation** in **niiu.mrii;** movements or arrests in ongoing movement.
    4 = Can barely perform the task.
25. Hand pronation-supination (pronation-supination movements of hands, vertically or horizontally, with as large an amplitude as possible, both hands simultaneously)
    0 = Normal.
    1 = Mild slowing or reduction in amplitude.
    2 = Moderately impaired. Definite and early fatiguing. May have occasional arrests in movement.
    3 = Severely impaired. Frequent hesitation in initiating movements or arrests in ongoing movement.
    4 = Can barely perform the task.
26. Leg agility (patient taps heel on ground in rapid succession, picking up entire lei',; amplitude should be about 3 inches)
    0 = Normal,
    1 = Mild slowing or reduction in amplitude.
    2 = Moderately impaired. Definite and early fatiguing. May have occasional arrests in movement.
    3 = Severely lmpaited. Frequent hesitation in initiating movements or arrests in ongoing movement.
    4 = Can barely perform the task.
27. Arising from chair (patient attempts to arise from a straight-back wood or metal chair with arms folded across chest)
    0 = Normal.
    1 = Slow, or may need more than one attempt.
    2 = Pushes self up from arms of seat.
    i Tends to fall **hack and may have** to **try more than one** time but can get up without help.
    4 = Unahle to arise without help.
28. Posture
    0 = Norma I.
    1 = Not quite erect, slightly stooped posture; could he normal for older person.
    2 = Moderately stooped posture, definitely abnormal; can be slightly leaning to one side.
    3 = Severely stooped posture with kyphosis; can be moderately leaning to one side.
    4 = Marked flexion with extreme abnormality of posture.
29. Gait
    0 = Norma I.
    1 = Walks slowly, may shuffle with short steps, but no festination or propulsion.
    2 = Walks with difficulty but needs little or no assistance; may have some fcstination, short steps, or propulsion.
    3 = Severe gait disturbance necessitating assistance.
    4 = Cannot walk at all, even with assistance.
30. Postural stability (response to sudden posterior displacement produced by pull on shoulders while patient erect with eyes open and feet slightly apart. Patient is prepared.)
    0 = Normal.
    1 = Retropulsion, but recovers unaided.
    2 — Absence of postural response, would fall if not caught by examiner.
    3 = Very unstable, tends to lose balance spontaneously.
    4 = Unable to stand without assistance.
31. Body bradykinesia (combining slowness, hesitancy, decreased arm swing, small amplitude, and poverty of movement in general)
    0 = None.
    1 = Minimal slowness, giving movement a deliberate character; could be normal for some people. Possibly reduced amplitude.

Continued

Table 24.3: Unified PD Rating Scale (UPDRS) definitions of 0-4 scale—cont'd

2 — Mild degree of slowness, giving and poverty of movement that is definitely abnormal. Alternatively, some reduced amplitude.
,i — Moderate slowness, poverty or small amplitude of movement.
4 = Marked slowness, poverty or small amplitude of movement.

Complications of Therapy

Score these items to represent the status of the patient in the week before the examination.

Dyskinesias

32. Duration

What proportion of the waking day are dyskinesias present? (historical information)

0 = None
1 = 1-25% of day
2 = 26-50% of day
3 = 51-75% of day
4 = 76-100% of day

33. Disability

How disabling are the dyskinesias? (historical information; may be modified by office examination!

0 = Not disabling
1 = Mildly disabling
2 = Moderately disabling
3 = Severely disabling
4 = Completely disabling

34. Pain

How painful are the dyskinesias?

0 = No painful dyskinesia
1= Slight
2 = Moderate
3 =Severe
4 = Marked

i5. Presence of early morning dystonia (historical information)

0 = No
1 = Yes

Clinical Fluctuations

36. "Offs" duration

What proportion of the waking day is the patient "off on average?

0 = None
1 = 1-25% of day
2 = 26-50% of day
3 = 51-75% of day
4 = 76-100% of day

37. "Offs" predictable

Arc any "off" periods predictable as to timing after a dose of medication?

0 = No
l=Yes

38. "Offs" unpredictable

Are any "off" periods unpredictable as to timing after a dose of medication?

0 = No
I=Yes

39. "Offs" sudden

Do any of the "off periods come on suddenly (e.g., over a few seconds)?

0 = No
1 = Yes

()ther complications

40. Anorexia, nausea, vomiting

Docs the patient have anorexia, nausea, or vomiting?

0 = No
1 = Yes

41. Sleep disturbances

Does the patient have any sleep disturbances (e.g., insomnia or hypersomnolence)?

0 = No
1=Yes

42. Symptomatic orthostasis

Does the patient have symptomatic orthostasis?

0 = No
l=Yes

Modified Hoehn and Yahr Staging

Stage 0 = No signs of disease
Stage I = Unilateral disease
Stage 1.5 = Unilateral disease plus axial involvement
Stage II = Bilateral disease, without impairment of balance
Stage 11,5 = Mild bilateral disease, with recovery on pull test
Stage IH = Mild to moderate bilateral disease; some postural instability; physically independent
Stage IV = Severe disability; still able to walk or stand unassisted
Stage V = Wheelchair bound or bedridden unless aided

Modified Schwab and England Activities of daily living scales

100%: Completely independent. Able to do all chores without slowness, difficulty, or impairment. Essentially normal. Unaware of any difficulty.
90%: Completely independent. Able to do all chores with some degree of slowness, difficulty, and impairment. Might take twice as long. Beginning to be aware of difficulty.
80%: Completely independent in most chores. Takes twice as long. Conscious of difficulty and slowness.
70%: Not completely independent. More difficulty some chores. Three to four times as long in some. Must spend a large part of the day with chores.
60%: Some dependency. Can do most chores, hut exceedingly slowly **and** with much effort. Errors; some impossible.
50%: More dependent. Help with half, slower, etc. Difficulty with everything.
40%: Very dependent. Can assist with all chores, but few alone.
30%: With effort, now and then does a few chores alone or begins alone. Much help needed.
20%: Nothing alone. Can be a slight help with some chores. Severe invalid.
10%: Totally dependent, helpless. Complete invalid.
0%: Vegetative functions such as swallowing; bladder and bowel are not functioning. Bedridden.

Examination and Clinical Signs

The diagnosis of parkinsonism often is immediately apparent on first contact with the patient. The facial expression, vocal characteristics, tremor, poverty of movement, and flexed posture give an immediate and irrevocable first impression. However, the physician must remember the need for detailed assessment in attempting to

distinguish between the various causes of this clinical syndrome.

Loss of facial expression (hypomimia) often is an early sign. Occasional patients have a wide-eyed, anxious expression, with deep facial folds, and this can be pronounced in cases of PSP. Blink frequency usually is reduced, although blepharoclonus (repetitive spasms of the lids on gentle eye closute) and reflex blepharospasm (e.g., precipitated by shining a light into the eyes or manipulating the lids) also may be seen. Spontaneous blepharospasm and apraxia of lid opening occur less often. Patients with apraxia of lid opening often open their eyes using their hands, and once the eyes are fixed on an object the eyelids remain open. In addition to the facial characteristics, patients with parkinsonian disorders develop excessive greasiness of the skin and seborrheic dermatitis, characteristically seen over the forehead, eyebrows, and malar area,

The voice of a patient with PD typically is hypophonic, monotonous, often hesitant, stuttering, and more rapid than normal. The speech, like the gait, may be festinating, that is, it gets faster and faster. One must attempt to discern additional pseudobulbar or cerebellar features that suggest alternative diagnoses. Palilalia and echolalia (involuntary repetition of wotds and phrases spoken by others) occur in several parkinsonian disorders. Careful observation of facial and vocal characteristics may be immediately rewarding. One example is the combination of poor eye contact caused by the disturbance of refixation eye movements, furrowing of the brow, and deepening of the nasolabial folds secondary to facial rigidity in patients with PSP. A harsher, higher-pitched nasal quality of the voice, which is quite distinctive from the hypophonic monotone of PD, also suggests the diagnosis of PSP.

Various types of tremor, most notably resting and postural varieties, often accompany parkinsonian disorders. Patients should be observed with hands resting on their laps or thighs, and they should be instructed to hold their arms in an outstretched position or in a horizontal position with shoulders abducted, elbows flexed, and hands palms-down in front of their faces, in the so-called wing-beating position. A true kinetic (intention) tremor, elicited by the finger-to-nose maneuver, is much less common in patients with PD and other parkinsonian disorders and usually indicates involvement of cerebellar connections. Head tremor (titubation) suggests a diagnosis other than PD, such as essential tremor, dystonic neck tremor, or a cerebellar tremor associated with multiple sclerosis.

Rigidity is an increase in muscle tone, usually equal in flexors and extensors and present throughout the passive range of movement. This contrasts with the distribution and velocity-dependent nature of spasticity. Paratonia (or gcgenhalten), on the other hand, increases with repetitive passive movement and with attempts to get the patient to relax. It may be difficult to distinguish between milder forms of paratonia and rigidity, especially in the legs. Characteristically, rigidity is brought out or aggravated by the performance of voluntary movements in the opposite limb (such as opening and closing the fist or abduction-adduction of the shoulder), a phenomenon known as activated rigidity (Froment's sign). Superimposed on the rigidity may be a tremor or cogwheel phenomenon. This, like the milder forms of rigidity, is better appreciated by placing one hand over the muscles being tested (e.g., the left thumb over the biceps and the remaining fingers over the triceps while flexing and extending the elbow with the right hand). The distribution of the rigidity sometimes is helpful in differential diagnosis. For example, pronounced nuchal rigidity with much less hypertonicity in the limbs suggests the diagnosis of PSP, whereas an extreme degree of unilateral arm rigidity might suggest corticobasal degeneration.

Akinesia and bradykincsia may be appreciated on examination in several ways. Automatic movements normally expressed in conversation, such as gesturing with hands while speaking, crossing and uncrossing the legs, and repositioning the body in the chair, are reduced or absent. Rapid, repetitive, and alternating movements, such as finget tapping, opening and closing of the fist, pronation-supination of the forearm, and foot tapping, arc performed slowly, with a gradual reduction in amplitude and eventual cessation of movement (freezing). In addition to fatiguing, there may be hesitation in initiating movement and arrests in ongoing movement. The severely afflicted patient may be barely able to perform the task. There is a tendency for rapid, repetitive movements to take on the frequency of an accompanying tremor. In such cases, the patient should be instructed to slow the movement and attempt to complete it voluntarily.

Watching the patient write is an important part of the examination. Observation may reveal great slowness and effort, even in someone with minimal change in the size of the script. In addition to micrographia, writing and drawing show a tendency to fatigue, with a further reduction in size as the task proceeds and a concomitant action tremor.

Postural disturbances are common in akinetic-rigid syndromes. The head usually tilts forward and the body becomes stooped, often with pronounced kyphosis and varying degrees of scoliosis. The arms become flexed at the elbows and wrists, with varying postural deformities in the hands, the most common being flexion at the metacarpophalangeal joints and extension at the interphalangeal joints, with adduction of all the fingers and opposition of the thumb to the index finger ("striatal hand"). Flexion also occurs in the joints of the legs. Variable foot deformities occur, the most common being hammet toe-like disturbances in most of the toes, occasionally with extension of the great toe ("striatal foot"), which may be misinterpreted as an extensor plantar response. Initially, abnormal foot posturing may be induced by action, occurring only during walking or weight bearing. The flexed or simian posture sometimes is extreme, with sevete flexion at the waist and maintenance of the hands above the beltline because

of flexion of the elbows. Occasional patients remain upright or even demonstrate a hyperextended posture. Hyperextension of the neck is particularly suggestive of PSP, whereas extreme flexion of the neck suggests MSA.

Postural instability is characteristic of parkinsonian disorders, particularly the postural instability and gait difficulty form of PD, PSP, and MSA. As patients rise from a sitting position, poor postural stability, slowness, narrow base, and not repositioning the feet often combine to cause patients to fall back into the chair "in a lump." The patient may need to make several attempts, push off the arms of the chair, or be pulled by an assistant. Gait disturbances in typical parkinsonism include lack of arm swing, shortened and later shuffling stride, freezing in the course of walking (especially at a door frame or when approaching a potential obstruction or a chair), and, in more severe cases, propulsion and spontaneous falls (J.inkovic, Nun, and Sudarsky 2001). In addition, walking often brings out or exacerbates a resting tremor. To assess postural instability, the physician performs the pull test. Standing behind the patient, the examiner pulls the patient backward by the shoulders (or by a hand on the sternum), carefully remaining close behind to prevent a fall. Once postural reflexes are impaired, there may be retropulsion or multiple backward steps in response to the postural perturbation, Later, there is a tendency to fall en bloc without retropulsion or even normal attempts to recover or to cushion the fall.

The base of the gait usually is narrow, and tandem gait is performed well. When the gait is wide based, a superimposed ataxia must be considered, as is seen in MSA with prominent cerebellar involvement, although some of the spinocerebellar atrophies may present with parkinsonism and ataxia (Abele et al. 2002). Toe walking (cock-walk) is seen in some parkinsonian disorders (e.g., those caused by manganese poisoning), and a peculiar loping gait may indicate the rare patient with akinesia in the absence of rigidity. The so-called magnetic foot or marche a petits pas of senility (also seen in multiple infarctions, Binswanger's disease, and normal pressure hydrocephalus) more commonly results in a lower-body parkinsonism, typically associated with cerebrovascular disorders such as lacunar strokes. A striking discrepancy of involvement between the lower body and the upper limbs, with normal or even excessive arm swing, is an important clue to this disorder (sec Chapter 25).

Differential Diagnosis

Although dementia occurs in some patients with PD, this feature must alert the physician to other possible diagnoses (see Chapter 72), including the coincidental association of unrelated causes of cognitive decline. Prominent eye movement disturbances are found in a number of conditions, including olivopontocerebellar atrophy form of MSA, postencephalitic parkinsonism, and PSP. It is important to assess optokinetic nystagmus in order to note whether vertical saccadic eye movements are impaired, as in PSP. The oculocephalic (doll's eye) maneuver must be performed where ocular excursions are limited, seeking supportive evidence of supranuclear gaze palsy (see Chapter 39). Although obvious pyramidal tract dysfunction nsu.ilk suggests another diagnosis or additional disorder, mild rigidity can accentuate the reflexes. When the parkinsonism is asymmetrical, this may cause confusing reflex changes. Primitive reflexes, including the inability to inhibit blinking in response to tapping over the glabella (Myerson's sign), are nonspecific and commonly present in many parkinsonian disorders. However, a pathologically brisk jaw jerk suggests an additional corticobulbar tract disorder. Palmomental reflex and exaggerated grasp response indicate disturbance of the frontal lobes and the possibility of a concomitant dementing process. Occasionally, a pronounced flexed posture in the hand may be confused with a grasp reflex, and the examiner must be convinced that there is active contraction in response to stroking of the palm. The abnormalities of rapid, repetitive, and alternating movements described earlier must not be confused with the disruption of rate, rhythm, and force typical of the dysdiadochokinesia of cerebellar disease. A helpful maneuver in testing for the presence of associated cerebellar dysfunction is to have the patient tap with the index finger on a hard surface. Watching and, in particular, listening to the tapping often allow a distinction between the slowness and decrementing response of parkinsonism and the irregular rate and force of cerebellar ataxia. Testing for apraxia as seen in corticobasal degeneration should also be performed by asking the patient to mimic certain hand gestures such as the "victory sign" or the "University of Texas hook 'em horns sign" (extension of the second and fifth finger and flexion of the third and fourth finger) or to simulate certain activities such as brushing teeth and combing hair. However, in the later stages of many parkinsonian disorders, rigidity and other motor disturbances may make these tests difficult to interpret.

The presence of other abnormal movements in an untreated patient may indicate a diagnosis other than PD. Stimulus-sensitive myoclonus should be sought by using light touch or pinprick in the digits and the proximal palm or the sole of the foot. Easily elicited and nonfatiguing myoclonic jerks in response to these stimuli may be seen in corticobasal degeneration and MSA.

Despite a variety of sensory complaints, patients with PD do not show prominent abnormalities on the sensory examination, aside from the normal increase in vibration threshold that occurs with age. Wasting and muscle weakness are also not characteristic of PD, although later in the course, severely disabled patients show disuse atrophy and severe problems in initiating and maintaining muscle activation that are often difficult to separate from true weakness. Combinations of upper and lower motor

neuron weakness may be seen in several other parkinsonian disorders (sec Table 24.1).

Autonomic function must be assessed. At the bedside this includes an evaluation of orthostatic changes in blood pressure and pulse and, in appropriate circumstances, their response to the Valsalva maneuver, mental arithmetic, and the cold pressor test, among others.

Finally, sequential examinations are needed over time, carefully searching for the development of additional findings that may provide a clue to the diagnosis. Several of the parkinsonian syndromes present initially as pure parkinsonism, and only later as the disease progresses do other signs develop,

TREMOR

Tremor is a rhythmic oscillation of a body part, produced by either alternating or synchronous contractions of reciprocally innervated antagonistic muscles. Tremors usually have a fixed periodicity, although the rate may appear irregular. The waveform and amplitude of the tremor can vary widely, depending on both physiological and psychological factors. Tremor usually is further categorized on the basis of the position, posture, or motor performance necessary to elicit it. Tremor terminology is confusing and is being redefined. A rest tremor is seen with the body part in complete repose, although when a patient is totally relaxed or asleep this tremor usually disappears. Maintenance of a posture, such as extending the arms parallel to the floor, reveals a postural tremor; moving the body part to and from a target brings out an intention tremor. The use of other descriptive categories has caused some confusion in tremor terminology. *Static tremor* has been used to describe both resr and postural tremors. *Action tremor* has been used for both postural and intention tremors. One source of confusion here is that many postural tremors appear as one approaches a target. The term *terminal tremor* probably avoids this confusion most successfully. In contrast, an intention tremor is present throughout goal-directed movement but is also exaggerated as the target is neared. The term *kinetic tremor* may be more accurate and is gradually replacing the traditional term *intention tremor. Ataxic tremor* has been used to refer to a combination of this type of tremor plus limb ataxia. Table 24.4 provides a list of differential diagnoses for the three major categories of tremor and other rhythmic movements that occasionally are confused with tremor.

Common Symptoms

Symptoms are described under the various categories of tremor. All people have a normal or physiological tremor that can be demonstrated with sensitive recording devices. Two common pathological tremor disorders that are often confused arc parkinsonian rest tremor and essential tremor.

Table 24,4: Classification and differential diagnosis of tremor

- Resting tremors
  - Parkinson's disease
  - Other parkinsonian syndromes (less common)
  - Midbrain (rubral) tremor: rest < postural < intention
  - Wilson's disease (also acquired hepatocerebral degeneration)
  - Essential tremor
- Postural tremors
  - Physiological tremor
  - Exaggerated physiological tremor; these factors can also aggravate other forms of tremor
    - Stress, fatigue, anxiety, emotion
    - Endocrine: hypoglycemia, thyrotoxicosis, pheochromocytoma, Cushing's disease
    - Drugs and toxins: adrcnocorticosteroids, beta agonists, dopamine agonists, amphetamines, lithium, tricyclic antidepressants, neuroleptics, theophylline, caffeine, valproic acid, alcohol withdrawal, mercury ("hatter's shakes"), lead, arsenic, others
  - Essential tremor (familial or sporadic)
  - Primary writing tremor and other task-specific tremors
  - Orthostatic tremor
  - With other CNS disorders
    - Parkinson's disease (postural tremor, rc-cmergent tremor, associated essential tremor)
    - Other akinetic-rigid syndromes
    - Idiopathic dystonia, including focal dystonias
  - With peripheral neuropathy
    - Charcot-Marie-Tooth disease (called the Roussy-Levy syndrome)
    - Other peripheral neuropathies
  - Cerebellar tremor
    - Intention tremors
  - Disease of cerebellar outflow (dentate nuclei, intcrpositus nuclei, or both, and superior cerebellar peduncle); multiple sclerosis, trauma, tumor, vascular disease, Wilson's disease, acquired hepatocerebral degeneration, drugs, toxins (such as mercury), others
- Miscellaneous rhythmic movement disorders
  - Psychogenic tremor
  - Rhythmic movements in dystonia (dystonic tremor, myorhythmia)
  - Rhythmic myoclonus (segmental myoclonus, e.g., palatal or branchial myoclonus, spinal myoclonus), myorhythmia
  - Oscillatory myoclonus
  - Asterixis
  - Clonus
  - Epilepsia partialis continua
  - Hereditary chin quivering
  - Spasmus nutans
  - Head bobbing with third ventricular cysts
  - Nystagmus

Although both conditions are discussed in detail in Chapter 77, we discuss helpful distinguishing points next, in view of the frequency of misdiagnosis.

Rest Tremor

A rest tremor occurs with the body part in complete repose and often dampens or subsides entirely with action. For this reason, patients with pure resting tremor experience greater social embarrassment than functional disability. Indeed, in some cases it is a family member or friend who first observes the tremor, which is noticeable to the patient only later. Alternatively, some patients complain of the sensation of trembling inside long before a rest tremor becomes overt. Early on, rest tremor may be intermittent and often is precipitated only by anxiety or stress. Most types of tremor are experienced first in the arms, often beginning asymmetrically. In the face, resting tremor usually affects the lips and jaw, and the patient may note a rhythmic clicking of the teeth. In the limbs, the tremor usually is most pronounced distally in the fingers {pill rolling} or may be manifested by a supination-pronation oscillatory movement of the wrist and forearm and flexion-extension movement of the ankle. In severe forms, it may be present more proximally, causing the entire body to shake. The complaint of prominent head tremor (titubation) should raise the possibility of essential tremor or of dystonic tremor associated with cervical dystonia or cerebellar outflow tremor, as is seen in patients with multiple sclerosis or posterior fossa disorders. Tremor in the legs, and especially in the feet while sitting, usually is caused by parkinsonian resting tremor. A history of progression from unilateral arm tremor ro additional involvement of the ipsilateral leg suggests parkinsonism rather than essential tremor. Once the tremor has become noticeable to the patient, a variety of methods are used to conceal the movement, such as holding one hand with the other, sitting on the affected hand, or crossing the legs to dampen a tremulous lower limb. Many patients find that they can aborr the tremor transiently at will.

Postural Tremor

In contrast to a pure resting tremor, postural rremors, especially with pronounced terminal accentuation, can result in significant disability. Many such patients are mistakenly thought to have "bad nerves." People who perform delicate work with their hands (e.g., jewelers and surgeons) become aware of this form of tremor earlier than most. The average person usually first appreciates tremor in the acts of feeding and writing. Carrying a cup of liquid, pouring, or eating with a spoon often brings out the tremor. Writing is tremulous and sloppy, and the patient's signature on a check may be questioned. The voice may be involved in essential tremor. Again, anxiety and stress worsen the tremor, and patients often notice that their symptoms are especially bad in public. The most common cause of postural tremor seen in movement disorders clinics is essential tremor (Jankovic 2002).

Patients often adopt compensatory mechanisms to lessen the disability caused by tremor. Many give up certain tasks, such as serving drinks and eating specific foods (e.g., soup), especially in public. When rhe tremor is very asymmetrical, patients often switch to using the less affected hand for many tasks, including wriring. Two hands may be used to bring a cup to the mouth; later, a straw may be needed. When writing, patients may use the other hand to steady the paper or the writing hand itself. Patients often switch to printing, and heavier or thicker writing instruments sometimes make the script more legible. In some patients with parkinsonian disorders and severe rest tremor, the tremor may also be presenr while the patient holds an outstretched or wing-beating posture. This tremor usually occurs afrer a latency of several seconds, hence the term "re-emergent tremor."

Other Types of Tremor

Various types of writing disturbances may be combined with tremor. Primary writing tremor is one form of task-specific tremor that affects the writing act in isolation, with little or no associated postural or terminal tremor interfering with other acts. Dystonic writer's cramp can involve additional tremulousness on wriring. This must be distinguished from the voluntary excessive squeezing of the pen or pressing onto the page often seen in patients with essential tremor or primary writing tremor, which is attributable to their attempts to lessen the effect of tremor on wtiting. In addition, patients with postural rremor may consciously slow their writing down to improve accuracy, but this is a voluntary compensatory mechanism not associated with the micrographia and fatigue that accompany parkinsonism.

Tremor in the head and neck, or titubation, can occur in isolation or can be combined with a postural tremor elsewhere, especially in the arms, as is seen in patients with essential tremor. When the head tremor is irregular and is associated with abnormal head posture and uneven contractions or hypertrophy of the neck muscles, the possibility of cervical dystonia should be considered (dystonic tremor). Head tremor is rarely a source of physical disability but may create social embarrassment. Patients occasionally complain of a similar tremor of the voice. This is particularly noticeable to others who are listening to the patient on the telephone, and many patients are asked whether they are sad or have been crying.

Less often, patients with postural tremors note a similar tremor in the legs and trunk. The awareness of this form of tremor clearly depends on rhe activity being performed. One unusual form of postural tremor has been called *orthostatic tremor.* Here, patients often do not note any tremor but complain of difficulty standing (associated with a 14- to 16-Hz tremor in the legs and trunk),

Characteristically, the tremor subsides if the patient can walk about, lean against something, or sit down.

Other Clites in the History

Although patients with several different types of tremor may indicate that alcohol transiently reduces their shaking, a striking response to small amounts of alcohol is particularly characteristic of essential tremor. Clues to the possible ptesence of factors aggravating the notmal physiological tremor (see Table 24.4} must also be sought by further inquiry.

Examination

In addition to clinical examination, tremor can be assessed by various physiological, aceelerometric, and other computer-hased techniques, but a clinical rating scale usually is most practical, particularly in clinical trials. The Tremor Research Group (TRG) has developed a rating scale that can be used to quantitatively assess all types of tremor, particularly essential ttemor, the most common type of tremor encountered in clinical practice (Table 24.5). The TRG scale also provides instructions on how to examine for tremor. Besides rest, postural, and kinetic limb tremot, patients should be examined for ttemor of the head. With the patient seated or standing, head tremor may be evident as vertical ("yes-yes") nodding *{tremblement affirmatif)* or side-to-side ("no-no") horizontal shaking *{tremblement negatif).* There may be combinations of the two, with rotatory movements. Head tremors usually range from 1.5 to 5.0 Hz and are most commonly associated with essential ttemor or cervical dystonia and with diseases of the cerebellum and its outflow pathways. A parkinsonian resting ttemor may involve the jaw and lips. A similar tremor of the perioral and nasal muscles, the rabbit syndtome, has been associated with antipsychotic dtug therapy but also occurs in PD. In many disorders, voluntary contraction of the facial muscles induces an action ttemor. In addition, a postural ttemor of the tongue often is present on tongue protrusion. In the case of tremors of head and neck structures, it is important to observe the palate at rest for the slowet rhythmic movements of palatal myoclonus (also called palatal ttemor). Occasionally, the palate is spared, with similar movements affecting othet branchial structures. A voice tremor is best demonstrated by asking the patient to hold a note as long as possible. Superimposed on the vocal trcmulousness may be a harsh, stfaincd quality or abrupt cessation of air flow during the course of maintaining the note, which suggests a superimposed dystonia of the latynx (spasmodic dysphonia).

A parkinsonian rest ttemor is chatactctistically in the 4- to 6-Hz range. The frequency of postural arm tremots varies depending on cause and severity. Essential tremot usually is in the range of 5-10 Hz, with the greater-amplitude tremors tending to be slower. Exaggerated physiological tremor has a frequency of 8-12 Hz. Many patients with parkinsonism demonstrate a combination of slower resting and faster postutal tremors. Some patients with slower, larger-amplitude forms of essential tremor have a definite testing component.

A rest tremor in the limbs is seen with the muscles in complete repose. Even a small amount of muscle activity, as may occur if the patient is somewhat anxious or the limb is not completely at rest, may bring out a higher-frequency action postural tremor. It is sometimes impossible to abate this postural tremor during a stressful office interview. An occult resting tremor also may be brought out by stress or concentration, such as the performance of serial sevens. Although a resting tremor characteristically subsides when the patient maintains a posture (e.g., holding the arms outstretched patallel to the floor), it may recur after a few seconds. Carrying out goal-directed movements, such as finger-to-nose testing, usually causes the tremor to dampen further or subside completely. On the other hand, a typical postural tremor usually is seen without significant latency after the initiation of a posture and may worsen further at the endpoints of goal-directed movement (terminal tremor), The slower intention tremor of cerebellar disease is seen throughout the movement but also worsens as the target is reached. Occasionally, pronounced bursts of muscle activity in a patient with terminal ttemot cause individual separate jerks, which give the impression of superimposed myoclonus.

Having the patient point the index fingers at each other under the nose (without touching the fingers together or touching the face) with the arms abducted at the sides and the elbows flexed can demonstrate both distal tremor in the hands and proximal tremors. An example of proximal tremor is the slower wing-beating tremor of cerebellar outflow pathway disease, as may be seen in Wilson's disease. Tremor during the course of slowly pronating and supinating the forearms with the arms outstretched or with forceful abduction of the fingers may be seen in patients with primary writing tremor. Holding a full cup of water with the arm outstretched often amplifies a postural tremor, and picking up the full cup, bringing it to the mouth, and tipping it to drink enhances the terminal tremor, often causing spillage. In addition to writing, one should have the patient draw with both hands separately. Useful drawing tasks include an Archimedes spiral, a wavy line from one side of the page to the other (Figure 24.1), and an attempt to draw carefully a line or spiral between two well-defined, closely opposed borders.

In the legs, in addition to the standard heel-to-shin testing, which brings out terminal and intention tremors, it may be possible to demonstrate a postural tremor by having the patient hold the leg off the bed and attempt to touch the examiner's finger with the great toe. With the legs flexed at the knees and abducted at the hips and the feet held flat on the bed, synchronous rhythmic 3-Hz abductions of the

Table 24,5: Tremor Research Group Rating Scale

Instructions for completing the observed tremor portion

1. Head tremor: Subject is seated upright. The head is observed for 10 seconds in midposirion and for 5 seconds each during several provocative maneuvers. First the subject is asked to rotate his or her head to the maximum lateral positions slowly in each direction. The subject is then asked to deviate his or her eyes to the maximum lateral positions while the examiner touches the subject's chin gently.
   0 = No tremor.
   1 = Tremor seen or felt during provocative maneuvers.
   2 — Mild tremor seen at midposirion or moderate tremor seen with provocative maneuvers.
   3 = Moderate tremor at midposition or severe tremor seen with provocative maneuvers.
   4 — Severe tremor seen at midposition.

2a. Face tremor: Subject is seated upright and asked to smile and pucker his or her lips, each for 5 seconds. Tremor is specifically assessed for the lower facial muscles (excluding jaw and tongue and upper face [eye closure]).
   0 = No tremor.
   1 = Mild tremor seen only with active muscle contraction.
   2 = Mild tremor seen at rest or moderate tremor seen with active muscle contraction.
   3 = Moderate tremor seen at rest or severe tremor seen with muscle contraction.
   4 = Severe tremor seen at rest.

2b. Tongue tremor: Subject is seated upright. The subject is asked to open his or her mouth for *5* seconds and then stick out his or her tongue for 5 seconds.
   0 = No tremor.
   1 = Mild tremor seen only with active muscle contraction.
   2 = Mild tremor seen at rest or moderate tremor seen with active muscle contraction.
   3 = Moderate tremor seen at rest or severe tremor seen with active muscle contraction.
   4 = Severe tremor seen at rest.

2c. Jaw tremor: Subject is seated upright. The subject is asked to maximally open his or her mouth and clench ihe j;iw I'or 5 seconds.
   0 = No tremor.
   1 =Mild tremor seen only with active muscle contraction.
   2 = Mild tremor seen at rest or moderate tremor seen with active muscle contraction.
   3 = Moderate tremor seen at rest or severe tremor seen with active muscle contraction.
   4 = Severe tremor seen at rest.

3. Voice tremor: First assess speech during normal conversation then ask subject to produce an extended "aaa" sound and "eee" sound for 5 seconds each.
   0 = No tremor.
   1= Barely perceptible tremor only during provocative maneuver ("aaa," "eee").
   1 — Mild but clear tremor present with speaking.
   3 = Moderate tremor (no voice breaks).
   4 = Severe tremor (with voice breaks or unintelligible speech).

4. Arm tremor: Subject is seated upright. Tremor is assessed during four arm maneuvers (rest, forward horizontal reach posture, lateral "wing beating" posture, and kinesis). Each arm is assessed for *5* seconds in each posture. Left and right arms may be assessed simultaneously. Amplitude assessment should be estimated using the maximally displaced point of the hand at the point of greatest displacement along any single plane. For example, the amplitude of a pure supination-pronation tremor, pivoting around the wrist, would be assessed at either the thumb or fifth digit.

   a. Rest tremor: The subject should have his or her elbows on the arm rests. (If this is the subject's natural posture after the previous assessment, no specific instructions should be given. If the subject did not naturally assume an acceptable arm position for "rest" evaluation, ask him or her to rest elbows on the arm rests with hands resting freely.) Begin the 10-second assessment only after the subject appears relaxed in the new position.
   b. Forward outstretched postural tremor: Subject should bring his or her arms forward, slightly lateral to midline and parallel to the ground. The wrists should also be straight and the fingers slightly and comfortably abducted so that they do not touch each other.
   c. Lateral "wing beating" postural tremor: Subject abducts his or her arms parallel to the ground and flexes the elbows so that the two hands do not quite touch each other, The fingers are slightly and comfortably abducted so that they do not touch each other, with the pointer finger at shoulder height.
   d. Kinetic tremor: Subject extends only his or her pointer finger. The subject then touches a set object or the examiner's finger located to the full extent of the subject's reach, which is at the same height (parallel to the ground) and slightly lateral to the midline. The subject then touches his or her own nose or chin and repeats this back-and-forth motion five times. Only the position along the trajectory of greatest tremor amplitude is assessed. This will typically be cither at the nose or chin or at the point of full finger.
   e. Tremor while walking: Have the patient walk a minimum *<it 6* m at a normal pace to and from the examiner and observe his or her hands.

   Rest tremor
      0 = No tremor.
      1 = Tremor is barely visible or present only with mental provocation or reinforcement.
      1.5 = Tremor is visible but less than 1 cm.
      2 — Tremor is 1-3 cm amplitude.
      2.5 = Tremor is 3-5 cm amplitude.
      3 = Tremor is 5-10 cm amplitude.
      3.5 = Trcmor is 10-20 cm amplitude.
      4 = Tremor is >20 cm amplitude.

   Postural tremor
      0 = No tremor.
      1 ^Tremor is barely visible.
      1.5 = Tremor is visible but less than I cm.
      2=Tremor is 1-3 cm amplitude.
      2.5 = Tremor is 3-5 cm amplitude.
      3 = Tremor is 5-10 cm amplitude.
      3.5 = Tremor is 10-20 cm amplitude.
      4 = Tremor is >20 cm amplitude.

   Kinetic tremor
      0 = No tremor.
      1 = Tremor is barely visible,
      1.5s= Tremor is visible but less than 1 cm.
      1 — Tremor is 1-3 cm amplitude.
      2,5 = Tremor is 3-5 cm amplitude.
      3 = Tremor is 5-10 cm amplitude.
      3.5 = Tremor is 10-20 cm amplitude.
      4 = Trcmor is >20 cm amplitude.

   Tremor while walking
      0 = No tremor.
      1 = Tremor is barely visible.
      1.5 = Tremor is visible but less than 1 cm.
      2 = Tremor is 1-3 cm amplitude.
      2.5 = Tremor is 3-5 cm amplitude.
      3 = Tremor is 5-10 cm amplitude.

Continued

Table 24.5: Tremor Research Group Raring Scale—cont'd

3.5 = Tremor is 10-20 cm amplitude.
4 — Tremor is >20 cm amplitude.

5. Trunk tremor: Subject is comfortably seated in a chair. The subject flexes both legs at rhe hips 30 degrees above parallel to the ground for 5 seconds. The knees are passively bent so that the lower leg is perpendicular to the ground. The legs are not allowed to touch. Tremor is evaluated around the hip joints and the abdominal muscles.
   0 = No tremor,
   1 = Present only with hip flexion.
   2 — Obvious but mild tremor.
   3 = Moderate tremor.
   4 = Severe tremor.
6. Leg tremor action: Subject is comfortably seated. The subject is asked to raise his or her legs parallel to the ground with knees extended for 5 seconds. The legs are slightly abducted so that they do nor touch. The tremor .miplinide is assessed at the end of the feet.
   0 = No tremor.
   1 = Barely perceptible.
   1 — Obvious but mild tremor.
   3 = Moderate tremor is <5 cm at any point.
   4 = Severe tremor is >5 cm.
7. Leg tremor rest: Subject is comfortably seated with knees flexed and feet resting on the ground. The tremor amplitude is assessed at the point of maximal displacement.
   0 = No tremor.
   1 = Barely perceptible.
   1 — Obvious but mild tremor.
   3 = Moderate tremor is <5 cm at any point.
   4 = Severe tremor is >*S* cm.
8. Standing tremor: Subject is standing, unaided if possible. The internal malleoli are 5 cm apart. Arms are down at the subject's side. Tremor is assessed at any point on the legs or trunk.
   0 No rreiiior.
   1 = Barely perceptible tremor,
   2 = Obvious but mild tremor.
   3 = Moderate tremor.
   4 = Severe tremor.
9. Spiral drawings: Ask rhe subject to draw rhe requested figures. Test each hand without leaving the hand or arm on the table. Use only a ballpoint pen.
   0 = Normal.
   1 = Slightly tremulous. May cross lines occasionally.
   2 = Moderately tremulous or crosses lines frequently.
   3 = Accomplishes the task with great difficulty. Figure still recognizable.
   4 = Unable to complete drawing. Figure not recognizable,
10. Handwriting: Have patient write "Today is a nice day."
   0 = Normal.
   1 = Mildly abnormal. Slightly untidy, tremulous.
   2 = Moderately abnormal. Legible, but with considerable **tremor.**
   3 = Markedly abnormal. Illegible.
   4 = Severely abnormal. Unable to keep pencil or pen on paper without holding down with the orher hand.
11. Hold pencil approximately 1 mm above a point on a piece of paper for 10 seconds.
   0 = No tremor.
   1 = Tremor is barely visible,
   1.5 = Tremor is visible but less than 1 cm.
   2 = Tremor is 1-3 cm amplitude.
   2.5 = Tremor is *i-S* cm amplitude.
   3 = Tremor is 5-10 cm amplitude.
   3.5 = Tremor is 10-20 cm amplitude.
   4 = Tremor is >20 cm amplitude.
12. Pour water from one glass inro another, using Styrofoam coffee cups filled 1 cm from rop. Rated separately for right and left hands.
   0 = Absolutely no visible tremor.
   1 = More careful than a person without tremor. No water is spilled.
   2 = Spills a small amount (<I0%).
   3 = Spills large amount (10-50%).
   4 = Unable to pour without spilling most.

thighs may be seen in patients with atrophy of the anterior vermis, as seen in alcoholic cerebellar degeneration,

On standing unsupported, patients with orthostatic tremor develop rapid, rhythmic contractions of leg muscles, causing the kneecaps to bob up and down. This dampens or subsides on walking. In contrast, cerebellar disease results in slower titubation of axial sttuctutcs and head seen in the upright position. Observing the gait often helps differentiate between uppet limb testing tremor and postural tremor that persists at rest as a result of stress. The former usually is clearly evident during walking, whereas the latter usually subsides. Obviously, observing additional featutes of the **gait is helpful in** making these distinctions as well.

Certain tremors persist in all positions. Disease in the midbrain involving the superior cerebellar peduncle near the ted nucleus (possibly also involving the nigrostriatal fibers) results in the so-called midbrain or rubral tremor (Holmes's tremor). Characteristically, this form of tremor combines features of the three tremor classes. It is often present at rest, increases with postural maintenance, and increases still further, sometimes to extreme degrees, with goal-directed movement. Tremor also may be a feature of psychiatric disease, representing a conversion reaction ot even malingering. Usually, certain features arc atypical ot incongruous. This psychogenic tremor differs from most organic tremors in that the ftequency often is quite vatiablc, and concentration and distraction often abate the tremor instead of incteasing it.

CHOREA

The tetm *chorea* is derived from the Greek *chore ia,* meaning "a dance." This hyperkinetic movement disorder consists of irregular, unpredictable, brief, jerky movements that flit randomly from one part of the body to another. The movements are brisk and abrupt in some conditions, such as Sydenham's chorea, whereas in others they are

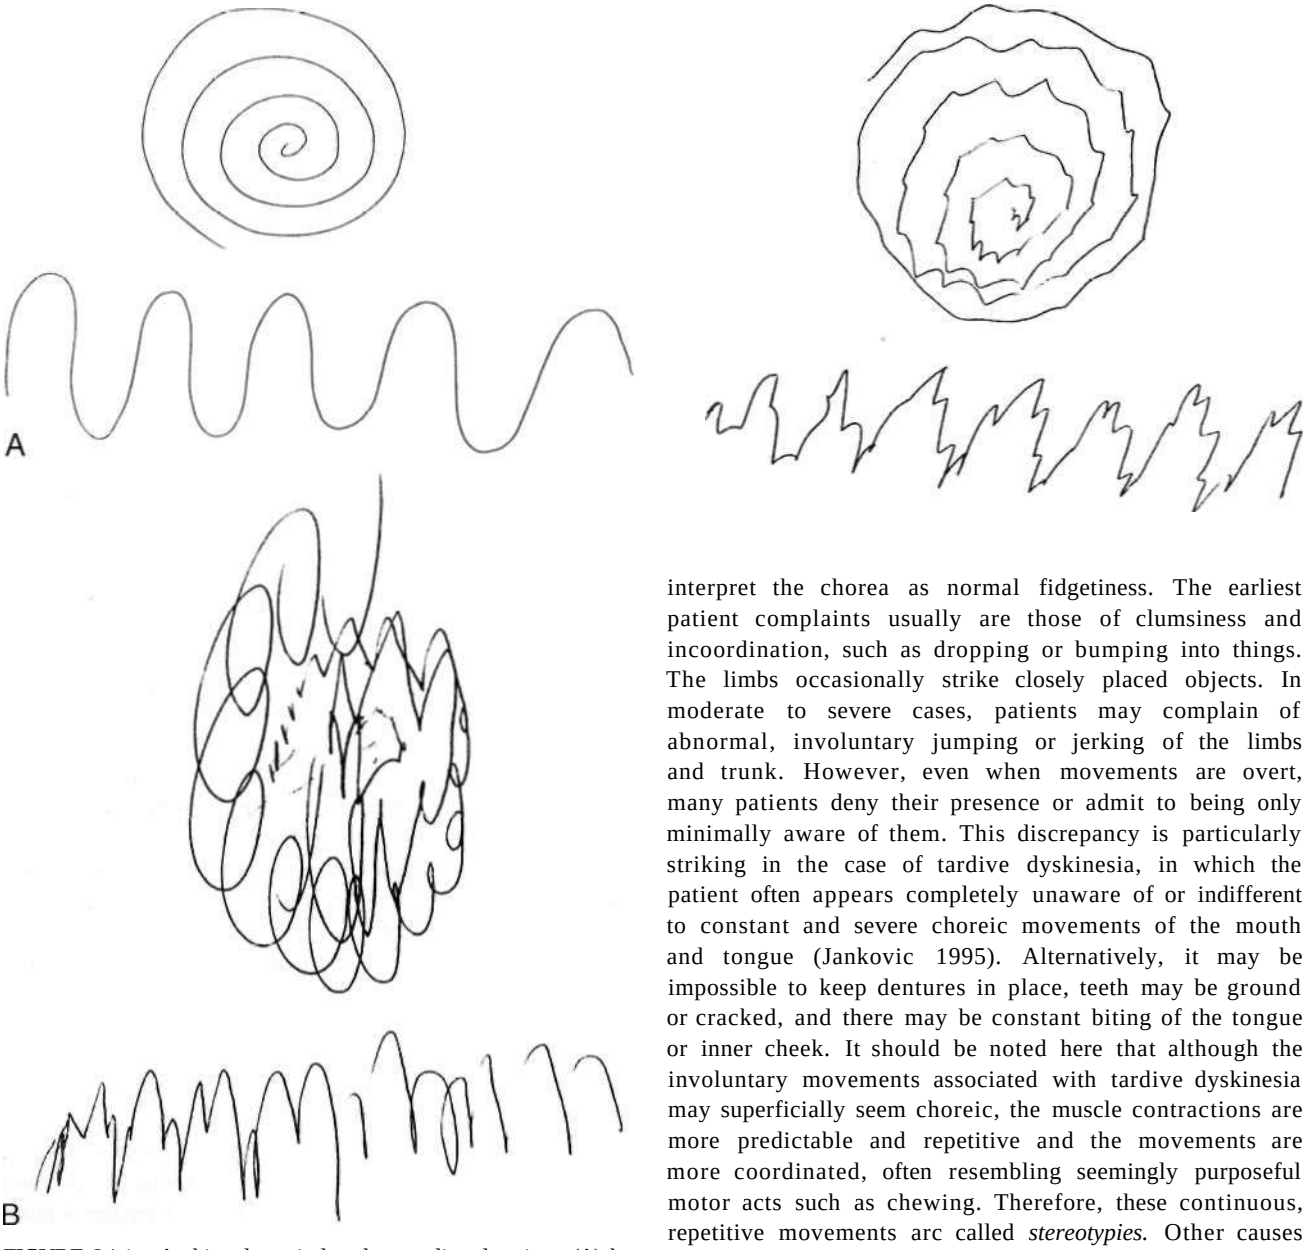

FIGURE 24,1 Archimedes spiral and wavy line drawings (A) by the examiner and a paticm with essential tremor in whom the tremor is asymmetrical and more evident (B) in the right hand than (C) in the left hand.

somewhat slower and more flowing, as in Huntington's disease. The term *choreoathetosis* has been used to describe slow chorea, typically seen in patients with cerebral palsy. There are numerous causes of chorea, most of which are listed in Table 24.6.

Common Symptoms

Initially, patients often are unaware of the presence of involuntary movements, and the family may simply interpret the chorea as normal fidgetiness. The earliest patient complaints usually are those of clumsiness and incoordination, such as dropping or bumping into things. The limbs occasionally strike closely placed objects. In moderate to severe cases, patients may complain of abnormal, involuntary jumping or jerking of the limbs and trunk. However, even when movements are overt, many patients deny their presence or admit to being only minimally aware of them. This discrepancy is particularly striking in the case of tardive dyskinesia, in which the patient often appears completely unaware of or indifferent to constant and severe choreic movements of the mouth and tongue (Jankovic 1995). Alternatively, it may be impossible to keep dentures in place, teeth may be ground or cracked, and there may be constant biting of the tongue or inner cheek. It should be noted here that although the involuntary movements associated with tardive dyskinesia may superficially seem choreic, the muscle contractions are more predictable and repetitive and the movements are more coordinated, often resembling seemingly purposeful motor acts such as chewing. Therefore, these continuous, repetitive movements arc called *stereotypies.* Other causes of stereotypies, besides tardive dyskinesia, include autistic disorders and schizophrenia.

Other features often associated with chorea, particularly Huntington's disease, include motor impersistence manifested by inability to maintain tongue protrusion (trombone tongue) and pendular reflexes, probably caused by motor hypotonia. Speech may be slurred, halting, and periodically interrupted, especially in Huntington's disease, in which speech disturbances arc severe and often do not correlate with the severity of chorea. Here, in addition to dysarthria, there is usually a reduction in the spontaneity and quantity iit speech output. Problems with feeding result from a combination of limb chorea, which causes sloppiness, and swallowing difficulties, which can result in choking and aspiration. Fating is particularly difficult for patients with neuroacanthocytosis (chorea-acanthocytosis), in which

Tahlc 24.6: Etiological classification of chorea

- Developmental and aging choreas
  - Physiological chorea of infancy
  - Cerebral palsy (anoxic), kernicterus
  - Buctal-ural-lingual dyskinesia and edentulous orodyskinesia
  - In older adults, senile chorea (probably several causes)
- Hereditary choreas
  - Huntington's disease
  - Benign hereditary chorea
  - Neuroacanthocytosis
  - Other central nervous system degenerations: olivopontocerebellar atrophy, Machado-Joseph disease and other spinocerebellar atrophies, ataxia telangiectasia, tuberous sclerosis, Friedreich's ataxia, familial calcification of basal ganglia, pantothenate kinase associated neurodegeneration, neurodegeneration with brain iron accumulation (Hallervorden-Spati disease)
- Neurometabolic disorders: Wilson's disease, Lesch-Nyhan syndrome, lysosomal storage disorders, amino acid disorders, Leigh's disease, porphyria
- Drugs: neuroleptics (tardive dyskinesia), antiparkinsonian drugs, amphetamines, cocaine, tricyclics, oral contraceptives
- Toxins: alcohol intoxication and withdrawal, anoxia, carbon monoxide, manganese, mercury, thallium, toluene
- Metabolic
  - Hyperthyroidism
  - Hypoparathyroidism (various types)
  - Pregnancy (chorea gravidarum)
  - Hypernatremia and hyponatremia, hypomagnesemia, hypocalcemia
  - Hypoglycemia and hyperglycemia (the latter may cause hemichorea, hemiballism)
  - Acquired hepatocerebral degeneration
  - Nutritional (e.g., beriberi, pellagra, vitamin B|i deficiency in infants)
- Infectious and postinfectious
  - Sydenham's chorea
  - Encephalitis lethargica
  - Various other infectious and postinfectious encephalitis, Creutzfeldt-Jakob disease
- Immunological
  - Systemic lupus erythematosus
  - Henoeh-Schonlein purpura
  - Others (rarely): sarcoidosis, multiple sclerosis, Behcet's disease, polyarteritis nodosa
- Vascular {often hemichorea)
  - Infarction or hemorrhage
  - Arteriovenous malformation, moyamoya disease
  - Polycythemia rubra vera
  - Migraine
- Tumors
  - Trauma, including subdural and epidural hematoma
  - Miscellaneous, including paroxysmal choreoathctosis

severe orolingual dystonia can cause the tongue to push the food out of the mouth almost as quickly as the patient puts it in. Here, patients often place food at the back of the tongue and throw the head back to initiate swallowing.

Disturbances of stance and gait can be an early complaint in patients with chotea. The patient may note a tendency to sway and jerk while standing and an unsteady, uneven gait often likened to a drunken stagger. Later still, added postural instability in Huntington's disease can tesult in falls. Respiratory dyskinesias may cause the patient to feel short of breath or unable to obtain enough air. Patients with involvement of the pelvic region may complain bitterly of thrusting and rocking movements in the lower trunk and pelvis. Respiratory and pelvic-involvement are sources of complaint more often in tardive dyskinesia than in other choreic movement disorders (Jankovic 1995a).

Other Clues in the History

It is obvious from a review of Table 24.6 that it is impractical to discuss additional historical clues for every cause of chorea. We therefore limit discussion here to a few practical and important points.

Age of onset and manner of progression vary depending on the cause. A helpful distinction can be made here between benign hereditary chorea and Huntington's disease. In the former, chorea typically begins in childhood with a slow progression and little cognitive change, whereas Huntington's disease presenting in childhood is more often of the akinetic-rigid variety, with severe mental changes and rapid progression.

In most cases, the onset of chorea is slow and insidious. An abrupt or subacute onset is more typical of many of the symptomatic causes of chorea, such as neuroleptic drug withdrawal (withdrawal emergent syndrome), Sydenham's chorea, hyperthyroidism, systemic lupus etythematosus (SLE), or multiple infarcts. A pattern of remissions and exacerbations suggests the possibility of drugs, SLE, and rheumatic fever, whereas brief (minutes to hours) bouts of involuntary movement indicate a paroxysmal dyskinesia.

A recent history of streptococcal throat infection and of musculoskeletal or cardiovascular problems in a child suggests a diagnosis of Sydenham's chorea. One may obtain a previous history of rheumatic fever, particularly in women who develop chorea during pregnancy or while taking the birth control pill. In women, chorea during pregnancy or a history of previous fetal loss suggests the possibility of SLE, even in the absence of other features of collagen vascular disease. Symptoms isolated to one side of the body suggest a structural lesion in the contralateral basal ganglia. However, many patients who complain of unilateral involvement have abnormalities of both sides on examination.

A careful family history is crucial. The most common cause of inherited chorea is Huntington's disease, which has fully penetrant autosomal dominant transmission (Jankovic and Ashizawa 2003). The family history can be misleading, however, because the clinical features of the disease in other family members may have been mainly behavioral and psychiatric disturbances and the chotea hardly noticed.

Examination

The range of choreiform movements is quite broad, including eyebrow lifting or depression, lid winking, lip pouting or pursing, cheek puffing, lateral or forward jaw movements, tongue rolling or protruding, head jerking in any plane (a common pattern is a sudden, backward jerk followed by a rotatory sweep forward), shoulder shrugging, trunk jerking or arching, pelvic rocking, and flitting movements of the fingers, wrists, toes, and ankles. Patients can be seen to incorporate choreic jerks into voluntary movement, perhaps in part to mask the presence of the dyskinesia (so-called parakinesis).

Performance of various tasks, such as finger-to-nose testing and rapid alternating movements, often is altered by the chorea, which can cause a jerky, interrupted performance. Standing and walking often aggravate the chorea. Particularly in Huntington's disease, the gait is irregular and lurching and has bizarre characteristics that may not simply be explained by increased chorea. The gait usually is wide based despite the absence of typical ataxia. Patients may deviate from side to side in a zigzag fashion, with lateral swaying and additional spontaneous flexion. In addition, the stride usually is shortened and the speed slowed, with some features similar to those of a parkinsonian gait, such as loss of arm swing, festination, propulsion, and retropulsion.

Respiratory irregularities are common, especially in tardive dyskinesia. Periodic grunting, respiratory gulps, humming, and sniffing may be present in this and other choreic disorders, including Huntington's disease. Other movement disorders often are combined with chorea. Dystonic features probably are the most common and are seen in many conditions. Less common but well recognized are parkinsonism (e.g., with juvenile Huntington's disease, neuroacanthocytosis, and Wilson's disease), tics (e.g., in neuroacanthocytosis), myoclonus (e.g., in juvenile Huntington's disease and others), tremor (e.g., in Wilson's and Huntington's diseases}, and ataxia (e.g., in juvenile Huntington's disease and some spinocerebellar ataxias). Tone usually is normal to low. Muscle bulk typically is preserved, although weight loss and generalized wasting are common in Huntington's disease. When distal weakness and amyotrophy are present, one must consider accompanying anterior horn cell or peripheral nerve disease, as in neuroacanthocytosis, ataxia telangiectasia, Machado-Joseph disease, and spinocerebellar ataxias (see Chapter 78; Abele et al, 2002). Here the reflexes may be reduced. On the other hand, chorea often results in a so-called hung-up reflex, probably caused by the occurrence of a choreic jerk after the usual reflex muscle contraction.

Depending on the cause (see Table 24.6), several other neurological disturbances may be associated with chorea. in 1 luntington's disease, for example, cognitive changes, motor impersistence (e.g., difficulty maintaining eyelid closure, tongue protrusion, or constant hand grip), apraxias {especially orolingual), and oculomotor dysfunction arc all quite common (see Chapter 77), "Milkmaid grip," appreciated as an alternating squeeze and release when the patient is asked to maintain a constant, firm grip of the examiner's fingers, probably is caused by a combination of chorea and motor impersistence.

TARDIVE DYSKINESIA

The usual movements seen in tardive dyskinesia should be distinguished from those of chorea. In contrast to the random and unpredictable flowing nature of chorea, tardive dyskinesia usually demonstrates repetitive stereotypical movements, which are most pronounced in the orolingual region (Jankovic 199.Sa). These include chewing and smacking of the mouth and lips, rolling of the tongue in the mouth or pushing against the inside of the cheek ("bon-bon sign"), and periodic protrusion or flycatcher movements of the tongue. The speed and amplitude of these movements can increase markedly when the patient is concentrating on performing rapid alternating movements in the hands. Patients often have a striking degree of voluntary control over the movements and may be able to suppress them for a prolonged period when asked to do so. On distraction, however, the movements return immediately. Despite severe facial movements, voluntary protrusion of the tongue is rarely limited, and this act often dampens or completely inhibits the ongoing facial movements. This contrasts with the pronounced impersistence of tongue protrusion seen in Huntington's disease, which is far out of proportion to the degree of choreic involvement of the tongue. Besides stereotypies, many other movement disorders arc associated with the use of dopamine receptor blockers (Table 24.7).

Besides impersistence typically seen in Huntington's disease, several other clinical factors help distinguish between Huntington's disease and tardive dyskinesia. Involuntary movements in tardive dyskinesia typically are localized to the lower face, whereas in Huntington's disease irregular contractions of the frontalis muscles and

associated elevation of the eyebrows is very common. Despite the rocking movements of the pelvis, tapping of the feet, and shifting of the weight from side to side while standing (some of which may be caused by akathisia), the gait often is normal in patients with tardive dyskinesia, although a bizarre ducklike gait can be seen. This contrasts with the strikingly abnormal gait in many other choreic disorders, especially in Huntington's disease.

Tardive dyskinesia caused by chronic neuroleptic drugs is not the only cause of stereotypical oro-bucco-linguo-masticatory movements. Other drugs, particularly dopamine agonists in PD, anticholinergics, and antihistamines, cause a similar form of dyskinesia. Multiple infarctions in the basal ganglia and possibly lesions in the cerebellar vermis result in similar movements. Older adults, especially the edentulous, often have a milder form of orofacial movement, usually with minimal lingual involvement. Here, as in tardive dyskinesia, inserting dentures in the mouth may dampen the movements; and placing a finger to the lips can also suppress them. Another important diagnostic consideration and source of clinical confusion is idiopathic oromandibular dystonia.

BALLISM

Ballism or ballismus is the least common of the well-defined dyskinesias. The name is derived from the Greek word meaning "to throw," and the movements of ballism are high in amplitude, violent, and flinging or flailing in nature. As in chorea, they are rapid and nonpatterned. The prominent involvement of more proximal muscles of the limbs usually accounts for the throwing or flinging nature. Lower-amplitude distal movements also may be seen, and occasionally there is even intermittent prolonged dystonic posturing. Some authors emphasize the greater proximal involvement and the persistent or ceaseless nature of ballism in contrast to chorea. However, it is more likely that ballism and chorea represent a continuum rather than distinct entities. The coexistence of distal choreic movements, the discontinuous nature in less severe cases, and the common evolution of ballism to typical chorea during the natural course of the disorder or with treatment all support tins theory. Ballism is most often confined to one side of the body, when it is called *hemiballismus.* Occasionally, only one limb is involved (monoballism), and, rarely, both sides (biballism) or both legs {paraballism) may be affected.

Table 24.8 lists the various causes of hemiballism. These flinging movements often are extremely disabling to patients, who drop things from their hands or damage closely placed objects. Self-injury is common, and examination often reveals multiple bruises and abrasions. Additional signs and symptoms depend on the cause, location, and extent of the lesion, which is usually in the contralateral subthalamic nucleus or striatum (see Chapter 77).

Table 24.8: Causes of ballism

Hyperglycemia (nonketotic hyperosmolar state)
Drugs (phenytoin, dopamine agonists in Parkinson's disease)

DYSTONIA

Dystonia can be defined as a disorder dominated by sustained muscle contractions, which often cause twisting and repetitive movements or abnormal postures (Jankovic and Fahn 2002). The term *dystonia* has been used in three major contexts. It may be used to describe the specific form of involuntary movements just described (i.e., a physical sign). It also may be used to refer to a syndrome caused by a large number of different disease states (Table 24.9).

Dystonic movements may be slow and twisting. In addition, however, dystonic movements may be quite rapid, resembling the shocklike jerks of myoclonus. There may be additional rhythmic movements, especially when the patient attempts to resist the involuntary movement actively. Here, if the patient is asked to relax and allow the limb to move as it pleases, the abnormal dystonic posturing usually becomes evident, and the rhythmic dystonic tremor lessens. A faster distal postural tremor also may occur. It is the varied nature of these movements that often causes the misdiagnosis of dystonia as some other type of movement disorder.

Another common error in diagnosis is the mislabeling of dystonia as hysteria. The movements typically are aggravated by stress and anxiety and are improved by rest and even hypnosis. Patients often discover a variety of peculiar maneuvers ("sensory tricks") that they can use to lessen or even completely abate the dystonic movements and postures (discussed later in this chapter and in Chapter 77). The abnormal movements and postures may occur only during [he performance of certain acts and not others that use the same muscles. An example of this action, task-specific dystonia, is involvement of the hand only in writing (writer's cramp or graphospasm) or playing a musical instrument but not with other manual tasks, such as using utensils. Dystonia of the oromandibular region only on speaking or eating is another example of task-specific dystonia, as is dystonia in legs and trunk occurring only on walking forward but not on walking backward, climbing stairs, or running. A final source of possible confusion with hysteria is the occurrence of dystonia after injury to the affected limb or after prolonged immobilization

Table 24.9: Etiologic classification of dystonia

- [. Primary dystonia
  - A. Sporadic
  - R. Inherited (all autosomal dominant)

such as casting. Such peripherally induced dystonia may be associated with a complex regional pain syndrome, depression, and personality changes and may occur on a background oi secondary gain or litigation.

Common Symptoms

Dystonia can affect almost all striated muscle groups. Common symptoms include forced eyelid closure (blepharospasm); jaw clenching, forced jaw opening, or involuntary tongue protrusion (otomandibular or lingual dystonia); a harsh, sttaincd, or breathy voice (laryngeal dystonia or spasmodic dysphonia); and involuntary deviation of the neck in any plane or combination of planes (cetvical dystonia or spasmodic torticollis). Other symptoms are spasms of the trunk in any direction, which vatiably interfere with lying, sitting, standing, or walking (axial dystonia); interference with manual tasks (often only specific tasks in isolation: the occupational cramps); and involvement of the leg, usually with inversion and plantar flexion of the foot causing the patient to walk on the toes. All these disorders may slowly progress to the point of complete loss of voluntary function of the affected part. On the othet hand, only certain actions may be impaired, and the disorder may remain focal in distribution. Chapter 77 deals with each of these forms of dystonia in mote detail.

"I lie age at onset and distribution of dystonia often are helpful in determining the possible cause. The many causes of secondary dystonia ate detailed in Table 24,9. Whereas some patients with dystonia have "pure dystonia" without any other neurological deficit (primary dystonia), others have additional clinical features (dystonia-plus syndrome), such as parkinsonism, spasticity, weakness, myoclonus, dementia, seizures, and ataxia. Typically, childhood-onset primary dystonia (e.g., classic, Oppenheim's DYT1 dystonia) begins in distal parts of the body (e.g., graphospasm or foot inversion) and spreads to a generalized dystonia. On the other hand, dystonia beginning in adult life usually is limited to one or a small number of contiguous regions, such as the face and neck, and it remains focal or segmental and rarely becomes generalized. Ceneralized involvement or onset in the legs in an adult nearly always implies the possibility of a secondary cause, such as PD or some other parkinsonian disorder. Involvement of one side of the body (hemidystonia) is strong evidence of a lesion in the contralateral basal ganglia, particularly the putamen.

Most ptimary dystonias start as action dystonia occurring during some activity such as writing and walking or running, but when the dystonia occurs at rest and consists of a fixed postutc, secondary causes, such as peripheral or central trauma, should be considered. A fixed posture maintained during sleep implies superimposed contractures or a musculoskeletal distutbance mimicking the postutes of dystonia. Although many patients find that dystonia is lessened by test and sleep, some note a striking diurnal variation. The diurnal variation manifests with little ot no dystonia on rising in the morning, followed by the progressive development of problems as the day goes on, sometimes to the point of becoming unable to walk late in the day. This diurnal variability strongly suggests a diagnosis of dopa-responsive dystonia. The natute of the onset of the symptoms (sudden versus slow) and their course, whether rapid progression, slow changes, or episodes of spontaneous remission, all provide important clues to the possible cause.

The family history must be reviewed in detail, with the awareness that affected relatives may have limited or distinctly different involvement from that of the patient. A birth and developmental history must be obtained in view of the frequency of dystonia after birth trauma, birth anoxia, and kernicterus. As with the other dyskinesias, a history of such features as previous encephalitis, drug use, and head trauma must be sought. Thete is also increasing support for the ability of peripheral trauma to precipitate various forms of dystonia, and occasionally this is combined with the syndrome of complex regional pain, also called reflex sympathetic dystrophy.

Examination

Action dystonia is commonly the earliest manifestation of primary (idiopathic) dystonia. It is important to observe patients performing the acts that ate most affected. Later, other tasks precipitate similar problems, the use of other

parts of the body causes the dystonia to become evident in the originally affected site, and the dystonia may overflow to other sites. Still later, dystonia is evident periodically at rest, and even later the posturing may be persistent and difficult to correct passively, especially when secondary joint contractures develop. A significant deviation from this progression, particularly with the early appearance of dystonia at rest, should encourage the physician to search carefully for a secondary cause (see Table 24.9).

It is important to recognize the natural variability of dystonia, especially the effects of stress and anxiety, which may be somewhat paradoxical. This is especially the case with blepharospasm, in which the increased concentration or anxiety associated with a visit to the doctor often mil lies the severity lit" the problem. It reliance is placed only on the degree of disability seen in the office, the physician may underestimate the severity of the blepharospasm and may misdiagnose the problem as hysterical.

Depending on the cause of the dystonia, several other neurological abnormalities may be associated. Wilson's disease should be considered in any patient with onset of dystonia before age 60 (Svctcl ct al. 2001). Many secondary dystonic disorders (listed in Table 24.9) result in additional psychiatric or cognitive disturbances, seizures, or pyramidal ttaet or cerebellar dysfunction. Ocular motor abnormalities suggest a diagnosis of I.eigh disease, dystonic lipidosis, ataxia telangiectasia, Huntington's disease, Machado-Joscph disease, or other spinocerebellar atrophies. Optic nerve or retinal disease raises the possibility of Leigh disease, other mitochondrial cytopathics, GM_2 gangliosidosis, ceroid lipofuscinosis, and neurodegeneration with brain iron accumulation or pantothenate kinase-associated neurodegeneration, previously called *Hallervorden-Spatz disease* (Hayflick ct al. 2003). Lower motor neuron and peripheral nerve dysfunction may be seen with neuroacanthocytosis, ataxia telangiectasia, metachromatic leukodystrophy, Machado-Joseph disease, and other multisystem degenerations. The dystonia itself may cause additional neurological problems, such as spinal cord or cervical root compression from long-standing torticollis and peripheral nerve entrapment from limb dystonia. Also independent of the cause, long-standing dystonic muscle spasms often result in hypertrophy of affected muscles {e.g., the sternocleidomastoid in cervical dystonia).

Although the general medical examination must be thorough, it is usually unrevealing. As always, the ophthalmological and systemic signs of Wilson's disease must be carefully sought. Abdominal organomegaly also may indicate a storage disease. Severe self-mutilation is typical of Lesch-Nyhan syndrome. Minor tongue and lip mutilation is seen in neuroacanthocytosis, in which orolingual action dystonia may be prominent. Oculocutaneous telangiectasia and evidence of recurrent sinopulmonary infections suggest ataxia telangiectasia. Musculoskeletal abnormalities may simulate dystonia and, rarely, dysmorphic features may serve as a clue to a mucopolysaccharidosis.

TICS

Tics are the most varied of all movement disorders. Patients with Tourcttc's syndrome, the most common cause of tics, manifest both motor, vocal, or phonic tics and a wide variety of associated symptoms (Jankovic 2001). Tics are brief and intermittent movements (motor tics) or sounds (phonic tics). Motor tics typically consist of sudden, abrupt, transient, often repetitive and coordinated (stereotypical) movements that may resemble gestutes and mimic fragments of normal behavior, vary in intensity, and are repeated at irregular intervals. The movements are most often brief and jerky (clonic); however, slower, more prolonged movements (tonic ot dystonic tics) also occur, Several other characteristic features arc helpful in distinguishing this movement disorder from other dyskinesias. Patients usually cxpcticncc an inner urge to make the movement or a local premonitory sensation, which is temporarily relieved by its performance. Tics are voluntarily suppressible for variable periods, but this occurs at the expense of mounting inner tension and the need to allow the tic to occur. Indeed, a large proportion of these patients, when questioned carefully, admit that the movements or sounds that make up their tics are produced intentionally (in contrast to most other dyskinesias) in response to the uncontrollable inner urge or a premonitory sensation, Table 24.10 provides examples of the various types of tics.

Motor and phonic tics can be further subdivided as simple or complex. Simple motor tics are random, brief, irregular muscle twitches of isolated body segments, particularly the eyelids and other facial muscles, the neck, and the shoulders. In contrast, complex motor tics are coordinated, patterned movements involving a number of muscles in their normal synergistic telationships. A wide variety of other motor disturbances may be

Table 24.10: Phenomenological classification of tics

Simple motor tics: eye blinking; eyebrow raising; nose flaring; grimacing; mouth opening; tongue protrusion; platysma contractions; head jerking; shoulder shrugging, abduction, or rotation; neck stretching; arm jerks; fist clenching; abdominal tensing; pelvic thrusting; buttock or sphincter lightening; hip flexion or abduction; kicking; knee and foot extension; toe curling

Simple phonic tics: sniffing, grunting, throat clearing, shrieking, yelping, barking, growling, squealing, snorting, coughing, clicking., hissing, humming, moaning

Complex motor tics: head shaking, teeth gnashing, hand shaking, finger cracking, touching, hitting, jumping, skipping, stamping, squatting, kicking, smelling hands or objects, rubbing, finger twiddling, echopraxia, copropraxia, spitting, exaggerated startle

Complex phonic tics: coprolalia (wide variety, including shortened words), uninrelligible words, whistling, panting, belching, hiccoughing, stuttering, stammering, eeholalia, palilalia (also mental coprolalia and palilalia)

associated with tic disorders, and it is sometimes difficult to separate complex tics from some of these. These motor disturbances include obsessive-compulsive behavior, copropraxia (obscene gestures), echopraxia (mimicked gesnires), hyperucriviry with aitcnrional deficits ;uul impulsive behavior, and externally directed and self-destructive behavior, including self mutilation. Some Tourette's patients also manifest sudden and transient cessation ot all motor activity (blocking tics), including speech, without alteration of consciousness. These "blocking" tics are caused by either prolonged tonic or dystonic tics that interrupt ongoing motor activity such as speech ("intrusions") or a sudden inhibition of ongoing motor activity ("negative tic").

Simple and complex phonic ties comprise a wide variety of sounds, noises, ot formed words (see Table 24.10). Possibly the best known (although not the most common) example of complex vocal tics is coprolalia, the utterance of obscenities or profanities. These are often slurred or shortened or may intrude into the patient's thoughts but not become verbalized (mental coprolalia).

Like most dyskinesias, tics usually increase with stress. In contrast to other dyskinesias, however, relaxation (e.g., watching television at home) often results in an increase in the tics, probably because the patient docs not feel the need to suppress them voluntarily. Distraction or concentration usually diminishes tics, which also differs from most other types of dyskinesia. Many patients with idiopathic tics note spontaneous waxing and waning in their nature and severity over weeks to months, and periods of complete remission are possible. Many people with tics are only mildly affected, and many are even unaware that they demonstrate clinical features. This must be kept in mind when reviewing the family history and planning treatment. Finally, tics are one of the few movement disorders that can persist during all stages of sleep.

Source: Modified from [ankovic, j. 2001, "Tourette's syndrome," *N Engl J Med,* vol. 345, pp. 1184-1192.

Common Symptoms

The causes of tic disorders are listed in Table 24.11. Most are primary or idiopathic, and within this group the onset is almost always iu childhood or adolescence (Tourette's syndrome). Men are affected more often than women. Idiopathic tics occur on a spectrum from a mild, transient, single, simple motor tic to chronic, multiple, simple, and complex motor and phonic tics.

Patients and their families complain of a wide variety of symptoms (see Table 24.10). They may have seen numerous other specialists (e.g., allergists for repetitive sniffing, otolaryngologists for throat clearing, ophthalmologists for excessive eye blinking or eye rolling, and psychologists and psychiatrists for various neurobehavioral abnormalities). The true diagnosis of Tourette's syndrome often is first suggested after someone close to the patient has learned about it in the media. Children may verbalize few complaints or feel reluctant to speak of the problem, especially if they have been subject to ridicule by others. Even young children, when questioned carefully, can provide the history of urge to perform the movement that gradually culminates in the release of a tic and the ability to control the tic voluntarily at the expense of mounting inner tension. Children may be able to control the tics for prolonged periods but often complain of difficulty concentrating on other tasks while doing so. Some give the history of tequesting to leave the schoolroom and then releasing the tics in private (e.g., in the washroom). Peers and siblings often chastise or ridicule the patient, and parents or teachers, not recognizing the nature of the disorder, may scold or punish the child for what are thought to be voluntary bad habits (indeed, an older term for tics is *habit spasms).*

The hisrory may include an exposure to stimulants for hyperactivity. The family history must be reviewed for rhe wide range of potential manifestations (especially obsessive-compulsive behavior). Additional neurological complaints, including other dyskinesias, suggest the possibility of a secondary cause of the tics.

Examination

In most patients with tics, the neurological examination is entirely normal. In patients with primary tic disorders, the presence of other neurological, cognitive, behavioral, and neuropsychological disturbances may simply relate to extension of the underlying cerebral dysfunction beyond the core that accounts for pure tic phenomena. Patients with secondary forms of tics (e.g., neuroacanthocytosis, tardive tics) may demonstrate other involuntary movements, such as chorea, dystonia, and other neurological deficits (see Table 24.11). Careful interview stressing the subjective features that precede or accompany tics usually allows the distinction between true dystonia or myoclonus, and dystonic or clonic tics.

Despite bitter complaints by the family, it is common for patients to show no evidence of a movement disorder during an office appointment. Aware of this, the physician must attempt to observe the patient at a time when he or she is less likely to be exerting voluntary control, such as in the waiting room. If no movements have been witnessed during the interview, the physician should seemingly direct attention elsewhere (e.g., to the parents) while observing the patient out of the corner of the eye. The patient often releases the tics while changing in the examining room, particularly if they have been held back during the interview. The physician should attempt to view the patient at this time or at least listen for the occurrence of phonic tics. Despite these maneuvers, one may have to ask the patient to voluntarily mimic the movements. This, in combination with associated symptoms, such as urge, voluntary release and control, and the often varied and complex nature of the movements, usually is enough to provide the diagnosis, even if the spontaneous tics are not witnessed in the office. Finally, the parents should be asked to provide home videos of the patient.

MYOCLONUS

Myoclonus can be defined as sudden, brief, shocklikc involuntary movements that may be caused by active muscle contraction (positive myoclonus) or inhibition of ongoing muscle activity (negative myoclonus). The differential diagnosis of myoclonus is broader than that of any other movement disorder (Table 24.12). To exclude muscle twitches, such as fasciculations caused by lower motor neuron lesions, some authors have insisted that an origin in the CNS be a component of the definition. Although the majority of causes of myoclonus originare in the CNS, occasional cases of brief shocklike movements, clinically indistinguishable from CNS myoclonus, occur with peripheral nerve disease.

A wide range of clinical patterns of myoclonus exist. The frequency varies from single, rare jerks to constant, repetitive contractions. The amplitude may range from a small contraction that cannot move a joint to a very large jerk that moves the entire body. The distribution ranges from focal involvement of one body part, to segmental (involving two or more contiguous regions), to multifocal, to generalized. When the jerks occur bilaterally, they may be symmetrical or asymmetrical. When they occur in more than one region, they may be synchronous in two body parts (within milliseconds) or asynchronous. Myoclonus usually is arrhythmic and irregular, but in some patients it is very regular (rhythmic), and in others there may be jerky oscillations that last for a few seconds and then fade away (oscillatory). Myoclonic jerks may occur spontaneously, without a clear precipitant, or in response to a wide variety of stimuli, including sudden noise, light, visual threat, pinprick, touch, or muscle stretch. Attempted movement (or even the intention to move) may initiate the muscle jerks (action or intention myoclonus). Palatal myoclonus is a form of segmental myoclonus manifested by rhythmic contractions of the soft palate. Symptomatic palatal myoclonus, usually manifested by contractions of the levator palatini, may persist during sleep; this form of palatal myoclonus usually is associated with some brainstem disorder. In contrast, essential palatal myoclonus consists of rhythmic contractions of the tensor palatini, often associated with a clicking sound in the ear, and disappears with sleep. When the tensor muscle contracts, as in essential palatal myoclonus, the entire soft palate moves, whereas only the edges of the soft palate move when the levator muscle contracts. Symptomatic but not essential palatal myoclonus often is associated with hypertrophy of the inferior olive.

Common Symptoms

As may be seen from the foregoing description and the long list of possible causes of myoclonus, the symptoms in these patients are quite varied. For simplification, we briefly review the possible symptoms with respect to four major etiological subcategories in Table 24.12.

Physiological forms of myoclonus occurring in normal subjects vary depending on the precipitant. Probably the most common form is the jerking most of us have experienced on falling asleep (hypnagogic jactitation). This very familiar phenomenon is rarely a source of concern. Occasionally, patients do become concerned by anxiety- or exercise-induced myoclonus. The history usually is clear, and there is little to find (including abnormal movements) when the patient is seen.

In the essential myoclonus group, patients usually complain of isolated muscle jerking in the absence of other neurological deficits (with the possible exception of tremor and dystonia). The movements may begin at any time from early childhood to late adult life and may remain static or progress slowly over many years. The family history may be positive, and some patients note a striking

Table 24.12: Etiological classification of myoclonus

- Physiological myoclonus (normal subjects}
  - Sleep jerks (hypnic jerks)
  - Anxiety-induced
  - Exercise-induced
  - Hiccough (singultus)
  - Benign infantile myoclonus with feeding
- Essential myoclonus (no known cause and no other gross neurological deficit)
  - Hereditary
  - Sporadic
- Epileptic myoclonus (seizures dominate and no encephalopathy, at least initially)
  - Fragments of epilepsy
    - Isolated epileptic myoclonic jerks
    - Epilepsia partialis continua
    - Idiopathic stimulus-sensitive myoclonus
    - Photosensitive myoclonus
    - Myoclonic absences in petit mal
  - Childhood myoclonic epilepsies
    - Infantile spasms
    - Myoclonic astatic epilepsy (Lennox-Castaut)
    - Cryptogenic myoclonus epilepsy (Aicardi's)
    - Awakening myoclonus epilepsy of Janz
  - Benign familial myoclonic epilepsy (Rabot's)
  - Progressive myoclonus epilepsy: Baltic myoclonus (Unvcrricht-Lundborg)
- Symptomatic myoclonus (progressive or static encephalopathy dominates)
  - Storage disease
    - I.afora body disease
    - Lipidoses, such as GM2 gangliosidosis, Tay-Sachs, Krabbe's
    - Ceroid lipofuscinosis (Batten's, Kufs's)
    - Sialidosis (cherry-red spot)
  - Spinocerebellar degeneration
    - Ramsay Hunt syndrome (many causes)
    - Friedreich's ataxia
    - Ataxia telangiectasia
  - Basal ganglia degenerations
    - Wilson's disease
    - Torsion dystonia
    - Hallervorden-Spatz disease
    - Progressive supranuclear palsy
    - Huntington's disease
    - Parkinson's disease
    - Cortical basal degeneration
    - Pallidal degenerations
    - Multiple system atrophy
  - Mitochondrial encephalopathies, including myoclonic epilepsy and ragged-red fibers

beneficial effect of alcohol. Associated dystonia, present in some patients, also may respond to ethanol.

Myoclonus occurring as one component of a wide range of seizure types is called *epileptic myoclonus.* Many of these patients give a clear history of seizures as the dominant feature. Myoclonic jerks may be infrequent and barely noticeable to the patient or may occur frequently and cause pronounced disability. Myoclonus on waking in the morning or an increasing frequency of the myoclonic jerks may forewarn of a seizure soon to come. The clinical pattern of myoclonus in this instance also varies widely. Sensitivity to photic stimuli and other sensory input may be prominent. Occasional patients demonstrate isolated myoclonic jerks in the absence of additional seizure activity. In these cases, the family history may be positive for seizures, and the electroencephalogram often demonstrates a typical centrencephalic seizure pattern that is otherwise asymptomatic (such as a 3-Hz spike and wave pattern). In others, myoclonus and seizures are equally prominent (the myoclonic epilepsies). These may or may not be associated with an apparent progressive encephalopathy (most often with cognitive dysfunction and ataxia} in the absence of a definable, underlying, symptomatic cause.

In the disorders classified as causing symptomatic myoclonus, seizures may occur, but the encephalop-athy (either static or progressive) is the feature that

predominates. All sorts of myoclonic patterns are seen in this broad category. As can be appreciated from review of Table 24.12, a plethora of other neurological and systemic symptoms may accompany the encephalopathy. Two clinical subcategories of this larger grouping have been distinguished to assist in differential diagnosis. In progressive myoclonic epilepsy, myoclonus, seizures, and encephalopathy predominate, whereas in progressive myoclonic ataxia (often called *Ramsay Hunt syndrome),* myoclonus and ataxia dominate the clinical picture, with less frequent or severe seizures and mental changes. Myoclonus may also originate in the brainstem and spinal cord. Spinal segmental myoclonus often is rhythmic and limited to muscles innervated by one or a few contiguous spinal segments. Propriospinal myoclonus is another type of spinal myoclonus that usually results in flexion jerks of the trunk.

Examination

Considering the varied causes, a wide range of neurological findings are possible. Alternatively, despite the complaint of abnormal movements, some patients with myoclonus (like those with tics and certain paroxysmal dyskinesias) have little to reveal on examination. This is particularly the case for the physiological forms of myoclonus and for those associated with epilepsy and some symptomatic causes. When myoclonus is clearly present on examination, the physician should try to characterize the movement, as outlined earlier in the chapter. When the jerks are single or repetitive but arrhythmic, one must differentiate these movements from tics. Myoclonus usually is briefer and less coordinated or patterned. Furthermore, myoclonus is not associated with a premonitory urge or sensation. Rhythmic forms of myoclonus may be confused with tremors. Here, the pattern of movement is more one of repetitive, abrupt-onset, square wave movements caused by contractions of the agonists, in contrast to the smoother sinusoidal activity of tremor produced by alternating or synchronous contractions of antagonist muscles. Rhythmic myoclonus usually is in the 1- to 4-Hz range, in contrast to the faster frequencies seen in most types of tremor. The oscillations of so-called oscillatory myoclonus may be faster. These are distinguished by their bursting or shuddering nature, usually precipitated by sudden stimulus or movement, lasting for a few seconds and then fading away.

The distribution of the myoclonus is helpful. Focal myoclonus may be more common in disturbances of an isolated region of the cerebral cortex. Segmental involvement, particularly when rhythmic, may occur with brainstem lesions (such as branchial or palatal myoclonus) or spinal lesions (spinal myoclonus). Multifocal or generalized myoclonus suggests a more diffuse disorder, particularly involving the reticular substance of the brainstem. When multiple regions of the body arc involved, it is helpful to attempt to estimate whether movements are occurring in synchrony. It is sometimes difficult to do this clinically, and multichannel electromyographic (EMG) monitoring may be needed.

Throughout the examination, it is important to define whether the movements occur spontaneously or with various precipitants, such as sudden loud noise, visual threat, perturbation, or a pinprick. A number of special sense and somesthctic sensory inputs should be tested. In addition, it is important to evaluate the effects of passive and active movement. In the case of action or intention myoclonus, jerking occurs during voluntary motor activity, especially when the patient attempts to perform a fine motor task, such as reaching for a target. This disturbance is often confused with severe ataxia. Action myoclonus may be evident in such activities as voluntary eyelid closutc, pursing of lips or speaking, holding the arms out, finger-to-nose testing, writing, bringing a cup to the mouth, holding the legs out against gravity, heel-to-shin testing, and walking. In addition to the positive myoclonus that results from a brief active muscle contraction, negative myoclonus also may occur. Although clinically these, too, appear as brief jerks, they are caused by periodic inhibition of ongoing muscle activity and sudden loss of muscle tone. The most common example of negative myoclonus is asterixis, which may be seen in liver failure ("liver flap") and, to a lesser extent, in other metabolic encephalopathies, and occasionally with focal brain lesions. The best-recognized location of asterixis is the forearm muscles, where it causes a flapping, irregular tremor-like movement when the wrists are held extended. When mild and of low amplitude, this may be confused with 5- to 6-Hz postural tremor. A similar form of negative myoclonus accounts for the periodic loss of postural tone in axial and leg muscles in some patients with action myoclonus syndromes, such as postanoxic action myoclonus. This results in a bobbing movement of the trunk while standing and may culminate in falls.

MISCELLANEOUS MOVEMENT DISORDERS

Hemifacial spasm is a common disorder in which irregular tonic and clonic movements involve the muscles of one side of the face innervated by the ipsilateral seventh cranial nerve. Unilateral eyelid twitching usually is the first symptom, followed at variable intervals by lower facial muscle involvement. Rarely, both sides of the face are affected, in which case the spasms are asynchronous on the two sides, in contrast to other pure facial dyskinesias, such as cranial dystonia.

The term *akatbisia* refers to a sense of restlessness and the feeling of a need to move. This was first used to describe what was thought to be a hysterical condition, and later the term was applied to the restlessness with inability to sit or stand still (motor impatience) seen in patients with idiopathic and postencephalitic parkinsonism. The syndrome is

now most commonly seen as a side effect of major tranquilizing or antiemetic drugs (neuroleptics) that act by blocking dopamine receptors. Akathisic movements occur in response to the subjective inner feeling of restlessness and need to move, although some authors believe that the subjective component is not necessary. The movements of akathisia are varied and complex. They include repetitive rubbing; crossing and uncrossing the arms; stroking the head and face; repeatedly picking at clothing; abducting and adducting, crossing and uncrossing, swinging, or up-and-down pumping of the legs; and shifting weight, rocking, marching in place, or pacing while sitting and standing. Occasionally, patients demonstrate a variety of vocalizations, such as moans, grunts, and shouts. Akathisia can be an acute ot delayed complication of antipsychotic drug therapy (acute akathisia and tardive akathisia, respectively). It also occurs in PD, secondary to selective serotonin reuptake inhibitors, and in cerrain confusional states or dementing processes.

Anothet disotder in which movements occur secondary to the subjective need to move is the restless legs syndrome (Ondo, Vuong, and Jankovic 2002). Here, unlike in akathisia, the patient typically complains of a variety of sensory disturbances in the legs, including pins and needles, creeping or crawling, aching, itching, stabbing, heaviness, tension, burning, or coldness. Occasionally, similar symptoms are appreciated in the upper limbs. These complaints usually are experienced during recumbency in the evening and often are associated with insomnia. This condition commonly is associated with another movement disorder, periodic leg movements of sleep, sometimes inappropriately called *nocturnal myoclonus.* These periodic, slow, sustained (1- to 2-second) movements range from synchronous or asynchronous dorsiflexion of the big toes and feet to triple flexion of one or both legs. More rapid myoclonic movements or slower, prolonged dystonic-like movements of the feet and legs also may be present in these patients while awake, and these too may have a natutal periodicity. Leg myoclonus or foot dystonia may be the presenting feature of the stiff man syndrome.

Another uncommon but well-defined movement disorder of the lower limbs has been called *painful legs and moving toes.* Here, the patient typically complains of a deep pulling or searing pain in the lower limb and foot associated with continuous wriggling or writhing of the toes, occasionally the ankle, and less commonly more proximal muscles of the leg. Rarely, a similar problem is seen in the upper limb as well. In some cases, there is a history of root or nerve injury, and the examination may demonstrate evidence of peripheral nerve dysfunction.

Some dyskinesias occur intermittently rather than persistently. This is typical of tics and certain forms of myoclonus. Dystonia often occurs only with specific actions, but this is usually a consistent response to the action rather than a periodic and unpredictable occurrence. Some patients with dystonia have a diurnal variation (dopa-responsive dystonia) characterized by essentially normal motor function in the morning with emergence or worsening of dystonia as the day progresses so that by the end of the day the patients are unable to ambulate because of severe generalized dystonia. A small group of patients with chorea or dystonia have bouts of sudden-onset, short-lived, involuntary movements known as *paroxysmal cboreoathetosis* or, more appropriately, *paroxysmal dyskinesia* (Table 24.13). Certain features characterize these disorders and sometimes help to separate them into diagnostic categories (such as precipitants, duration, frequency, age of onset, and family history} (sec Chapter 77). Thus, paroxysmal dyskinesias may be categorized as kinesigenic (precipitated by voluntary movement such as arising from a chair or starting to tun), nonkinesigenic, exertional, or nocturnal. In many cases, the movements are so infrequent that the physician never sees them, and so a careful history is needed to determine the nature of the disorder (Jankovic and Demirkiran 2002). There may be a family history of seizures or migraines. Periodic ataxias often are included in the group of paroxysmal movement disorders.

There are also disorders in which an abnormal or excessive response to startle occurs. In some patients, one simply finds an exaggerated startle response, which habituates poorly after repeated stimuli. In others, there is an abnormal response to the stimuli that normally evoke startle. Hyperekplexia, also known as *startle disease,* may be more akin to certain forms of myoclonus than to a normal startle response. A variety of other unusual disorders, first described in the nineteenth century together with Tourette's syndrome, manifest excessive startle. Jumping disease, latah, and myriacbit also involve sudden striking out, echo phenomena, automatic obedience, and several other less common features. It is believed that these disorders arc quite distinct from Tourette's syndrome and possibly represent culturally related operant-conditioned behavior rather than true neurological disease, although this point remains conrroversial.

Tahle 24.13: Classification of paroxysmal dyskinesias

Paroxysmal kinesigenic dyskinesia
Paroxysmal nonkinesigenic dyskinesia
Paroxysmal exertion-induced dyskinesia
Paroxysmal nocturnal dyskinesia
Paroxysmal psychogenic dyskinesia
  Each category includes the following:
    Short-lasting (<5 minutes)
      Idiopathic (familial fir sporadic)
      Secondary
    Long-lasting (>5 minutes)
      Idiopathic (familial or sporadic)
      Secondary

Source: Modified from Jankovic, J. 8c Demirkiran, M. 2002, "Classification of paroxysmal dyskinesias and ataxias," in *Myoclonus and Paroxysmal Dyskinesias, Advances in Neurology,* eds S. Fruchr & S. Fahn, Lippineott Williams *&c* Wilkins, Philadelphia, pp. 387-400.

Finally, psychogenic movement disorders, characterized by abnormal slowness or excessive movements or postures that cannot be directly attributed to a lesion or an organic dysfunction in the nervous system, are emerging as one of the most common groups of disorders encountered in movement disorder clinics (Miyasaki et al, 2003). Derived primarily from psychiatric or psychological disorders, because of their rich spectrum of phenomenology and variable severity, psychogenic movement disorders present a major diagnostic and therapeutic challenge. Diagnosis of psychogenic movement disorders is facilitated by various clues that include somatic and psychiatric complaints and movement disorders whose phenomenology is incongruous with typical movement disorders. These include sudden onset often related to some emotional trauma, secondary gain, variable frequency of tremor, distractibility, exaggeration of symptoms, or lack of concern, called "la belle indifference" (Table 24.14).

Tabic 24.14: Clues to the presence of a psychogenic movement disorder

- Physical Factors
  - Movement disorder
    - Abrupt onset
    - Incongruous movements
    - Inconsistent movements
    - Response to placebo or suggestion
    - Selective disability
    - Dramatic resolution
    - Maximum early disability
    - Deliberate slowing
    - Rhythmic shaking
    - Bizarre gait
  - Other neurological findings
    - Transient weakness
    - Sensory symptoms
    - Dizziness and fainting

  - Work-related injuries
  - Litigation
  - Relationship problems (spouse or children)
  - Physical abuse
  - Sexual abuse
  - Substance abuse
  - Secondary gain

INVESTIGATION OF MOVEMENT DISORDERS

The nature and extent of the investigation of a patient presenting with a movement disorder vary depending on the clinical circumstances. When the historical and clinical features are typical of certain primary (idiopathic) disorders, further investigations may be unnecessary. Examples of these include normal physiological tremor and myoclonus, essential tremor {especially if familial), adult-onset focal dystonias, childhood tic disorders, and even PD. However, one must always he mindful of the possibility of additional occult aggravating factors superimposed on a known pre-existing movement disorder. The reverse is also possible, in which the presumed cause is actually an aggravating factor or simply a coincidental association, particularly in the case of patients thought to have drug-induced disturbances. For example, chorea apparently caused by the birth control pill (or chorea gravidarum) may be a manifestation of underlying SLE. When dealing with presumed neuroleptic-induced movement disorders, it is important to consider the possibility that the antipsychotic drug was given for initial psychiatric manifestations of a disease that is now causing the movement disorder in question. Huntington's disease and Wilson's disease are two disorders in which this may occur,

The importance of excluding Wilson's disease cannot be overemphasised. This includes slit-lamp examination, measurement of serum ceruloplasmin and copper, liver function tests, and, if necessary, measurement of 24-hour urinary copper excretion and liver biopsy. Children, adolescents, and young adults presenting with parkinsonism, chorea, or a dystonic or myoclonic syndrome need additional careful hematological and biochemical assessment, as indicated in Table 24.15.

Although in the majority of movement disorders the diagnosis depends on the recognition of typical clinical phenomenology, diagnosis of certain movement disorders can be aided by blood tests. Ncuroacanthocytosis, usually presenting in adolescence or early adulthood with chorea, dystonia, tics, and progressive weakness, may be diagnosed by demonstrating blood acanthocytes, elevated serum creatine kinase, and altered nerve conduction studies (Thomas and Jankovic 2003a). Biochemical screening may also reveal evidence of hypoparathyroidism, which can cause calcification of the basal ganglia, resulting in several movement disorders. Hyperthyroidism, polycythemia rubra vera, and SLE are common enough causes of

Note: The extent of investigation depends on factors such as age of onset, nature of progression, and presence of historical or clinical atypical features suggesting a secondary cause of the movement disorder in question.
A = akinetic rigid syndrome; B = hemiballism; C = chorea; l) = dystonia; M = myoclonus; T = tics.
++ = very important or often useful; + = sometimes helpful; + = questionably helpful; - tarely or never helpful.

undiagnosed chorea in an adult to necessitate exclusion in all cases. Early clues are a history of recurrent fetal loss, an elevated partial thromboplastin time, a false positive Venereal Disease Research Laboratories test, and thrombocytopenia, which indicates the presence of amiphospholipid immunoglobulins, such as the lupus anticoagulant and anticardiolipin ami bodies. Sydenham's chorea must be considered in a child presenting with chorea of unknown origin; antistreptolysin O titer, antihyaluronidase, and electrocardiogram should be obtained, In a patient with hemiballism, one should search for potential risk factors for vascular disease by measuring levels of blood sugar, hemoglobin, platelets, erythrocyte sedimentation rale, cholesterol, and triglycerides. Adults with generalized dystonia or dystonia beginning in the legs must be suspected of having a symptomatic cause and investigated accordingly. A test for DYT'l dystonia is available commercially, and some research laboratories perform tests for *e-sarcoglycan (SGCE)* gene responsible for the myoclonus-dystonia syndrome. Other DNA tests that may be helpful in the diagnosis of movement disorders include tests for Huntington's disease; spinocerebellar atrophies; Friedreich's ataxia; dentatorubral-pallidoluysian atrophy; pantothenate kinase-associatcd neurodegeneration (PKAN), formerly known as Ilallervorden-Spatz disease; Unverricht-Lundborg disease (EPM1), celiac disease (antigliadin antibodies), anti-GAD antibodies (stiff man syndrome}, and antibodies for various paraneoplastic syndromes.

Imaging studies, such as computed tomography (CT) and, particularly, magnetic resonance imaging (MRI), are useful in certain disorders. Most patients with heimdystoiua have a definable lesion in the contralateral basal ganglia (most often the putamen). Hemiballism or hemichorea usually is caused by a structural lesion in the contralateral subthalamic nucleus or striatum. The cause is commonly a small lacunar infarction, so MRI typically is more successful than CT in localizing the lesion. In patients with parkinsonism, imaging must assess the possibility of hydrocephalus (either obstructive or communicating), midbrain atrophy (as in PSP), and cerebellar and brainstem atrophy (as in olivopontocerebellar atrophy). MRI clearly is much more effective in demonstrating these posterior fossa abnormaiities than is CT. Atrophy of the bead of the caudate nucleus is found in Huntington's disease, but it is not specific for this disorder and does not correlate with the presence or severity of chorea. Multiple infarctions, intracerebral calcification (better seen on CT), mass lesions (such as tumors and arteriovenous malformations), and basal ganglia lucencies (as seen in various disorders) may be found in patients with

several movement disorders, such as parkinsonism, chorea, and dystonia. In patients with striatonigral degeneration (one subcategory of MSA with prominent parkinsonism), T2-weighted and proton density MRf scans often demonstrate a combination of striatal atrophy and hypointensity, with linear hypcrintensity in the posterolateral putamen. Striatal Tl hyperintensity is seen in hyperglycemia, manganese toxicity, hepatocerebral disease, Wilson's disease, abnormal calcium metabolism, neurofibromatosis, hypoxia, and hemorrhage; striatal T1 hypointensity and T2 hyperintensity suggest mitochondria] disorders; striatal T2 hypointensity with hyperintensity of the mesencephalon sparing the red nucleus and the lateral aspect of the substantia nigra gives the appearance of "face of the giant panda sign," the typical MRI appearance of Wilson's disease; and striatal T2 hypointensity is typically seen in MSA, PSP, and pantothenate kinase-associated neurodegeneration. In the latter disorder, a T2-weighted MRI brain scan typically shows hypointensity in the globus pallidus surrounding an area of hyperintensity, the "eye of the tiger" sign. The "hot cross bun" sign in the pons also suggests MSA, as does T2-weighted gradient echo MRI, which often demonstrates hypointense putaminal changes. Further developments in MRI promise to improve our ability to differentiate between various degenerative disorders, especially if they are associated with characteristic pathological features, such as deposition of pigments or heavy metals.

Magnetic resonance spectroscopy also holds promise for differentiating disorders with various neurodegenerative patterns or ncurometabolic disturbances. Positron emission tomography using fluorodeoxyglucosc, fluorodopa, and other radiolabeled compounds (e.g., demonstrating labeling of dopamine receptors) has shown reproducible changes in such conditions as Huntington's disease and parkinsonian disorders. For example, F-dopa positron emission tomography scans show reduced uptake in both the putamen and caudate in patients with atypical parkinsonism, such as PSP and MSA, whereas the caudate usually is preserved in patients with PD. The patterns of abnormalities seen may predict the underlying pathological changes and thus may be useful in differential diagnosis. Developments in single photon emission CT suggest that this will probably become a useful diagnostic tool in evaluating and diagnosing certain movement disorders.

Routine electrophysiological testing, including electroencephalography, somatosensory evoked potentials, EMG, and nerve conduction studies, may provide supportive evidence of disease involving structures outside the basal ganglia. EMG analysis of the activity in various muscle groups has been used extensively to study most movement disorders, and tremor can be further documented by accelerometric recordings. Although these and other electrophysiological procedures have contributed to the understanding of the pathophysiology of movement disorders, they have been most crucial to the study of myoclonus. Here, a variety of disturbances may be found on routine electroencephalography, such as spikes, spike-and-wave patterns, and periodic discharges. Occasionally, spikes are seen ro precede EMG myoclonic discharges, particularly if the myoclonus is associated with epilepsy. In the majority of cases, however, it is impossible to determine a correlation between spike discharges and myoclonic jerks by simple visual inspection. Special electrophysiological techniques averaging cortical activity that occurs before a myoclonic jerk (triggered back-averaging) may show focal contralateral central negativity lasting 15-40 milliseconds, preceding the muscle jerk by 10-25 milliseconds in the upper limbs or 30-35 milliseconds in the legs. This is evidence of so-called cortical myoclonus, indicating that cortical activity results in the muscle jerks. In other forms of myoclonus that originate in subcortical areas, cortical discharges may be seen but arc not time-locked in the same fashion to the jerks. In these cases, there may be generalized 25- to 40-millisecond negativity before, during, or after the muscle jerking.

The muscle bursts as seen on EMG typically are synchronous in antagonistic muscles and usually are less than 50 milliseconds in duration. In one form of essential myoclonus, ballistic reflex myoclonus, the EMG bursts show alternating activity in antagonists that lasts 50-150 milliseconds. With multichannel EMG recording, it may be possible to demonstrate the activation order of muscles. In cortical myoclonus, muscles are activated in a rostrocaudal direction, with cranial nerve muscles firing in descending order before the limbs. In myoclonus originating from subcortical or reticular sources, it may be possible to show that the myoclonus propagates in both directions from a point source, up the brainstem, usually starting in muscles innervated by the eleventh cranial nerve, and down the spinal cord. In propriospinal myoclonus, the spread up and down the spinal cord occurs at a speed that suggests the involvement of a slowly conducting polysynaptic pathway,

Somatosensory evoked potentials and late EMG responses (C reflexes) often are enhanced in patients with myoclonus. Giant sensory evoked potentials can be seen in the hemisphere contralateral to the jerking limb in patients with cortical myoclonus. This is especially true in patients with focal myoclonus that is sensitive to a variety of sensoty stimuli applied to the affected part (cortical reflex myoclonus). The cortical components of the sensory evoked potentials usually are not enhanced in subcortical or spinal myoclonus, but the latencies may be prolonged, depending on the location of the disease process.

In caring for a patient with a movement disorder, the clinician must always keep an open mind to the possibility of finding a secondary cause. This should be the case even when the onset, progression, and clinical features of the movement disorder in question ate typical of an idiopathic condition and the pteliminary laboratory testing has not revealed another cause. Thorough neurological examination should be repeated periodically in a search for clues

that might indicate the need to pursue the investigation further,

Chapter 25
Gait Disorders

Philip D. Thompson

The maintenance of an upright posture and the act of walking are among the first and the most complex motor skills humans acquire. From an early age, these skills are modified and refined. In later years, the interplay between voluntary and automatic control of posture and walking provides a rich and complex repertoire of movement. The pattern of walking may be so distinctive that an individual can be recognized by the "motor fingerprint" of his or her gait. Many diseases of the motor system produce characteristic disturbances of gait and posture that permit the identification of an underlying disease by the manner in which gait is altered.

PHYSIOLOGICAL AND BIOMECHANICAL ASPECTS OF GAIT

Humans assume a stable upright posture before beginning to walk. Mechanical stability when standing is based on musculoskeletal linkages between the trunk and legs. Dynamic equilibrium in the upright posture is maintained by a hierarchy of postural reflexes. These postural responses are generated by the integration of visual, vestibular, and proprioceptive inputs in the context of voluntary intent and any ongoing changes in the environment in which the subject is moving. Postural responses consist of coordinated synergistic axial and limb muscle contractions, correcting for and controlling body sway and maintaining an upright posture of the trunk. These range from automatic righting reflexes keeping the head upright on the trunk, supporting reactions controlling antigravity muscle tone, anticipatory postural reflexes occurring before limb movement (feed forward) or in response to perturbation during movement (feedback), and reactive postural responses counteracting body perturbations, to actions that are modified by voluntary control in accordance with the circumstances, such as rescue reactions to preserve the upright posture (a step or windmill arm movements), and protective reactions to prevent injury (an outstretched arm to break a fall).

Once the trunk is upright and stable, locomotion may begin. The initiation of gait is heralded by a complex shift in the center of pressure beneath each foot, first posteriorly, then laterally toward the stepping foot, and finally away toward the stance foot to allow the stepping foot to swing forward {Elble et al. 1994). This sequence is then **followed** by the stetcoryped stance, swing, and step phases of the gait cycle.

ANATOMICAL ASPECTS OF GAIT

The ncuroanatomical structures responsible for these components of normal walking are poorly understood in humans. Studies in lower species suggest two basic-anatomical components. Supraspinal centers signal when to

start walking, when to stop, the speed of locomotion, and the size and direction of stepping. These signals descend to the spinal level where spinal locomotor centers elaborate walking patterns of muscle activity.

In quadripedal animals, spinal locomotor centers are capable of maintaining and coordinating rhythmic stepping movements after spinal transection. This spinal stepping is generated by assemblies of interneurons, referred to as *central pattern generators*, which activate limb muscles in a locomotor synergy. They exist for the hind limb, forelimb, and trunk and are interlinked by propriospinal networks to facilitate interlimb coordination. In monkeys, spinal stepping requires preservation of the ventrolateral tracts of the spinal cord containing descending reticulospinal and vestibulospinal pathways. The isolated spinal cord in humans can produce spontaneous movements, but cannot genetate rhythmic stepping or maintain truncal balance. Higher brainstem and cortical connections are therefore necessary for bipedal walking. Brainstem locomotor centers arc present in lower species and probably exist in humans, High-frequency stimulation in the region of the mesencephalic locomotor region in the posterior midbrain elicits locomotor activity in the thalamic monkey. This region overlaps with the peduneulopontinc nucleus, which is thought to be important in rhythm generation. The basal ganglia are involved in the initiation of walking and the quality of stepping, mediated through the cerebral cortex and brainstem structures such as the pedunculopontine nucleus. The cerebellum is important in modulating the rate, thythm, amplitude, and force of voluntary movement and accordingly regulates these aspects of stepping. The cerebral cortex is required for precision movements of the legs when walking. Corticospinal activation modifies spinal locomotor activity to start and stop walking, conveying the voluntary commands. Sensory feedback during the walking cycle in turn modifies motor cortical activity.

Brainstem structures arc important in maintaining postural righting reflexes that control axial extensor tone. Lesions of the medial brainstem interrupt descending reticulospinal, vestibulospinal, and tectospinal systems rh.it innervate proximal and axial muscles, resulting in dysequilibrium. In humans, postural reflexes controlling truncal equilibrium are organized by a poorly understood network involving the flocculonodular and anterior lobes of the cerebellum, the brainstem, central vestibular pathways, basal ganglia, thalamus, and frontal lobes. Lesions of each of these areas interfere with postural control, particularly when standing.

HISTORY AND COMMON SYMPTOMS OF GAIT DISTURBANCE

A detailed account of the walking difficulty and its evolution provides the first clues to the underlying diagnosis. When evaluating the history, we find it helpful to note the particular circumstances in which the walking difficulty occurs, the leg movements most affected, and any associated symptoms. Because disorders at many levels of the peripheral and central nervous systems give rise to difficulty walking, it is necessary to consider whether the problem is primarily motor, caused by muscle weakness, a defect of higher motor control, or imbalance, due to cerebellar disease or proprioceptive sensory loss.

Walking on uneven ground exacerbates most walking difficulties and leads to tripping, stumbling, and falls. A ligamentous ankle strain or even a bony fracture may result from tripping and falling in this situation and may be the presenting symptom of a gait disorder. Fear of falling may lead to various voluntary protective measures to minimize the risk of injury. In some patients, particularly the elderly, a fear of falling and a "cautious" gait may dominate the clinical picture and be a presenting feature.

Weakness

Weakness of the legs may be described several ways. Complaints of stiffness, heaviness, or "legs that do not do what they arc told" may be the presenting symptoms of a spastic paraparesis or hemiparesis. Patients with spastic paraparesis often report that they drag their legs to walk or their legs may suddenly give way, causing them to stumble and fall.

Weakness of certain muscle groups also may be described in terms of difficulties in performing particular movemenrs. A tendency to trip because of catching or scraping the toe on the ground may be the presenting symptom of hemiplegia {causing a spastic cquinovarus foot posture) or footdrop caused by weakness of ankle dorsiflexion. Similarly, weakness of certain movements may first become apparent in particular situations; for example, difficulty in climbing stairs or rising from a seated position is suggestive of proximal muscle weakness, which is most commonly caused by a myopathy. Rarely, these complaints may be the presenting symptoms of an acute inflammatory polyneuropathy (Guillain-Barre syndrome). Weakness of knee extension (caused by a femoral neuropathy or quadriceps myopathy) may impose difficulty walking down stairs.

Slowness

Slowness of walking and limb stiffness are common in extrapyramidal disease. These symptoms are produced by difficulty engaging the legs in brisk motion and increased muscle tone (rigidity). This slowness of movement may be accompanied by shuffling with small shallow steps. Difficulty initiating the first few steps when starting to walk (start hesitation), pronounced shuffling for a few steps, and freezing at the slightest obstacle, a doorway, or

other distraction are common. Some patients, particularly those with Parkinson's disease, overcome the shuffling and facilitate stepping and walking by carefully watching and treading over lines on the floor or other objects such as the handle of an upturned walking stick. It is useful to inquire about axial mobility. Difficulty rising from a chair or getting out of bed may be due to a loss of truncal mobility and axial rigidity in diffuse cerebrovascular disease, hydrocephalus, and extrapyramidal diseases. Axial muscle weakness resulting from peripheral neuromuscular diseases may also interfere with truncal mobility. Fatigue during walking occurs in muscular weakness of any cause and is often a symptom of the extra effort required to walk in upper motor neuron (UMN) syndromes and extrapyramidal disease.

The circumstances in which leg stiffness occurs when walking may be revealing. For example, the presenting symptom of idiopathic torsion dystonia in childhood may be stiffness and abnormal posturing of one leg, with inversion and plantar flexion of the foot and a tendency to walk on the toes, because of an action dystonia of the leg and foot. This may be evident only when walking or running. Patients with dopa-rcsponsive dystonia and prominent diurnal fluctuation develop their symptoms only in the afternoon.

Loss of Balance

Symptoms of poor balance and unsteadiness are cardinal features of the ataxic syndromes caused by cerebellar disease or proprioceptive sensory loss. The patient with a cerebellar gait ataxia complains of unsteadiness and an inability to walk in a straight line or turn and change direction suddenly without veering to one side or staggering as if intoxicated. A sensory ataxia may first give rise ro symptoms of unsteadiness when walking in the dark because visual compensation for the proprioceptive loss is not possible. Patients with impaired proprioception and sensory ataxia complain of being uncertain of the exact position of their feet when walking. They may be unable to appreciate the texture of the ground beneath their feet and describe abnormal sensations in the feet that give the impression of walking on a spongy surface or cotton wool. Acute disturbances of balance and equilibrium suggest a vascular insult to the cerebellum, thalamus, or basal ganglia. Acute severe vertigo caused by a peripheral vestibulopathy may also lead to a sensation of imbalance and a tendency to veer toward one side.

Falls

When taking a history of falls, wc must establish the circumstances in which they occur and whether there are any clear precipitants. Tripping may be due to footdrop or shallow steps, the effect of which may be exaggerated when walking on uneven ground. Proximal muscle weakness may result in the legs giving way. Unsteadiness and poor balance in an ataxic syndrome may lead to falls. Spontaneous falls or falls following postural adjustments, either forward or backward, suggest an impairment of postural reflexes. Falls when looking upward are common in the elderly. In the extreme form of loss of postural reflexes, patients may fall backward "like a board". In the setting of the early stages of an akinetic-rigid syndrome, spontaneous falls are an important clue to diagnoses such as multiple system atrophy or progressive supranuclear palsy {Steele-Richardson-Olszewski syndrome) rather than Parkinson's disease.

Sensory Symptoms and Pain

The distribution of any accompanying sensory complaints provides further information about the site of the lesion producing walking difficulties. A common example is cervical spondylosis and myelopathy presenting with cervical radicular pain or paresthesias and a spastic paraparesis. Paresthesias in a radicular distribution (caused by radiculopathy) and sensations of tight bands around the trunk {caused by spinal sensory tract compression), or a combination of truncal and limb sensory symptoms and a spastic paraparesis, are suggestive of a myelopathy. Distal symmetrical paresthesias affecting the limbs point toward a peripheral neuropathy.

It is important to determine whether complaints of leg pain and weakness in patients with difficulty walking share a common cause or whether the pain is of musculoskeletal origin and exacerbated by walking. An example of the former is cxcrcisc-induccd pain and weakness of the legs caused by neurogenic intermittent claudication of the cauda equina. These symptoms are often accompanied by transient paresthesias or radicular sensory loss in the legs, which is relieved after a few minutes by sitting and leaning forward. This should be distinguished from vascular intermittent claudication in which ischemic muscle pain, usually of the calves, interrupts walking but is relieved after a few seconds of rest. Skeletal pain caused by degenerative joint disease is common in elderly patients. It is often present at rest and aggravated by leg movements. The normal pattern of walking is often modified in these situations. The patient may voluntarily engage various strategies to minimize pain by avoiding bearing the full weight on the affected limb and by limiting its range of movement (antalgic gait).

Incontinence

Loss of the voluntary control of sphincter function in a patient with a spastic gait suggests a spinal cord lesion.

Parasagittal cere bra I lesions Mich as frontal lobe rumors (parasagittal meningioma), frontal lobe infarction caused by anterior cerebral artery disease, and hydrocephalus should also be considered, in addition to spinal cord disease. Impairment of higher mental function may be an important clue to a cerebral cause of paraparesis.

EXAMINATION OF POSTURE AND WALKING

The examination of posture and walking is summarized in Table 25.1. A convenient starting point is to observe the overall pattern of whole-body movement during walking. Normal walking progresses in a smooth and effortless manner, with an upright posture of rhe trunk. The legs swing in a free and fluid motion with regular strides of appropriate length accompanied by flowing associated synergistic head, trunk, and upper limb movement. Careful observation of the overall pattern of body movement during walking often enables rhe experienced observer to decide whether the gait problem is caused by a focal leg abnormality, muscle weakness, or a more generalized disorder ol movement, and whether it is unilateral or bilateral. After observing the overall walking pattern, the clinician should examine a number of specific aspects of gait, as outlined in rhe checklist for clinical examination of posture and gait (see Table 25.1).

Table 25.1: Checklist for the clinie.il examination of posture and gait

- Posture
  - Trunk posture (upright or stooped)
  - Postural reflexes (displace the paiii-m's center of gravity forward and backward)
  - Stance (narrow or wide based)
- Walking
  - Initiation (start hesitation, shuffling, magnetic feet)
  - Stepping
  - Rhythm (regular, irregular)
  - Length (normal, short)
  - Trajectory (shallow, high stepping)
  - Speed
  - Festi nation
  - Freezing
- Associared trunk movement and arm swing
- Special maneuvers
  -] led to roe walking
  - Romberg test
  - Walking backward or running
- Formal motor and sensory examination (supine)
  - Leg size and length
  - Range of joint movement
  - Muscle bulk
  - Muscle tone
  - Muscle strength
  - Voluntary movement
  - Trunk movement (rolling over)
  - Leg movement when not standing
  - Tendon reflexes
  - Sensation: proprioception
  - I kel-shin test

Posture

Trunk Posture

The trunk is normally upright during standing and walking. Flexion of the trunk is a prominent feature of Parkinson's disease but also may be seen in cautious gait syndromes in which the center of gravity is lowered to minimize body sway and the risk of falling. Neck and trunk extension is characteristic of progressive supranuclear palsy. Tilt of the trunk to one side may be a sign of dystonia but can also be seen in acute thalamic, basal ganglia, and vestibular lesions. An exaggerated lumbar lordosis, caused by hip-girdle weakness, is typical of proximal myopathies. Paraspinal muscle spasm and rigidity also produce an exaggerated lumbar lordosis and are striking features of the stiff person syndrome. A variety of axial muscle spasms are seen in torsion dystonia, with the most common being exaggerated flexion of rhe trunk and hip when walking. Abnormal thoracolumbar postures also may result from spinal ankylosis and spondylitis. Paraspinal myopathies may lead to severe rruncal weakness and a posture of marked truncal flexion (bent spine or eamptocormia). A restricted range of spinal movement and persistence of an abnormal spinal posture when supine or during sleep are useful pointers toward a bony spinal deformity as the cause of an abnormal trunk posture. Altered truncal postures, particularly in the lumbar region, may occur either to compensate for a shortening of one lower limb or disease of the hip, knee, or ankle or in response to leg pain.

Postural Reflexes

Postural teflcxes arc examined with patients standing and gently pulling the upper trunk backward or forward. The examiner should sr.md in front of or behmd patients and be prepared to catch or support them to prevent them from falling. An impairment of postural righting reactions is evident after each displacement by a few short shuffling steps backward (retropulsion) or forward (propulsion). Severe loss of postural reflexes abolishes reflex stepping or compensatory arm movements to adjust posture and restore balance and may render a patient susceptible to falls after minor perturbations or postural changes. A tendency to fall backward spontaneously is a sign of impaired postural reflexes in progressive supranuclear palsy. A pronounced rruncal rilr is observed in some thalamic and basal ganglia hemorrhages with rhe rrunk leaning away from the side of the lesion, leading to a fall to that side or backward (Masdeu and Gorelick 1988; Labadie et al. 1989). In the lateral medullary syndrome, the trunk may sway or tilt

Tabic 25.2: Summary of the major clinical features distinguishing different types of gait ataxia

Vi-atum	*Cerebellar ataxia*	*Sensory ataxia*	*Frontal lobe ataxia*
Trunk posture	Stooped, leans forward	Stooped, upright	Upright
Stance	Wide based	Wide based	Wide based
Postural reflexes	Variable	**Intact**	Impaired or absent
Initiation of gait	Normal	Normal	Start hesitation
Steps	Staggering, lurching	f ligh stepping	Short, shuffling
Speed	Normal, slow	Normal, slow	Very slow
Heel-toe test	Unable	Variable	Unable
Turning corners	Veers away	Minimal effect	Freezing, shuffling
Romberg test	Variable	Increased unsteadiness	Variable
Heel-shin test	Usually abnormal	Variable	Normal
Falls	Uncommon	Yes	Very common

toward the side of the lesion as a result of the acute imbalance in vestibulat postural control (lateropulsion). The presence of injuries to the knees, shins, face, or back of the head sustained during falls provides a clue to the loss of postural reactions, including impairment of the rescue reaction of an outstretched arm to break a fall.

Stance

Stance base (the distance between the feet during quiet standing) and walking give some indication of balance. Wide-based gaits are typical of cerebellar or sensory ataxia but may be seen in diffuse cetebtal vascular disease and frontal lobe lesions {Table 25.2). People whose balance is insecure for any reason tend to adopt a wider stance, adopt a posture of mild generalized flexion, and take shorter steps. Widening the stance base is an efficient method of reducing body sway in the lateral and anteroposterior planes. Those who have attempted to walk on ice ot other slippery surfaces will recognize this phenomenon.

Walking

Initiation of Gait

Difficulty initiating the first step (start hesitation) is a featutc of Parkinson's disease and frontal lobe disease and is occasionally seen in relative isolation in the syndrome of gait-ignition failure (Atchison et al. 1993). Start hesitation ranges in severity from a few shuffling steps, to small shallow steps on the spot without forward progress ("slipping clutch'"), to complete immobility with the feet seemingly glued to the floor ("magnetic feet"). Patients may make exaggerated upper body movements in an effort to engage their legs in motion.

Stepping

Once walking is undetway, the rhythm of stepping and the length and trajectory of each step should be noted. Short, regular, and shallow steps or shuffling is characteristic of the akinetic-rigid syndromes. Shuffling is usually most evident when starting to walk, stopping, ot turning corners. Repeatedly observing these maneuvers may highlight a subtle tendency to shuffle. Once underway, freezing may interrupt walking with further shuffling and start hesitation.

Jerky steps of irregular rhythm and variable length and trajectory suggest an ataxic syndtome. Abnormal leg and foot trajectories occur in sensory ataxia, footdrop, spasticity, and dystonia. Each is associated with a distinctive leg posture during stepping.

The speed of walking is revealing. Slowness is charactetistic of the akinetic-rigid syndromes but is also seen in ataxic and spastic syndromes. Festination (increasingly rapid, small steps) is common in Parkinson's disease but is rare in other a kinetic-rigid syndromes, which usually are associated with poor balance and falls rather than festination.

A reduction in associated trunk movement and arm swing is most evident in unilateral UMN, extrapyramidal, and acute cerebellar syndromes. Bilateral loss of synergistic arm movement when walking is a valuable sign of Parkinson's disease in the early stages, when most symptoms are unilateral.

Subtle degrees of cerebellar ataxia may be unmasked by asking the patient to walk in a straight line heel to toe (tandem gait), to stand on one leg, or to walk and turn quickly. If vision is important in helping maintain balance, as in sensory ataxia caused by proprioceptive loss, the removal of vision greatly exaggerates the ataxia. This is the basis of **the** Romberg test in which eye closure leads to a dramatic increase in unsteadiness and even falls in the patient with sensory ataxia. When pctforming the Romberg test, the patient must be standing comfortably before eye closure and **the** observer must remember that normal subjects and patients with cerebellar ataxia also show a modest increase in body sway with eye closure.

It may be necessary to examine the patient running to identify an action dystonia of the legs in the early stages of primary torsion dystonia.

MOTOR AND SENSORY EXAMINATION

After observing the patient walking, the clinician examines motor and sensory function in the limbs with the patient supine in the conventional examination position. The size and length of the limbs should be measured in any child presenting with a limp. An asymmetry in leg si/e is suggestive of a congenital malformation of the spinal cord, brain, or (rarely) local overgrowth of tissue. The spinal column should be inspected for scoliosis and the lumbar region for skin defects or hairy patches, which are indicative of spin a 1 dysraphism.

Changes in muscle tone such as spasticity, lead-pipe or cogwheel rigidity, or paratonic rigidity (gegenhalten) point toward diseases of the UMN, basal ganglia, and frontal lobes, respectively. In the patient who complains of symptoms in only one leg, a detailed examination of the other leg is important. If signs of a UMN syndrome are presenr in both legs, a disorder of the spinal cord or parasagittal region is likely.

Muscle bulk and strength are examined, and evidence of muscle wasting and the presence and distribution of muscle weakness are documented. Examination reveals whether the abnormal posture of the leg in a patient with a footdrop (Table 25.3) is caused by spasticity or weakness of ankle dorsiflexors, which in turn may be due to anterior horn cell disease, a peripheral neuropathy, a peroneal compression neuropathy, or an L5 root lesion. Subtle degrees of ankle dorsiflexion weakness may be detected by observing the patient walking on his or her heels. Joint position sense should he examined for defects of proprioception in the ataxic patient.

Discrepancies on Examination of Gait

Several conditions are notable for producing minimal abnormal signs on physical examination of the recumbent patient, in striking contrast to the observed difficulty when walking.

Patients with a cerebellar gait ataxia caused by a vermis lesion may perform the heel shin test normally when supine but when standing are unable to walk heel to toe. The finding of normal muscle strength, muscle tone, and tendon reflexes is common in dystonic syndromes in which an action dystonia causes abnormal posturing of the feet only when walking. A dystonic gait may exhibit a striking discrepancy between the difficulty walking forward, which may not be evident when walking backward. Gegenhalten, with or without brisk tendon reflexes, may be the only abnormal signs in the legs of the recumbent patient with a frontal lobe lesion, hydrocephalus, or diffuse cerebrovascular disease who is totally unable to walk. Moreover, such patients may be able to perform the heel-shin test and make bicycling movements of their legs when lying on a bed. A similar discrepancy can be seen in spastic paraplegia caused by hereditary spastic paraplegia, cerebral palsy (Little's disease), or cervical spondylotic myelopathy, in which only minor changes in muscle tone, strength, and tendon reflexes are evident during the supine examination in contrast to the profound leg spasticity apparent when walking.

Multiple Sensory Deficits

Elderly patients with walking difficulties and falls often have signs of multiple deficits. The most common are cervical spondylotic myelopathy with a mild spastic paraparesis and a degree of proprioceptive loss, as well as a peripheral neuropathy with absent ankle reflexes and mild proprioceptive loss. Additional sensory deficits such as visual, hearing, and vestibular impairment also contribute to imbalance, falls, and gait difficulties. Musculoskeletal factors and postural hypotension also interfere with mobility in this age-group.

The Cautious Gait

Finally, due account must be taken of the fear of falling that often accompanies gait difficulties. This may lead to a marked loss of confidence when walking and a cautious or protected gait (Nutt, Marsden, and Thompson 1993). Such patients may be unable to walk without support. They hold on to furniture, lean on walls, and avoid crowded or open spaces because of a fear of falling. Their gait may improve dramatically when support is provided.

PHYSICAL SIGNS AND INVESTIGATIONS

Spastic Gait

Spasticity of the arm and leg on one side produces the characteristic clinical picture of a spastic hemlparesis. The arm is held adducted, internally rotated at the shoulder,

and flexed at the elbow, with pronation of the forearm and flexion of the wrist and fingers. The leg is slightly flexed at the hip and extended at the knee, with plantar flexion and inversion of the foot. The swing phase of each step is accomplished by slight lateral flexion of the trunk toward the unaffected side, and hyperextension of the hip on that side to allow the slow circumduction of the stiffly extended paretic leg, as it is swung forward from the hip, dragging the toe or catching it on the ground beneath. A minimum of associated arm swing occurs on the affected side. The stance may be slightly widened, and the speed of walking is slow. Balance may he poor because the hemiparesis interferes with corrective postural adjustments on the affected side. Muscle tone in the affected limbs is increased, clonus may be present, and the tendon reflexes are abnormally brisk with an extensor plantar response. Examination of the sole of the shoe may reveal wear of the toe and outer borders of the shoe, suggesting that the spastic gait is long standing.

After identifying a spastic hemiparesis, the next step is to determine the level of the lesion that is responsible. Attention should be paid to the face, because UMN facial weakness on the same side indicates that the level probably lies above the pons, the most common cause of which is cerebral infarction, suggested by a history of acute onset. A UMN type of facial weakness on the side opposite the hemiparesis (crossed hemiparesis) suggests a pontine lesion. When the face is not involved, ciues to the site of the lesion must he sought by examining the motor function of the lower cranial nerves. Weakness of shoulder shrugging on the same side points to a lesion above the foramen magnum. A cervical spinal cord lesion involves the arms unci legs only, whereas a lesion ot the thoracic cord affects only the legs. When lesions of the spinal cord are suspected, magnetic resonance imaging (MRI) of the cord is indicated.

Spasticity of both legs gives rise to a spastic paraparesis. The legs are stiffly extended at the knees, plantar flexed at the ankles, and slightly flexed at the hips. The gait is slow and labored. The legs are dragged forward with each step, both legs circumduct, and there is a tendency of adduction of the legs, particularly when the disorder begins in childhood. This appearance gave rise to the term *scissor gait.* The causes of a spastic paraparesis include hereditary spastic paraplegia, in which the arms and sphincters are unaffected and there may be little or no leg weakness, and other myelopathies. An indication of the extent and level of the spinal cord lesion can be obtained from the presence or absence of weakness or sensory loss in the arm, a spinothalamic sensory level or posterior column sensory loss, and alterations in sphincter function. Most patients with paraparesis of recent onset should be investigated with MRI of the spinal cord or myelography, to exclude potentially treatable causes, such as spinal cord compression.

Occasionally, bilateral leg dystonia (dystonic paraparesis) may mimic a spastic paraparesis. This typically occurs in dopa-responsive dystonia in childhood, which may be misdiagnosed as hereditary spastic paraplegia or cerebral diplegia. Differentiation between these conditions can be difficult. Brisk tendon reflexes may occur in both, and spontaneous extension of a great toe in patients with striatal disorders may be interpreted as a Babinski response. Fanning of the toes and knee flexion suggest the latter. Other distinguishing features include changes in muscle tone, such as spasticity in hereditary spastic paraparesis and rigidity in dystonic paraparesis. In young children, the distinction is important, because a proportion of such patients can be treated successfully with L-dopa {discussed in the following sections).

Cerebellar Ataxia

The gait disorder that accompanies disease of the vermis and anterior lobe of the cerebellum consists of a loss of normal truncal balance resulting in increased body sway and dyseqiulibrium. The patient adopts a wide-based stance and may flex the hips slightly to crouch forward and minimize body sway. Patients with anterior lobe atrophy develop a 3-Hz anteroposterior sway of the trunk, which may be accompanied by a rhythmic truncal and head tremor (titubation). Patients with lesions of the flocculo-nodular lobe of the cerebellum (the vestibulocerebellum) exhibit multidirectional body sway and dysequilibrium and may fall. Limb ataxia resulting from involvement of the cerebellar hemispheres is characterized by a decomposition of normal leg movement with steps that are irregular and variable in timing (dyssynergia), length, and direction (dysmetria). Steps are taken slowly and carefully to reduce the tendency to lurch and stagger. These defects are exacerbated when attempting to walk heel to toe in a straight line. Ataxia is also made worse by the rapid postural adjustments needed when changing direction to turn a corner, avoid obstacles, and when stopping or starting to walk. Cerebellar ataxia may be improved by minor support, such as holding the patient's hand during walking. Visual compensation helps the patient with a cerebellar ataxia reduce body sway or plot a secure path ahead while walking. Eye closure may increase anxiety about falling but does not produce the dramatic deterioration in balance seen in a sensory ataxia,

With lesions confined to one cerebellar hemisphere, ataxia is limited to the affected (ipsilateral) limb and affects coordination of limb movement more than balance, if the vermis is not involved. Conversely, a purely truncal ataxia may be the sole feature of a midline (anterior lobe and vermis) cerebellar syndrome. As discussed earlier, this may escape notice if the patient is not examined when standing because leg coordination during the heel-shin test may be relatively normal when the patient with a vermis lesion is examined in the supine position.

An isolated cerebellar gait ataxia may be caused by malnutrition in alcoholism, producing a relatively selective vermis and anterior lobe syndrome. Midline cerebellar masses and paraneoplastic, hereditary, or sporadic cerebellar degenerations may also produce a predominantly truncal cerebellar ataxia.

Spastic Ataxia

A combination of spasticity and ataxia produces a characteristic springing or bouncing gait. Such gaits may be seen in multiple sclerosis, the Amold-Chiari malformation, and hydrocephalus in young people. The gait is wide based, and clonus is readily elicited by stretching the leg muscles when examining muscle tone or tapping the tendon reflexes. Even voluntary leg movements may precipitate clonus, which throws the ataxic patient off balance. Compensatory reflex and voluntary movements, made in an effort to regain balance, set up a vicious cycle of ataxic movements, clonus, and increasing unsteadiness, so such patients may be totally unable to stand and walk. Bouncing gaits must be distinguished from action myoclonus of the legs and from leg and truncal tremors seen in cerebellar disease (see Action Myoclonus and Tremor of the Legs, later in this chapter).

Sensory Ataxia

The loss of proprioceptive input from the legs deprives patients of knowledge of their position in space, the progress of ongoing movement, the state of muscle contraction, and finer details of the texture of the surface of the ground on which they are walking. Patients without such information tend to adopt a wide base and take slow steps, advancing cautiously with the aid of visual guidance. The feet are thrust out with each step, and the sole of the foot strikes the floor forcibly, giving rise to a slapping noise (slapping gait). Patients with sensory ataxia find it difficult to walk on uneven surfaces or at night. Lesions at any point in the sensory pathways that interrupt large-diameter proprioceptive afferent fibers may produce this clinical picture. Peripheral neuropathies, posterior root or dorsal root ganglion lesions such as tabes dorsalis, and dorsal column lesions, for example, in vitamin B_{12} deficiency, are some of the diseases responsible for a sensory ataxia of gait.

Akinetic-Rigid Gait

The most common akinetic-rigid gait disturbance is that seen in Parkinson's disease. The patient adopts a stooped posture with flexion of the shoulders, neck, and trunk. Tremor of the upper limbs may be evident when walking (but parkinsonian tremor of the legs rarely affects walking). The gait is typically slow and shuffling, with small shallow steps on a narrow stance base. These signs may be dramatically reversed by L-dopa treatment. There is little associated body movement. Arm swing is reduced or absent and the arms are held immobile at the sides or slightly forward of the trunk. A characteristic feature is the tendency to begin walking with a few rapid, short shuffling steps {start hesitation) before breaking into a more normal walking rhythm. Walking, once underway, may be interrupted by further shuffling or even complete cessation of movement (freezing) if a doorway or other obstacle is encountered. Freezing becomes increasingly troublesome in the later stages of Parkinson's disease when it is helped more by sensory cues to trigger a step than L-dopa medication.

The posture of generalized flexion of the patient with Parkinson's disease exaggerates the normal tendency to lean forward when walking. To maintain balance when walking and avoid falling forward, the patient may advance with a series of rapid small steps (festination). Rctropulsion and propulsion are similar manifestations of a flurry of small-si/.ed parkinsonian steps made in an effort to preserve equilibrium in response to external perturbations. Instead of a single large step, a series of small steps are taken to restore balance. If these compensatory festinating steps are too small to maintain or restore balance, the patient may fall forward. Other causes of falls in Parkinson's disease include tripping or stumbling over rough surfaces, because each step is too small or shallow to clear obstacles, as well as profound start hesitation or freezing. In each of these examples, falling stems from locomotor hypokinesia and a lack of normal-sized, rapid, compensatory voluntary movements, Late in the illness, falls may occur either spontaneously or after minor perturbations resulting from loss of postural and righting reflexes. These deficits do not respond to L-dopa medication, unlike the hypokinetic steps and flexed truncal posture early in the disease,

A similar slowness of leg movement and shuffling when walking may occur in various other akinetic-rigid syndromes (Table 25.4). These include multiple system atrophy, cerebrovascular disease, and progressive supranuclear palsy. A number of clinical signs help distinguish between these conditions (Table 25.5). In progressive supranuclear palsy, the typical neck posture is one of extension rather than flexion, as in Parkinson's disease. A stooped posture with exaggerated neck flexion is sometimes a feature of multiple system atrophy. A distinguishing feature of progressive supranuclear palsy and multiple system atrophy is the early loss of postural and righting reflexes in comparison ro the preservation of these reflexes in Parkinson's disease until the late stages of the illness. There also may be an element of ataxia in these akinetic-rigid syndromes, which is not evident in Parkinson's disease. Accordingly, the patient who presents with falls and an akinetic-rigid syndrome is more likely to

Tabic 25.4: Differential diagnosis in the patient presenting with an a kinetic-rigid syndrome and a gait disturbance

Parkinson's disease

juvenile Huntington's disease
Wilson's disease
Cerebral anoxia
Neurosyphilis

have symptomatic parkinsonism, rathet than Parkinson's disease.

The gait of patients with hydrocephalus and Binswanger's disease caused by periventricular white mattet ischemia is characterized by short shuffling steps, often of variable length, with a wide-based stance (and stride width) and a degree of imbalance. The truncal posture is upright with exaggetated arm swing during walking, giving the **gait a** military appearance. Examination also teveals preservation of upper body movement in contrast to Parkinson's disease. These stance and stepping chatactctisties have also been demonstrated by kinematic studies of gait in hydrocephalus and Binswanger's disease (Ebcrsbach et al. 1999; Stolze et al. 2001). Finally, the dramatic response to L-dopa that is typical of idiopathic Patkinson's disease does not occur in symptomatic parkinsonism, although sonic patients with multiple system atrophy respond partially for a short period.

Dystonic Gait

Of all gait disturbances, dystonic syndromes may produce the most bizarre and often the most difficult diagnostic problcms. The classic presentation of childhood-onset primary torsion dystonia (dystonia musculorum deformans) is an action dystonia of a leg with a sustained abnormal posture of the foot (typically, plantat flexion and inversion) on attempting to run. In contrast, walking forward or backward or even running backward may be entirely normal at an early stage. An easily ovctlooked sign in the early stages is tonic extension of the great toe (the striatal toe) when walking. This may be a subtle finding but occasionally is so pronounced that a hole is worn in che roe of the shoe. With time, dystonia may progress to involve the whole leg and then become generalized.

More difficult to identify are those dystonic syndromes that ptesent with bizarre, seemingly inexplicable postures of the legs and trunk when walking. A characteristic featute common to all these dystonic postures is excessive flexion of the hip when walking. These patients may hop or walk sideways in a crablike fashion with hypcrflexion of the hips, producing an attitude of general body flexion in a simian posture, or with a birdlikc (peacock) gait with excessive flexion of the hip and knee and plantar flexion of the foot during the swing phase of each step. Many of these patients have been thought to be hysterical because of the bizarre nature of their gait disturbance and because formal neurological examination shows no abnormalities if the patient is examined when lying supine. Each of these gait patterns has been described in association with identifiable secondary dystonic syndromes, including postencephalitic movement disorders, manganese poisoning, and Wilson's

Table 25.5; Summary of the clinical features that help differentiate between Parkinson's disease and symptomatic or secondary parkinsonism in patients with an akinetic-rigid gait syndrome

Feature	*Parkinson's disease*	*Symptomatic parkinsonism*
Posture	Stooped (trunk flexion)	Stooped or upright (trunk flexion or extension)
Stance	Narrow	Often wide based
Initiation of walking	Start hesitation	Start hesitation, magnetic feet
Steps	Small, shuffling	Small, shuffling
Stride length	Short	Short
Freezing	Common	Common
Leg movement	Stiff, rigid	Stiff, rigid
Spi-cd	Slow	Slow
Festi nation	Common	Rare
Arm swing	Minimal or absent	Reduced or excessive
Heel-to-toe walking	Normal	Poor (truncal ataxia)
Postural reflexes	Preserved in early stages	Absent at early stage
Falls	Late (forward, tripping)	Early and severe (backward, tripping or without apparent reason)

disease. Finally, tardive dystonia after the ingestion of neuroleptic drugs also may produce similar bizarre abnormalities of gait,

It is always important to look for asymmetry in the assessment of childhood-onset dystonia, because a hemidystonic syndrome should be investigated to exclude symptomatic causes. Similarly, an isolated dystonic leg also should point toward symptomatic causes in an adult, though not in childhood, Should there be an early loss of postural responses and righting reflexes in association with a dystonic gait disturbance, attention also should be directed toward excluding underlying secondary causes.

Dystonia with diurnal fluctuation (dopa-rcsponsive dystonia) characteristically presents with walking difficulties in childhood. Typically, the child walks normally in the early morning but develops increasing rigidity and dystonic posturing of the legs with difficulty walking as the day progresses. These dystonic leg postures usually become evident or worsen after exercise. Examination reveals a dystonic foot posture of plantar flexion and inversion, with the additional feature of brisk tendon reflexes. Some of these patients respond dramatically to L-dopa-containing preparations, and early recognition is important. Indeed, all children presenting with a dystonic foot or leg should have a therapeutic trial of L-dopa before other therapies, such as anticholinergic drugs, are commenced.

Paroxysmal dyskinesias also may present with difficulty walking. Paroxysmal kincsigenic choreoathetosis may present with the sudden onset of difficulty walking as a result of dystonic postures and involuntary movements of the legs that often appear after standing from a seated position. Similarly, dystonia of the legs, cither paroxysmal or exercise induced, may interfere with walking.

Choreic Gait

The random movements of chorea are accentuated and often most noticeable during walking. The gait is often described as having a dancing quality because of the supcrimposition of chorea on the trunk and leg movements of the walking cycle. Chorea may be incorporated into the stepping and truncal movements of the walking cycle, resulting in exaggerated motion of the legs when stepping and excessive associated arm swing. Chorea may interrupt the normal movements of walking, leading to a hesitant gait, and there may be additional voluntary compensatory movements in response to perturbations from the chorea. Choreic movements in Sydenham's chorea or chorea gravidarum may be sufficiently violent to throw patients off their feet or be unable to walk at **all.** Chorea of this severity is uncommon in Huntington's disease and usually causes a lurching or occasionally stumbling gait with frequent additional steps cither forward, backward, or to one side. In Huntington's disease, walking is slow, the stance is wide based, the trunk sways excessively, and steps are variable in length and timing. Spontaneous knee flexion and leg raising are also common. Haloperidol reduces the chorea but does not improve gait in Huntington's disease. Balance and equilibrium usually are maintained until the terminal stages of Huntington's disease, when an akinetic rigid syndrome may supervene.

Mixed Movement Disorders and Gait

Many conditions, notably athetoid cerebral palsy, produce :i range of motor signs that refleci abnormalities at many levels of the nervous system. All interfere with and disrupt normal patterns of walking. These include spasticity of the legs, truncal and gait ataxia, and dystonic spasms and postures affecting the trunk and limbs. Difficulties may arise in distinguishing such patients from those with primary torsion dystonia, which may begin at a similar age in childhood. The patient with cerebral palsy usually has a history of hypotonia and delayed achievement of developmental motor milestones. Often, there is a history of perinatal injury or birth asphyxia, but in a substantial proportion of patients, such an event cannot be identified. A major distinguishing feature is poor balance at an early age, which may be a contributing factor to the delay in sitting and later walking. As the child begins to walk, the first signs of dystonia and athetosis appear. The presence of spasticity and ataxia also helps distinguish **this** condition from primary dystonia.

Childhood neurodegenerative diseases also may first manifest as a disorder of walking with a combination of motor syndromes. A progressive course should raise the possibility that the syndrome is symptomatic and secondary to an underlying cause.

ACTION MYOCLONUS AND TREMOR OF THE LEGS

Some causes of involuntary movements of the legs when standing or walking are listed in Table 25.6.

Action Myoclonus

Action myoclonus and reflex myoclonus affecting the legs are rare but striking disorders. Postanoxic action myoclonus of the legs is often accompanied by negative myoclonus (or astcrixis) and severely disrupts normal postural control and any attempts to use the legs to stand or walk. Repetitive action myoclonus produces jerky movements of the legs, throwing the patient off balance, and lapses of muscle activity between the jerks (negative myoclonus) cause the patient to sag toward the ground. This sequence of events gives rise to an exaggerated bouncing appearance, which the patient is able to sustain for only a few seconds

Table 25.6: Differential diagnosis of involuntary movements of the legs when standing

Action myoclonus of legs (as in postanoxic myoclonus)
Benign essential tremor
Orthostatic tremor
Cerebellar truncal tremor
Clonus in spasticity
Spastic ataxia

before falling or seeking relief by sitting down. Difficulty walking is one of the major residual disabilities of postanoxic myoclonus, and many patients remain wheelchair bound. The stance is wide based, and there is often an element of cerebellar ataxia, although this may be difficult to distinguish from the severe action myoclonus. Stimulus-sensitive cortical reflex myoclonus also may produce a similar disorder of stance and gait, with reflex myoclonic jerking of leg muscles, particularly the quadriceps, resulting in a bouncing posture.

Tremor of the Trunk and Legs

An action tremor of the legs may produce a similar though less severe bouncing standing posture and gait. Leg tremor in benign essential tremor is occasionally symptomatic. Trunk and leg tremor may be a cause of unsteadiness in cerebellar disease. Orthostatic tremor has a unique frequency of 16 Hz and distribution, affecting trunk and leg muscles while standing. It produces an intense sensation of unsteadiness, rather than shaking, which is relieved by walking or sitting down. Patients avoid standing still, for example, in a queue, and may shuffle on the spot or pace about in an effort to avoid the unsteadiness experienced when standing still. Falls are rare. Examination may reveal only a rippling of the quadriceps muscles during standing, and the rapid tremor is often only appreciated by palpation of leg muscles. The differentiation among leg tremors and the diagnosis of orthostatic tremor is best made by recording the clectromyographical activity of leg muscles during standing and measuring tremor frequency.

GAIT IN THE ELDERLY

Healthy, neurologically normal elderly people tend to walk at slower speeds than their younger counterparts (Murray, Kory, and Clarkson 1*969).* The slower speed of walking is related to shorter and shallower steps with reduced excursion at lower limb joints. In addition, stance width may be slightly wider than usual, and synergistic arm and trunk movements are less vigorous. The rhythmiciry of stepping is preserved. These changes give the normal elderly gait a cautious or guarded appearance. Factors contributing to this general decline in mobility of the elderly include degenerative joint disease, reduced range of limb movement, and dcctcascd cardiovascular fitness, limiting exercise capacity. The reduced speed of walking and associated changes in gait pattern in the elderly also may represent one method of providing a more secure base to compensate for a subtle age-rein red deterioration in balance. In imsclccicd elderly populations, a more pronounced deterioration in gait is evident (Imms and F.dholm 1981). Steps are shorter, stride length is reduced, and the stance phase of walking is increased, leading to a reduction in walking speed, particularly in those who fall.

Neurological causes of walking difficulty in the elderly, such as myelopathy, parkinsonism, cerebellar disease, and imbalance caused by sensory loss, are common etiologies, as are frontal gait disorders and gait apraxias (Sudarsky and Ronthal 1983). The etiology of imbalance and an insecure gait in the elderly is often multifactorial. The cumulative effects of lesions at many sites can interfere with walking without any one lesion being severe enough to explain the difficulty. Multiple sensory deficits affecting vision, vestibular, and proprioceptive function cause imbalance and an insecure gait. Multiple mild sensory deficits of peripheral nerve or posterior column origin, combined with modest leg weakness of peripheral nerve or corticospinal tract origin, as in cervical and lumbar spondylosis, are also common causes of this clinical picture. Loss of confidence, especially after falls, adds to the multifactorial age-related gait disturbance. A formal program of gait retraining may correct this loss of confidence and improve the ability to walk.

In some patients, difficulty walking and even standing is related to dysequilibrium because of impaired postural reflexes and a tendency to fall, often with injury. Acute vascular lesions of the thalamus (thalamic astasia) or basal ganglia produce this clinical picture with falls away from the side of the lesion without corrective postural adjustments. Similar dysequilibrium with impaired postural reflexes occurs in progressive supranuclear palsy and multiple system atrophy, with falls forward or backward. Impaired central vestibular function may also account for isolated dysequilibrium in some elderly patients and correlate with increased body sway (Fife and Baloh 1993).

The mechanisms responsible for the disturbances of gait that accompany lesions of the frontal lobes are poorly understood {Thompson 2001). Frontal lobe tumors (glioma or meningioma), anterior cerebral artery infarction, obstructive or communicating hydrocephalus (especially normal pressure hydrocephalus), and diffuse cerebrovascular disease (multiple lacunar infarcts and Binswanger's disease) all produce a similar disturbance of gait. The clinical appearance of the gait of patients with such lesions vanes from a predominantly wide-based ataxic gait to an akinetic-rigid gait with slow short steps and a tendency to shuffle. It is common for a patient to present with a combination of these features. In the early stages, the stance

base is wide with an upright posture of the trunk and short shuffling steps. This may be most noticeable on starting to walk or turning corners. There may be episodes of freezing. Arm swing is often normal or even exaggerated when walking, but the normal fluidity of trunk and limb motion is lost, giving the appearance of a "military two-step" gait. Examination often reveals normal voluntary upper limb and hand movements and a lively facial expression. This lower half parkinsonism is commonly seen in diffuse cerebrovascular disease. The marchc a petits pas of Dejerine and Critchley's atherosclerotic parkinsonism refers to a similar clinical picture. Patients with this clinical syndrome commonly are often misdiagnosed as having Patkinson's disease. The normal motor function of the upper limbs, the upright truncal posture, UMN signs, including a pseudobulbar palsy, and the absence ot a resting tremor distinguish this syndrome from Parkinson's disease. In addition, the lower half parkinsonism of diffuse cerebrovascular disease does not respond to i.-dopa treatment, further distinguishing it from Parkinson's disease (see Table 25.4). The slowness of movement and the lack of heel-shin ataxia distinguish the wide-stance base of this syndrome from cerebellar gait ataxia.

As the underlying condition progresses, the elements of ataxia and parkinsonism become more pronounced. There may be great difficulty initiating a step, as if the feet were glued to the floor (the magnetic foot response). Attempts to take a step require assistance with the patient clutching for the support of neatby objects or persons. There may be excessive upper body movement as the patient tries to ftee the feet to initiate walking, and when undetway, shuffling becomes even more pronounced. Such patients rarely exhibit the festination of Parkinson's disease, but a few steps of propulsion or retropulsion may be taken. Postural and righting reactions are impaired and eventually lost, and falls are common at the slightest perturbation. By contrast, these patients often can move their legs with greater facility when seated or lying supine. They may be able to make stepping, walking, or bicycling leg movements when lying but be quite unable to do so when standing.

A severe loss of truncal mobility and truncal balance may develop in the advanced stages of a frontal gait disorder, so patients are unable to stand or turn over when lying in bed. Walking then becomes impossible, and even simple leg movements ate slow and clumsy when lying down. Paratonic rigidity (gegcnhalten) of the arms and legs is common. Tendon reflexes may be brisk with extensor plantar responses. Gtasp reflexes in the hands and feet may be elicited and urinary incontinence and dementia commonly occut. Investigation by MRI or computed tomography of the brain reveal the majority of conditions causing this syndrome.

Some patients display fragments of this clinical picture. Those with gait-ignition failure exhibit profound start hesitation without disturbance of stepping once walking is underway. Balance while standing or walking is normal. Initiation of the first step is hampered by shuffling, and walking may be interrupted by freezing (Atchison ct al. 1993). Sensory cues may facilitate stepping. These findings are similar to walking in Parkinson's disease, but speech and upper limb function are normal and there is no response to i.-dopa. Results of imaging of the brain are normal. The cause of this syndrome is not known, but the slowly progressive evolution of symptoms suggests a degenerative condition.

Occasionally, isolated episodic festination with truncal flexion is encountered. Others complain of a loss of the normal fluency of stepping when walking and a conscious effort is required to maintain a normal stepping rhythm and step size. These symptoms may be associated with subtle dysequilibrium manifesting as a few brief staggering steps to one side or a few steps of retropulsion after standing up, turning quickly, or other rapid changes in body position. Finally, there remain elderly patients with severe walking difficulties that resemble those described in frontal lobe disease. The history in these syndromes is one of gradual onset, without strokclike episodes or identifiable structural or vascular lesions of the frontal lobes or cerebral white matter on imaging. The cause of these syndromes is not known. The criteria fot normal pressure hydrocephalus are not fulfilled, there are no signs of parkinsonism, L-dopa is ineffective, and thcte is no evidence of more generalized cerebral dysfunction, as occurs in Alzheimer's disease. Indeed, it is rare for patients with Alzheimer's disease to develop difficulty walking until the later stages of the disease.

Nomenclature of Gait in the Elderly

Early descriptions of frontal gait syndromes emphasized the imbalance and ataxic components. The term *frontal ataxia* was used to reflect the perceived involvement of the frontopontocerebellar pathway as the most likely mechanism. Indeed, the gait ataxia of many midline cerebellar lesions associated with obstructive hydrocephalus can be out of ptoportion to the degree of lower limb heel-shin ataxia and may be largely relieved by the insertion of a ventricular drain or shunt. This observation confirms the importance ot hydrocephalus in the gait ataxia associated with these lesions. Others were impressed by the slowness of movement and the discrepancy between the pronounced disability when attempting to walk and the preservation of leg movements when lying or sitting. This combination of signs was considered a form of limb-kinetic apraxia and referred to as *frontal apraxia* and later *gait apraxia.* Gait apraxia is defined as an inability to properly use the lower limbs in the act of walking that cannot be accounted for by demonstrable sensory impairment or motor weakness (Meyer and Barron 1960). Meyer and Barron (1960) emphasized that gait apraxia included ataxia plus

hypokinesia, rigidity (gegenhalten), and brisk reflexes, the latter signs distinguishing apraxia of gait from cerebellar ataxia. The combination of bradykinesia and ataxia in frontal lobe or diffuse cerebral white matter disease is explained by interruption of the connections between motor, premoror, and supplementary motor cortex and other subcortical motor areas, such as the cerebellum and basal ganglia. Use of the term *apraxia* in this context remains controversial because these gaits probably encompass a spectrum of higher motor syndromes (Nutt, Marsden, and Thompson 1993). Discussions concerning the classification of higher gait syndromes have variously emphasized the presumed anatomical or physiological basis of the problem (Nutt, Marsden, and Thompson 1993; Jankovic, Nutt, and Sudarsky 2001). For example, a frontal gait disorder refers to a combination of elements of dyseciuilibrium, marche a petits pas, and gait-ignition failure. Subcortical dysequilibrium refers to a predominant disorder of equilibrium with a loss of postural reflexes and severe falls as seen in thalamic and basal ganglia astasia and progressive supranuclear palsy.

MYOPATHIC WEAKNESS AND GAIT

Weakness of proximal leg and hip-girdle muscles interferes with the stabilization of the pelvis and legs on the trunk during all phases of the gait cycle. Failure to stabilize the pelvis produces exaggerated rotation of the pelvis with each step (waddling or Trendelenburg gait), the hips are slightly flexed as a result of weakness of hip extension, and an exaggerated lumbar lordosis occurs. Weakness of hip extension interferes with the ability to stand from a squatting or lying position and patients may use their arms to push themselves up from a squatting position (Gowers' sign). The classic descriptions of this gait were of patients with Duchenne's muscular dystrophy, but any myopathy affecting these muscles results in such a picture. Similarly, neurogenic weakness of proximal muscles, for example, spinal muscular atrophy and, occasionally the Guillain-Barre syndrome, may mimic this waddling gait.

NEUROGENIC WEAKNESS AND GAIT

Muscle weakness of peripheral nerve origin, as in a peripheral neuropathy, typically affects distal muscles of the legs and results in a steppage gait. The patient lifts the leg and foot high above the ground with each step because of weakness or paralysis of ankle dorsiflexion and a foordrop (steppage gait). When this clinical picture is confined to only one leg (unilateral footdrop), a common peroneal or sciatic nerve palsy or an L5 radiculopathy is the usual cause. Less common is footdrop caused by myopathic weakness, for instance, in the scapuloperoneal syndromes.

A femoral neuropathy, such as in diabetes mellitus, is another example of a strategic mononeuropathy that may disable walking. Weakness of knee extension allows the knee to buckle when walking or standing. This may first be evident when walking down stairs. Such focal weakness also may be the presenting feature of the progressive muscular atrophy in motor neuron disease or be an early feature of quadriceps myopathy, for instance, caused by inclusion body myositis.

HYSTERICAL AND PSYCHOGENIC GAIT DISORDERS

The wide range of abnormalities of gait seen in lesions of different parts of the nervous system make hysterical and psychogenic gaits among the most difficult to diagnose. In a hysterical paralysis, there may be complete inability to use a leg when walking, but normal synergistic movements of the affected leg may be observed when the patient is examined while lying down or when changing position. This discrepancy is further illustrated by Hoover's sign. The patient with an apparently paralyzed leg or legs is examined when supine. As the patient lifts the normal leg, the examiner places his or her hand under the "paralyzed" leg and feels the presence (and strength) of synergistic hip extension. The apparent severe weakness of hysterical paresis often presents little disability or inconvenience. In contrast, other patients with hysterical paraplegia may he totally confined to bed and may even develop contractures from lack of leg movements.

A gait disorder is one of the more common manifestations of a psychogenic or hysterical movement disorder and various gait patterns are encountered. These include transient fluctuations in posture while walking, knee buckling without falls, excessive slowness and hesitancy, a crouched, stooped, or other abnormal posture of the trunk, complex postural adjustments with each step, exaggerated body sway or excessive body motion, and trembling weak legs. Suggestibility and improvement with distraction are common features, as is the case with other psychogenic movement disorders.

The more acrobatic hysterical disorders of gait indicate the extent to which the nervous system is functioning normally. These patients are able to take advantage of high-level motor skills and coordination to perform various complex maneuvers. This is an important observation in the assessment of suspected hysterical gait disorders, as is a rapid, dramatic, and complete recovery. One must be cautious in accepting a diagnosis of hysteria though, because a bizarre gait may be a presenting feature of primary torsion dystonia and unusual truncal and leg postures may be encountered in truncal and leg tremors.

MISCELLANEOUS GAIT DISORDERS

Space Phobia and Gait

A syndrome of space phobia is described in which middle-aged people develop an inability to walk and a fear of falling in open spaces. These patients seek the support of nearby fences or walls and may even crawl about on all fours. Falls may occur in the course of the illness. Other neurological symptoms and cardiovascular disease are common accompaniments. Some patients may experience symptoms while driving or simply standing, suggesting the condition is related to the perception of visuospatial information and is distinct from simple agoraphobia.

Painful (Antalgic) Gaits

At one time or another, most people experience a limp caused by a painful or injured leg. Limps and gait difficulties that are caused by joint disease or by local bony or soft tissue injury are not usually accompanied by muscle weakness or by reflex or sensory change. Limitation of the range of movement at the hip, knee, or ankle joinrs may lead ro short steps with a fixed leg posture.

Pain in the leg caused by intermittent claudication of the cauda equina is most commonly caused by spinal stenosis with lumbar spondylosis and, rarely, by a spinal tumor. Diagnosis is confirmed by spinal imaging. Occasionally, it may be difficult to distinguish this syndrome from claudication of the calf muscles caused by peripheral vascular disease, although the duration of the pain after rest (see earlier discussion) is usually characteristically different in the two syndromes. Examination of the patient after inducing the symptoms by exercise may resolve rhe issue by revealing a depressed ankle jerk or radicular sensory loss, with preservation of arterial pulses in the leg.

Skeletal Deformity and Joint Disease

Degenerative osteoarthritis of the hip may produce leg shortening, in addition to mechanical limitation of leg movement at the hip, giving rise to a waddling gait or a limp.

Leg shortening with limping in childhood may be the presenting feature of hemiatrophy caused by a cerebral or spinal lesion. Such walking difficulties between the ages of 1 and 5 years are the most common mode of presentation of spinal dysraphism. On examination, various additional abnormalities may be detected, including lower motor neuron signs in the legs and sensory loss with trophic ulcers of the feet. Occasionally, UMN signs, such as a brisk knee reflex, are present in the same limb. Lumbosacral vertebra] abnormalities (spina bifida), bony foot deformities, and a cutaneous hairy patch over the lumbosacral region are clues to the diagnosis. In adult life, spinal dysraphism (diastcmatomyelia with a tethered cord) may first become symptomatic after a back injury, with the development of walking difficulties, leg and lower back pain, neurogenic bladder disturbances, and sensory loss in a leg. Imaging of the spinal canal reveals the abnormality.

Epileptic Falls in Childhood

Seizure disorders of the myoclonic or akinetic-atonic type typically produce falls but may present as an unsteady or uncoordinated gait in childhood. Tonic seizures or flexor spasms also may produce this clinical picture. Simultaneous video, electroencephalographical, and electromyographic recordings arc helpful in diagnosing and identifying these various seimre patterns.

Chapter 26
Hemiplegia and Monoplegia

Karl E. Misulis

ANATOMY

Accurate neurological diagnosis begins with anatomical localization. Many disorders have diffuse localizations, but hemiplegia and monoplegia arc more likely to be due to focal structural lesions and are therefore easier to localize. Imaging studies are often confirmatory of the structural lesion, but clinical localization must precede imaging studies.

Hemiplegia and monoplegia are motor symptoms and signs, but associated sensory abnormalities are discussed along with the motor findings because they are commonly-present and helpful for accurate localization. Sensory deficit syndromes are discussed in more depth in Chapter 31.

Motor power begins with initiative or volition, lack of which does not produce weakness, but akinesia. Projections from the premotor regions of the frontal lobes to the motor strip result in activation of corticospinal tract (CST) neurons. The descending fibers pass through the internal capsule and the cerebral peduncles, and then remain in the ventral brainstem before crossing in the medulla at the pyramidal decussation. Most of the CST crosses at this point. Descending CST axons project to the spinal cord segments where the fibers exit the CST and enter the spinal gray. Here, motoneurons are activated, which then conduct action potentials in the motor axons to the muscle. Transmission at the neuromuscular junction provides for one action potential in the muscle fiber for each action potential in the motor axon. Depolarization of the muscle fiber results in release of calcium, which then promotes the repeated cross-linking and release of actin and myosin filaments, which results in contraction. The contraction is terminated when the calcium is sequestered and prepared for reuse.

Localization begins with identification of weakness. Differentiation is made between the following distributions:

- Generalized weakness
- Monoplegia
- Hemiplegia
- Paraplegia

Only hemiplegia and monoplegia are discussed here.

HEMIPLEGIA

Cerebral Lesions

Cerebral lesions arc the most common causes of hemiplegia with lesions in either conical or subcortical structures (Table 26.1).

Cortical Lesions

Cortical lesions produce weakness, which is more focal than the weakness seen with subcortical lesions. Figure 26.1 shows a diagrammatic representation of the surface of the brain, showing how the body is mapped on the surface of the motor sensory cortex. This is the *homunculus.* In this representation, the face and arm are laterally represented on the hemisphere, whereas the leg is draped over the top of the hemisphere and into the interhemispheric fissure. Small lesions of the cortex can produce prominent focal weakness of one area, such as the leg or the face and hand, but hemiplegia—prominent involvement of both the leg and arm—is not expected unless there is a stroke involving the whole territory of the internal carotid artery.

Table 26.1; Cerebral lesions

Lesion	*Symptoms*	*Signs*
.Motor cortex	Weakness and poor control of the affected extremity, which may involve face, arm, and leg to different degrees	Incoordination and weakness that depends on the location of the lesion within the cortical homunculus; often associated with neglect, apraxia, aphasia, or other signs of cortical dysfunction
Internal capsule	Weakness rhar usually affects the face, arm, and leg almost equally	Often associated with sensory impairment in same distribution
Basal ganglia	Weakness and incoordination on the contralateral side	Weakness, often without sensory loss; no neglect or aphasia
Thalamus	Sensory loss	Sensory loss with tittle or no weakness

Infarction. Cortical infarctions are more likely to be associated with sensory abnormalities than subcortical infarctions. Also, cortical infarctions are associated with a so-called *cortical sign*—neglect with non-dominant hemisphere lesions and aphasia with dominant hemisphere lesions. Unfortunately, this distinction is not absolute, because rarely subcortical lesions can produce these signs.

Diagnosis of infarction is usually made on clinical grounds, especially early in the course. The abrupt onset of the deficit is typical. Weakness that progresses over several days is unlikely to be caused by infarction, although some infarcts can show worsening for a few days after onset. Progression over days suggests demyelinating disease. Progression over weeks suggests a mass lesion, such as a tumor or an abscess. Progression over seconds to minutes in a marching fashion suggests cither epilepsy (which usually produces convulsions and not weakness) or migraine; remember that not all migraine-associated deficits are associated with subsequent headache.

Computed tomography (CT) scans often do not show infarction for up to 3 days after the event, and magnetic resonance imaging (MRI) is not available on an urgent basis in most hospitals. Confirmation of the ischemia can be made by MRI or follow-up CT scan 2-3 days after the onset of symptoms. Infarcts show particularly well on flair images of the MRI. Recent infarction can be distinguished from remore infarction on diffusion-weighted imaging.

Middle Cerebral Artery. The middle cerebral artery (MCA) supplies rhe lateral aspect of the motor sensory cortex, which controls the face and arm. In addition, on the

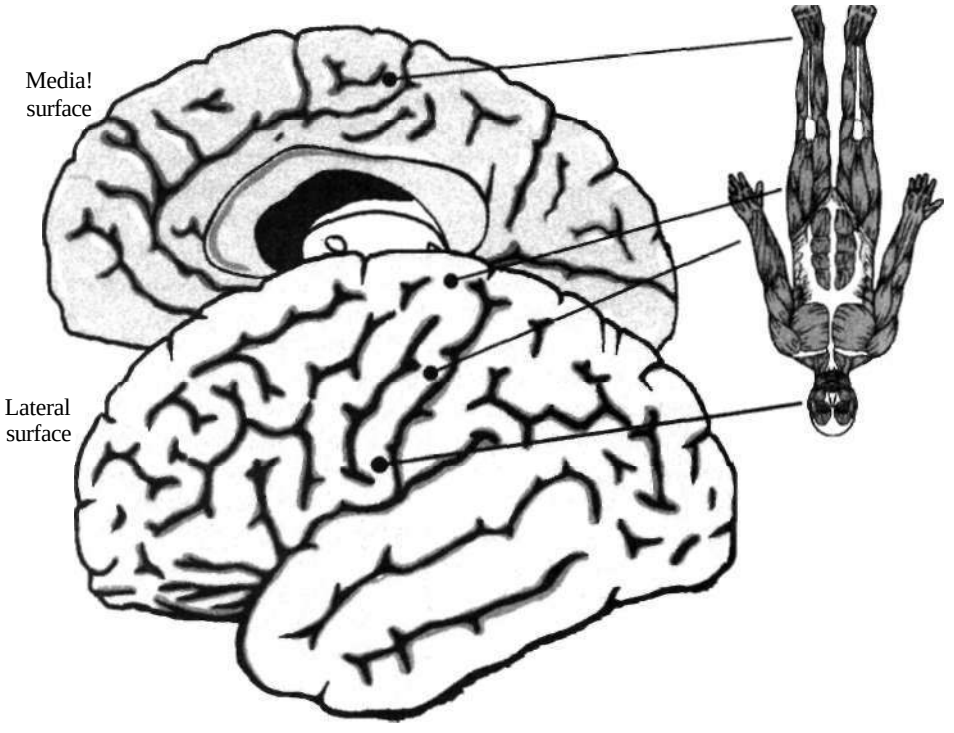

FIGURE 26.1 Representation of the body on the motor cortex. The face and arms are represented laterally, and the legs are represented medially, with the distal legs of the cortex bordering on the central sulcus.

dominant side, speech centers are also supplied—Broca's area in the posterior frontal region and Wernicke's area on the superior aspect of the temporal lobe.

Cortical infarction in the territory of the MCA produces contralateral hemiparesis, usually associated with other signs of cortical dysfunction such as aphasia with left hemisphere lesions, or neglect with right hemisphere lesions. The arm, hand, and face are affected much more than the leg. Diagnosis is suspected with hemiparesis, which affects predominantly the face and arm. Aphasia or neglect is confirmatory of the cortical localization.

Anterior Cerebral Artery. The anterior cerebral artery (ACA) supplies the inferior frontal and parasagittal regions of the frontal and anterior parietal lobes. This region is responsible for leg movement and is important for bowel and bladder control. Infarction in the ACA distribution produces contralateral leg weakness. The arm may be slightly affected, especially the proximal arm, with sparing of hand and face. Diagnosis is suspected when a patient presents with leg weakness and CST signs. The leg weakness can be bilateral if both ACAs arise from the same trunk; this situation can he mistaken for myelopathy.

Posterior Cerebral Artery, The posterior cerebral arteries (PCAs) are the terminal branches of the basilar artery. They supply most of the occipital regions and the medial temporal regions. PCA infarction is not expected to produce weakness but produces contralateral hemianopia, often with memory deficits. Diagnosis may be missed, because the examiner may not look for hemianopia in a patient who otherwise may present only with confusion. The visual complaints may be vague or nonexistent.

Subcortical Lesions

Subcortical lesions are more likely to produce equal weakness of the face, arm, and leg on the contralateral side, because the descending axons that project to the brainstem and spinal cord converge into a small volume in the internal capsule to ultimately form the CST, Lesions of sudden onset are most likely to be stroke, usually lacunar infarction, but hemorrhage can occur. Demyelinating disease has a subacute onset. Tumors have a slower onset and can get quite large in subcortical regions before reaching medical attention.

Infarction, Infarction is usually a clinical diagnosis but can be confirmed by CT or MRI scans, as discussed (see Cortical Lesions, Infarction, earlier in this chapter).

Lenticulostriate Arteries. These small penetrating arteries arise from the proximal MCA and supply the basal ganglia and internal capsule. Infarction commonly produces contralateral hemiparesis with little or no sensory involvement ("pure motor hemiplegia," which can also be due to a brainstem lacuna).

Thaiamoperforate Arteries. These small penetrating arteries arise from the PCAs and supply mainly the thalamus. Infarction in this distribution produces contralateral sensory disturbance but can also cause movement disorders such as chorcoathetosis or hemiballismus; hemi paresis is not expected.

Demyelinating Disease. Demyelinating disease is a group of conditions whose pathophysiology implicates the immune system. Diagnosis is based on clinical grounds for most patients but is suggested by finding areas of increased signal intensity on T2-weighted images of the MRI. Active demyelinating lesions often show enhancement on Tl-weighted gadolinium-enhanced images. Cerebrospinal fluid (CSF) examination is usually performed and can be normal or show elevated protein, a mild lymphocytic pleocytosis, and/or oligoclonal bands of immunoglobulin G (IgG) in the CSF.

Multiple Sclerosis. Multiple sclerosis (MS) presents with any combination of white matter dysfunction, Hemiparesis can develop especially if there are large plaques affecting the CST fibers in the hemispheres. However, hemiparesis is even more likely with brainstem or spinal demyelinating lesions, because smaller lesions can produce more profound deficits in these areas.

The diagnosis is suspected by the progression over days and a history of episodes of relapsing and remitting neurological deficits. Episodes of weakness that last for only minutes are likely not to be due to demyelinating disease, but to be vascular or a migraine equivalent.

Parainfectious Encephalomyelitis, Parainfectious encephalomyelitis (acute disseminated encephalomyelitis) is a demyelinating illness that is monophasic but in other respects presents like a first attack of MS. Symptoms and signs at all levels of the central nervous system (CNS) are common, including hemiparesis, paraplegia, ataxia, and brainstem signs.

Diagnosis is based on clinical grounds because MRI scans cannot distinguish between MS and parainfectious encephalomyelitis. CSF may show a mononuclear pleocytosis and elevation in protein, but these findings arc neither always present nor specific. Even the presence or absence of oligoclonal IgG in the CSF cannot differentiate between this and MS, When a patient presents clinically with this, the patient should be warned of the possibility of recurrent events.

Progressive Multifocal Leukocnccphalopathy. Progressive multifocal leukocnccphalopathy (PML) is a demyelinating disease caused by reactivation of the JC virus, especially seen in immunodeficiency. Patients with acquired immunodeficiency syndrome, leukemia, lymphoma, tuberculosis, and sarcoidosis are predisposed to develop PML.

Visual loss is the most common symptom and weakness is the second most common. MRI scan shows multiple

white matter lesions. CSF is either normal or shows a lymphocytic pleocytosis and/or elevated protein. Brain biopsy is required for specific diagnosis.

Migraine. Migraine is often associated with an aura of visual symptoms (classic migraine), but motor and sensory symptoms can also develop (complicated or hcmiplegic migraine). Sensory symptoms may include loss of sensation or paresthesias. Motor symptoms can include hemiparesis. The deficit progresses across the extremities in a manner that looks like the spreading of cortical localization. Headache does not always follow the neurological deficit, making the diagnosis even more difficult.

Diagnosis is suspected when the patient is young, has few risk factors, and the deficit marches in a manner that can be visualized as a migration of spreading electrical depression across the cerebral cortex. Imaging is often necessary to rule out hemorrhage, infarction, and demyelinating disease.

Tumors. Tumors affecting the cerebral hemispheres commonly present with progressive deficits including hemiparesis. Cortical dysfunction is also commonly present, such as aphasia with dominant hemisphere lesions. Other signs of expanding tumors may include headache, seizures, confusion, and visual field defects. The hemiparesis often is manifest as a disorder of coordination developing before the weakness.

Diagnosis is suspected in a patient with progressive motor deficit over weeks, especially if there are coexistent seizures and/or headache. MRI with contrast enhancement is more sensitive for identification of tumors than CT

Alternating Hemiplegia of Childhood. Alternating hemiplegia of childhood is characterized by attacks of unilateral weakness, often with signs of other motor deficits (e.g., dyskinesias or stiffness) and oculomotor abnormalities (e.g., nystagmus). Attacks begin in young childhood, usually before age 18 months; they last hours, and deficits accumulate. Initially, patients are normal, but with time, neurological deficits, including motor deficits and cognitive decline, become obvious. Diagnostic studies show no abnormalities, including MRI, electroencephalography, and angiography.

Hemiconvulsion-Hemiplegia Syndrome. Young children with this rare condition develop unilateral weakness after the sudden onset of focal seizures. The seizures are often incompletely controlled. Neurological deficits ate not confined to the motor system and may include cognitive, language, and visual deficits. Unlike alternating hemiplegia, the seizures and motor deficits are consistently unilateral, although eventually the unilateral seizures may become generalized. Imaging may be normal initially but eventually shows atrophy of the affected hemisphere. CSF analysis is not specific, but a mild mononuclear pleocytosis may develop because of the CNS damage and seizures.

Brainstem Lesions

Brainstem lesions producing hemiplegia are among the easiest to localize, because associated signs of brainstem dysfunction are almost always present.

Brainstem Motor Organization

Figure 26.2 shows the anatomical organization of the motor systems of the brainstem. Discussion of the complex anatomical organization of the brainstem can be simplified by concentrating on some important functions:

- Appendicular motor and sensory function
- Facial motor and sensory function
- Appendicular coordination
- Ocular motor function
- Descending sympathetic tracts

Motor pathways descend to the pyramidal decussation in the medulla, when they cross to innervate the

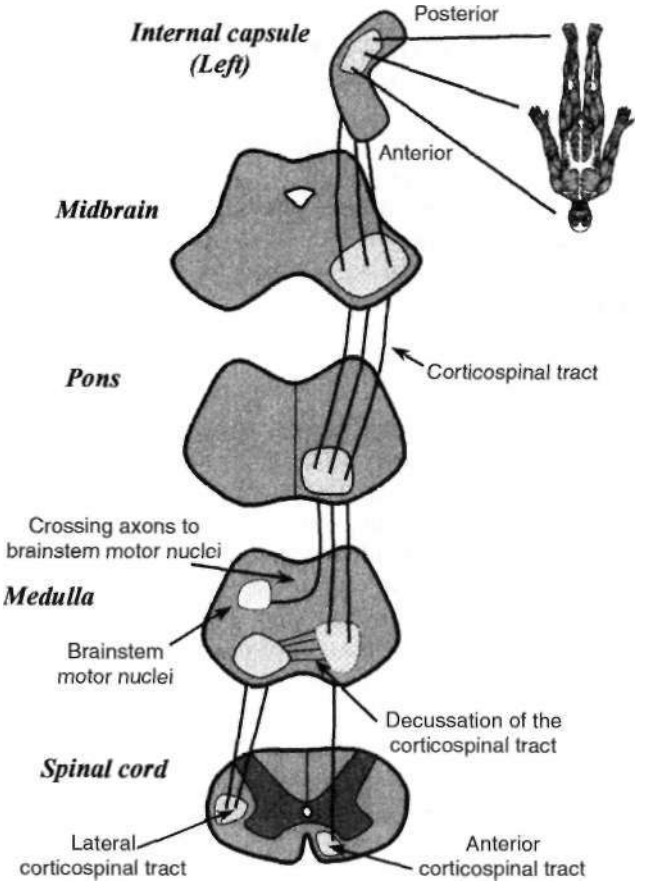

FIGURE 26.2 Brainstem motor organization, beginning with the internal capsule. The corticospinal tract remains topographically organized throughout the brainstem and spinal cord, although isolated lesions below the cerebral cortex are unlikely to produce topographically specific damage.

contralateral body. Lesions of the pons and midbrain above this level produce contralateral hemiparesis, which may involve the contralateral face. Rostral lesions of the medulla produce contralateral weakness, whereas more caudal medullary lesions produce ipsilateral cranial nerve signs with a contralateral hemiparesis and sensory deficit.

Sensory pathways from the nucleus gracilis and nucleus cuneatus cross at about the same level as the motor fibers of the CST, so deficits m light touch and position sense tend to parallel the distribution of the motor deficit. In contrast, the spinothalamic tracts have already crossed in the spinal cord and ascend laterally in the brainstem. Therefore lesions of the lower medulla may produce contralateral loss of pain and temperature sensation and ipsilateral loss of touch and position sense. Lesions above the mid medulla produce a contralateral sensory defect of all modalities indistinguishable from cerebral lesions, yet the clues to brainstem localization can include the following:

- Ipsilateral facial sensory deficit from a trigeminal lesion
- Ipsilateral hemiataxia from damage to the cerebellar hemispheres or nuclei
- Ocular motor weakness, resulting in diplopia
- Ipsilateral Horner's syndrome from damage of the descending sympathetic tracts

Common Lesions

Table 26.2 shows some of the important lesions of the brainstem and their associated motor deficits. Brainstem lesions are usually due to damage to the penetrating branches of the basilar artery. Patients present with contralateral weakness along with other findings that help localize the lesion. Hemiataxia often develops and can be mistaken for hemiparesis, so careful examination is essential; the implications for localization of the differentiation of hemiataxia and hemiparesis are tremendous. Demyelinating disease and tumors are the other most common causes of brainstem dysfunction.

Spinal Lesions

Spinal lesions can produce hemiplegia sparing the face, although they mostly will cause bilateral findings typical of myelopathy. Diagnosis of a spinal cord lesion is suspected in a patient if there is bilateral weakness, bowel- and/or bladder-control deficits, or back pain.

Spinal Hemisection (Brown-Sequard's) Syndrome

Spinal hemisection is seldom seen in clinical practice. However, components of the syndrome are occasionally identified. This is usually seen in intradural tumors, trauma,

Tabic 26.2: brainstem lesions

Named disorder	*Location*	*Signs*
Midbrain		
Weber's syndrome	Cranial nerve III, ventral midbrain, corticospinal tract	Contralateral hemiparesis, third nerve palsy
Benedikr's syndrome	Cranial nerve HI, ventral midbrain, corticospinal tract, red nucleus	Contralateral hemiparesis, third nerve palsy, intention tremor, cerebellar ataxia
Top-of-the-basilar syndrome	Occipital lobes, midhrain oculomotor nuclei, cerebral peduncle, medial temporal lobe, thalamus	Contralateral hemiparesis, cortical blindness, oculomotor deficits, memory difficulty, contralateral sensory deficit
Pons		
Millard-Gubler syndrome	Cranial nerve VI, cranial nerve VII, ventral pons	Contralateral hemiparesis, sixth nerve and seventh nerve palsies
Clumsy-hand syndrome	Corticospinal tract, facial nerve	Contralateral hemiparesis; dysarthria, often with facial weakness
Pure motor hemiparesis with lesion in the pons	Ventral pons	Contralateral hemiparesis with corticospinal tract signs
Ataxic hemiparesis with lesion in the pons	Corticospinal and cerebellar tracts	Contra lateral hemiparesis with impaired coordination
Fovilie's syndrome	Cranial nerve VII, vcnrral pons, paramedian pontine reticular formation	Contralateral hemiparesis, seventh-nerve palsy, gaze palsy to side of lesion
Medulla		
Media! medullary syndrome	Corticospinal tract, medial lemniscus, hypoglossal nerve	Contralateral hemiparesis, loss of position and vibratory sensation, ipsilateral tongue paresis

and inflammatory conditions. Spondylitic myelopathy, disc-disease, and most extradural tumors usually produce symmetrical findings.

Patients with the spinal hcmisection syndrome present with weakness ipsilateral to and below the lesion. In addition, segmental motor loss may be seen wirh involvement of the motoneurons at the level of the lesion. Sensory findings include loss of pain and temperature contralateral to and below the lesion. Position sense may be affected ipsilateral to the lesion.

Transverse Myelitis

Transverse myelitis is an acute myelopathic process that is presumed to be autoimmune in origin. Patients present with motor and sensory deficits below the lesion. Findings are typically bilateral yet may be asymmetrical.

Spinal Cord Compression

Spinal cord compression is usually due to disc protrusion or spondylosis. Neoplastic and infectious causes should always be considered. Disc disease and spondylosis are typically in the midline, so unilateral findings are not expected. Extradural tumors are less likely than intradural tumors to produce unilateral symptoms. Lastly, lesions below the cervical spinal cord would not produce hemiplegia, hut monoplegia of the lower limb or paraplegia.

Spondylosis with cord compression produces lower motor neuron (LMN) weakness at the level of the lesion and CST signs below the level of the lesion. Spinal cord compression resulting in paralysis should be evaluated as quickly as possible with MRI if available. Myelography should be considered if MRI is not urgently available.

Spinal Cord Infarction

Anterior spinal artery infarction usually causes paraparesis and spinothalamic sensory loss below the level of the lesion. Rarely, one segmental branch of the anterior spinal artery can be involved with unilateral spinal cord damage and monoparesis or hemiparesis.

Peripheral Lesions

Peripheral lesions are not expected to produce hemiplegia. However, a pair of peripheral lesions affecting both the arm and the leg oil the same side may occasionally masquerade as hemiplegia. Differentiation depends on identification of the individual lesions as being within the distribution of one nerve, nerve root, or plexus. The tendon reflexes are likely to be depressed in patients with CST lesions. Amyotrophic lateral sclerosis can produce weakness of one limb, followed by weakness of the other limb on the same side, with progression over months or even years. Usually the combined presence of upper motor neuron (UMN) and LMN involvement, without sensory changes, assists in making the diagnosis. If the predominant involvement is UMN in type, the picture can look like a progressive hemiparesis.

Conditions that predispose to separate lesions affecting one arm and leg are disorders producing mononeuropathy multiplex. Diabetes is the most common cause, hut other causes include leprosy, vasculitis, and predisposition to pressure palsies. Diagnosis is by electromyography (EMG), which can differentiate mononeuropathy from polyneuropathy. Radiculopathy would not give hemiparesis but is in the differential diagnosis of monoplegia (see Radiculopathies, later in this chapter).

Functional Hemiplegia

Functional or psychogenic weakness includes both conversion reaction and malingering. In conversion reaction, the patient is not conscious of the nonorganic nature of the deficit, whereas in malingering the patient is making a conscious effort to fool the examiner. In both circumstances, there is some secondary gain for the patient, whether psychological or economic. In malingering, the secondary gain is usually more obvious and includes disability payments, litigation, family attention, and avoidance of stressors or tasks.

Clues to functional weakness include the following:

- Improvement in strength with coaching
- Give-way weakness
- Inconsistencies in examination, for example, inability to extend the foot but able to walk on toes
- Hoover's sign: The patient lies supine on the bed and lifts one leg at a time. If the leg is truly paralyzed, the examiner should feel effort to press down with the opposite heel. Failure to do so is a positive Hoover's sign.
- Paralysis in the absence of other signs of motor system dysfunction, including tone and reflex changes

Diagnosis of functional weakness is based on consistencies on examination and elimination of the possibility of organic disease. Functional weakness should be diagnosed with caution. It is easy to dismiss the patient's complaints after an inconsistent feature is seen, especially if some secondary gain is obvious. Unfortunately, the diagnosis of functional weakness is difficult, because a patient with organic problems may have a functional overlay, which may exaggerate an otherwise subtle clinical finding. For example, weakness and incoordination of the hand may seem subtle on examination and may be missed completely if the patient gives incomplete effort with the extremity.

Some diagnostic testing is often required to rule out neurological disease, although this should be kept to a minimum. Prescription of multiple tests and treatments may serve to reinforce the presumed presence of illness, and thereby augment illness behavior. Psychological evaluation and treatment can be key.

MONOPLEGIA

Cerebral Lesions

Cerebral lesions more commonly produce hemiplegia than monoplegia, but isolated limb involvement can occasionally occur, especially with cortical involvement. The arm segment of the motor sensory cortex lies on the lateral part of the hemisphere, adjacent to the sylvian fissure.

Subcortical infarction is less likely to produce monoplegia than cortical lesions because of the dense packing of the fibers of the CST in the internal capsule. The internal capsule is generally organized with the arm segments represented anteriorly in the capsule relative to the leg sections. Infarction in the distribution of the lenticulostriate arteries, however, usually affects both divisions.

Infarction

The arm region of the cerebral motor cortex is supplied by the MCA. Infarction of a branch of the MCA can produce isolated arm weakness, although facial involvement and cortical signs are expected—language deficit with left hemisphere lesions and neglect with right hemisphere lesions. With more extensive lesions, visual fields can be abnormal because of infarction of the optic radiations. Mild leg weakness can also occur. The leg segment lies in the parasagittal region and is supplied by the ACA. ACA infarction produces weakness of the contralateral leg,

Migraine

Migraine can produce sensation that marches along one limb, usually the arm. The progression through the limb differs from the abrupt onset of stroke. Involvement of only the leg is unusual. The headache phase typically begins as the neurological deficit is resolving. Weakness can develop as part of the migraine aura, but this is much less likely than sensory disturbance.

Seizure and Transient Ischemic Attacks

Seizure can rarely produce negative motor symptoms rather than positive symptoms. Episodic paralysis can seem like a transient ischemic attack (TIA), and evaluation for vascular disease is often indicated. Focal seizure activity may be suggested by subtle twitching or disturbance of consciousness associated with the episodes. Seizures are usually more frequent and have a shorter duration than TIAs.

Multiple Sclerosis

MS can produce monoplegia through a discrete white matter plaque, but hemiparesis is more common.

Tumors

Tumors deep to the cortex rarely produce monoplegia because the involvement is not sufficiently discrete to affect only one limb. Cortical involvement makes single limb involvement more likely. Parasagittal lesions often produce leg involvement, which can be initially unilateral. Meningiomas often arise from one side of the falx, so they predominantly affect one leg. The presentation is of CST findings referable to only one leg. The single leg weakness could be mistaken for a thoracic spinal lesion, although paraparesis is more common in such a situation.

Metastatic tumors are often found at the gray-white junction and as such are in position to produce focal cortical damage. Early on, the lesion may be too small to produce definite neurological symptoms, but with increasing growth, the lesion is more likely to produce focal seizures or loss of function.

Brainstem Lesions

Brainsrem lesions seldom produce monoplegia because of the tight packing of the fibers of the CSTs in the brainstem. Unilateral cerebellar hemisphere lesions may produce appendicular ataxia, which is most obvious in the arm, although this should be distinguished from monoparesis by the absence of weakness and the presence of ataxia.

Spinal Lesions

Spinal lesions can produce weakness from segmental damage to nerve roots, or CSTs. CST signs below the level of the lesion are expected. Weakness in one leg can develop from damage ro the spinal nerve roots, and in this case, the weakness is associated with muscle wasting and lost reflexes in a radicular distribution.

Peripheral Lesions

Peripheral lesions usually produce monoparctic weakness in the distribution of a single nerve, nerve root, or plexus. A few conditions, such as amyotrophic lateral sclerosis and focal spinal muscular atrophy, may produce weakness in a monomelic (monopk'j;ic) distribution.

Pressure Palsies

Intermittent compression of a peripheral nerve can produce transient paresis of part of a limb. The patient may think the entire limb is paralyzed, but detailed examination shows that the paresis is limited. The weakness usually improves so quickly that examination is often not possible before the improvement. Predisposition to pressure palsies can be seen in two main circumstances: on a hereditary basis and in the presence of peripheral polyneuropathy.

Hereditary Neuropathy Ptcd is position to Pressure Palsies. Hereditary neuropathy with predisposition to pressure palsies is associated with episodic weakness and sensory loss associated with compression of isolated nerves. Nerve conduction studies may show distal slowing of conduction velocities.

Pressure Palsies in Polyneuropathy. Patients with polyneuropathy may have an increased susceptibility to pressure palsies. Areas of demyelination are more likely to have a depolarizing block produced by even mild pressure,

Mononeuropathies

Table 26.3 shows some important peripheral nerve lesions of the arm. Table 26.4 shows some important peripheral nerve lesions of the leg.

Median Nerve

Carpal Tunnel Syndrome. Carpal tunnel syndrome is the most common mononeuropathy. The median nerve is compressed as it passes under the flexor retinaculum at the wrist. Patients present with numbness on the palmar aspects of the first through third digits. Fotccd flexion or extension of the wtist commonly exacerbates the sensory symptoms. Weakness of the abductor poilicis brevis may develop in advanced cases.

This condition would not normally be considered in the differential diagnosis of monoparesis, but because the patient can complain of weakness that is more extensive than the actual deficit, it is considered here. Nerve conduction studies show slow motor and sensory velocities through the carpal tunnel. KMG shows denervation in the abductor poilicis brevis muscle with severe disease.

Table 26.3: Peripheral nerve lesions of the arm

Lesion	*Clinical findings*	*EM.G findings*
Median neuropathy		
Carpal runnel syndrome	Abductor poilicis brevis wasting and weakness when severe. Sensory loss on palmar aspect of the first through third dibits	Slow motor and sensory NCV through carpal tunnel; abductor poilicis brevis denervation if severe
Anterior interosseous syndrome	Weakness of flexor digitorum profundus, pronator titiadratus, flexor poilicis longus	Denervation in flexor digitorum profundus, flexor poilicis longus, pronator quadratus
Pronator teres syndrome	Weakness of distal median-innervated muscles; tenderness of pronator teres	Slow median motor NCV through proximal forearm; denervation of distal median-innervated muscles
Compression at the ligament of Strurhers	Weakness of distal median-innervated muscles	As for pronator teres syndrome, with the addition of denervation of pronator teres
Ulnar neuropathy		
Palmar branch damage	Weakness of dorsal interossei; no sensory loss	Normal ulnar NCV; denervation of first dorsal intcrosseus but not abductor digiti minimi
Entrapment at Guyon's canal	Weakness of ulnar intrinsic muscles; numbness over fourth and fifth digits	Slow ulnar motor and sensory NCV through wrist
Entrapment at or near the elbow	Weakness of ulnar intrinsic muscles; numbness over fourth and fifth digits	Slow ulnar motor NCV across elbow, denervation in abductor digiti minimi and ulnar half of flexor digitorum profundus
Radial neuropathy		
Posterior interosseous syndrome	Weakness of ringer and wrist extensors; no sensory loss	Denervation in wrist and finger extensors; supinator and extensor carpi radialis spared
Compression at the spiral groove	Weakness of finger and wrist extensors; triceps spared; sensory loss on dorsal aspect of first digit	Slow radial motor NCV across spiral groove; denervation in distal radial-innervated muscles; triceps may be affected with proximal lesions

NCY = nerve conduction velocity.

Table 26.4: Peripheral nerve lesions of the leg

Lesion	*Clinical findings*	EMG *findings*
Sciatic neuropathy	Weakness of tibial- and peroneal-innervated muscles with sensory loss on posterior leg and foot	Denervation distally in tibial- and peroneal-innervated muscles; contralateral muscles normal
Peroneal neuropathy	Weakness of foot extension and eversion and of toe extension	Denervation in peroneal-innervated muscles; conduction across fibular neck may be slowed
Tibial neuropathy	Weakness of foot plantar flexion	Denervation in gastrocnemius and soieus
Femoral neuropathy	Weakness of knee extension; weakness of hip flexion if psoas involved	Denervation in quadriceps, and sometimes psoas

Anterior Interossetts Syndrome. The anterior interosseous nerve is a branch of the median nerve in the forearm that supplies some of the forearm muscles. Damage can occur distal to the elbow, producing a syndrome that is essentially purely motor. Weakness of finger flexion is prominent. Affected muscles include the flexor digitorum profundus to the second and third digits (the portion to the fourth and fifth digits is innervated by the ulnar nerve). The distal median nerve entering the hand is unaffected, because the anterior interosseous nerve arises from the main trunk of the median nerve.

Diagnosis is suspected by weakness of the median-jj-mervared finger flexors with sparing of the abductor pollicis brevis and ulnar-innervated flexors. EMG can confirm the diagnosis, but because this entrapment is not commonly looked for by many electromyographers, study of the appropriate muscles must be specifically requested.

Pronator Teres Syndrome. The median nerve distal to the elbow can be damaged as it passes through the pronator teres muscle. All median-innetvated muscles of the arm are affected except for the pronator teres itself. The clinical picture looks like an anterior interosseous syndrome plus distal median neuropathy. The pronator teres may be tender, and palpation may exacerbate some of the distal pain.

Ulnar Nerve. Ulnar entrapment is most common near the elbow and at the wrist, Entrapment at the elbow produces weakness of the ulnar-innervated intrinsic muscles. Weakness of long flexors of the fourth and fifth digits also can develop. When the entrapment is at the wrist, the weakness is isolated to the intrinsic muscles of the hand, and more proximal muscles are unaffected. Although most of the intrinsic muscles of the hand are ulnar innervated, a few arc median innervated and arc unaffected in ulnar neuropathy.

Diagnosis of ulnar neuropathy is suspected when a patient complains of pain or numbness on the ulnar aspect of the hand. The diagnosis is reinforced when the patient has weakness and wasting of the intrinsic muscles of the hand, which is especially easy to see in the first dorsal interosseous.

Radial Nerve Palsy. Radial neuropathy is most commonly seen above the elbow, such that wrist and finger extensors are mainly affected. The triceps can also be affected. This is most commonly a pressure palsy seen in alcoholic intoxication. Peripheral neuropathy makes the development of pressure neuropathy of the radial nerve more likely.

Femoral Neuropathy. Femoral neuropathy can occur from compression by intra-abdominal contents (fetus or neoplasm), but we have also seen it from damage around the time of angiography or surgery. Patients present with pain in the thigh and weakness of knee extension. The complaint is usually not so specific but is of the leg "giving out" during walking or of the patient being unable to get out of a chair without using the arms. Examination may show quadriceps weakness, but this muscle group is so strong that the examiner may not be able to detect the weakness. Lower leg muscles must be examined to ensure that muscles in the sciatic distribution arc normal.

Diagnosis is confirmed by EMG, showing denervation confined to the femoral nerve distribution. Unfortunately, electrical signs of denervation may not be obvious for up to 4 weeks after the injury.

Sciatic Neuropathy. Sciatic neuropathy can have multiple causes, including acute trauma and chronic compressive lesions. The term *sciatica* describes pain in the distribution of the sciatic nerve in the back of the leg. It is usually due to radiculopathy (see Radiculopathies, later in this chapter). An intramuscular injection into the sciatic nerve rather than the gluteus is an occasional cause of sciatic neuropathy and is characterized by initial severe pain followed by a lesser degree of pain and weakness. Pyriformis syndrome is an uncommon condition in which the sciatic nerve is compressed by the pyriformis muscle. This is a difficult diagnosis to make, requiring demonstration of increased pain on tensing the pyriformis muscle by flexing and adducting the hip.

Diagnosis of sciatic neuropathy is considered when a patient presents with pain and/or weakness of the lower leg muscles. EMG can confirm the distribution of denervation. Nerve conduction studies are usually normal. MRI of the lumbosacral plexus is occasionally needed to look for

tumors and other causes of sciatic nerve or plexus compression.

Peroneal Neuropathy. Peroneal neuropathy can develop from a lesion at the fibular neck, the popliteal fossa, or even ihi[1] sciatic nerve in the thigh. The peroneal division of rhe sciatic nerve is more susceptible to injury than the tibial division, so incomplete sciatic injury affects predominantly the peroneal innervated muscles.

The peroneal nerve innervates the tibialis anterior, extensor digitorum brcvis, and pcronei muscles. In addition, the peroneal division innervates the short head of the biceps femoris in the distal posterior thigh. This is an important muscle to remember, because distal peroneal neuropathy spares this muscle, whereas a proximal sciatic neuropathy, a peroneal division lesion, or a radiculopathy is expected to cause denervation not only in the tibialis anterior but also the short head of the biceps femoris.

Radiculopathies

Radiculopathy produces weakness of one portion of a limb. Common radiculopathies are summarized in Table 26.5. Complete paralysis of all of the muscles of an arm or leg is not caused by radiculopathy, other than traumatic avulsion of the nerve roots, which may occur in the upper limbs with distraction injuries of the arm from the neck. Roots serving arm power include chiefly C5 to T1. Roots serving leg power are chiefly L2 to SI. A lesion at the L5 level often elicits a complaint of the entire limb being weak because of the footdrop, which interferes with gait.

Reflex abnormalities are often present early in a radiculopathy and are a manifestation of the sensory component. Motor deficits develop with increasingly severe radiculopathy.

Diagnosis of radiculopathy can be facilitated by EMG, which is an aid to localization and helps determine whether acute changes are developing. V1RI shows the structural cause of a definite radiculopathy in most patients, although the diagnostic yield in patients with back pain without clear radicular symptoms is far less (see Chapter 34). Myelography with post-myelographic CT scanning is still more sensitive for structural imaging, although it is not performed as a first-line investigation because of the invasive nature of the procedure.

Plexopathies

Brachial and Lumbar Plexitis (or Piexopathy). Brachial plexitis is an acute neuropathic syndrome of presumed autoimmune etiology. Patients present with shoulder and arm pain followed by weakness as the pain abates. Eventually the weakness improves, although this takes months and is occasionally incomplete. Brachial plexitis is somewhat more common than lumbar plexitis. The upper plexus, C5-C6, is most commonly affected, although the lower plexus can be involved. Lumbar plexitis has a similar clinical course to brachial plexitis.

Diagnosis of plexitis is considered when a patient presents with single limb pain and weakness, which docs not follow a single root or nerve distribution. MRI of the region is normal, unless there is neoplastic infiltration, Nerve conduction studies may be normal distally in the limbs, but F waves will be slowed or absent. EMG may be normal initially but eventually shows denervation in the distribution of the affected portion of the plexus.

Differentiation of plexitis from radiculopathy is made on the basis of not only the more extensive deficits in patients with plexitis, but also the time course of pain followed by weakness as the pain abates; this pattern is not expected in patients with radiculopathy.

Neoplastic Plexus Infiltration, The brachial and lumbar plexuses are in proximity to the areas that can be infiltrated by tumors, including those involving the lymph nodes, lungs, kidneys, and other abdominal organs. The first symptom of tumor infiltration is usually pain. Weakness and sensory loss are less common symptoms. Neoplastic plexus compression or infiltration presents as a progressive

Table 26,5: Radiculopathies

Level	*Motor findings*	*Sensory findings*
Cervical radiculopathy		
C5	Deltoid, biceps	Lateral upper arm
C6	Biceps, brachioradialis	Radial forearm and first and second digits
C7	Wrist extensors, triceps	Third and fourth digits
C8	Intrinsic hand muscles	Fifth digit and ulnar forearm
Lumbar radiculopathy		
L2	Psoas, quadriceps	Lateral and anterior upper thigh
L3	Psoas, quadriceps	Lower medial rhigh
L4	Tibialis anterior, quadriceps	Medial lower leg
L5	Peroneus longus, gluteus medius, tibialis anterior, extensor ballucis longus	Lateral lower kg
SI	Gastrocnemius, gluteus maximus	Lateral foot and fourth and fifth digits

painful monoparesis. Limb movements that stretch the plexus elicit pain, and the patient tends to hold the limb immobile to avoid exacerbating the pain.

Neoplastic infiltration of the brachial plexus usually involves the lower plexus, C8-T1. Lung cancer and lymphoma are the most common tumors to cause this, Horner's syndrome can develop with lower brachial plexus involvement. The main differential diagnosis is radiation plexopathy.

Diagnosis is suspected as a result of the severe pain and weakness. EMG often shows denervation that spans single nerve and root distributions. Detailed knowledge of the plexus anatomy is essential during examination and EMG. MRI usually shows the infiltration or compression of the plexus.

Radiation Plexopathy, Radiation therapy in the region of the plexus can produce progressive dysfunction. The upper brachial plexus is especially susceptible because of the lesser amount of surrounding tissues to attenuate the radiation. Symptoms are dysesthesias and weakness. The dysesthesias may be uncomfortable but are seldom described as painful. This is one key to differentiation from neoplastic plexus infiltration, which is typically quite painful.

Diagnosis is suspected in the clinical setting of progressive painless weakness in a patient with cancer who has received radiation to the region, MRI is essential to rule out tumor infiltration. EMG shows denervation, which is not a differentiating feature, but myokymia is more commonly seen in patients with radiation plexopathy than in those with neoplastic infiltration.

Plexus Hematomas. Hematomas can develop adjacent to and compress the brachial and lumbosacral plexuses producing motor and sensory findings. Brachial plexus hematomas are usually from bleeding disorders or instrumentation such as central line placement. Lumbosacral plexus hematomas can also develop from coagulopathies including anticoagulant treatment, and after procedures such as abdominal surgeries or after femoral arterial catheterization. In the latter circumstance, blood leaking from the puncture site can flow proximally, and a substantial amount of blood may be lost without a clinically obvious hematoma.

Hematomas interfere with the function of the peripheral nerves and plexus by blocking conduction. The prognosis is generally good as long as the plexus or nerve has not been directly injured, because the condition is usually neurapraxia rather than neurotmesis, and conduction is usually restored when the blood is resorbed. Large hematomas should be evacuated if severe plexopathic damage is present.

Plexus Trauma. A history of trauma makes the etiology of the plexopathy quite obvious. The main difficulty is differentiating plexopathy from radiculopathy (nerve root avulsion) or peripheral nerve damage. Also, spinal cord damage must be considered, because cord contusion and hemaromyelia may present with weakness that is more prominent in one extremity. Motor vehicle accidents, deliveries, and occupational injuries arc the most common causes of traumatic plexopathy. In many cases of plexus stretch, the mechanism is forced extension of the arm over the head or forced downward movement of the shoulder. Forced extension of the arm over the head damages the lower plexus, with the intrinsic muscles of the hand being especially affected *(Klumpke's palsy).* Forced depression of the shoulder produces damage to the upper plexus, giving prominent weakness of the deltoid, biceps, and other proximal muscles *(Erb's palsy).*

Diagnostic studies should include imaging not only of the plexus but also of the proximate spinal cord, looking for disc herniation, spondylosis, subluxation, or other anatomic deformity. Plain radiograph should always be performed. MRI and/or CT of the region is also helpful.

Trauma includes not only stretch injury, but also penetrating injury, such as knife and bullet wounds. Knife wounds are less likely to affect the lumbar plexus, but downward strike with a knife can easily affect the brachial plexus and nearby vessels. Gunshot wounds may directly affect the plexus, and the shock waves of high-velocity bullets may damage the plexus without direct involvement. Unfortunately, the speed and effectiveness of recovery from these types of injuries is poor.

Thoracic Outlet Syndromes, Thotacic outlet syndrome is an overdiagnosed condition characterized by weakness of muscles innervated by the lower trunk of the brachial plexus. The motor axons in the lower trunk supply both the median- and ulnar-innervated intrinsic muscles of the hand, Finger and wrist flexors may occasionally be affected, causing marked impairments in use of the hand, which is not restricted to a single nerve distribution. This must be differentiated from a cortical lesion. Sensory loss is mainly in an ulnar distribution because the sensory fibers of the median nerve ascend through the middle trunk rather than the lower trunk.

Diagnosis of thoracic outlet syndrome depends on demonstration of low-amplitude median and ulnar nerve compound motor action potentials and ulnar sensory nerve action potentials. Median sensory nerve action potentials are normal. Cervical ribs are usually asymptomatic, so their presence does not confirm the diagnosis of thoracic outlet syndrome. MRI of the plexus may be necessary to rule out infiltration by nearby tumor.

Diabetic Amyotrophy. *Diabetic amyotrophy* is the term given to the syndrome of damage to the proximal lumbar plexus, serving mainly the femoral nerve, seen in diabetics. Patients present with weakness and pain in a femoral nerve distribution. Although there may bq an additional

length-dependent diabetic peripheral neuropathy, the femoral distribution symptoms and signs overshadow the other findings. Patients eventually improve, although the recovery is often prolonged and incomplete.

It is difficult to study the nerve conduction of the femoral nerve. EMG usually shows denervation with chronic lesions, although up to 4 weeks may pass before electrical signs of denervation are seen.

Neuronnpathies

Neuronal degenerations usually affect multiple individual nerve distributions and more than one limb. However, a few focal motor neuropathies can produce single limb defects. Monomelic amyotrophy is a condition in which motoneurons of one limb degenerate; often the distribution suggests involvement of specific motoneuron columns in the spinal cord.

Monomelic Amyotrophy. Monomelic amyotrophy is a degenerative condition that affects only one limb, usually an arm. The opposite limb can be affected to a much lesser extent. There is no pain or sensory loss. Progressive weakness develops over months to years and may eventually produce weakness that plateaus.

Onset is usually in young adult life, about the age of 20 years, and men are predominantly affected. Diagnosis is confirmed by clinical presentation and EMG findings of active and chronic denervation without sensory abnormalities.

Poliomyelitis. Poliomyelitis is now uncommon but still occurs in some parts of the world. A poliomyelitis-like syndrome can result from viruses other than the poliovirus itself. The illness usually presents with acute asymmetrical weakness after an initial phase of encephalitic symptoms, including headache, meningeal signs, and possibly confusion or seizures. The paralysis may involve only one limb but is more commonly generalized. After recovery, only one limb may remain weak (monoparesis).

PITFALLS IN THE DIAGNOSIS OF HEMIPLEGIA AND MONOPLEGIA

Diagnosis of hemiplegia and monoplegia can always be a challenge, but some diagnoses can be especially difficult.

Weakness in Intrinsic Muscles of the Hand: Median, Ulnar, Plexus, or Small Cerebral Cortical Lesion?

Most of the intrinsic muscles of the hand arc innervated by the ulnar nerve, so an isolated distal ulnar lesion produces profound loss of use of the hand. This lesion must be differentiated from a lateral frontocentral cerebral lesion, which if located in the hand region produces prominent loss of independent digit use.

A median nerve lesion produces impaired hand function because of loss of function of the finger and wrist flexors more than of the intrinsic muscles of the hand. With stabilization of the hand, intact function of ulnar- and radial-innervated muscles can be demonstrated to rule out lesions at or above the plexus.

Lower brachial plexus lesions produce dysfunction of the median- and ulnar-innervated intrinsic muscles of the hand and may also affect the long finger flexors. This dramatic loss of function can be mistaken for central weakness, because the deficit spans peripheral nerve distributions. EMG usually documents the axonal damage.

A small cerebral cortical lesion can produce disuse of the hand without signs of other deficit. Reflexes should be exaggerated, although acutely they may not be. Cupping of the outstretched hand and pronator drift strongly suggests a central lesion. EMG cannot rule out a peripheral nerve lesion, because several weeks may be required before signs of axonal damage are evident on needle study. MRI of the brain is the most sensitive imaging study for a small cerebral lesion.

Radial Neuropathy or Small Cerebral Cortical Infarcts?

Radial neuropathy presents with weakness of the wrist extensors, which if severe can result in destabilization of the intrinsic muscles of the hand and long finger flexors, because opposition from the radial-innervated extensors is required for these median- and ulnar-innervated muscles to work well. Therefore the deficit seems more extensive than would be expected on the basis of a radial lesion alone. A cerebral lesion is suggested. Although cerebral lesions span neural distributions, wrist extension may be more obviously affected than grip and/or finger flexion.

Differential diagnosis of radial neuropathy from cerebral lesion depends on the examiner stabilizing the finger flexors and wrist to demonstrate intact median and ulnar nerve function. Also, CST signs and other signs of cortical damage (aphasia or neglect) should be looked for in a patient with a possible cerebral infarct.

Leg Weakness: Peroneal Nerve Palsy or Paramedian Cerebral Cortical Lesion?

Peroneal nerve palsy results in weakness of foot dorsiflcxion and eversion with relative preservation of other motor functions. Small lesions of the leg region of the homunculus on the medial aspect of cerebral hemispheres cause weakness that is most prominent in the same distribution as a peroneal nerve palsy. Differentiation is by absence of inverter weakness with peroneal palsy. EMG signs of

denervation do not develop with cerebral lesions. Cerebral causes of lower leg weakness also cause upgoing plantar response and hyperactivity of the Achilles tendon reflex, despite little clinical evidence of gastrocnemius muscle involvement.

Leg Weakness: Cauda Equina Lesion, Myelopathy, or Paramedian Cerebral Cortical Lesion?

This chapter discusses monoplegia rather than paraplegia (Chapter 27), but it is important to differentiate between lower spinal cord dysfunction and cauda equina compression; between upper spinal cord involvement and cervical spondylotic myelopathy; and between these problems and midline cerebral lesions producing leg weakness.

Cauda equina lesions are usually due to acute disc herniations, spondylosis, or tumors in the lumbosacral spinal canal. The lumbar and sacral nerve roots are compressed, resulting initially in a depolarizing block but later axonal degeneration, which produces motor and sensory loss. With the syndromes of intermittent claudication of the cauda equina, repetitive nerve action potentials result in severe pain that is relieved by rest only after a few minutes and that may be accompanied by neurological dysfunction. Pain, sensory loss, and weakness are typically worsened by standing and relieved by flexing the lumbar spun-.

Spondylotic myelopathy is compression of the spinal cord by degenerative spondylosis above the cauda equina. Compression of the CSTs produces weakness of the legs. Pain is usually near the level of the lesion, although the localizing value is not precise. Midline cerebral lesions produce unilateral or bilateral leg weakness, depending on the cause and exact location, with CST signs. Spine pain is not expected.

Differentiation between these three lesion locations (cauda equina, spinal cord, and cortical) can be tricky, but in general the following apply:

- Bowel and bladder incontinence can develop with all three locations but is more common with cauda equina lesions.
- Cauda equina lesions are associated with depressed reflexes, whereas spinal cord and cerebral lesions have hyperactive reflexes and upgoing plantar responses.
- Sensory loss is more prominent with cauda equina lesions than higher lesions.
- Pain in the spine is approximately at the level of the lesion, although the localization is not exact.

Chapter 27
Paraplegia and Spinal Cord Syndromes

Thomas N. Byrne and Stephen G. Waxman

The clinical presentations of spinal cord disease are diverse, The protean manifestations of spinal cord disease may mislead even the most astute clinician. Patients may present with vague numbness or weakness. Alternatively, their first complaint may be pain without neurological signs, which may he incorrectly attributed to musculoskeletal disease or visceral pathology. Because it is essential to evaluate and treat such patients with spinal cord compression expeditiously, a thorough understanding of the clinical manifestations of spinal cord diseases and those of the n on-neurological diseases that may mimic spinal disease is necessary. The purpose of this chapter is to provide an understanding of the clinical pathophysiology of the spinal cord and to demonstrate the methods of history taking and physical examination that are helpful in assessing the patient suspected of suffering from spinal cord disease.

The localization of spinal cord pathology is described by the following three coordinates. The first two are anatomical: (1) the level in the rostrocaudal axis and (2) the extent in the transverse plane of spinal cord involvement, These coordinates are determined by clinically assessing neurological functions served by both nerve roots and spinal cord tracts. The third coordinate is the time course of evolution of spinal cord dysfunction, which is often important in predicting the etiology, the physiological response of the cord to the disease, and the prognosis (Byrne, Benzel, and Waxman 2000),

SEGMENTAL INNERVATION

Ventral Root Dysfunction

Ventral root dysfunction is manifested by characteristic motor disturbances that are usually quite distinct from those arising from corticospinal tract disease or from plexus or peripheral nerve disease. Important aspects of the physical examination are the assessment of the distribution of abnormalities of muscle strength, tone, and bulk. The pattern of weakness is often the most important physical finding that distinguishes root disease from peripheral nerve disease.

Muscle strength or power may be determined by individual muscle testing or by functional assessment. Because each muscle usually is innervated by several nerve roots, complete lower motor neuron (LMN) paralysis of a muscle or muscle group typically signifies plexus or peripheral nerve disease, rather than a monoradiculopathy. The lattet usually produces partial weakness of a muscle. Despite this fact, with a monoradiculopathy, a single muscle often suffers greater dysfunction than others. Such muscles have been termed *segment-pointer* muscles. Table 27,1 lists a group of muscles that may point the examiner to a specific nerve root. This listing, however, should not be considered infallible, because some individuals have prefixed or postfixed plexuses (i.e., are one nerve root higher or lower than the usually described anatomical localization).

Table 27.1: S eg me nr-pointer muscles

Root	*Muscle*	*Primary function*
CA	Diaphragm	Respiration
CA	Diaphragm	Respiration
CS	Deltoid	Arm abduction
CA	Biceps	Forearm flexion
C6	Brachioradialis	Forearm flexion
C7	Triceps	Forearm extension
C8	Intrinsic hand muscles	Finger adduction/abduction
Tl	Intrinsic hand muscles	Finger adduction/abduction
LI	Iliopsoas	Hip flexion
L3	Quadriceps femoris	Knee extension
14	Quadriceps reiuoris	Knee extension
14	Tibialis anterior	Foot dorsiflexion
L5	Extensor hallucis longus	Great toe dorsiflexion
SI	Gastrocnemius	Plantar flexion

Source: Modified with permission from Schliack, H. 1969, "Segmental innervation and the clinical aspects of spinal nerve root syndromes," in *Handbook of Clinical Neurology,* vol. 2, eds P. J. Vinken, G. *8c* W. Rruyn, North! lolhuul Publishing, Amsterdam.

Denervation of a muscle causes muscular atrophy (neurogenic atrophy). Other common causes of muscular atrophy are disuse, endocrinological disturbance, and malnutrition. Neurogenic atrophy develops in cases of radiculopathy. With a monoradiculopathy, however, the atrophy is not as prominent as that occurring with peripheral nerve injury because most muscles receive innervation from several nerve roots. In cases of chronic radiculopathy, such as that caused by cervical spondylosis, atrophy may precede weakness. Alternatively, in cases of acute radiculopathy, for instance, caused by acute disc herniation, weakness may ptecedc atrophy.

Neurogenic atrophy may be associated with fasciculations, which represent spontaneous contraction of a group of muscle fibers innervated by a single motor neuron (a motor unit). Usually, they are seen as a twitching or rippling movement just beneath the skin. Exercise, cold, medications, and metabolic derangements often cause similar movements. Fasciculations are seen commonly in motor neuron disease but are widesptead in this case. In cases of compressive root lesions, fasciculations may be tcstricted to the myotomal distribution of the compressed root. These fasciculations are different from those seen in antctiot horn cell disease in that they occur tepetitively in the same fasciculus during minimal contraction and are usually absent during complete test. The syndtome of benign fasciculations is more diffuse and is not associated with weakness or atrophy.

Muscle tone is often a valuable sign in distinguishing the site of a lesion causing weakness. When measuring muscle tone, the clinician must ensure that the patient's muscles are relaxed, and it is often helpful to distract the patient's attention. In cases of radiculopathy, either muscle tone is not affected ot tone is decteased unless there is muscle spasm, as often occurs if there is severe pain. Alternatively, *spasticity* and *rigidity* refer to common fotms of incteased muscle tone caused by central nervous system disease. In spasticity, the increased rone is caused by an exaggeration of the sttetch reflex and accordingly is dependent on stretch rate. Thus if the muscle is slowly stretched, tone may be normal; however, if the muscle is stretched more rapidly, increasing amounts of resistance occur. Spasticity has been referred to as *rate sensitive* for this teason. The weakness of upper motor neuron (UMN) damage preferentially involves the deltoid, triceps and wrist extensors in the upper limbs, and the iliopsoas, hamsttings, and tibialis anterior muscles in the lower extremities, whether caused by cortical or corticospinal tract disease. Spasticity usually results from dysfunction of the descending spinal tracts, including but not limited to the corticospinal ttact (Ditunno and Formal 1994).

Rigidity refers to increased muscle tone, which does not depend on the fate of movement. Unlike spasticity, it is found equally in both extensors and flexors. Rigidity is commonly caused by extrapyramidal disease or is a side effect of antidopamincrgic drugs (e.g., halopcridol).

Dorsal Root Dysfunction

Disturbance of dorsal root function most commonly produces pain and to a lesser extent sensory impairment. The pain may be local or projected elsewhere in a tadiculat or nonradicular distribution (referred pain).

Local Pain

Local or regional back or neck pain is usually secondary to irritation or damage of innervated structures of the spine. The periosteum, ligaments, dura, and apophyseal joints are innervated structures. The clinical characteristics of local pain are that it is appreciated in the local tcgion of the spine

and that it is deep, aching, and exacerbated by activity that places an increased load on the diseased structures. Patients suffering from pain caused by an epidural tumor often report that their pain is made worse by the supine position, wiu-RMs those sntiering from spondylosis and musculoligamentous strain generally favor bed rest. Palpation or percussion of the spinal column may exacerbate the local pain regardless of the cause. Irritation of local innervated structures also causes secondary muscle spasm and local or somewhat diffuse pain.

Projected Pain

Projected pain is pain that arises from one anatomical site but is projected to a site some distance from the location of the pathology. When the spine is the source, the projected pain may be either radicular or nonradicular. Projected pain that arises from irritation of posterior nerve roots is of a radicular type, whereas that caused by irritation of other spinal structures is usually of a nonradicular type, herein termed *referred pain.* Although these forms of pain are not always easy to differentiate, it is important to distinguish between them because radicular pain has strong localizing value and nonradicular pain does not.

Referred Pain. The pain in normal volunteers after injection of 6% saline into the facet joints of L1-L2 and L4-L5 is cramping and aching in quality. As shown in Figure 27.1, there is overlap in the regions of pain referral from upper and lower lumbar injections, with most of the pain being referred to the flanks, buttocks, groins, and thighs. It is of clinical interest that referred pain in normal volunteers does not project below the knee despite rhe fact that the L4-L5 level is stimulated, whereas it can radiate below the knee in symptomatic individuals. It appears that unlike tadicular pain, referred pain does not follow segmental dermatomes and is not usually helpful in localization.

Although there may be paresthesias in the cutaneous area of pain referral, as well as tenderness to deep palpation of the muscles, no neurological abnormalities are found in cases of referred pain of nonradicular origin. This situation is in contrast to cases of radicular pain, in which disturbance of the nerve root often may be present in the form of sensory loss, hyporcflexia, ventral root dysfunction, or a combination of these. Referred pain generally is aggravated and relieved by the same maneuvers that alter local pain.

Radicular Pain. Radicular pain, which has great localizing value, arises from irritation of dorsal roots, with pain being projected to the dermatome of the nerve root. Tables 27.2 and 27.3 list the differential diagnoses of lesions of the cervical and lumbosacral nerve roots and the common sites to which pain of radicular origin is projected.

Radicular pain often has a sharp, stabbing quality. Maneuvers that stretch or further compress the nerve root, such as Valsalva maneuver, coughing, straight-leg raising, and neck flexion, generally aggravare the pain. The patient may avoid certain activities and postures that place further strerch on the nerve. For example, in the case of sciatica (pain in the distribution of the sciatic nerve) caused by a compressive SI radiculopathy (Figure 27,2), the patient may maintain the leg in a flexed posture at the hip and knee and plantar flex the foot. Such a posture may result in

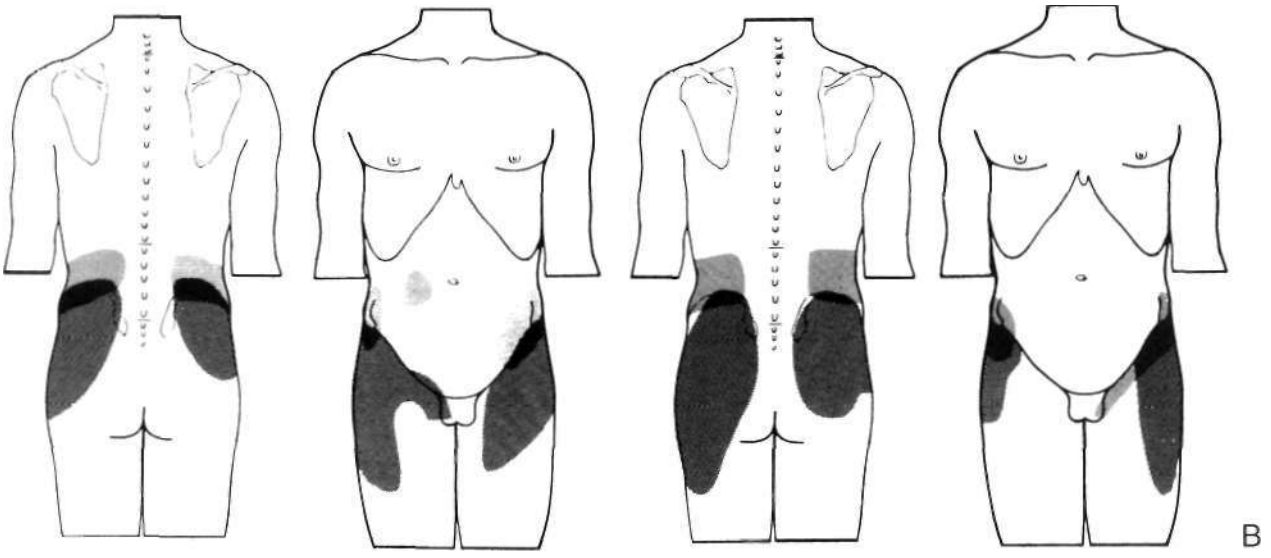

FIGURE 27.1 Patterns of referred pain. The distributions of pain referral from L1-L2 *(diagonal Shies)* and L4-L5 *(crosshatching)* are superimposed following (A) intracapsular and (B) pericapsular injections of 6% saline into the apophyseal joints. Overlap of the patterns is shown in the region of the iliac crest and groin. (Reprinted with permission from Mccall, J. W,, Park, W.M., & O'Brien, J, P. 1979, "Induced pain referral from posterior lumbar elements in normal subjects," *Spine,* vol. 4, pp. 441-446.)

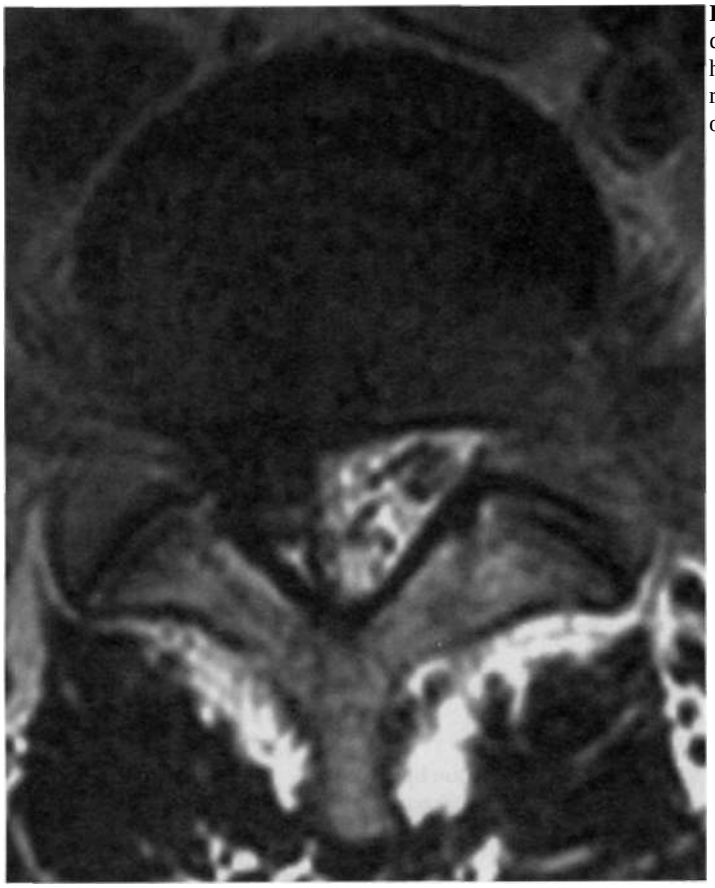

FIGURE 27.2 MRI (axial image) of the lumbar spine demonstrating a right-sided herniated L5-S1 disc (Note: The herniated disc is on rhe left side of the figure). The patient had right-sided sciatica and an absent ankle reflex and sensory loss ot 1111 L- lateral foot.

a characteristic gait. As with referred pain, cutaneous paresthesias and tenderness of tissues in the region of pain projection are common. However, in radicular pain, unlike referred pain, there may be sensory disturbances and at times reflex and motor abnormalities corresponding to the injured nerve root.

SENSORY DISTURBANCES

Dermatomes

A knowledge of the dermatomal map is valuable in recognizing and localizing radicular syndromes, A currently recognized dermatomal map is shown in Chapter 31 {see Figure 31.4). A few points deserve emphasis:

- On the trunk, the C4 and T2 dermatomes are contiguous.
- The thumb, middle finger, and fifth finger are innervated by C6, C7, and C8, respectively.
- The nipple is at the level of T4.
- The umbilicus is at the T10 level.
- In the posterior axial line of the leg {medial thigh), the lumbar and sacral dermatomes arc contiguous.

Finally, it should be recognized that there arc variations in dermatomal innervation between individuals that may make it difficult to base clinical conclusions on sensory testing alone.

DEEP TENDON REFLEXES

In addition to motor and sensory disturbances, deep tendon reflex abnormalities can be of precise localizing value. When deep tendon reflexes are segmentally hypoactive, they can be sensitive indicators of specific root disturbance. When they arc hyperactive below a specific spina! level, they may indicate a myelopathy at or above that level. The combination of hypoactive tendon reflexes at a segmental level with hyperactive reflexes caudal to that level is found commonly with cervical spine disease. For example, cervical spondylosis may cause hyporcflcxia of the biceps, brachioradialis, or triceps because of impingement on C5, C6, or C7 roots, respectively, and hyperreflexia below this level secondary to an associated myelopathy. At times, attempts to elicit the brachioradialis reflex produce no direct response but paradoxically cause contraction of the finger flexors rather than flexion and supination of the **hand. Such** a response is called *inversion of the radial reflex.*

NERVE ROOT VERSUS PERIPHERAL NERVE LESION

Monoradiculopathies rarely cause complete paralysis of *a* single muscle or muscle group. In contrast, with peripheral nerve disease, it is common for paralysis of such muscle groups to occur. A knowledge of innervation of muscle groups is important in making the distinction between peripheral nerve, plexus, or nerve root lesions. The sensory examination may be helpful in distinguishing peripheral nerve lesions from radiculopathies.

Autonomic disturbances may also be valuable in distinguishing peripheral nerve lesions from root disturbances. Ordinarily, mo no radiculopathies are not associated with autonomic disturbances such as sweat loss, whereas peripheral nerve injuries often arc associated with autonomic complaints. Tables 27.2, 27.3, 27,4, and 27.5 review the locations of sensory loss, projected pain, reflex loss, motor deficit, and some causative lesions of the more common radiculopathies and peripheral neuropathies.

Electrodiagnostic studies are often helpful in differentiating radiculopathies from peripheral neuropathies. With radiculopathies, the sensory action potentials are unaffected, whereas they are typically decreased in amplitude or absent in petiphcral nerve disease. Motor conduction

studies and patterns of denervation also may be helpful (see Chapter 36B). In dorsal root ganglionopathics, the sensory axons degenerate, often causing loss of sensory nerve action potentials in the affected segment.

LOCALIZATION OF LESIONS IN THE TRANSVERSE PLANE

Motor Disorders

As mentioned previously, the abnormalities on neurological examination of LMN dysfunction are weakness associated with atrophy, hypotonia, fasciculations, and depressed reflexes. In contrast, corticospinal tract disease often manifests with spasticity, hyper-reflexia, and Babinski's sign (except during the early phase of spinal shock), as well as weakness that usually involves more than a single extremity. In cervical spine disease, one may find a combination ot IAIN disturbance involving the upper extremity and UMN findings in one or both lower extremities. UMN disease usually affects the distal extremity more prominently than the proximal. For example, hand and foot dexterity are usually more impaired with UMN lesions than are shoulder and hip strength.

Perhaps the most important clue suggesting a spinal origin to weakness is the pattern of weakness. Hemiparesis involving the face, arm, and leg usually localizes the problem to the brain. Proximal muscle weakness of the arms and legs with intact sensation and notmal deep tendon reflexes directs the examiner to myopathic disorders. When the pattern is distal and associated with stocking-glove sensory loss and decreased deep tendon reflexes, peripheral neuropathies are considered. In patients with paraparesis or quadriparcsis, the examiner usually is directed to the spinal cord. Monoparesis creates the greatest diagnostic confusion. Early in the development of spinal cord disease, the patient may present with unilateral leg weakness, and examination may not reveal findings in the contralateral leg or the arms.

Lesions of the cranioccrvical junction and cervical spine often present with a pattern of unilateral arm weakness before progressing to ipsilateral leg weakness, and then contralateral involvement. However, although weakness involving an ipsilateral arm and leg with sparing of the face suggests a high cervical lesion, it should be recognized that cerebral disturbances or lacunar infarction in the internal capsule or medullary pyramidal may cause this pattern of involvement. Babinski's response is a sign of corticospinal tract disease. Plantar stimulation therefore helps differentiate UMN causes from othet etiologies in patients with leg weakness.

Sensory Disturbances

Subjective sensory complaints generally precede objective sensory signs, and therefore sensory complaints without abnormal sensory signs may be the first sign of serious underlying neurological disease. One corollary is that in the absence of sensory complaints, the sensory examination is usually normal.

Dysfunction of the dorsal (or posterior) columns and of the lateral spinothalamic pathways usually causes characteristically different symptoms. Tingling paresthesias, which may be vibratory in nature, are sometimes reported below the level of a dorsal column lesion. Subjective reports of the skin being "too tight" or an extremity or trunk being "wrapped in bandages" also may be caused by dorsal column disturbances. Spinothalamic tract disturbance is often first manifested by pain that is poorly characterized and localized. It should be recognized that many of the complaints of patients with imiMinediiihii'v lesions are nut-associated with any abnormal signs early in their course, so the complaints may be dismissed inappropriately after a negative sensory examination.

Pain sensation, usually measured by pinprick, and temperature sensation are conveyed via the lateral spinothalamic tract. These pathways are somatotopically organized so that the sacral fibers are most peripheral and the cervical fibers are most central. Because a laterally placed extramedullary lesion compresses the peripheral fibers before the more centrally located fibers, a compressive lesion in the rostral spine may give rise to an apparency ascending loss of pain and temperature sensation (Adams et al. 1996). These findings underscore the importance of recognizing that a rostral lesion may give rise to a sensory level *far below the site of the compression.* In practical terms therefore when spinal cord compression is suspected, one may need to image the entire spine rostral to the sensory level to exclude a lesion above the sensory level.

Position and vibration sensation classically arc thought to be transmitted through the posterior columns. However, both modalities of sensation also probably travel in other pathways (Glendinning and Vierck 1993). Spinal cord impairment of position and vibration sensation generally arc easily evaluated. Ataxia caused by spinal lesions is not as readily recognized. Disturbances of posterior columns or possibly the spinocerebellar tracts may result in an ataxic gait. This may be particularly evident in vitamin B_{12} deficiency. Light touch is conveyed by both lateral and posterior columns and usually is not impaired as early in spinal cord disease as the more specific modalities described previously.

Several incomplete lesions of the spinal cord result in characteristic sensory signs. A hemisection of the spinal cord results in a Brown-Sequard syndrome, in which there is loss of appreciation of pain and temperature contralateral to the lesion, loss of sensation for position and vibration, and UMN paralysis ipsilateral to the lesion (Figure 27.3).

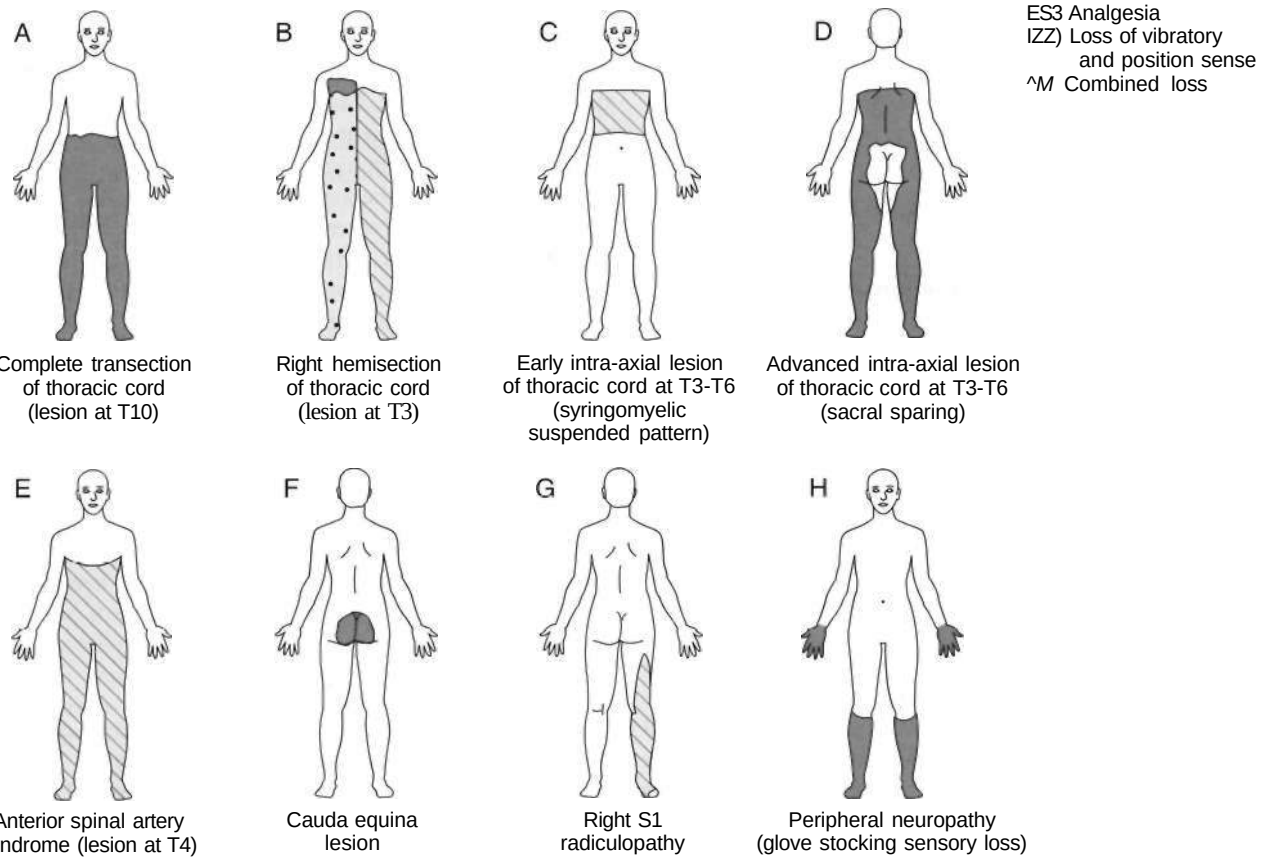

FIGURE 27.3 Characteristic sensory disturbances found in various spinal cord lesions in comparison with peripheral neuropathy.

An early intramedullary lesion such as a syrinx, intramedullary tumor, or contusion may give rise to a *dissociated sensory loss* in which damage to the decussating fibers at the level result in sensation of pain and temperature being lost or decreased, whereas the position and vibratory sensibilities remain unimpaired. Central cord lesions also may result in a suspended sensory level (see Figure 27.3). In such cases, sacral sensation is preserved until late in the course because these fibers are most peripheral in the lateral spinothalamic tracts and they tend to be involved later.

AUTONOMIC AND RESPIRATORY DISTURBANCES

Dysfunction of the spinal cord and cauda equina is often manifested as symptoms and signs of bladder, bowel, and sexual dysfunction (see Chapter 42). A high cervical cord lesion may cause respiratory compromise. Although the diaphragm, intercostal muscles, and abdominal muscles are used for normal respiration, individuals may ventilate adequately with only the diaphragm intact (see Tabic 27.1). In cases of complete cord transection above the C3 level, respiration cannot be maintained. Trauma, foramen magnum tumors, atlantoaxial dislocation, and congenital disturbances of the craniocervical junction are common causes of upper cervical spine injury,

The urinary bladder and its sphincters are innervated by (1) sympathetic nerves beginning in the intermediolateral cell column at the lumbar level (primarily LI and L2); (2) parasympathetic nerves exiting at S2-S4; and (3) somatic efferent nerves to the skeletal muscles of the external urethral sphincter exiting at S2-S4 to form the pudendal nerves. In complete transverse lesions of the cord, the bladder immediately becomes flaccid. In unilateral lesions, voluntary control of micturition is not lost. This corresponds to the clinical observation in spinal cord compression in which it is unusual to have sphincter function disturbed early when there is only unilateral or equivocal bilateral lower extremity weakness or sensory disturbance. The most common exception is when the conus medullars or sacral nerve roots arc compressed.

Immediately after acute spinal cord injury, there is often an initial period of *spinal shock,* which is often accompanied by urinary retention and overflow incontinence (as well as flaccid areflexia); Liter, a reflex (neurogenic or spastic) bladder typically develops (see Chapter 42). If the disturbance of UMN function evolves slowly, then the reflex bladder may develop without a preceding period of spinal shock and flaccid bladder. The reflex bladder is characterized by overactivity of both the detrusor muscle and the external sphincter. This causes incontinence of urine. In addition, the bladder capacity is diminished because of the detrusor contraction. The sensation of bladder distention may be lost if ascending tracts are involved. The anal reflex is often intact in cases of reflex bladder. On cystometry, the detrusor muscle demonstrates excessive contraction to small increments of fluid volume.

In contrast to the reflex bladder, when the damage occurs in the region of the conus medullaris or the cauda equina, a decentralized or autonomous flaccid bladder develops (see Chapter 42), Voluntary control over bladder function is impaired or abolished entirely. In such cases, detrusor tone is lost and the bladder distends to the point that overflow incontinence occurs. Bladder sensation is impaired. Control over the anal sphincter and the anal reflex usually is lost. A region of saddle anesthesia may be present (see Figure 27.3). Unlike the situation in the reflex bladder, cystometrography usually demonstrates diminished or absent contractions of the detrusor muscle.

The anatomical pathways subserving bowel function are similar to those controlling the urinary bladder. Spinal shock generally is associated with ileus, and a neurogenic megacolon may develop. The anal reflex usually is lost in cases of spinal shock. In lesions above the sacral level that evolve slowly, voluntary control of the sphincter ani may be lost, but in such cases, the anal reflex remains intact unless complete cord transection occurs, in which case it may be absent. In disturbances of the conus medullaris and cauda equina {nerve roots S3-S5), fecal incontinence and a flaccid anal sphincter with loss of the anal reflex may be a presenting manifestation of neurological disease. Saddle anesthesia (i.e., loss of sensation in the perianal area) is often seen in such cases. Partial impairment may be present in any of these syndromes before frank paralysis and a flaccid sphincter ensue,

Disturbances of sexual function arc common in spinal cord disease, especially in men. The descending pathways from the neocortex, limbic system, and hypothalamus course adjacent to the corticospinal tracts in the lateral funiculi. Penile erection occurs via the sacral parasympathetics {S3 and S4), the pudendal nerves, and nervi erigenres, and via inhibition of the sympathetic vasoconstrictor center located in the intermediolateral cell column at L1-L2, and then through the superior hypogastric plexus. Ejaculation is performed via the reflex arc beginning with the afferent limb arising in the genital epithelium and passing centrally via the dorsal nerve of the penis and pudendal nerve to the S3 and S4 dorsal roots. The perineal branch of the pudendal nerve is an important peripheral efferent pathway.

COMMON SPINAL CORD SYNDROMES

Spinal Shock

A complete transverse lesion of the spinal cord results in total loss of motor and sensory functions below the level of the lesion. If the lesion is slow in development, such as may occur with a benign tumor or cervical spondylosis, or if it is

incomplete, then spinal reflexes such as hyperactive deep tendon reflexes and Eabinski's signs genetally arc present. Alternatively, if the lesion is acute, a condition known as *spinal shock* ensues, in which there is temporary loss of all spinal reflex activity below the level of the lesion along with motor paralysis and sensory loss. Spinal shock is characterized by flaccid, areflexic paralysis of skeletal and smooth muscles. A complete loss of autonomic functions occurs below the level of the lesion, which results in a loss of urinary bladder tone and paralytic ileus. Sweating and piloerection also are diminished or absent below the level of the lesion. Because vasomotor tone is lost, dependent lower extremities may become edematous and temperature regulation may be a major problem. Genital reflexes such as penile erection, the cremasteric reflex, and bulbocavernosus reflexes are losr. Sensation below the level of the lesion is completely absent.

Incomplete Lesions of the Spinal Cord

Unilateral Transverse Lesion

A unilateral lesion or hemisection of the spinal cord produces a Brown-Scquard syndrome. In reality, pure unilateral lesions are rare, and therefore most clinical cases are described as a *modified* or *partial Brown-Sequard syndrome.* The clinical presentation of pure Brown-Sequard's syndrome is that of ipsilatcral weakness and loss of position and vibration below the level of the lesion, as well as contralateral loss of pain and temperature caudal to the lesion. The loss of pain and temperature usually is manifest a few segments below the level of the lesion because the decussating fibers enter the spinothalamic tract a few segments rostral to the level of entry of the nerve root. At the level of the insult, there may be a small ipsilateral area of anesthesia, analgesia, and LMN weakness because the segmental afferent and efferent pathways arc disrupted (see Figure 27.3).

Trauma such as a bullet or stab wound is probably the most common cause of a Brown-Scquard syndrome. Spinal metastases rarely present with a Brown-Sequard syndrome. In the large series of spinal metastases, fewer than 2% of patients with signs of myelopathy have a pure Brown-Sequard syndrome. Approximately 8% have greater weakness ipsilateral to the lesion and more marked pain and temperature loss contralateral to the lesion, without dorsal column signs (modified Brown-Sequard's syndrome). Radiation necrosis also has been reported to presenr with Brown-Sequard's syndrome.

Central Cord Syndrome

The central cord syndrome is caused by an jntra-axial lesion disturbing the normal structures of the central or paracentral region of the spinal cord. Such disturbances are either acute, in which case they are usually caused by hemorrhage or contusion following trauma (see Chapter 56C), or chronic, in which case they may be caused by tumor or syringomyelia. A demyelinating process occasionally may cause *a* similar syndrome, but it usually is not confused with the other more typical causes. Though clinically distinct, the presentations of these disorders share some common features. Contusions following trauma and syringomyelia often occur in the cervical spine and cervicotboracic junction. Spontaneous hematomyelia generally presents with the acute onset of severe back or neck pain followed by paralysis.

When the cervical spine or cervicothoracic junction is the site of a central cord syndrome, the upper extremities show weakness of an LMN type. Characteristically, there is loss of sensation in the upper extremities of a dissociated type, with loss of pain and temperature sensation and preservation of position and vibration sensation. This is caused by the decussating fibers destined for the spinothalamic tracts being interrupted, whereas those projecting within the dorsal columns are spared (see Figure 27.3). As a result of the laminated structure of the spinothalamic tract, sensation from the more caudal regions is preserved, with a capelike distribution of sensory loss in some patients with sacral sparing of pain and temperature sensation being the rule (Figure 27.4).

Anterior Spinal Artery Syndrome

Spinal cord infarction has been seen more frequent!) in recent years, in part because of an increased number of invasive procedures such as vascular and thoracoabdominal surgery and improved survival after cardiac arrest and hypotension. The anterior horns and anterolateral tracts are involved in this syndrome (see Chapter 57F). The thoracic vascular watershed zone at about T6 is especially susceptible. Corticospinal deficits develop below the level of the infarction; dysfunction of autonomic pathways occurs, causing loss of bowel, bladder, and sexual functions; and a sensory disturbance develops in which posterior column function remains intact and the spinothalamic tracts arc disrupted. Initially spinal shock with areflexia is expected, followed later by spasticity.

Anterior spinal artery syndrome is differentiated from acute central cord syndrome, as occurs in traumatic contusions and hematomyelia, by the sacral sensory sparing that tends to occur in the latter. Moreover, the anterior spinal artery syndrome can be differentiated from that of acute complete transverse myelopathy caused by the loss of posterior column function in the latter.

Anterior Horn and Pyramidal Tract Syndromes

Disturbances of the anterior horns and pyramidal tracts alone with sparing of the sensory functions and autonomic nervous system are seen in motor neuron disease. Clinically,

FIGURE 27.4 Magnetic resonance imaging scan of the cervical spine showing a contrast-enhancing mass. The patient presented with a capclike sensory loss to pain and temperature. Resection of the mass revealed a glioma.

one typically finds a combination of both LMN weakness with its attendant atrophy and fasciculations (and fibrillations and dcncrvation/reinnervatlon on electromyography) and upper motor weakness with spasticity, hyperrcflcxia, and Babinski's signs. Virtually diagnostic is the presence of LMN and UMN signs in the same muscle group. Alternatively, either the LMN or the UMN disturbance may predominate for months or years. Ultimately, as the LMN disease progresses, increasingly severe atrophy and evolution from hyperreflexia to hyporeflexia occur.

Combined Posterior and Lateral Column Disease

The clinical presentation of loss of posterior column and lateral column (pyramidal! (unction is that ot spastic ataxic gait. The ataxia is of a sensory type and may be bizarre in appearance. Although Friedreich's ataxia may cause such a syndrome, the classic cause for this is subacute combined degeneration associated with vitamin B_L2 deficiency.

CHARACTERISTIC CLINICAL FEATURES OF LESIONS AT DIFFERENT LEVELS

Spinal lesions at different levels often present with characteristic symptoms and signs referable to the segmental levels involved. In cases of extramedullar compression, disturbances at the segmental level (i.e., nerve root signs) usually herald the presentation. Conversely, intramedullary diseases frequently do not present with segmental disturbances but rather with tract dysfunction.

Foramen Magnum

Lesions of the foramen magnum, which include trauma, tumors, syringomyelia, multiple sclerosis, Arnold-Chiari malformation, atlantoaxial dislocation, and other bony abnormalities of the craniocervical junction, present a most challenging diagnostic problem for the clinician because symptoms are often vague or may be distant from the foramen magnum. Occipital or neck pain, often increased by neck movement, is a common initial manifestation. The pain may radiate also into the shoulders or the ipsilateral arm. In the latter situation, the pain may be similar to that of cervical spondylosis. The neurological signs associated with foramen magnum tumors also may be perplexing. Cranial nerve symptoms and signs are inconstant; nystagmus, often downbeating, impaired sensation over the upper face (caused by involvement of the descending tract of cranial nerve V), and dysarthria, dysphonia, and dysphagia arc present in some patients. Motor system involvement characteristically presents as spastic weakness. The corticospinal tract compression causes weakness that typically begins in the ipsilateral arm and is loll owed by weakness of the ipsilateral leg, spreading to the contralateral leg and then the arm,

Alternatively, foramen magnum tumors may cause signs of LMN weakness, atrophy, and depressed reflexes in the arms and hands. The mechanism of this LMN disturbance well below the level of the tumor is uncertain but possibly is secondary to circulatory disturbances affecting the (descending) distribution of the anterior spinal artery.

Sensory disturbances consisting of pain and numbness are early manifestations of foramen magnum tumors. Pain and paresthesias affecting the same upper extremity first

involved by spastic weakness is an early finding. The sensory disturbances in these patients are often of the dissociated type so patients suffer from loss of pain and temperature sensation but have preserved tactile sensation. In addition, a suspended sensory loss also has been reported in some cases and vibratory sensory loss over the clavicles in others. This pattern of sensory loss may be caused by a secondary syrinx, which may direct attention away from the causative lesion at the cervicomedullary junction. Magnetic resonance imaging (MRI) has become the test of choice for imaging the craniocervical junction.

Upper Cervical Spine

Compressive lesions of the upper cervical spine have similar clinical characteristics to those arising at the foramen magnum. Pain in the neck, occipital region, or shoulder is a common presenting complaint. The second cervical root innervates the posterior aspect of the scalp, which explains the pattern of radicular pain. If the compression is at the third or fourth cervical level, radicular pain may be projected to the neck or top of the shoulder. When pain does occur, it is usually provoked by neck movements, resulting in marked limitation of head turning and nodding.

With progressive compression, upper extremity weakness usually becomes apparent on the side of pain. The weakness may be of a UMN or LMN type. Some patients therefore may have spasticity and hyper-reflexia and others may have atrophy and hyporeflexia of a portion or the entire upper extremity including the hand. When UMN findings develop in the ipsilateral leg, a spinal hemiplegia is present. Weakness may then progress to the contralateral lower extremity and then the contralateral upper extremity.

Lower Cervical and Upper Thoracic Spine

Spinal cord and root compressions at the levels of C5-T1 most frequently betray their presence by radicular symptoms at the affected level in the shoulder or upper extremity in the form of pain and later reflex, motor, and sensory disturbances. With lesions at the C4-C6 level, pain and sensory disturbances are frequently reported along the radial aspect of the arm, forearm, and thumb (see Table 27.2). With intramedullary neoplasms, pain is also common at these levels, but the localization is usually more diffuse and less typically radicular.

At the C7-T1 level, pain and sensory symptoms often are localized to the ulnar aspect of the arm, forearm, and hand. Tumors at the Tl and T2 levels often cause pain to radiate into the elbow and hand, together with sensory complaints along the ulnar border of the hand. As at other locations, intramedullary neoplasms usually give rise to more diffuse symptoms, which are often bilateral. Conversely, extramedullar)' compression often presents with exquisite localizing symptoms.

Weakness usually follows pain, particularly at the affected segmental level. As might be expected based on the myotomal map of the upper extremity, intramedullary and extra medullary lesions at the C4-C6 level show a predilection to involve the muscles in the shoulder and upper arm (see Table 27,2), Atrophy and weakness of the hand can rarely occur with lesions at the C4-C6 level. This may be caused by vascular factors affecting the lower cervical segments. Such a pattern of weakness and atrophy is usually caused by a lesion at the C7-T2 level.

The pattern of extremity weakness may be a guide in distinguishing intramedullary from extramcdullary disorders. Although exceptions are encountered, extramedullary lesions tend to affect the ipsilateral upper and lower extremity before involving the contralateral side. In contrast, intramedullary lesions may involve both upper extremities before the lower extremities are affected or show bilateral arm and leg involvement from the onset.

The deep tendon reflexes are helpful in localizing the segmental level of involvement in the cervical spine. Disease at the C5-C6 level is often associated with depressed biceps (C5), brachioradialis reflex (C6), or both (see Table 27.2). Alternatively, one may encounter depressed biceps and brachioradialis reflexes associated with a hyperactive triceps reflex if there is a compressive myelopathy at the C5-C6 level. Suggestive of cervical spondylosis is a depressed brachioradialis (C6) reflex with hyperactive finger flexors (C8-T1), indicaring a C6 radiculoneuropathy with myelopathy; neoplasms or other diseases at the C6 level may cause a similar clinical presentation. When the lesion is at the C7 level, the triceps reflex may be depressed.

With lesions at C8 and T1, the finger flexor response may be impaired. Hoffmann's sign is performed by dorsiflexing the patient's wrist and then flicking the distal phalanx of the middle finger with the examiner's thumb. The patient's middle finger is thus flexed and suddenly extended. When Hoffmann's sign is present, this maneuver is followed by reflex flexion of the patient's thumb and other fingers. When present bilaterally, Hoffmann's sign is usually an indication of hyperactive deep tendon reflexes. Although disease of the pyramidal pathways may be responsible, healthy individuals with hyperactive reflexes may have bilateral Hoffmann's signs such as in the case of anxiety, hyperthyroidism, and stimulatory drugs. When Hoffmann's sign is present unilaterally, it usually signifies disease of the nervous system.

Thoracic Levels

The thoracic dcrmatomal landmarks that guide the examiner ro the level of involvement are the nipple (T4),

Table 27.6: Differentiation of con us lesions from cauda equina lesions

	Cotius medullar is	*Cauda equina*
Spontaneous pain	Unusual and not severe; bilateral and symmetrical in perineum or thighs	Often very prominent and severe, asymmetrical, radicular
Motor findings	Not severe, symmetrical Fibrillary twitches are rare	May be severe, asymmetrical, fibrillary twitches of paralyzed muscles arc common
Sensory findings	Saddle distribution, bilateral, symmetrical, dissociated sensory loss (impaired pain and temperature sensibility with sparing of tactile sensibility)	Saddle distribution, may be asymmetrical, no dissociation of sensor; loss
Rdk'\ dump's	Lpiconus: only Achilles reflex absent Conns: Achilles and patellar present	Patellar and Achilles reflexes may be absent
Sphincter disturbance	Early and marked (both urinary and fecal incontinence)	Late and less severe
Male sexual function	Impaired early	Impairment less severe
Onset	Sudden and bilateral	Gradual and unilateral

the umbilicus (T10), and the inguinal ligament (LI). Pain or sensory alterations in a radicular distribution are localized to a specific dermatome using these levels as points of reference. The relatively small vertebral canal and the vascular watershed area of the spinal cord at about T6 in the thoracic region make the thoracic spinal cord extremely vulnerable to injury from compression. Consequently, the temporal course of symptoms of cord compression is often shorter in this region than elsewhere in the spine. Thus pain often evolves rapidly into weakness, sensory loss, and reflex abnormalities caudal to the lesion. Sphincter disturbances ultimately develop.

Conus Medullaris and Cauda Equina

Lesions of the cauda equina and conus medullaris (Table 27.6) cause similar symptoms and signs including local, referred, and radicular pain, sphincter disturbances, loss of buttock and leg sensation, and leg weakness. Although it may be relatively easy to establish the level of a single radiculopathy based on sensory, motor, and reflex changes, it is much more difficult to assign the cause and localization when several lumbosacral levels are involved. In such situations, one must consider the possibility of a lower spinal cord lesion or a cauda equina syndrome. Although there has been a long effort to differentiate conus medullaris lesions from those of the cauda equina, it is not always possible to accurately discriminate between them. Although rare in its pure form, the conus medullaris syndrome presents with sphincter disturbances, saddle anesthesia (S3-S5), impotence, and absence of lower extremity abnormalities. If the cauda equina is involved, patients may experience difficulty with external rotation and extension of the thigh at the hip, flexion of the knee, and weakness of all muscles below the knee.

DISTINGUISHING INTRAMEDULLARY FROM EXTRAMEDULLARY LESIONS

The earlier sections of this chapter describe several features that help distinguish between intramedullary lesions and extra medullary compressive lesions of the spinal cord. However, as stressed earlier, this may be a vexing clinical problem that ultimately requires elucidation by imaging techniques. The explanation for this clinical experience has been provided by clinicopathological studies of extra-medullary spinal neoplasms. It has been demonstrated that extramedullary compression can cause ischemia and demyelination in the posterior and lateral column, with relative sparing of the anterior columns regardless of the location of the extramedullary tumor. Both coup and contrccoup injuries occur in the spinal cord. The areas of infarction and demyelination are often deep and do not follow a specific pattern. In some instances, the pathological findings are more marked ipsilatcral to the tumor, and in other cases, they are primarily contralateral to the mass. It follows therefore that stereotypical clinical patterns of evolution cannot be expected.

CLASSIFICATION OF DISEASES AFFECTING THE SPINAL CORD

This chapter emphasizes the clinical pathophysiology of spinal cord disorders. Table 27.7 lists a classification of disorders that may cause a spinal cord syndrome; discussion of specific diseases can he found elsewhere in

Table 27.7: Differential diagnosis of diseases affecting the spinal cord

Compressive lesions
- Non-neoplastic
  - Trauma
  - Spondylosis
  - Intervertebral disc herniation
  - Spinal stenosis
  - Infectious disorders (e.g., abscess, tuberculosis)
  - Inflammatory (e.g., rheumatoid arthritis, ankylosing spondylitis, sarcoid)
  - Spinal hemorrhage
  - Syringomyelia
  - Congenital disorders
  - Arachnoid cysts
  - Paget's disease
  - Osteoporosis
- Neoplastic
  - Epidural
  - Intradural extramedullar (e.g., meningioma, neurofibroma, and leptomeningeal metastasis)
  - Intramedullary

Noncompressive myelopathies
- Demyelinating (e.g., multiple sclerosis, acute disseminated encephalomyelitis)
- Viral myelitis (e.g., roster, acquired immunodeficiency syndrome-related myelopathy, human T-lymphotropic virus type 1)
- Vitamin B12 deficiency and other nutritional deficiencies
- Infarction
- Ischemia and hemorrhage resulting from vascular malformations
- Spirochetal diseases (syphilis and Lyme disease)
- Toxic myelopathies (e.g., radiation induced)
- Autoimmune diseases (e.g., lupus, Sjogren's syndrome)
- Paraneoplastic
- Neuronal degenerations
- Acute and subacute transverse myelitis of unknown cause

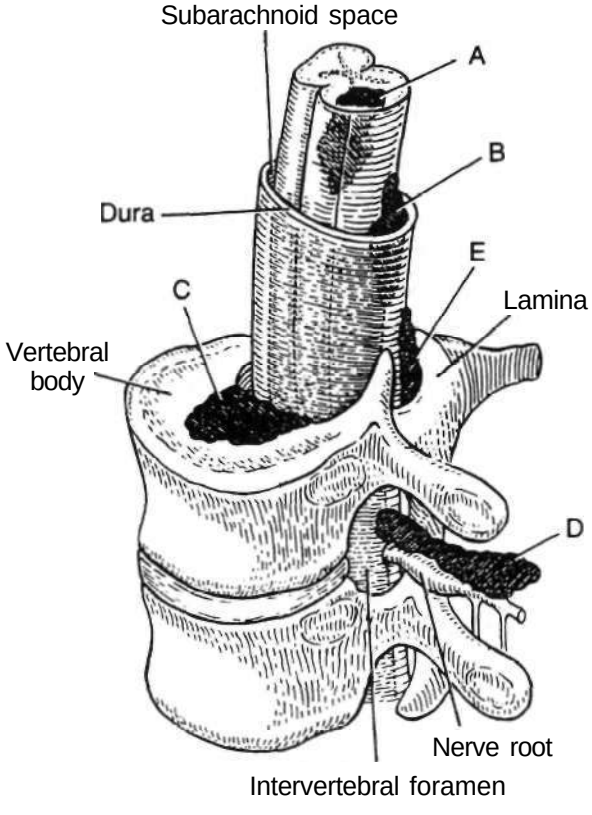

FIGURE 27.5 Anatomical locations of spine metastases. (A) Intramedullary metastasis is located within the spinal cord. (B) Leptomeningeal metastasis is in the subarachnoid space and is extra medullary and intradural. Epidural metastases arise from the extension of metastases located in one of the adjacent structures: (C) vertebral column; (D) paravertebral spaces via the intervertebral foramina; or rarely, (E) the epidural space itself. As these epidural metastases grow, they compress adjacent blood vessels, nerve roots, and the spinal cord, resulting in local and referred pain, radiculopathy, and myelopathy. (Reprinted with permission from Byrne, T. N. 1992, "Spinal cord compression from epidural metastases," N *Engl J Med*, vol. 327, pp. 615.)

this book. Diseases arc classified according to their etiology and location. With the availability of MRI, this classification permits the clinician to consider the differential diagnosis before and after the imaging has been obtained. Furthermore, because compressive lesions may be surgical emergencies, this classification considers the therapeutic nature of many of the diseases that must be considered.

METASTATIC EPIDURAL SPINAL CORD COMPRESSION

Metastatic epidural spinal cord compression (MESCC) deserves special comment because it affects approximately 20,000 patients with cancer in the United Stares annually. Figure 27.5 demonstrates the location of tumors of the spine, distinguishing among intramedullary, extramedullar, intradural, and extradural tumors. As with **other** causes of spinal cord compression, the major presenting clinical signs and symptoms of MESCC are pain, weakness, sensory loss, and autonomic disturbance. In approximately 95% of adults and 80% of children, progressive axial, referred, radicular, or all three kinds of pain are the most common initial complaint of both vertebral metastasis and MESCC, Because the neurological prognosis depends directly on the level of neurological function at the time of initiation of therapy, there is a great incentive to make an early diagnosis while the patient is still ambulatory.

The imaging test of choice in evaluating patients for MESCC is MRI when available in a timely fashion. Alternatively, myelography should be performed when management is delayed by inability **to** obtain an MRI, in patients unable to undergo MRI (e.g., those with pacemakers and pain precluding recumbency) or when a technically adequate **MRI** cannot be obtained. The mainstays of treatment include corticosteroids, radiotherapy, and, in selected patients, surgical decompression of the cord. Approximately 80% of patients who arc ambulatory at the initiation of radiotherapy remain so at the end of treatment, whereas fewer than 10% who are paraplegic at the beginning of radiotherapy recover ambulation.

Chapter 28
Proximal, Distal, and Generalized Weakness

David C. Preston, Barbara E. Shapiro, and Michael H. Brooke

Muscle weakness may be due to disorders of the central or peripheral nervous system (CNS and PNS, respectively), the neuromuscular junction, or the muscle. The neurological examination allows separation of weakness arising from these different locations. If the pattern of weakness is characteristic of upper motor neuron (UMN) weakness {i.e., weakness of the extensors of the upper limbs and the flexors of the lower limbs), together with hyper-reflexia and an extensor plantar response, weakness is clearly of CNS origin. If there is clear sensory impairment, the weakness is likely to arise from dysfunction of the peripheral nerves, nerve roots, or CNS. If there is marked fatigue and weakness involves the extraocular, bulbar, and proximal upper limb muscles, the diagnosis is likely to be myasthenia gravis.

If weakness is not accompanied by sensory loss, marked fatigue, or signs of CNS involvement, then it is likely to be due to a disorder of the motor unit. The motor unit includes the anterior horn cell, the motor nerve, rhe neuromuscular junction, and the muscle itself. This chapter concentrates on disorders of the motor unit, discussing disorders of the neuromuscular junction and PNS as they enter into the differential diagnosis.

The clinical features of motor unit disorders arc determined mostly by which muscles are weak. Muscle weakness changes functional abilities that are more or less specific to the muscle groups affected. Recognizable patterns of symptoms and signs often allow a reasonable estimation of the anatomical involvement. Recognizing these patterns is the first step in the differential diagnosis of weakness, as certain disorders have a predilection for certain muscle groups. This chapter begins with a discussion of symptoms of muscular weakness, depending on which muscle groups are affected. This is followed by a discussion of the bedside and functional physical examinations and comments on laboratory tests often employed in patients with muscle weakness. The chapter concludes with an approach to the diagnosis of muscle weakness, based on which muscle groups are weak, whether the muscle weakness is constant or fluctuating, and whether the disorder is acquired or inherited.

SYMPTOMS OF WEAKNESS

As muscles begin to weaken, symptoms depend more on which muscles are involved than on the cause of involvement. A complicating factor in evaluating weakness is the difference in the patient's interpretation of the word *weak.* Although physicians use the word to denote a loss of muscle power, the patient may use the word more loosely. Even more confusing, many people use the words *numb* and *weak* interchangeably. Thus the complaint of weakness should not be taken at face value but should be questioned until it is clearly shown to mean a loss of muscle strength. If the patient has no objective weakness when examined, the clinician must rely on the history. Patients with weak

muscles have a fairly stereotypical set of symptoms depending on which muscle groups are weak (see the following sections). The patient whose weakness is caused by depression or malingering will have much more vague symptoms, and if leading questions are avoided, the stereotypical symptoms of weakness are seldom volunteered. Instead, patients make statements such as, "I have no strength to do the housework,[1]" "I just can't do the task," and "I can't climb the stairs because I get so tired and have to rest." When ptcsscd regarding these symptoms, it soon becomes apparent that specific details are lacking. Patients who cannot get out of a low chair because of real weakness explain exactly how they have to maneuver themselves into an upright position (e.g., pushing on the chair arms, leaning forward in the seat, and bracing their hands against the furniture). The examiner should avoid providing patients with the details for which they are searching. Asking patients whether they have to push on the arms of the chair to stand up provides patients with information that can be used later in response to the questions of baffled successive examiners. In addition, it is often difficult to differentiate true muscle weakness from apparent weakness that accompanies tendon or joint contractures or that occurs secondary to pain. For example, patients with primary orthopedic conditions often complain of weakness. However, in these situations, pain with passive or active motion is often a prominent part of the symptoms.

In evaluating weakness, the first key task is to discern which muscle groups are affected. In this regard, it is helpful to divide the symptoms of weakness into the following body regions: ocular; facial and bulbar; neck, diaphragm, and axial; proximal upper extremity; distal uppet extremity; proximal lower extremity; and distal lower extremity.

Ocular Muscles

Extraocular muscle weakness results in ptosis and/or diplopia. Drooping of the eyelids may be noticed by the patient when looking in the mirror or may be pointed out by family and friends. It is important to keep in mind that older patients occasionally develop ptosis as a consequence of aging (i.e., partial dehiscence of the levator muscles) or as a consequence of ocular surgery (e.g., lens implanrs for cataracts). To differentiate between acute and chronic ptosis, it is often helpful to look at prior photographs or because the ocular myopathies are often familial to look at family photographs. Bilateral ptosis may result in compensatory backward tilting of the neck to look ahead or upward. Rarely, this may lead to neck pain and fatigue as the prominent symptoms. In addition, true ptosis often results in compensatory contraction of the frontalis muscles to lessen the ptosis, resulting in a characteristic pattern of a droopy eyelid with prominent contraction and furrowing of the frontalis muscle above. Weakness of extraocular muscles may result in diplopia. However, mild diplopia may cause only blurring of vision, sending the patient to the ophthalmologist for new eyeglasses. It is also worth asking the patient if closing one eye corrects the diplopia, because neuromuscular weakness is not among the causes of monocular diplopia.

Facial and Bulbar Muscles

Facial weakness is usually experienced by the patient as a feeling of stiffness or sometimes as a twisting or altered perception in the face (note that patients often use the word *numbness* in describing facial weakness). Drinking through a straw, whistling, and blowing up balloons are particularly difficult tasks and may be sensitive tests for facial weakness, parricularly when such weakness dates from childhood. Acquaintances may notice that the patient's expression is somehow changed. A pleasant smile may turn into a snarl because of weakness of the levator anguli oris muscles in myasthenia gravis. In lower facial weakness, patients may have difficulty with drooling and retaining their saliva, often requiring them to carry a tissue in their hand (so-called "napkin sign," which often accompanies bulbar involvement in amyotrophic lateral sclerosis |ALS|). A common observation in mild long-standing facial weakness, for instance, in facioscapulohumeral (FSH) muscular dystrophy, is a tendency for the patient to sleep with the eyes open from weakness of the orbicularis oculi. Weakness of masticatory muscles may result in difficulty chewing, sometimes with a sensation of fatigue and discomfort, as may occur in myasthenia gravis. Pharyngeal, palatal, and tongue weakness disturbs speech and swallowing. A flaccid palate is associated with nasal tegurgitation, choking spells, and aspiration of liquids. Speech may become slurred, nasal, or hoarse. In contrast to central lesions, there is no problem with fluency or language function.

Neck, Diaphragm, and Axial Muscles

Neck muscle weakness is first noticed in situations in which the patient is called on to stabilize the head. Riding as a passenger in a car when the brake or the accelerator is used, particularly in an emergency situation, may be disconcerting for the patient with neck weakness because the head tocks forward or backward. Similarly, when the patient is stooping or bending forward, weakness of the posterior muscles may cause the chin to fall on the chest. A patient with neck flexion weakness often notices difficulty lifting the head off the pillow in the morning. As neck weakness progresses, patients may develop the L'dtopped head" syndrome, in which they can no longer extend the neck and their chin rests against the chest (Figure 28.1).

FIGURE 28.1 Dropped head syndrome. In severe weakness of the neck extensor muscles, patients can no longer extend the neck and their chin rests against the chest.

This posture leads to several secondary difficulties, especially with vision and swallowing.

When diaphragm muscles weaken, patients often develop shortness of breath, especially when lying flat or with exertion, and these symptoms can be mistaken for lung or heart disease. Severe diaphragmatic weakness leads to hypoventilation and carbon dioxide retention. This may first manifest as morning headaches and/or vivid nightmares. Latet, hypercapnia results in sedation and a depressed mental state.

Rarely, axial and trunk muscles can be involved early in the course ol a neuromuscular disorder. Weakness ol the abdominal muscles may make sit-ups impossible. Focal weakness of the lower abdominal muscles results in an obvious protuberance that superficially mimics an abdominal hernia. Patients with weakness of the paraspinal muscles are unable to maintain a straight posture when sitting or standing as compared to lying on the bed (so-called "bent spine" syndtome).

Proximal Upper Extremity

A feeling of tiredness is often the first expression of shoulder weakness. The weight of the arms is sufficient to cause fatigue. Eatly on, the patient expetiences fatigue on performing sustained tasks with the hands held up, especially over the head. The most problematic activities include painting the ceiling, shampooing ot combing the hair, shaving, or simply trying to lift an object off a high shelf.

Distal Upper Extremity

Hand and forearm weakness is easily noticed because it interferes with so many common activities of daily living. Difficulty with activities that require dextetity is often noticed first, such as buttoning and using a zipper. With further decreased hand strength, other activities are affected, especially opening a jat, turning on a faucet or the car ignition, using a key, holding silvetware, writing, or opening a car door.

Proximal Lower Extremity

Weakness of the proximal lower extremity is often responsible for the earliest symptoms experienced by patients who develop weakness. Patients notice that they have difficulty arising from the floor or horn a low chair and have to use the support of the hands ot knees. Getting out of a bath or a toilet without handrails is particularly difficult. Older patients may interpret this as arthritis or some similar minor problem. Walking becomes clumsy, and the patient may stumble. In descending stairs, people with quadriceps weakness tend to keep the knee locked and stiff. If the knee bends slightly as the weight of the body is transferred to the lower stair, the knee may collapse. Greater problems coming down staits than going up suggest quadriceps weakness, whereas the reverse is true for hip extensor weakness. Once patients with hip-girdle weakness are up and on level ground, they feel more secure. Howevct, others will often notice an obvious change in their gait. Patients with hip-girdle weakness often develop a waddling gait, because weakness of the hip abductors of the weight-bearing leg results in the hip falling as the patient walks (a *Trendelenburg* gait).

Distal Lower Extremity

Weakness of the distal lower extremity is most often manifested by symptoms of the antetiot compartment (i.e., peroneal) muscles. Weakness of the anterior tibial and ankle evertor muscles often results in tripping, even over small obstacles, and an increased tendency to sprain the ankle repeatedly. If the weakness becomes severe, a footdrop is noted, and the gait assumes a slapping quality. To compensate for a dropped foot, patients must raise their knee higher when they walk, so the dropped ankle and toes cleat the floor (i.e., steppage gait). Weakness of both anterior and postetiot muscles of the lower leg often makes the stance unstable, which causes the patient to complain of poor balance. Isolated weakness of the posterior calf makes standing on tiptoes impossible.

BEDSIDE EXAMINATION OF THE WEAK PATIENT

The neurological examination of patients with muscle weakness is the same as that used for patients with other

neurological problems. However, special attention to the observation and functional evaluation of the patient are particularly rewarding in the patient with weakness.

Observation

It is useful to spend a few moments observing the patient and noting natural posture and motion. When patients, particularly children, are aware that they arc being examined, they often concentrate on performing as normally as possible. When unaware of scrutiny, their posture and movements may be more natural. At one time or ::.n(>iikT, wc ha\e heard the parents' exasperated cry, "He never does it that way at home." For example, ptosis may be obvious on inspection of the head and neck. The more severe the ptosis, the greater is the patient's tendency to throw the head backward. The eyebrows are elevated and the forehead is wrinkled in an attempt to raise the upper lids. This is sometimes so successful that ptosis is apparent only when the examiner smooths out the wrinkled forehead and allows the eyebrows to assume a more normal position, Psychogenic ptosis is easy ro detect because raising of the lower lid (due to contraction of both parts of the orbicularis oculi muscle, i.e., blepharospasm) accompanies the lowered upper lid.

Weakness of the face that has been present since childhood may give a smooth, unlined appearance to the adult face. In addition, facial expression is diminished or altered. A smile may become a grimace or snarl, with eversion of the upper lip. The normal blink may be slowed or eyelid closure may be incomplete so the sclera is always visible. The normal preservation of the arch of the upper lip may be lost, and the mouth may assume either a tented or a straight-line configuration. Actual wasting of the facial muscles is difficult to see, but temporal and massctcr atrophy produces a characteristic scalloped appearance above and below the cheekbone. Because the hairstyle may be rearranged to cover the wasting, the examiner should make a conscious effort to check the upper portion of the face. The tongue should be inspected for atrophy and fasciculations. This is best accomplished by inspecting the tongue at rest with the mouth open looking for random, irregular twitching movements of fasciculations. When the tongue is fully protruded, many patients will have some normal quivering movements. It is wise to diagnose fasciculations of the tongue only when atrophy is associated,

Facial weakness causes the normal labial sounds (that of *p* and *b)* to be softened. The examiner with a practiced car can detect other alterations of speech. Lower motor neuron (LMN) involvement of the palate and tongue gives the speech a hollow, nasal, echoing timbre, whereas UMN dysfunction causes the speech to be monotonous, forced, and strained. Laryngeal weakness may also be noticed in speech when the voice becomes harsh or brassy, often associated with the loss of the glottal stop {the small sound made by the larynx closing, as at the start of a cough).

Weakness of the shoulder muscles causes a characteristic change in posture. Normally, the shoulders are braced back by the tone of the muscles, so the thumbs tend to face forward when the arms are held by the side. As the shoulder muscles lose their tone, the point of the shoulder rotates forward. This forward rotation of the shoulder is associated with a rotation of the arm, so that the backs of the hands now face forward. Additionally, the loss of tone causes a rather loose swinging movement of the arms in normal walking. When shoulder weakness is severe, the patient may fling the arms by using a movement of the trunk, rather than lifting the arms in the normal fashion. In the most extreme example, the only way the patient can get the hand above the head is to use a truncal movement to throw the whole arm upward and forward so the hand rests on the wall, and then to creep the hand up the wall using finger movements.

Atrophy of the pectoral muscles leads to the development of a horizontal or upward sloping of the anterior axillary fold. This is particularly seen in FSH muscular dystrophy,

The examiner may observe winging of the scapula, a characteristic finding in weakness of muscles that normally fix the scapula to the thorax {i.e., the serratus anterior, rhomboid, or trapezius). As these muscles become weak, any attempted movement of the arm causes the scapula to rise off the back of the rib cage and protrude like a small wing. The arm and shoulder may be thought of as a crane: The boom of the crane is the arm and the base is the scapula. Obviously, if the base is not fixed, any attempt to use the crane results in the whole structure falling over. This is how it is with attempts to elevate the arm; the scapula simply pops off the back of the chest wall in a characteristic fashion. In the most usual type of winging, the entire medial border of the scapula protrudes backward. In some diseases, particularly FSH muscular dystrophy, the infero-medial angle juts out first, and the entire scapula rotates and rides up over the back. This is often associated with a trapezius hump, in which the middle part of the trapezius muscle, in the web of the neck, is mounded over the upper border of the scapula (Figure 28.2). A word of caution pertains to the examination of the slender person or a child, in whom a prominent shoulder blade is often seen. The shoulder configuration returns to normal, however, when the individual attempts to use the arm forcibly, as in a push-up.

Muscle Bulk **and** Deformities

The examination of muscle bulk, looking both for atrophy and hypertrophy, is an important part of the neuromuscular examination. Prominent muscle wasting usually accompanies neurogenic disorders associated with axonal loss. However, severe wasting can also be seen in chronic

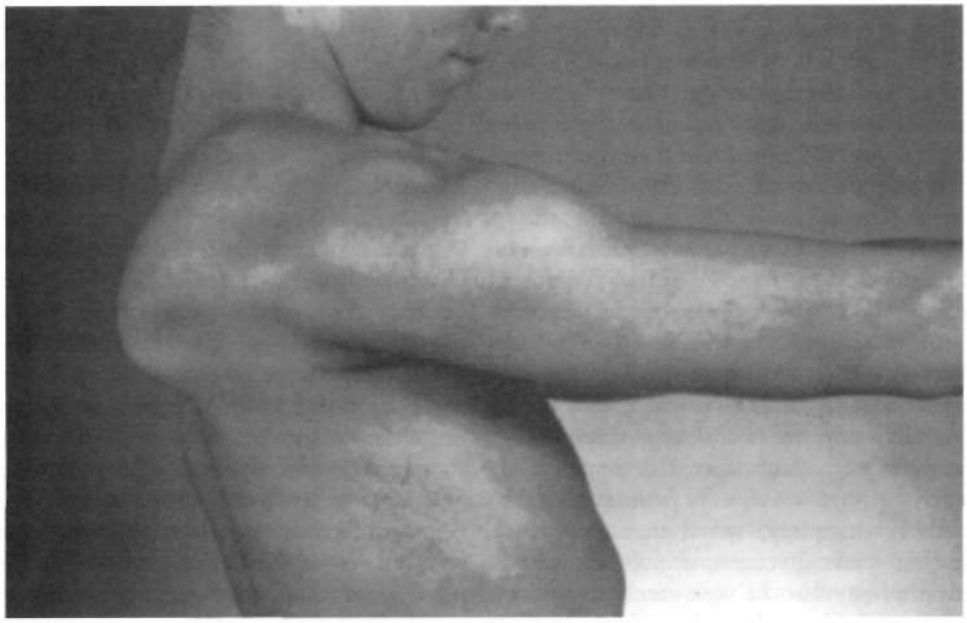

FIGURE 28.2 The scapular winging of facioscapulohumeral muscular dystrophy is distinguished by the prominent protrusion of the inferior medial border of the scapula. When viewed from the front, the elevation of the scapula under the trapezius muscle produces the trapezius hump.

myopathic conditions. Wasting is most often best appreciated in the distal hand and foot muscles and around bony prominences. In the upper extremity, wasting of the intrinsic hand muscles produces the characteristic claw hand, in which the thumb rotates outward so that it lies in the same plane as the fingers; the interphalangeal joints are slightly flexed and the metacarpophalangeal joints are slightly extended (the simian hand). Wasting of the small muscles leaves the bones easily visible through the skin, resulting in the characteristic guttered appearance of the back of the hand. In the foot, one of the easier muscles to inspect is the extensor digitorum brevis, a small muscle on the lateral dorsum of the foot that helps to dorsiflex the toes (Figure 28.3). It often wastes early in neuropathies and anterior horn cell disorders. In myopathic conditions in which proximal muscles are affected more than distal muscles, the extensor liis'jtoiuni brevis may actually hypertrophy to try to compensate for weakness of the long toe dorsiflexors above.

Muscle mass of the leg is so variable among people that it is sometimes difficult to decide whether the muscles are wasted. Any marked asymmetry indicates an abnormality, but distinguishing a slender thigh from quadriceps muscle atrophy is often difficult. One way to try to distinguish these conditions is to ask the patient to tighten the knee as firmly as possible. The firm medial and lateral bellies of the normal quadriceps that bunch up in the distal part of the thigh just above the knee fail to appear in the wasted muscle. The same technique may be used to evaluate anterior tibial wasting. In a severely wasted muscle, a groove on the latetal side of the tibia (which should be filled by the anterior tibial muscles) is apparent. A moderate degree of wasting is difficult to distinguish from a thin leg, but if the patient is asked to dotsiflcx the foot, the wasted muscle fails to develop the prominent belly seen in a normal muscle.

Abnormal muscle hypertrophy is uncommon but may be a key finding when present. Beyond the expected increase in muscle bulk that accompanies exercise, generalized muscle hypertrophy is seen in patients with myotonia congenita

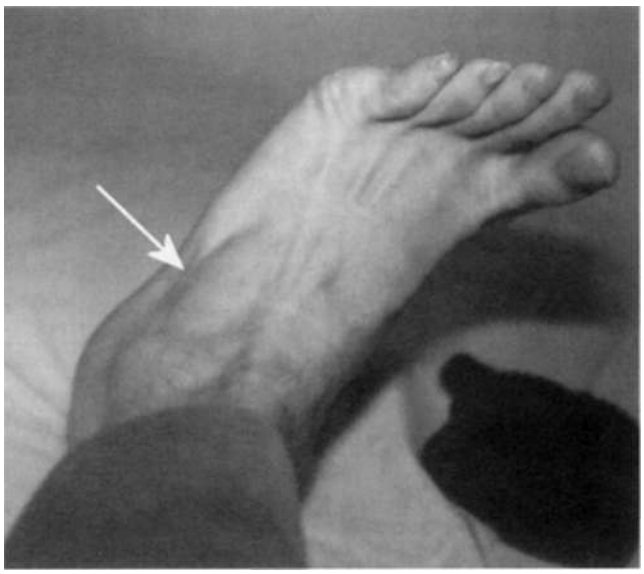

FIGURE 28.3 Extensor digitorum brevis (EDB) muscle *{arrow)* is a small muscle on the lateral dorsum of the foot, which helps dorsiflex the toes. It often wastes early in neuropathic conditions but may become hypcrtrophicd in proximal myopathic conditions.

and paramyotonia congenita, giving them the appearance of weight lifters. Hypertrophy is a common finding in the rare syndrome of acquired ncuromyotonia, in which the continuous discharge of motor axons results in the muscle effectively exercising itself. Exceptionally, hypertrophy can be seen in chronic denervating disorders, especially in the posterior calf muscle in SI radiculopathies. Electromyography (EMG) of these patients often reveals spontaneous discharges in these muscles (usually complex repetitive discharges) as a consequence of the chronic denervation. In contrast, there are conditions in which muscle hypertrophy is not from true muscle enlargement but from infiltration of fat, connective tissue, and other material (i.e., pseudohypertrophy). Focal hypertrophy may be seen in calf muscles of patients with Duchenne's and Becker's muscular dystrophy, as well as in patients with the limb-girdle muscular dystrophies, spinal muscular atrophies (SMA), and in some glycogen storage disorders. Similarly, hypertrophy may also be seen rarely in sarcoidosis, cysticercosis, amyloidosis, hypothyroid myopathy, and focal myositis. Palpable masses in muscles may be seen with muscle tumors, ruptured tendons, or muscle hernias.

Several bony deformities are often important clues in neuromuscular conditions. Proximal and axial muscle weakness often leads to scoliosis. Intrinsic foot muscle weakness, present from childhood, often leads to the characteristic foot deformity of pes cavus, in which the arch is high, the foot is foreshortened, and hammer toes, where the toes are cocked up (Figure 28.4). Pes cavus is a sign that weakness has been present at least since early childhood and implies a genetic disorder in most patients. Likewise, a high-arched palate often develops from chronic neuromuscular weakness present from childhood,

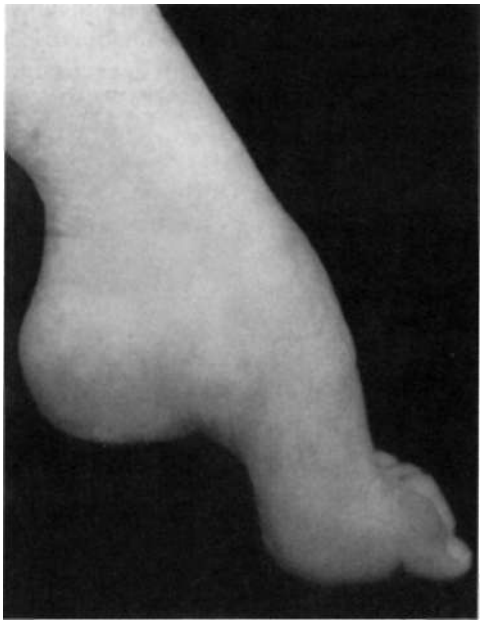

FIGURE 28.4 Pes cavus is caused by intrinsic foot muscle weakness present as a child develops. It is recognized as a high arch, foreshortened foot, and hammer toes. It is often a sign that weakness has been present since early childhood and implies an inherited disorder in most patients.

Muscle Palpation, Percussion, and Range of Motion

Palpation and percussion of muscle provide additional information. Fibrotic muscle may feel rubbery and hard, whereas denervated muscle may separate into separate strands that can be rolled under the fingers. Muscle in inflammatory myopathies or rheumatologic conditions may be tender to palpation, but severe muscle pain on palpation is unusual. An exception to this is the patient experiencing an acute phase of viral myositis or rhabdomyolysis, whose muscles may be very sensitive to either movement or touch. Percussion of muscle may produce the phenomenon of myotonia, in which a localized contraction of the muscle persists for some seconds after percussion. This is best noted percussing the thenar eminence and watching for a delayed relaxation of the thumb abductors. This phenomenon, which is characteristic of myotonic dystrophy and myotonia congenita, is to be distinguished from myoedema, which is found occasionally in patients with thyroid disorders and other metabolic problems. In myoedema, the percussion is followed by the development of a dimple in the muscle, which then mounds to form a small hillock.

In addition to its diagnostic value, the presence of muscle contracture across a joint may cause disability, even in the absence of weakness. Thus an evaluation of range of morion at major joints is an important part of the cluneal examination. In a standard examination, contractures are evaluated at the fingers, elbows, wrists, hips, knees, and ankles. Wrist and finger flexor contractures can be evaluated only with the fingers extended; otherwise, the dorsiflcxion of the wrist is compensated for by flexion of the fingers. At the hips, both flexion and iliotibial band contractures should be evaluated.

Strength

Evaluation of individual muscle strength is an important part of the clinical examination. Many methods are available. Fixed myomctry has become popular with the research community. This uses a strain gauge attached to a rigid supporting structure, often integrated into the examining couch on which the patient lies. The patient then uses maximum voluntary contraction, which can be quantitated in Newtons. The merits of this method are debated, and for the average clinician, the expense of the machinery is prohibitive. In an office situation, and in many clinical drug trials, manual muscle testing gives perfectly adequate results and is preferable to fixed myometry in young children. It is based on the Medical Research Council grading system with some modification (Table 28.1).

Table 28.1: The Medical Research Council scale for grading muscle strength

0	No contraction
1	Flicker or trace of contraction
2	Active movement, with gravity eliminated
3	Active movement against gravity
4	Active movement against gravity and resistance
5	Normal power

This is adequate for use in an office situation, particularly if it is supplemented by the functional evaluation. A scale of 0-5 is used. Grade 5 is normal strength. A grade 5 is used only if the examiner is certain that a muscle is normal and should not be used for muscles that are slightly weak. Muscles that can move the joint against resistance may vary quite widely in strength; grades of 4+, 4, and 4— are often used to indicate differences, particularly between one side of the body and the other. Grade 4 represents a wide range of strength, from slight weakness to moderate weakness, which is a disadvantage. For this reason, the scale has been more useful in following the average strength of many muscles during the course of a disease, rather than the course of a single muscle. Averaging the scores of many muscles smooths out the stepwise progression noted in a single muscle and may demonstrate a steadily progressive decline in an illness. Grade 3+ is used when the muscle can move the joint against gravity and can exert a tiny amount of resistance but then collapses under the pressure of the examiner's hand. It is not used to denote the phenomenon of sudden give way, which occurs in conversion disorders and in patients limited by pain. Grade 3 indicates that the muscle can move the joint throughout its full range against gravity, but not against any added resistance. Sometimes, particularly in muscles acting across large joints like the knee, the muscle is capable of moving the limb partially against gravity, but not through the full range of movement. A muscle that cannot extend the knee horizontally when in a sitting position but can extend the knee to within 30-40 degrees of horizontal is graded 3—. Grades 2, 1, and 0 are as defined in Table 28.1.

Although it is commendable and sometimes essential to examine each muscle separately, most of us test muscle groups rather than individual muscles. In our clinic, we test neck flexion, neck extension, shoulder abduction, internal rotation, external rotation, elbow flexion and extension, wrist flexion and extension, finger abduction and adduction, thumb abduction, hip flexion and extension, knee flexion and extension, ankle dorsiflexion and plantar flexion, and dorsiflexion of the great toe.

Fatigue

Fatigue is a common symptom in many neuromuscular disorders and in many medical conditions. Anemia, heart disease, lung disease, cancer, poor nutrition, and depression are among the many disorders that can result in fatigue. However, in certain neuromuscular conditions, strength is normal at rest but progressively worsens with use. This most often occurs in the postsynaptic neuromuscular transmission disorders, especially myasthenia gravis. Repetitive or sustained muscle resting brings out true muscle fatigue. In patients with a suspected neuromuscular transmission disorder, fatigue should be formally tested. Ptosis may be provoked by sustained upgaze for 2-3 minutes. Counting out loud from 1-100 may result in the voice becoming slurred, nasal, or hoarse. Repetitively testing the strength of shoulder abduction or hip flexion may result in progressive weakness in patients with myasthenia gravis.

Reflexes

In disorders of the motor unit, reflexes are either normal, reduced, or absent. ALS is the exception because both UMN and LMN dysfunction coexist and hyperreflexia and spasticity often accompany signs of LMN loss. In neurogenic disorders, demyelinating conditions tend to lose reflexes early, as occurs in Guillain-Barre syndrome from blocking and desynchronization of muscle spindle afferents and motor efferents. Disorders resulting in axonal loss depress reflexes in proportion to the amount of axonal loss. As most axonal neuropathies predominantly affect distal axons, the distal reflexes (ankle reflexes) are depressed or lost early and the more proximal ones remain normal. In myopathies, reflexes tend to be diminished in proportion to the amount of muscle weakness. The same is true for postsynaptic neuromuscular transmission disorders. Presynaptic neuromuscular transmission disorders (e.g., Lambert-Eaton myasthenic syndrome) tend to have depressed or absent reflexes at rest that can be elicited after brief (10 seconds) periods of exercise.

Sensory Disturbances

Disorders of the motor unit are generally not associated with disturbances of sensation unless there is a second superimposed condition. Motor neuron disorders, neuromuscular transmission disorders, and myopathies generally follow this rule. Among the few exceptions is the minor sensory loss in patients with X-linked spinobulbar muscular atrophy (Kennedy's disease) and inclusion body myositis, in which some coexistent degeneration of the peripheral nerves and dorsal root ganglion cells may occur. In **the** paraneoplastic Lambert-Faton myasthenic syndrome, patients often have minor sensory signs reflecting a more widespread paraneoplastic process.

Sensory findings often accompany peripheral neuropathies that are predominantly motor and usually thought of

as motor ncuroparhies. These include the Guillain-Barre syndrome, multifocal motor neuropathy with conduction block, Charcot-Maric-Tooth disease, and some toxic neuropathies (e.g., lead). In these conditions, sensory abnormalities on examination and/or electrophysiological testing help identify the disorder as a neuropathy and thus limit the differential diagnosis.

Peripheral Nerve Enlargement

Palpation of peripheral nerves may yield important information in several neuromuscular conditions. Diffusely enlarged nerves occur in some patients with chronic demyclinating peripheral neuropathies, especially Charcot-Marie-Tooth disease type 1, Dejerine-Sottas disease, chronic inflammatory demyelinating polyneuropathy (CIDP), and Refsum's disease. In addition, nerves may be focally enlarged in the presence of a nerve sheath tumor (neurofibromatosis) or with infiltrative lesions (e.g., amyloidosis, leprosy). Nerves that are often easily palpated include the greater auricular nerve in the neck, the ulnar nerve at the elbow, 111L- superficial radial sensory nerve ;i\ il crosses the extensors to the thumb distal to the wrist, and the peroneal nerve at the fibular head at the knee.

Fascicurations, Cramps, and Other Abnormal Muscle Movements

All limbs should be examined to determine the presence or absence of fascicular ions. Fasciculations are brief twitches caused by the spontaneous firing of one motor unit. Fasciculations may be difficult or impossible to see in infants or obese individuals. They can be present in normal people, so their presence in the absence of wasting or weakness is probably of no significance (benign fasciculations). Fasciculations that are widespread and seen on every examination may indicate denervating disease, particularly anterior horn cell disease. Mental or physical fatigue, caffeine, cigarette smoking, or drugs such as amphetamines exacerbate fasciculations. Patients whose fasciculations appear benign should be re-evaluated after avoiding exposure to exacerbating factors. Abundant fasciculations may be difficult to differentiate from myokymia, which is a more writhing, bag of worms-like motion of muscle. Myokymia is caused by repetitive bursting of a motor unit (i.e., grouped fasciculations) and is characteristically associated with certain neuromuscular conditions (e.g., radiation injury and Guillain-Barre syndrome).

Similar to fasciculations, cramps may be a benign phenomenon or accompany a variety of neuropathic conditions. Cramps are painful and occur when a muscle is contracting in a shortened position. During a cramp, the muscle becomes hard and well defined. Stretching the muscle relieves the cramp. Superficially, a muscle contracture that occurs in a metabolic myopathy may resemble a cramp, although it is completely different on electrophysiological testing. Electrical silence occurs during a contracture and numerous motor units fire at high frequencies during a cramp.

Functional Evaluation of the Weak Patient

Walking

Gait is altered by weakness of muscles of the hip and back, leg, and shoulder. In normal walking, when the heel hits the ground, the shock is taken up by the action of the hip abductors, which stabilize the pelvis. In a sense, the hip abductors act as shock absorbers; their weakness disturbs the normal fluid movement of the pelvis during walking so when the heel hits the ground, the pelvis dips to the other side; when the weakness is bilateral, this results in a waddle. Additionally, weakness of the hip extensors and back extensors makes it difficult for the patient to maintain a normal posture. Ordinarily the body is carried so the center of gravity is slightly forward of the hip joint. To maintain an erect posture, the hip and back extensors are in continual activity. If these muscles become weak, the patient often throws the shoulders back so the weight of the body falls behind the hip joints. This accentuates the lumbar lordosis. Alternatively, if there is much weakness of the quadriceps muscles, the patient stabilizes the knee by throwing it backward. When the knee is hyperextended, it is locked; it derives its stability from the anatomy of the joint, not from the support of the muscles. Finally, weakness of the muscles of the lower log may result in a steppage gait, in which dorsiflexion of the foot is affected by a short throw at the ankle midswing. The foot is then brought rapidly to the ground before the toes fall back into plantar flexion. Shoulder weakness may be noted as the patient walks; the arms hang loosely by the sides and tend to swing in a pcndular fashion, rather than with a normal conrrolled swing.

Arising from the Floor

The normal method for arising from the floor depends, to a certain extent, on the age of the patient. The young child can spring rapidly ro his or her feet without the average-observer being able to dissect the movements. The elderly patient may turn to one side, place a hand on the floor, and rise to a standing position with a deliberate slowness. In spite of this vatiability, abnormalities caused by muscle weakness are easily detected. The patient with hip muscle weakness will turn to one side or the other to put the hand on the floor for support. The degree of turning is proportional to the severity of the weakness. Some patients have to turn all the way around until they are in a prone

position before they draw their feet under them to begin the standing process. Most people arise to a standing position from a squatting position, but the patient with hip extensor and quadriceps muscle weakness finds it easier to keep the hands on the floor and raise the hips high in the air. This has been termed the *butt-first maneuver;* the patient forms a triangle, with the hips at the apex and the base of support provided by both hands and feet on the floor, and then laboriously rises from this position, usually by pushing on the thighs with both hands to brace the body upward. The progress of recovery or progression of weakness can be documented by noting whether the initial turn is greater than 90 degrees, whether unilateral or bilateral hand support is used on the floor and thighs, whether this support is sustained or transitory, and whether there is a butt-first maneuver. The entire process is known as *Gower's maneuver,* but it is useful to break it up into its component parts (Figure 28.5).

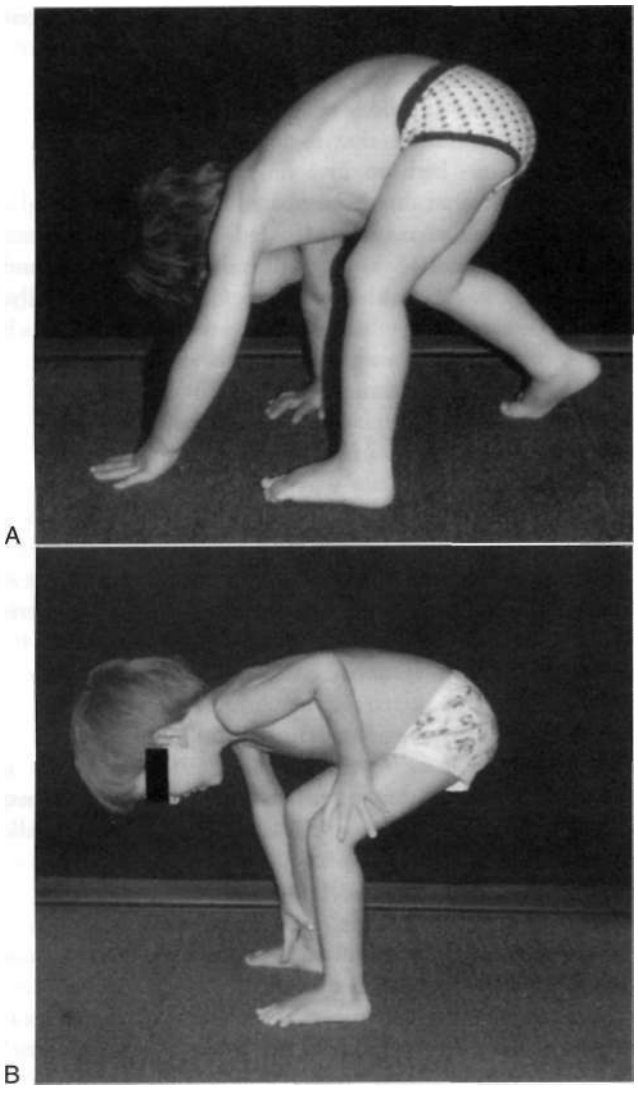

FIGURE 28.5 Gowers' maneuver. (A) Butt-first maneuver as the hips are hoisted in the air. (B) Hand support on the thighs.

Stepping onto a Stool

For a patient with hip and leg weakness, stepping onto an 8-inch-high footstool is equivalent in difficulty to a normal person's stepping onto a table. This analogy is apt because similar maneuvers are performed in both cases. Whereas the patient with normal strength readily approaches a footstool and easily steps onto it, the patient with weakness often hesitates in front of the stool while contemplating the task, There then occurs a curious little maneuver that is known colloquially as the *fast-foot maneuver.* Normal individuals can easily take the weight of their body on one leg, straightening out the knee as they stand on the footstool. Patients with weakness feel unsafe. They like to get both feet under them before straightening the knees and arising to their full height. To accomplish this, they place one foot on the footstool. While the knee of this leg is still bent, they quickly transfer the other foot from the floor to the footstool and then straighten the knees. This gives the impression of a hurried transfer of the trailing foot from floor to footstool, hence the name *fait foot.* As the weakness increases, the pelvis may dip toward the floor as the leading leg takes up the straiti and the patient's weight is transferred from the foot on the floor to the foot on the stool, the so-called *hip dip.* Finally, if the weakness is severe, patients may either use hand support on the thighs or gather themselves in and throw their bodies onto the footstool. Analysis of the various components, the hesitation, fast foot, hip dip, and throw, together with the presence or absence of hand support, may provide a sensitive measure of changes in an illness.

Psychogenic Weakness

An experienced examiner should be able to differentiate real weakness from psychogenic weakness. The primary characteristic of psychogenic weakness is that it is unpredictable and fluctuating. Muscle strength may suddenly give out when being evaluated. The patient has a difficult time knowing exactly how much strength is expected and therefore cannot adequately counter the examiner's resistance. This gives rise to a wavering, collapsing force. Tricks may be used to bring out the discrepancy in muscle performance when the patient is being tested and not aware of being observed. For example, if the thigh cannot be lifted off the chair in *a* seated position because of weakness, then the legs should not be able to swing up onto the mattress when the patient is asked to sit on the examining table. When an examiner suspects that weakness of shoulder abduction is feigned, the patient's arm can be put in abduction, with the examiner's hand on the elbow, and the examiner can instruct the patient to push toward the ceiling.

At first, the downward pressure is kept very light and the patient is unable to move the examining hand toward the ceiling. However, the arm does not fall down either, and as the downward pressure is gradually increased, continued exhortation to push the examiner's hand upward results in increasing resistance to the downward pressure. The examiner ends up putting maximum weight on the outstretched arm, which remains in abduction. The examiner concludes that the strength is normal. Patients do not realize this because they believe that because they did not move the examiner's hand upward, they must be weak.

INVESTIGATING THE WEAK PATIENT

In the investigation of diseases of the motor unit, the most helpful tests are measurement of the serum concenrration of creatine kinase (CK), elec trod i a gnosis, and muscle biopsy, which are available to virtually all physicians. Genetic testing is being used increasingly for definitive diagnosis. In addition, if facilities are available, exercise testing can provide useful information.

Serum Creatine Kinase

The usefulness of measuring the serum CK concentration in the diagnosis of neuromuscular diseases is to differentiate between neurogenic disease, in which there may be normal or mild to moderate elevations of CK, and myopathics, in which the CK concentration is often markedly increased. Serial CK measurements may be used to follow the progress of the disease. Both of these uses have problems. Foremost is the determination of the normal level. A survey of 250 hospitals in Ontario, Canada, showed a surprising ignorance of the basic mechanisms involved in the test and the way in which normal values were derived. Some hospital laboratories were unaware that race, gender, age, and activity level must be taken into account in determining normal values. When blood samples are obtained from truly normal controls and not from inactive hospital patients who happen not to have overt muscle disease, the normal serum CK concentration is higher than anticipated. Furthermore, all studies on CK concentration show that values are affected by gender and race. A log transformation does much to convert this to a normal distribution curve, but even then the results are not perfect. In a survey of 1500 hospital employees, using carefully standardized methods, it was possible to detect three populations, each with characteristic CK values. The upper limits of normal (97.5 percentile) are as follows:

Black men only: 520 U/liter
Black women, non-black men: 345 U/liter
Non-black women: 145 U/liter

The non-black population included Hispanics, Asians, and whites. Because the upper limit is expressed as a percentile of the mean, it must be understood that by definition 2.5% of the normal population will be above that. Although this does not seem to be a large number, in a town of 100,000, it means that 2500 would be considered abnormal. The point is that the upper limit of normal CK concentration is not rigid and should be interpreted intelligently. The serum CK concentration can be useful in determining rhe course of an illness, although again judgment should be used because changes in CK values do not always mirror the clinical condirion. In treating inflammatory myopathies with immunosuppressive drugs Or corticosteroids, a steadily declining CK concentration is a reassurance, whereas concentrations that are creeping back up again when the patient is in remission are not.

Serum CK concentrations also can be used to determine whether an illness is monophasic. A bout of myoglobinuria may be associated with very high concentrations of CK. The concentration then declines steadily by approximately 50% every 2 days. This indicates that a single episode of muscle damage has occurred. Patients with CK concentrations that do not decline in this fashion or that vary from high to low on random days have an ongoing illness that should be treated as such. Interestingly, CK concentrations may be elevated as high as 10 times normal in patients with spinal muscular atrophy and occasionally in those with ALS (see Chapter 80). Finally, exercise may cause a marked elevation in CK, which usually peaks 12-18 hours after the activity but may occur days later. CK concentrations are more likely to increase in people who are sedentary and then undertake unaccustomed exercise than in a trained individual.

Electromyography

The EMG is an observer-sensirive study, and an experienced electromyographer is essential to interpret EMG correctly. The principles of EMG are discussed in Chapter 36B. The EMG may provide much useful information. An initial step in the assessment of the weak patient is determination of whether the disease is caused by a neuropathic, myopathic, or neuromuscular junction transmission disorder. Nerve conduction studies and needle electrode examination arc particularly useful for identifying neuropathic disorders and localizing the abnormality to anterior horn cells, roots, plexus, or peripheral nerve territories (see Chapters 80-82). Repetitive nerve stimulation and single-fiber EMG can aid in elucidating disorders of the neuromuscular junction. Needle electrode examination may help establish the presence of abnormal muscle activity, including acute and chronic denervation, myotonia, neuromyotonia, fascicular ions, cramps, and myokymia.

Muscle Biopsy

The use of muscle biopsy is important for establishing the diagnosis in most disorders of the motor unit. Histochemistry evaluation is available at most hospitals and is particularly useful, and electron microscopy may provide a specific diagnosis. An important newer aspect of the muscle biopsy is the analysis of the muscle proteins. Individual muscle proteins, including dystrophin, sarcoglycans, and other structural proteins, may be missing in specific illnesses, and diagnosis is definitive with these analyses.

The details of muscle biopsy are reviewed in Chapter 85, but a word about the selection of the muscle to be biopsied is appropriate here. In all biopsies, there is a risk of sampling error. Not all muscles are equally involved in any given disease, and it is important to select a muscle that is likely to give the most useful information. The gastrocnemius muscle, which is often chosen for muscle biopsy, is not ideal because it has the disadvantage of demonstrating type 1 fiber predominance in the normal individual and often shows denervation changes caused by minor lumbosacral radiculopathy. Also, it has more than its fair share of random pathological changes, such as fiber necrosis and small inflammatory infiltrates, even when no clinical suspicion of a muscle disease exists. For this reason, it is preferable to select either the quadriceps femoris or the biceps brachii if cither of these muscles is weak. Never perform a biopsy on a muscle that is the site of a recent EMG or intramuscular injection, because these produce focal muscle damage. If such a muscle has to be biopsied, allow at least 2-3 months after the procedure before performing the biopsy.

In the patient with a relatively acute (duration of weeks) disease, it is wise to select a muscle that is obviously clinically weak. In patients with long-standing disease, it may be better to select a muscle that is clinically fairly normal to avoid an end-stage muscle. Sometimes an apparently normal muscle is selected for biopsy. For example, in a patient who is suspected of having motor neuron disease and who has wasting and weakness of the arms with EMG changes of denervation in the arms but no apparent denervation of the legs, biopsy of the biceps muscle would show the expected denervation and would add no useful information. If a biopsy of a quadriceps muscle showed denervation, this would provide support for widespread denervation, supporting the diagnosis of motor neuron disease. However, if the biopsy from the quadriceps muscle was normal, this would make the diagnosis of ALS less likely, because even strong muscles in patients with ALS usually show some denervation. Biopsies are generally not indicated in patients with ALS, unless the diagnosis is in question.

Genetic Testing

The details of genetic testing and counseling are covered in Chapter 44. Genetic analysis has become a routine part of the clinical investigation of neuromuscular disease and in many situations has supplanted muscle biopsy and other diagnostic tests. This is a distinct advantage to the patient if a blood test may be substituted for a muscle biopsy. The use of genetic testing for diagnosis in an isolated individual implies that the gene is well characterized and that intragenic probes are available that allow the determination of whether the gene in question is abnormal. Examples of such abnormalities are deletions in the dystrophin gene seen in many cases of Duchenne's muscular dystrophy and the expansion of the triplet repeat in the myotonic dystrophy gene.

Linkage studies can be used when the location of the gene is known, but tests for mutations of the gene itself arc not available. The success of such studies depends on having probes that are close to the gene. By using these closely situated probes, one can often demonstrate that the individual is or is not carrying the part of the chromosome (in which ;ui involved gene must have occurred in another affected family member. For linkage studies to be successful, a sufficient number of family members must be available for testing, both with and without the illness, to allow an identification of the segment of the chromosome at fault. This type of study is hampered by the tendency of parts of the chromosome to become detached during mciosis and to be exchanged with parts of another chromosome, a phenomenon known as *recombination.* The closer the probe is to the actual gene, the less likely recombination is to separate them. Genetic counseling based on linkage studies is less likely to be successful when only one or two patients with the illness and few family members are available. It is difficult to keep up with the mushrooming list of genes known to be associated with neuromuscular diseases, and yet it is imperative if we are to provide suitable advice for our patients. Useful references arc found in the journal *Neuromuscular Disorders,* which carries a list of all known neuromuscular generic abnormalities each month, and the Web sites Online Mcndelian Inheritance in Man (www.ncbi.nlm.nih.gov/omim/) and GeneTests-GeneClinics(www.genetests.org),

Exercise Testing

Exercise testing may be an important part of the investigation of muscle disease, particularly in metabolic disorders. The two primary types of exercise tests that are used are forearm exercise and bicycle exercise. Forearm (grip) exercise has been designed ro provide a test of glycolytic pathways, particularly those involved in power exercise. Incremental bicycle ergometry gives additional information regarding the relative use of carbohydrates, fats, and oxygen.

Forearm exercise is performed according to several schedules. The traditional method is to ask the patient to

grip a dynamometer repetitively, with a blood pressure cuff on the upper arm raised above systolic pressure. If the work performed by rhe patient is sufficiently strenuous, the cuff is unnecessary, because the muscle is working at a level that surpasses the ability of blood-borne substances to sustain it. An adequate level of forceful exercise is maintained for 1 minute, and then venous blood is drawn at intervals after the exercise to monitor changes in metabolites. In the norma] individual, the energy for such short-duration work is derived from intramuscular glycogen. Lactate is formed when exercise is relatively anaerobic, as it is when the exercise is strenuous. Additionally, serum concentrations of hypoxanthinc and ammonia are elevated. Patients with defects in the glycolytic pathways produce normal to excessive amounts of ammonia and hypoxanthine, but no lactate. Patients with adenylate deaminase deficiency show the reverse situation; ncithet ammonia nor hypoxanthine appears, but lactate production is normal. In patients who cannot cooperate with the testing and whose effort is poor, neither lactate nor ammonia concentrations are very high.

In mitochondrial disorders and other instances of metabolic stress, the production of both lactate and hypoxanthine is excessive. More recently, a modification of the ischemic forearm test has been reported as a sensitive and specific screen fot mitochondrial disorders. During exercise in normal individuals, mitochondrial oxidative phosphotylation increases 100-fold from that measured during rest. In mitochondrial disorders, the disturbed oxidative phosphorylation results in an impaired systemic oxygen extraction. In one study, 12 patients with mitochondrial myopathy were compared with 10 patients with muscular dystrophy and 12 healthy subjects. Cubital venous oxygen saturation was measured after 3 minutes at 40% of maximal voluntary contraction of the exercised arm. Oxygen desaturation in venous blood from exercising muscle was markedly lower in patients with mitochondrial myopathy than in patients with othct muscle diseases and healthy subjects.

Incremental bicycle ergometry allows one to measure the oxygen consumption and carbon dioxide production associated with varying workloads. The patient pedals a bicycle at a steady rate. The workload is increased every minute or two. Excessive oxygen consumption for a given work level suggests an abnormality in the energy pathway in muscle. In addition, the respiratory exchange ratio (RER), the ratio of carbon dioxide produced to oxygen consumed, is characteristic for various fuel sources. Carbohydrate metabolism results in an RER of 1.0. Fat, on the other hand, has an RER of 0.7. The resting RFR in normal individuals is approximately 0.8. For complex reasons, at the end of an incremental exercise test, the RFR is often as high as 1.2 in the normal individual. Patients with disorders of lipid metabolism often have an unusually high RFR because they preferentially metabolize carbohydrates, whereas patients with disorders of carbohydrate metabolism may never increase RER to more than 1,0 because they preferentially metabolize lipids.

APPROACH TO THE PATIENT WITH WEAKNESS

Once it is established that a patient has weakness, either by history or examination, the clinical features may be so characteristic that the diagnosis is obvious. At other times, the clinician may be uncertain. Figure 28.6 displays an outline of diagnostic considerations based on the characteristics of the weakness, such as whether it is fluctuating or constant. The following sections amplify this approach,

Disorders with Prominent Ocular Weakness

In oculopharyngeal muscular dystrophy, a slowly progressive weakness of the eye muscles causing ptosis and external ophthalmoplegia is associated with difficulty in swallowing. This disorder is an autosomal dominant trait and does not seem to shorten life. A number of patients also have facial weakness and hip and shoulder weakness. Swallowing difficulty may become severe enough to necessitate gastrostomy tube placement.

The Kearns-Sayre syndrome is a distinctive collection of physical findings, including ptosis, extraocular muscle palsies, pigmentary degeneration of the retina, cerebellar ataxia, pyramidal tract signs, short stature, mental retardation, and cardiac conduction defects. These findings accompany an abnormality of the mitochondria in muscle and other tissues. It may be slowly progressive or nonprogressive.

In addition, several other disorders may display prominent extraocular muscle involvement. Among these is centronuclear myopathy, one of the congenital myopathics. However, this condition is not restricted to the eye muscles and has prominent involvement of the limbs as well. Lastly, myasthenia gravis often, and occasionally Lambert-Eaton myasthenic syndrome, presents with isolated ptosis or extraocular muscle weakness. A subset of patients with myasthenia gravis will never generalize to other muscles and remain in the restricted ocular group.

Disorders with Distinctive Facial or Bulbar Weakness

FSH muscular dystrophy may nor be noted until early adult life. Weakness of the face may lead to difficulty with whistling or blowing up balloons and may be severe enough to give rhe face a smooth, unlined appearance with an abnormal pout to the lips (Figure 28.7A). Weakness of the muscles around the shoulders is always seen, although the deltoid muscle is surprisingly well preserved and even pseudohypertrophic in its lower portion. When the patient attempts to hold the arms extended in front, winging of the scapula occurs that is quite characteristic. The whole scapula may slide upward on the back of the thorax. The inferomedial border always juts backward, producing the appearance of a triangle at right angles to the back, with the

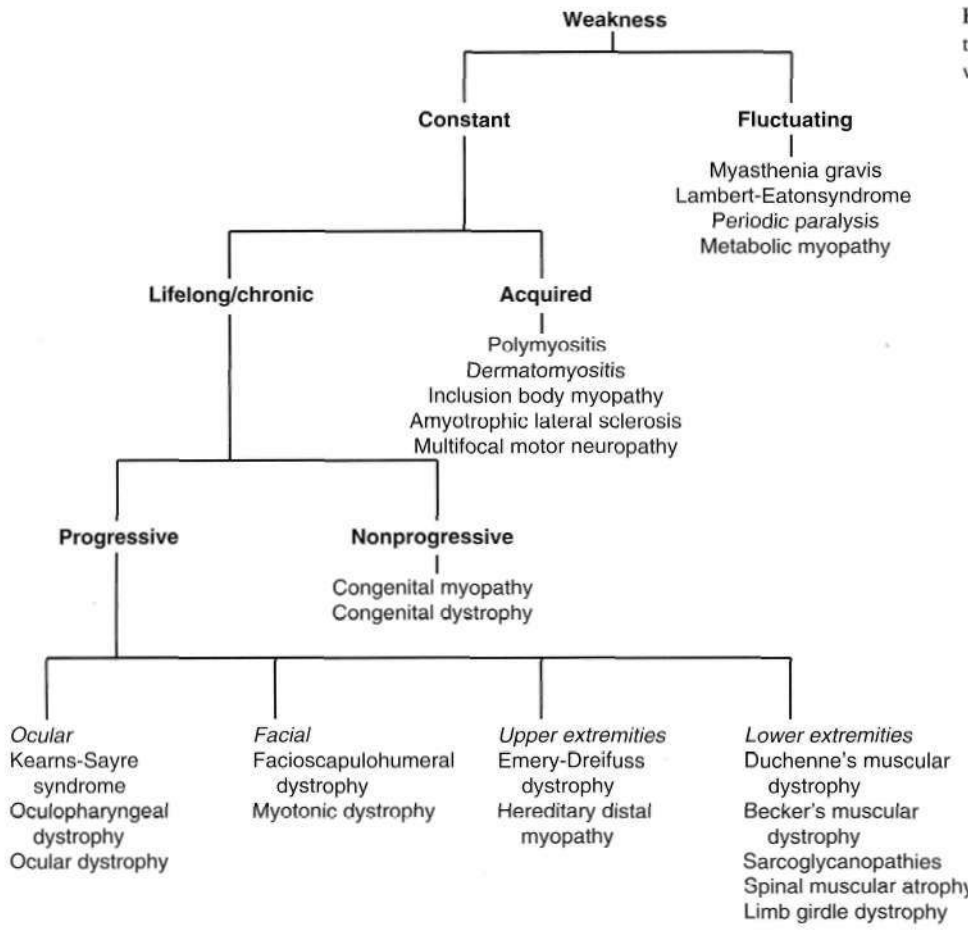

FIGURE 28.6 An algorithm for the approach to the patient with weakness.

base of the triangle still attached to the thorax. In addition, a discrepancy in power is often seen between the wrist flexors, which are strong, and the wrist extensors, which are weak. Similarly, the plantar flexors may be strong, whereas the dorsiflexors of the ankles are weak. It is common for the weakness to be asymmetrical, with one side much less involved than the other (Figure 28.8). The disorder is inherited as an autosomal dominant trait, although mild forms of the illness may be missed in the parents.

Myotonic dystrophy type I is a common illness with distinctive features, including distal predominance of weakness. It is inherited as an autosomal dominant trait, but often no family history is reported because the patients may be unaware that other family members have the illness. This is due to the phenomenon of anticipation, whereby successive generations are more severely affected, because of the expansion of the trinucleotide repeat. The diagnosis may be suspected in any patient with muscular dystrophy and predominantly distal weakness. The neck flexors and temporal and masseter muscles are often wasted. More charactetistic than the distribution of the weakness is the long, thin face with hollowed temples, ptosis, and frontal balding (Figure 28.7B). Percussion myotonia and grip myotonia are seen in most patients after age 13 years. An EMG can be diagnostic. Muscle biopsy may also show characteristic changes, and genetic testing shows the characteristic trinucleotide repeat in the myotonin gene on chromosome 19.

A subset of patients with ALS present with isolated bulbar weakness of LMN type (i.e., progressive bulbar palsy) or UMN type (i.e., progressive pseudobulbar palsy). Frequently the condition shows a combination of UMN and LMN involvement. In these patients, dysarthria, dysphagia, and difficulty with secretions are the prominent symptoms. On examination, the tongue is often atrophic and fasciculating (Figure 28.9), and the jaw and facial reflexes are exaggerated- The voice is often harsh and strained as well as slurred, reflecting the coexistent UMN and LMN dysfunction. In patients with X-linked spino-bulbar muscular atrophy {Kennedy's disease), bulbofacial muscles are also affected prominently. Patients often have a characteristic finding of chin fascial kit ions.

Disorders with Distinctive Shoulder-Girdle or Arm Weakness

In Emery-Dreifuss muscular dystrophy, an abnormal gene on the X chromosome produces wasting and weakness of muscles around the shoulders, upper arms, and lower part

FIGURE 28.7 Facial weakness is a prominent feature of both facioscapulohumeral dystrophy (FSH) and myotonic dystrophy. However, the characteristic features are so distinctive that they are readily recognizable and not easily confused. (A) The patient with FSH dystrophy is unable to purse his or her lips when attempting to whistle. (B) The typical appearance of a patient with myotonic dystrophy includes frontal balding, temporalis muscle wasting, ptosis, and faeial weakness. Related to F5H dystrophy is scapuloperoneal dystrophy, which has similar fearures but lacks the facial weakness. The two are differentiated because the scapuloperoneal distribution of weakness may be seen in some other congenital nonprogressive myopathies, which may lead to some confusion in the diagnosis.

of the legs, with contractures of the elbow, posterior neck, and Achilles tendon. Cardiac conduction abnormalities are **common,** and death may occur as a result of acute heart block.

Distal muscular weakness and atrophy are most commonly seen in neurogenic disorders. Among these **is** Charcot-Marie-Tooth disease, which is almost always characterized by distal weakness and wasting that starts

FIGURE 28.8 Asymmetrical scapular winging in facioscapulohumeral muscular dystrophy.

FIGURE 28.9 Tongue atrophy in a patient with amyotrophic lateral sclerosis. (Reprinted with permission from Katirji, B., Kaminski, H. J., Preston, D. C, et a1, eds, *Neuromuscular Disorders in Clinical Practice,* Buttcrworth-Heincmann, Boston.)

in the distal lower limbs before involving the hands. ALS often begins as weakness and wasting in one distal limb. More important because it is treatable is multifocal motor neuropathy with conduction block, a rare demyelinating polyneuropathy that may be confused clinically with I.iVIN ALS. The initial features are often weakness, hyporcflexia, and fasciculations, especially of the hands. Clues to the diagnosis are a slow indolent coutse, weakness out of proportion to the amount of atrophy, and asymmetrical involvement of muscles of the same myotome but with a different peripheral nerve supply (e.g., weakness of ulnar-innervated C8 muscles out of proportion to weakness of median-innervated C8 muscles). Benign focal amyotrophy (Sobue's syndrome) presents with the insidious onset of weakness and atrophy of the hand and forearm muscles, predominantly in men between the ages of IS and 22.

Two muscular dystrophies that are predominantly distal may affect the upper extremity: myotonic dystrophy, which has been discussed earlier in this chapter, and the hereditary distal myopathics. The hereditary distal myopathies are a heterogenous group of disorders. Welander's myopathy, transmitted as an autosomal dominant trait, is one of the more common forms. Ir has a predilection for the intrinsic hand and wrisr extensor muscles.

In the older individual, involvement of the finger flexors with relative preservation of the finger extensors is commonly seen in inclusion body myositis. However, in these latter cases, weakness is also prominent in the lower extremities, especially die quadriceps.

Disorders with Prominent Hip-Girdle or Leg Weakness

Although patients with these disorders often have more diffuse weakness, including arm and shoulder-girdle weakness, it is the hip and leg weakness that brings them to medical attention. Acute infantile spinal muscular atrophy (Werdnig-Hoffmann disease) is a severe and usually fatal illness with marked weakness of the limbs and respiratory muscles. Children with the intermediate form of spinal muscular atrophy (chronic Werdnig-Hoffmann disease or spinal muscular atrophy type 2) also are severely affected, rarely maintaining the ability to walk for more than a few years, so they are confined to a wheelchair in adult life. The progression of the illness is not steady; plateaus last for some years, interspersed with more rapid deterioration. Scoliosis is common. In the intermediate form of spinal muscular atrophy, a fine tremor of outstretched hands is characteristic.

In juvenile spinal muscular atrophy the muscle weakness is more severe proximally, and the term *pseudomyopatbic spinal muscular atrophy* has been applied. The illness begins sometime during the first decade of life, and patients walk well into the second decade or even into early adult life. Scoliosis is less common than in the infantile form.

The inherited muscular dystrophies cause progressive, nonfluctuating weakness. Duchenne's muscular dystrophy-is an X-linked recessive disorder associated with an absence of dystrophin. Clinically, the combination of proximal weakness that is greater than distal weakness with hypertrophic calf muscles and contractures gives the clue to the diagnosis. The serum CK concentration is markedly elevated, and the muscle biopsy is diagnostic (see Chapter 85}. The clinical features of Becker's muscular dystrophy are identical except for later onset and slower progression.

Severe childhood autosomal recessive muscular dystrophies, also known as *sarcoglycanopathies,* arc caused by deficiency in muscle of one of rhe dystrophin-associated glycoproteins (sarcoglycans) and have been linked to chromosomes 4, 5, 13, and 17. Severe childhood autosomal recessive muscular dystrophy is phenotypically similar to Duchenne's muscular dystrophy, including the calf hypertrophy, but affects both boys and girls. Cardiac involvement is rare, and mental retardation is not seen.

The limb-girdle dystrophies are a well-accepted diagnostic classification, despite their clinical heterogeneity. Weakness begins in the hips, shoulders, or both and spreads gradually to involve the rest of the limbs and the trunk. The diagnosis is often established by exclusion of everything else. The most helpful test is the muscle biopsy, which shows dystrophic changes, separating limb-girdle dystrophy from other (inflammatory) myopathies and from denervating diseases. Immunohistochcmical analysis of dystrophic muscle will further clarify the diagnosis, followed by genetic analysis of the sarcoglycan genes.

In patients with inclusion body myositis, the quadriceps and forearm ulnar finger flexor muscles are often preferentially involved. In some patients, this may be asymmetrical at the onset. The other inflammatory myopathies, polymyositis and dermatomyosiris, affect proximal, predominantly hip-girdle muscles in a symmetrical fashion, Though rare, the Lambert-Eaton myasthenic syndrome can also present with proximal lower extremity weakness, similar to a myopathy. Hyporeflexia and autonomic and sensory symptoms may suggest the diagnosis. EMG is often diagnostic.

Distal muscle weakness and atrophy are most often caused by neurogenic disorders. In Charcot-Marie-Tooth disease of both the demyelinating form (type 1) and the axonal form (type 2) the problem in the legs antedates that in the hands. In ALS, the weakness is often asymmetrical and may be combined with UMN signs.

As mentioned earlier, the last group is the hereditary distal myopathics. Distal leg weakness is usually the initial featute. Among these disorders are the Markesbcry-Griggs/Udd, Nonaka, and Laing myopathies, which affect anterior compartment muscles, and Miyoshi myopathy, which affects predominantly the posterior calf muscles.

Disorders with Fluctuating Weakness

The first step is to determine whether the weakness is constant or fluctuating. Even constant weakness may vary somewhat depending on how the patient feels. We are all capable of better physical performance on the days when wc feel energetic and cheerful and do less well on days when we are depressed or sick. Such factors also affect the patient with neuromuscular weakness. Specific inquiries should be made to determine how much variability exists. Is the fluctuation related to exercise or time of day? Symptoms and signs that are provoked by exercise imply a disorder in the physiological or biochemical mechanisms governing muscle contraction, l'ain, contractures, and weakness after exercise are often characteristic of abnormalities in the biochemistry of muscle contraction. Pathological fatigue is the hallmark of neuromuscular junction abnormalities.

Factors other than exercise may result in worsening or improvement of the disease. Some patients notice that fasting, carbohydrate loading, or other dietary manipulations make a difference in their symptoms. Such details may provide a clue to underlying metabolic problems. Patients with a defect in lipid-based energy metabolism are weaker in the fasting state and may carry a candy bar or sugar with them. The patient with hypokalemic periodic paralysis may notice that rest after a high-carbohydrate meal precipitates an attack.

Weakness that fluctuates markedly on a day-to-day basis or within .1 space of several hours is more often caused by a defect in neuromuscular transmission or a metabolic abnormality (e.g., periodic paralysis} than by one of the muscular dystrophics. Most neurologists recognize that the cardinal features of myasthenia gravis arc ptosis, ophthalmoparesis, dysarthria, dysphagia, and proximal weakness (see Chapter 84). On clinical examination, the hallmark of myasthenia gravis is pathological fatigue. Normal muscles fatigue if exercised sufficiently, but in myasthenia gravis, fatigue occurs with little effort. Failure of neuromuscular transmission may prevent maintenance of the arms in an outstretched position for more than a few seconds or maintenance of sustained upgaze. One of the problems with the diagnosis of myasthenia is that the patient may be relatively normal when examined in the office; the history and ancillary studies (acetylcholine receptor antibodies and EMG with repetitive stimulation or single-fiber EMG) must be relied on to establish the diagnosis.

In the Lambert-Eaton myasthenic syndrome, fluctuating weakness may also occur but is less marked than in myasthenia gravis. Weakness of the shoulder and especially the hip girdle predominates, with the bulbar, ocular, and respiratory muscles relatively spared. There are exceptions to this latter rule, with few patients with Lambert-Eaton myasthenic syndrome mimicking myasthenia gravis. Reflexes are typically reduced or absent at test. After a brief exercise, weakness and reflexes are often improved {facilitation), which is the opposite of the situation in myasthenia gravis. The electrophysiological correlate of this phenomenon is the demonstration of a marked incremental response to rapid, repetitive nerve stimulation. The underlying pathophysiology of Lambert-Easton myasthenic syndrome is an autoimmune or paraneoplastic process mediated by anti-voltage-gated calcium channel antibodies; commercial testing for these antibodies is available.

Patients with periodic paralysis note attacks of weakness, typically provoked by rest after exercise (see Chapter 85), In the primary periodic paralyses, the disorder is inherited as an autosomal dominant trait, secondary to a sodium or calcium channel defect (see Chapter 70), In the hyperkalemic (sodium channel) form, patients experience weakness that may last from minutes to days, beginning in infancy to early childhood, which is provoked by rest after exercise or potassium ingestion. Potassium levels are generally high during an attack. In the hypokalemic (calcium channel) form, weakness may last hours to days, is quite severe, beginning in the early teens, and is provoked by rest after exercise or high-carbohydrate ingestion. Potassium levels are generally low during an attack. In both types, patients may become totally paralyzed, although notably sparing bulbofacial muscles. Rarely, respiratory muscles are affected in hypokalemic periodic paralysis. Patients with paramyotonia congenita may also experience attacks of weakness, especially in the cold.

Disorders Exacerbated by Exercise

Fatigue and muscle pain provoked by exercise, the most common complaints in the muscle clinic, are often unexplained, and diagnoses such as fibromyalgia and the aches, cramps, and pain syndrome are used to cloak our ignorance (see Chapter 29). Biochemical defects are being found in an increasing number of patients with exercise-induced fatigue and myalgia. The metabolic abnormalities that impede exercise are disorders of carbohydrate metabolism, lipid metabolism, and mitochondrial function. The patient's history may give some clue to the type of defect.

Fatty acids provide the main source of energy metabolism for resting muscle. The initiation of vigorous exercise requires the use of intracellular stores of energy, because blood-borne metabolites are initially inadequate. It takes some time for the cardiac output to increase, for capillaries to dilate, and for the blood supply to muscle to be increased, and .111 even longer time for fat stores in the body to be mobilized so the level of fatty acid increases in the blood. Muscle must use its glycogen stores in this initial phase of heavy exercise. Thus defects of glycogen metabolism cause fatigue and muscle pain in the first few minutes of exercise. As exercise continues in the normal individual, the blood supply increases, resulting in an increased supply

of oxygen, glucose, and fatty acids. After 10-15 minutes, the muscle begins to use a mixture of fat and carbohydrate. The use of carbohydrate cannot be tolerated for long periods, because it would deplete the body's glycogen stores and might result in hypoglycemia. After 30-40 minutes of continued endurance exercise, the muscle is chiefly using fatty acids as an energy source. Patients with a defect of fatty acid metabolism can exercise in the initial phase easily but may become incapacitated with endurance exercise lasting 30-60 minutes. Similarly, in the fasting state, the body is more dependent on fatty acids, which it uses to conserve glucose. Thus the patient with a disorder of fatty acid metabolism may complain of increased symptoms when exercising in the fasting state. Ingestion of a candy bar may give some relief, because this boosts the blood sugar level. Patients with fatty acid metabolism defects often have well-developed muscles, because their favorite exercise is relatively intense, brief power exercise, such as weight lifting,

Disorders of mitochondrial metabolism are varied in presentation. In some types, recurrent eneephaloparhic episodes occur, often noted in early childhood and resembling Reye's disease (see Chapter 69). In others, there is particular weakness of the extraocular and other skeletal muscles. In some types, usually affecting young adults, the symptoms are predominantly of exercise intolerance. Defects occur in the electron transport system or cytochrome chain that uncouples oxygen consumption from the useful production of adenosine triphosphate. This causes metabolic pathways to run at their limit, even to keep up with the demands of a light exercise load. Resting tachycardia, high lactic acid levels in the blood, excessive sweating, and other indications of hypermetabolism are noted. This may lead to an erroneous diagnosis of hyperthyroidism. It is always worth measuring the scrum lactic acid concentration if a mitochondrial myopathy is suspected. In addition to lactate, ammonia and hypo-xanthine concentrations also may be elevated. Patients with suspected metabolic defects require forearm exercise and bicycle exercise tests. Myoglobinuria may occur during an exercise test, so the patient should be cautioned about the possibility.

Disorders with Constant Weakness

With constant weakness, the course is one of stability or steady deterioration. Without treatment, the periods of sustained, objective improvement or major differences in strength on a day-to-day basis are lacking. The division of this group into subacute and chronic also needs clarification. *Subacute* means that weakness appeared over weeks to months in a previously healthy person. In contrast, *chronic weakness* implies a much less definite onset and prolonged course. Although the patient may say that the weakness came on suddenly, a careful history elicits symptoms that go back many years. This division is not absolute. Patients with polymyositis, usually a subacute disease, may have a slow course, mimicking a muscular dystrophy. Patients with a muscular dystrophy may have a slow decrease in strength but suddenly lose a specific function, such as standing from a chair or climbing stairs, and believe their disorder to be acute.

Acquired Disorders Causing Weakness

Acquired disorders producing weakness are usually either motor neuron diseases, inflammatory, toxic, or endocrine disorders of muscle, neuromuscular transmission disorders, or peripheral motor neuropathies. The first task is to determine whether the weakness is neuropathic, myopathic, or secondary to a neuromuscular transmission defect. In some cases, this is straightforward clinically; in others, it may be very difficult. For instance, some cases of predominantly LMN ALS may mimic inclusion body myositis; Lambert-Easton myasthenic syndrome may mimic polymyositis. If fasciculations are present, the disorder must be neuropathic. If reflexes arc absent and clearly out of proportion to muscle bulk, one should suspect a demyelinating neuropathy, although presynaptic neuromuscular junction disorders may also have hypore-flexia. The presence of sensory signs or symptoms, even if mild, may indicate a peripheral neuropathy or involvement of the CNS. Often, serum CK concentration, EMG, and sometimes muscle biopsy are needed to separate these conditions.

ALS is the most common presentation of an acquired motor neuron disease. Although more common in the 55-65-year-old age-group, it can occur at any adult age. It often follows a relatively rapid course, often preceded by cramps and fasciculations. Examination shows wasting and often widely distributed fasciculations. If the bulbar muscles are involved, difficulty with swallowing and speaking are also present. The diagnosis is relatively simple if unequivocal evidence of UMN dysfunction accompanies peripheral wasting and fasciculations. These signs include slowness of movement, hyper-reflexia, Babinski's signs, and spasticity. A weak wasted muscle, associated with an abnormally brisk reflex, is almost pathognomonic of ALS. The electrophysiological diagnosis is supported by the finding of widespread denervation on needle electrode examination in the absence of any sensory abnormalities or demyelinating features on nerve conductions. In all patients without bulbar involvement, it is important to rule out spinal pathology because the combination of cervical and lumbar stenosis may occasionally mimic the clinical and electrophysiological findings of ALS. In patients with only LMN dysfunction, it is essential to exclude the rare diagnosis of multifocal motor neuropathy with conduction block, a condition that is usually treatable with intravenous gammaglobulin. Parients with multifocal motor neuropathy with conduction block

usually have no bulbar features or UMN signs and have characteristic findings of demyelination (i.e., conduction block) on motor nerve conductions. Although most adults with motor neuron disease have ALS or one of its variants, sporadic forms of adult-onset spinal muscular atrophy and especially X-linked spinobulbar muscular atrophy (Kennedy's disease) can occur as well. In these cases, the progression of weakness is much slower and UMN involvement is absent. Of importance, these latter cases, especially Kennedy's disease, often have elevated CK levels in the 500-1500 range.

If the patient is shown to have an acquired myopathy, one must consider inflammatory myopathies, including polymyositis, dermatomyositis, or inclusion body myopathy, in addition to a large number of toxic, drug-induced, and endocrine disorders. Inflammatory myopathies, as exemplified by polymyositis, often run a steadily progressive course, although some fluctuation may be noted, particularly in children. If an associated skin rash is present, there is little doubt about the diagnosis of dermatomyositis. In its absence, polymyositis may be difficult to differentiate from any of the other causes of proximal weakness. Sometimes the illness occurs as part of an overlap syndrome, in which fragments of other autoimmune diseases, such as scleroderma, lupus, or rheumatoid arthritis, are involved. Polymyositis is sometimes difficult to differentiate from a limb-girdle muscular dystrophy, even after a muscle biopsy; some inflammatory changes may be seen in the latter. Other signs of systemic involvement, such as malaise, transient aching pains, mood changes, and loss of appetite, are more common in polymyositis than in limb-girdle dystrophy.

Inclusion body myopathy also may mimic polymyositis clinically. More often it may mimic LMN ALS. Clues to the diagnosis are male gender, age older than 40 years, slower progression, and characteristic involvement of certain muscles, especially the quadriceps and long finger flexors. Some patients may have proximal muscle weakness, similar to polymyositis, whereas others may have predominantly distal weakness mimicking ALS and other neuropathic conditions. Scrum CK is generally elevated but may occasionally be normal. Like other chronic inflammatory myopathics, the interpretation of the EMG study may be difficult and requires an experienced examiner, because inclusion body myopathy often shows a combination of myopathic and neuropathic features. Inclusion body myopathy, unlike polymyositis, is often unresponsive to immunosuppressive therapy and has rimmed vacuoles and intracytoplasmic and intranuclear filamentous inclusions in muscle fibers on biopsy.

Toxic, drug-induced, and endocrine disorders must always be considered in acquired myopathies. Among toxins, alcohol is still the most common and may produce both an acute and a chronic syndrome. A large number of prescription medicines are associated with myopathies. Most prominent are corticosteroids, cholesterol-lowering agents (the statins), and colchicine.

Although neuromuscular transmission disorders arc most often considered with disorders with fluctuating symptoms, the Lambert-Faton myasthenic syndrome may be an exception and often presents similar to a myopathy with progressive proximal lower extremity weakness. Clues to the diagnosis include a history of cancer, especially small cell lung cancer (although in many patients the myasthenic syndrome may predate the discovery of the cancer), hyporeflcxia, facilitation of strength and reflexes after brief exercise, and coexistent autonomic symptoms, especially urinary and sexual dysfunction in men.

Most peripheral neuropathies are easily separated from disorders of the motor unit by the presence of clear-cut sensory symptoms and signs. The notable exception is multifocal motor neuropathy with conduction block discussed earlier. Other neuropathies may also present with predominantly motor symptoms. Among these are toxic neuropathies (dapsone, vincristine, lead, acute alcohol-related neuropathy) and some variants of the Guillain-Barre syndrome (especially the acute motor axonal neuropathy syndrome).

Lifelong Disorders

Most patients in the neuromuscular clinic have lifelong or at least very chronic, presumably inherited disorders. These include inherited disorders of muscle (e.g., dystrophies, congenital myopathies), anterior horn cell (e.g., spinal muscular atrophies), peripheral nerves (e.g., Charcot-Marie-Tooth polyneuropathy), or very rarely neuromuscular transmission (e.g., congenital myasthenic syndromes). In some, the responsible genetic abnormality has been identified. An important point in the differential diagnosis is to determine whether the weakness is truly progressive. The examiner should ask questions until the progressive or nonprogressive nature of the disease is certain. The severity of the disease is often taken as proof of progression. It is difficult to imagine that a 16-ycar-old girl, confined to her wheelchair with spinal muscular atrophy and scoliosis and having difficulty breathing, has a relatively nonprogressive disorder, but careful questioning may show that there has been no loss of function for the last several years. Further, it is not sufficient to ask the patient in vague and general terms whether the illness is progressive. Questioning should be specific, such as "Arc there tasks that you cannot perform now that you could perform last week, month, or year?" One must also be alert for denial, which is common in young patients with increasing weakness. The 18-year-old boy with limb-girdle dystrophy-may claim to be the same now as in years gone by, but questioning may reveal that he was able to climb stairs well when he was in high school, whereas he now needs assistance in college.

Lifelong, Nonprogressive Disorders. Some patients complain of lifelong weakness that has been relatively

unchanged over many years. Almost by definition such disorders have to start in early childhood. Nonprogression of weakness does not preclude severe weakness. Later-life progression of such weakness may occur as the normal aging process further weakens muscles that have little functional reserve. One major group of such illnesses is the congenital nonprogressive myopathies, including central core disease, nemaline myopathy, and congenital fiber-type disproportion. The typical clinical picture in these diseases is that of a slender dysmorphic individual with diffuse weakness {Figure 28.10A). There may be associated skeletal abnormalities, such as high-arched palate, pes cavus, and scoliosis. Deep tendon reflexes are depressed or absent. Though unusual, severe respiratory involvement has been noted in all of these diseases. The less severe (non-X-1 inked) form of myotubular (centronuclear) myopathy may be suspected because of the occurrence of ptosis, extraocular muscle weakness, and facial diplegia. Muscle biopsy usually can be relied on to provide the diagnosis in the congenital myopathies.

Several varieties of congenital muscular dystrophy are recognized. The weakness in congenital muscular dystrophy is usually severe, contractures are prominent, and there may be associated findings. For example, in Fukuyama's muscular dystrophy, there are associated mental retardation and seizures. Other signs of damage to the CNS may be present, such as increased tendon reflexes and extensor plantar responses. Most patients with Fukuyama's dystrophy are severely disabled, both physically and intellectually. The serum CK concentration may be elevated markedly. The muscle biopsy is different from that in the congenital nonprogressive myopathies and shows fiber necrosis with fibrosis and phagocytosis.

There are also patients whose biopsies show dystrophic changes but whose illnesses are much milder. One such illness has been termed *stick man dystrophy* because of the almost skeletal appearance of the limbs, with severely atrophic muscles (Figure 28.10B). Although there is diffuse weakness, the atrophic muscles generate more force than one would expect on the basis of their bulk. Patients also

B

FIGURE 28.10 The patient with a congenital myopathy is slender, without focal atrophy. Shoulder-girdle weakness is apparent from the horizontal scr of rhe clavicles. (B) The patient with congenital muscular dystrophy of the "stick man" type is distinguished by his skeletal appearance and the presence of the prominent contractures.

have severe heel cord contractures and often have contractures of the posterior cervical muscles.

Lifelong Disorders Characterized by Progressive Weakness. Most diseases in this category are inherited progressive disorders of anterior horn cells, peripheral motor nerve, or muscle. Among these are the spinal muscular atrophies, Charcot-Marie-Tooth polyneuropathies, and muscular dystrophies. Mild day-to-day fluctuations in strength may occur, but the overall progression is steady (i.e., the disorder is slowly progressive from the start and it remains that way); it will not suddenly change course and become rapidly progressive. As mentioned earlier, patients may experience long periods of stability when their disease is seemingly nonprogressive.

Attempts to categorize disorders have traditionally been based on whether the disorder was caused by anterior horn cell, peripheral motiir nerve, or muscle disease, along with .1 specific pattern of muscle weakness. Certain characteristic patterns of weakness often suggest specific diagnoses. For example, FSH and oculopharyngeal muscular dystrophies are so named because of their selective involvement of muscles. In the modern day, all of these disorders are being further redefined and categorized based on their specific genetic abnormality and in some the specific structural protein the involved gene encodes.

Other Conditions

No scheme of analysis is perfect in clinical medicine, and many exceptions exist to the guidelines provided earlier. Most notable are disorders that are restricted to various parts of the body. The etiology and the reasons for such localized illness are not clear, but examples include branchial myopathy and quadriceps myopathy, as well as the focal form of motor neuron disease, which often remains in one segment of the body for years to decades (benign monomelic amyotrophy). These diseases are often "benign" in that they do not shorten life. The weakness may cause disability, although it is usually mild.

Chapter 29
Muscle Pain and Cramps

Waqar Waheed and Alan Pestronk

Pain is an uncomfortable sensation with sensory and emotional components. Short episodes of muscle pain or discomfort are a universal experience. Common causes of short-term muscle discomfort are unaccustomed exercise, trauma, cramps, and systemic infections. Chronic muscle discomfort is also relatively common. In the U.S. population between the ages of 25 and 74 years, 10-14% complain of chronic pain rehired to the joints and musculoskeletal system. Pain localized to muscle may be caused by noxious stimuli in muscle but also may be referred from other structures, including connective tissue, joints, and bone. The referral of pain may involve secondary contraction of muscle during the pain or indirect neural activation evoked by the noxious stimulus. Some patients with small-fibet polyneuropathies have spontaneous pain that is localized to muscle.

Pain in muscle and other tissues can be categorized according to temporal and qualitative features. Pain elicited by noxious stimulation of normal tissue has an early ("first") phase that is perceived as sharp and well localized and that lasts as long as the stimulus. This is followed by a somewhat delayed ("second") phase of pain that is dull, aching or burning, and more diffuse. Second-phase pain has both sensory and affective components and may predominate with visceral and chronic pain. Pain from stimulation of diseased tissue is often associated with *hyperalgesia,* in which a noxious stimulus produces an exaggerated pain sensation, or with *allodynia,* in which pain is induced by a normally innocuous stimulus. Neuropathic pain is associated with incteased activity in abnormal afferent axons and occurs spontaneously or after peripheral stimuli.

MUSCLE **PAIN:** BASIC CONCEPTS

Nociceptors

Many of the afferent nerve fibers that transmit painful stimuli from muscle (nociceptors) have small unmyelinated (free) axon terminals (Graven-Nielsen and Mense 2001; Julius and Basbaum 2001). These terminal axons (nerve endings) are mainly located near blood vessels and in connective tissue but do not contact muscle fibers. Free nerve endings have a small diameter (0.5 *jim)* with varicosities (expansions). They contain glutamate and neuropeptides. Noxious stimuli produce graded receptor potentials in nerve endings, with the amplitude dependent on strength of the stimulus. If the amplitude is large enough to reach threshold, an action potential is generated. Action potentials arising in nociceptor terminals play two roles in inducing pain. Direct centripetal conduction along afferent axons brings nociceptive signals to the central nervous system (CNS). Indirect effects occur when action potentials are conducted centrifugally, invading other nerve terminals, which then release glutamate and neuropeptides into the extracellular medium. These algesic substances can stimulate or sensitize terminals on other nociceptive axons.

Nociceptor Stimulation and Sensitization

Muscle pain is induced by chemical or mechanical stimuli. The specific chemical factors that are involved in the peripheral generation of pain arc better defined in tissues other than muscle. Intramuscular injections of hypertonic saline arc used experimentally to induce pain that is similar to acute clinical muscle pain, without producing associated morphological abnormalities in muscle. Increased levels of glutamate in muscle correlate temporally with the appearance of pain due to hypertonic saline and after exercise. Other possible chemical algesic stimuli in muscle include ions (acid pH and potassium |high|), and neurotransmitters (adenosine triphosphate |ATP|, bradykinin, 5-hydroxytryptamine [5-HT], and adrenaline).

Sensitization of nociceptive axon terminals is defined as reduction, into the innocuous range, of the threshold for their stimulation. Vanilloid receptors and tetrodotoxin-rcsistant sodium channels can play roles in the sensitization of nerve terminals. The reduction in threshold of axon

terminals is induced by factors released during muscle damage or repetitive stimulation. Stimuli implicated in the sensitization of terminals include algesic substances (5-HT, prostaglandin E_z [$PGE_2$1, and bradykinin), nerve growth factor, and repeated stimulation {heat, protons, or capsaicin via vanilloid receptors). Effects of stimuli may be mediated intracellularly by calcium and kinases. Sensitization of nociceptor terminals can increase the frequency of action potentials in normally active nociceptors or induce new action potentials in a population of normally silent small axons that is especially prominent in viscera. Substance P induces a low-frequency discharge in afferent axons that could contribute to spontaneous pain. Lcukotriene D_4 may have a desensitizing effect on muscle nociceptors. The depression of muscle nociceptor activity by aspirin may reflect inhibition of the effects of PGE_2.

Afferent Axons Involved in Nociception

AS group III and C group IV class axons play important roles in the conduction of pain-inducing stimuli from muscle to the CNS. The ability to detect acute noxious stimuli is largely eliminated by blockade of both *AS* and C class axons. *AS class nociceptive axons* are thinly myelinated, conduct impulses at moderately slow velocities (3-13 m per second), and have membrane sodium channels that are tetrodotoxin sensitive. AS axons are high-threshold medianoceptors that are stimulated by strong local pressure and mediate rapid, acute, sharp ("first") muscle pain. Spontaneous pain and dysesthesias are probably mediated by A3 class axons. C *class nociceptive axons* are unmyelinated, conduct impulses at very slow velocities (0.6-1.2 m per second), and have membrane sodium channels that are tetrodotoxin resistant. C class axons in muscle are often poly modal, responding to a range of stimuli, but stimulus-specific axon terminals are also present. C fibers mediate somewhat delayed, diffuse, dull, or burning ("second") pain evoked by noxious stimuli. Constituents of muscle nociceptor C axons include substance P, calcitonin gene-related peptide, and somatostatin. These constituents may place the nociceptive axons in a subgroup of C fibers that mediate hyperalgesia in response to inflammation. *AS class axons* are large and myelinated and conduct impulses at rapid velocities. They normally mediate innocuous stimuli and stimulation may reduce the perception of pain, liitlaiiiin.ivion or repetitive stimulation can sensitize *AS* axons, which then mediate mechanical allodynia in some tissues. This "phenotypic switch" in *AS* axons may be mediated by uprcgulation of neuropeptide Y and sprouting of terminals in the spinal cord from lamina III and IV into lamina II, with subsequent stimulation of ascending central pain pathways.

Central terminations of nociceptive axons from muscle are located in lamina I in the dorsal horn of the spinal cord. Ascending central neurons, with cell bodies in lamina I or II, are stimulated by glutamate from the terminals of primary afferent axons and convey sensory pain modalities via the contralateral spinothalamic tract to thalamic nuclei (Ren and Dubncr 2002). Transmission of affective features of pain may involve other pathways to the parabrachial nucleus, amygdala, thalamic intralaminar nucleus, and anterior cingulate gyrus. Inrerncurons and descending CNS pathways modulate afferent input, especially with chronic pain. Central sensitization to pain is associated with neurons containing substance-P receptors. Glutamate acting at N-mcthyl-D-aspartate (NMDA) receptors is essential for the initiation of central sensitization and for the hyperexcitability of spinal cord neurons and persistent pain. Facilitation via descending CNS pathways may lead to allodynia and the maintenance of hyperalgesia. Inhibitory descending pathways are associated with increased opioid sensitivity and may provide a system of endogenous analgesia. There is enhanced net descending inhibition at sites of primary hyperalgesia associated with inflammation.

Pathological Conditions Producing Muscle Pain

Episodes of pain originating in muscle are commonly associated with exercise, inflammation, and trauma. Exercise can produce muscle pain by several pathways, including exhaustion of fuel supply (with lack of training, vascular insufficiency, or metabolic detect-,;, cramps, or injury to muscle fibers or tendons. When muscle contracts while it is being stretched (eccentric contraction), damage and pain are especially likely. During exercise with eccentric contraction, the shearing forces on connective tissue may directly activate muscle nociceptors. Similar painful shearing forces occur during cramps, when the contracting segment stretches the remainder of the muscle. Delayed-onset muscle soreness (DOMS) may be due to several factors, including muscle fiber and connective tissue damage, inflammation, and edema. Pain with DOMS is associated with increased levels of glutamate in muscle.

In damaged muscles, tenderness, a decrease in pressure pain threshold, and pain with movement are due to sensitization of muscle nociceptors. The sensitized nociceptors have a lowered threshold of excitation and a greater response to noxious stimuli. With muscle inflammation, pain at rest may be due to nociceptive axons that develop a raised level of background discharge. Mediators of this phenomenon could include algesic substances including substance P, bradykinin, and serotonin. Pain during muscle ischemia may also be related to accumulation of algesic substances, but probably not to lactate accumulation. It has been suggested that myofascial (trigger-point) pain syndromes arc associated with hypercontraction of muscle fibers. However, this has not been well documented and the possible afferent pathway is unclear because muscle fibers are not innervated by nociceptive axons. A more objective

definition of clinical and pathophysiological features of myofascial and fibromyalgia syndromes would be helpful.

CLINICAL FEATURES OF MUSCLE **PAIN**

General Fearures of Muscle Pain

Muscle discomfort is described using several different terms, including *pain, soreness, aching, fatigue, cramps,* or *spasms.* Pain that originates from muscle is perceived to arise from deep tissues. This property of muscle pain may reflect convergent afferent axons from various tissues that mask identification of a specific source by higher centers. Chronic muscle pain may be poorly localized, referred to another (usually deep) location, and associated with autonomic and affective symptoms. Pain with muscle cramps has an acute onset and short duration. Cramp pain is associated with palpable muscle contraction and is immediately relieved by stretching the muscle. Pain originating from fascia and periosteum is relatively precisely localized. Cutaneous pain differs from muscle or fascial pain by its distinct localization and sharp, pricking, stabbing, or burning nature. In fibromyalgia syndromes, patients commonly complain that fatigue accompanies their muscle discomfort. Depression is approximately twice as common in patients with chronic musculoskeletal pain (18%) than in a population without chronic pain (8%).

Evaluation of Muscle Discomfort

Disorders underlying muscle discomfort can be classified based on anatomy, temporal relation to exercise, muscle pathology, and the presence or absence of active muscle contraction during the discomfort {Kincaid 1997; Pestronk 2003). Evaluation of muscle discomfort typically begins with a history, including the type, localization, inducing factors and evolution of the pain, drug use, and mood disorders. The physical examination is conducted with special attention to the localization of weakness. However, accurate assessment of strength may be difficult in the presence of pain. The sensory examination is important because small-fiber sensory neuropathies commonly cause discomfort with apparent localization in muscle. A general examination is important to evaluate the possibility that pain may be arising from other tissues, such as joints. Blood studies may include a complete blood cell count, erythrocyte sedimentation rate, creatine kinase (CK), potassium, calcium, phosphate, and lactate levels, thyroid functions, and evaluation for systemic immune disorders. Urine myoglobin concentration should be evaluated in patients with a high CK level and severe myalgias, especially when they are related to exercise. Electromyography (EMG) is a sensitive test for myopathy. A normal EMG result suggests that muscle pain is arising from other anatomical loci. Nerve conduction evaluation may detect an underlying neuropathy, but objective documentation of small-fiber adenopathies can require quantitative sensory testing or skin biopsy with staining of distal nerve fibers (generally a research technique). Magnetic resonance imaging or radionuclide scans may reveal focal or diffuse anomalies in muscle, joints, or fascia and can be used to guide biopsy procedures. Phosphorous magnetic resonance spectroscopy may become useful in the evaluation and monitoring of some metabolic myopathies, but its specific utility is not yet determined. Muscle biopsy is most often useful in the presence of another abnormal test result, such as a high scrum lactate or CK level or an abnormal EMC. However, important clues to treatable disorders, such as fasciitis or systemic immune disorders (perivascular inflammation or granulomas), may be present in muscle in the absence of **other** positive testing. The yield of muscle biopsy in syndromes with muscle discomfort is increased if both muscle and connective tissue are examined. There is increased diagnostic yield from muscle biopsies if histochemistry includes staining **for** acid phosphatase, alkaline phosphatase, esterase, mitochondrial enzymes, glycolytic enzymes, and myoadenylate deaminase, in addition to routine morphological analysis and processing. **Ultra**-structural examination of muscle rarely provides additional information.

MUSCLE DISCOMFORT: SPECIFIC CAUSES

Muscle pain can he broadly divided into groups depending on its origin and whether it occurs at the time of muscle contraction. Myopathies may be associated with muscle pain without associated muscle contraction (myalgias) (Tables 29.1 and 29.2). Muscle pain during muscle activity (Tables 29.2 and 29.3) may occur with muscle injury, myopathy, cramps, or long-term tonic contraction. Some pain syndromes that are perceived as arising from muscle originate in other tissues or have no clear morphological explanation for the pain (Table 29.4).

Myopathies with Muscle Pain

Myopathies that produce muscle pain (see Table 29,1) are usually associated with weakness, a high serum CK level, and an abnormal EMC; (Griggs, Mendel I, and Miller I 995; Pestronk 2003). Only a minority of inflammatory myopathies are associated with pain and muscle tenderness. Pain is a typical feature of childhood dcrmatomyositis, immune myopathies with systemic disorders, eosinophilia myalgia syndromes, and infections. Myopathies caused by infections, including bacterial, viral, toxoplasmosis, and trichinosis, are usually painful. Metabolic myopathics, including phosphorylase and carnitine palmitoyltransferase II deficiencies, typically produce muscle discomfort or fatigue

that arises toward the end or after the completion of exercise and is less prominent at rest. As a general rule, disorders of carbohydrate use produce pain and fatigue after short intense exercise, whereas lipid disorders cause muscle discomfort with sustained exercise. Rhabdomyolysis is usually associated with muscle pain and tenderness that can persist for days after the initial event. It may occur with a defined metabolic or toxic myopathy or sporadically, in the setting of unaccustomed exercise, especially with hot weather. Because rhabdomyolysis may produce renal failure—a life-threatening complication—diagnosis, treatment, and avoidance of further precipitating factors should be aggressively pursued. Medications, including "'*[s]-aminocaproic acid and cholesterol-lowering agents, may produce a painful necrotic myopathy that can be associated with rhabdomyolysis. Muscular dystrophy and mitochondrial disorders are usually painless, but a small proportion of patients, including some with mild Becker's muscular dystrophy with minimal or no weakness, may experience myalgias and cramps or rhabdomyolysis. Several myopathies defined by specific morphological or physiological changes in muscle commonly have myalgias or exercise-related discomfort as part of their associated clinical syndrome. Features of these myopathies include tubular aggregates with or without cylindrical spirals, focal depletion of mitochondria, internalized capillaries, and proximal myotonic myopathy (myotonic dystrophy type 2, DM2).

Muscle Overuse Syndromes

Cramps (see Table 29.3) are a localized form of muscle contraction and overuse. Pain syndromes associated with cramps include discomfort during a muscle contraction and soreness after the contraction due to muscle injury. Cramps

Table 29.3: Cramps*

- Cramp syndromes
  - Ordinary
    - Common in normal subjects, especially gastrocnemius
    - Pregnancy
  - Systemic disorders

""Usual features: muscle pain; may interfere with effort, but no true weakness; present at rest, may increase with movement; muscle morphology and serum creatine kinase level normal.

are common in normal people in the gastrocnemius muscle and in patients with fasciculations. They usually atisc duting sleep or exercise and are more likely to occur when muscle is contracted while in a shortened posirion. Relief of cramps is often obtained rapidly by stretching the affected muscle. Active stretching, by contracting the antagonist, may be especially effective treatment because it evokes reciprocal inhibition. Cramps that occut ftequcntly in muscles othet than the gastrocnemius usually herald an underlying neuromuscular disorder.

The EMG is useful for defining the specific type of cramp. Cramps of muscular origin include electrically acrive contractions, electtically silent contractures and myotonic types. Electrically active muscle cramps due to myopathy are manifest by itrcgular triphasic action potentials occurring at a rate of 40-60 Hz. They may be a feature of Becker's muscular dystrophy and thyroid disorders. Muscle contractures are active muscle contractions in the absence of electrical activity. These electrically silent muscle contractions occur in myophosphorylase deficiency and other glycolytic disorders, Brody's syndrome, rippling muscle disease, and hypothyroidism (myoedema). Contractures in myophosphorylase deficiency are typically provoked by exercise and may be prolonged and painful. Myotonia appears on EMG as repetitive bursts of action potentials in individual muscle fibers that last 1-30 seconds and have a variable frequency. The action potentials may be triggered by mechanical or electrical stimulation. Myotonic cramps are frequently not painful. Patients with recessive myotonia congenita often note fatigue.

Neurogenic cramps may arise from peripheral nerves or the CNS, They often ptoduce discomfort. The common muscle cramp usually arises from motor netve terminals. EMG shows irregular triphasic action potentials at 40-150 Hz that increase and then decrease during the course of the ctamp. Several drugs may precipitate cramps

(see Table 29.2). Muscle spasms are defined as intense painful muscle contractions that are more persistent than a cramp. There is often palpable tightness and resistance to movement in muscle. Occasionally there is distortion of posture. EMG shows tonic firing of motor unit action potentials. Neurogenic disorders that are associated with cramps, painful muscle spasms, or muscle discomfort include amyotrophic lateral sclerosis, neuromyotonia, spinal stenosis, stiff person syndrome, spasticity, restless legs syndrome, and focal dystonias. Treatment of cramps involves remedy of the underlying disorder or symptomatic trials of a variety of medications. Quinine was effective in treating nocturnal muscle cramps in a double-blind, placebo-controlled trial.

Diffuse muscle contraction syndromes are often related to CNS disorders associated with drugs or toxins (see Table 29.2). They include malignant hyperthermia, neuroleptic malignant syndrome, and toxic disorders related to phencyclidine, amphetamine, tetanus, and strychnine. Diffuse contraction syndromes produce great discomfort in the awake patient. In the postoperative period, myalgia and fasciculations often occur after the use of succinylcholinc (suxamethonium).

Myalgia Syndromes without Chronic Myopathy

Polymyalgia syndromes (see Table 29.4) are characterized by pain localized to muscle and other structures without muscle weakness. The pain may produce the appearance of weakness by preventing full effort. This type of "weakness" is characterized on examination by sudden reductions in the level of effort, rather than the smooth movement through the range of motion that is detected with true muscle weakness. Polymyalgic pain is often present at rest and is variably affected by movement. Serum CK levels and EMG are normal. There are no major pathological changes jn muscle unless the discomfort produces disuse and atrophy of type II muscle fibers. Muscle biopsies may show changes associated with systemic immune disorders, including inflammation around blood vessels or in connective tissue. Many polymyalgia syndromes have clear underlying disorders, including systemic immune disease, drug toxicity, and small-fiber polyneuropathies.

Some syndromes associated with muscle discomfort, such as polymyalgia rheumatica, fibromyalgia, and chronic fatigue syndrome, are defined by a series of clinical criteria and have no well-defined pathophysiology. Polymyalgia rheumatica usually occurs after age 50 years and manifests with pain and stiffness in joints and muscles, weight loss, and low-grade fever. The pain is symmetrical, involves the shoulder, neck, and hip girdle, and is greatest after inactivity and sleeping. Polymyalgia rheumatica can be associated with temporal arteritis. Patients often have an elevated erythrocyte sedimentation rate (>40 mm/hour). Pain improves within a few days after treatment with corticosteroids (prednisone, 20 mg/day). The diagnosis of fibromyalgia depends on a history of widespread musculoskeletal pain, most commonly around the neck and shoulders, for 3 months or more, and examination findings of tender points on the extremiries and trunk. Patients also may note fatigue and disturbed sleep, headache, irritable bowel syndrome, and aggravation of symptoms by exercise, anxiety, or stress. The diagnosis of chronic fatigue syndrome requires symptoms of muscle fatigue for at least 6 months. Myalgias, paresthesias, headache, dizziness, diaphoresis, fainting, and memory loss may also be noted. Findings on examination may include a low-grade fever, pharyngitis, and enlarged cervical or axillary lymph nodes. Many patients with chronic fatigue syndrome improve spontaneously over time. Treatment of both fibromyalgia and chronic fatigue syndrome frequently includes the use of tricyclic antidepressants. Among controversial syndromes that include myalgias are myoadcnylatc deaminase deficiency, adjuvant breast disorders, Gulf War syndrome, and multiple chemical sensitivity,

Pain or discomfort localized to muscle may arise in other structures. For example, hip disease can be misdiagnosed as a painful proximal myopathy with apparent leg weakness. In this situation, external or internal rotation of the thigh commonly evokes proximal pain. Radiological studies confirm the diagnosis. Disorders of bone and joints, connective tissue, endocrine systems, vascular supply, peripheral nerve and roots, and the CNS may also present with discomfort localized to muscle.

Pain originating from muscle, often acute, may occur in the absence of a chronic myopathy. Muscle ischemia causes a squeezing pain in the affected muscles during exercise. Ischemia produces pain that develops particularly rapidly (wirhin minutes) if muscle is forced to contract at the same time and subsides quickly with rest. Cramps and overuse syndromes are associated with pain during or immediately after muscle use. DOMS occurs 12-48 hours after exercise and lasts for hours to days. It is most commonly prccipiratcd by eccentric contraction or unaccustomed exercise.

Chapter 30
The Floppy Infant

Thomas O. Crawford

The floppy infant is one of the more common neurological syndromes encountered in the premature neonate (<37 weeks' gestational age), full-term neonate (birth to 30 days), and infant (1 month to 1 year). The terms *hypotonic infant* or *weak infant* are often applied to this syndrome, but each has both a distinct technical meaning and an accepted common usage. The more colloquial term *floppy* may be a better generic definition for the syndrome because it carries no such ambiguity. The differential diagnosis of the floppy infant is broad and includes many rare disorders and syndromes, some with precise nosologic definitions and others with only vague descriptive value (Table 30.1). As in all of neurology, the differential diagnosis is first narrowed by localization of the problem to a portion of the nervous system on the basis of the history and the physical examination. Once the site of dysfunction is suspected, a specific diagnosis can often be reached with a small number of confirmatory tests that may include an imaging study, electromyography (EMG) and nerve conduction study, muscle biopsy, or molecular genetic test.

Normal movement and tone depend on the coordinated fusion of multiple hierarchical and parallel central nervous system (CNS) pathways acting on an adequate number and distribution of functioning motor units. Each motor unit consists of a motor neuron, its peripheral nerve fiber consisting of an axon and the surrounding Schwann cell-produced myelin sheath, and the multiple muscle fibers connected with the motor neuron through the neuromuscular junction. Fortunately for the process of differential diagnosis, a disturbance in function at different locations within the CNS or the motor unit is often associated with a characteristic clinical syndrome of disturbed power and tone. The cardinal features that characterize these syndromes in the floppy infant are tone, power, range of movement, reflexes, endurance, muscle bulk, sensation, and associated CNS or systemic abnormalities (Table 30.2).

CARDINAL SIGNS

Tone

Muscle tone is defined by different authors in different ways; these definitions often are not easily translated from **one** discussion to another. In general, *tone* can be defined as the unconscious and automatic induction of muscle power in response to an applied load. Different, nonexclusive forms of tone can be distinguished and elicited by various **tests.** Resting tone is that which is present with the subject in an awake, alert state at rest. It is generally assessed by inspection, as for example when evaluating a neonate or premature infant before handling (Figure 30.1). Static or passive tone is that which is induced by passive movement of an otherwise immobile muscle. The subject must be awake, cooperative, and voluntarily nonresisting during the assessment, a state that is not common in the examination of infants. Postural tone involves resistance to gravity and is important to the maintenance of stable

posture in space. It is evoked in response to the pull of gravity and testable at diffctcnt ages by different methods, such as in infants by withdrawing head support, applying traction to the arms to pull to a sitting position from a supine position (Figure 30.2), ot simply by axillary support in vettical suspension (Figure 30.3). Dynamic tone, which is closely telated to postutal tone, is that which is evoked in a phasic manner during automatic movements such as walking. At each stage of human development each of these diffetent foims of tone is assessed easily (Table 30.3).

At all stages diminished tone in the setting of normal muscle power implies involvement of the CNS. Increased tone can be further subdivided by characteristics of the resistance into the categories of spasticity, rigidity, or dystonia. Hypertonia always implies involvement of the

Table 30.2: Cardinal features for evaluation of the floppy infant

* Commonly associated with motor unit origin.
Commonly associated with central nervous system origin.

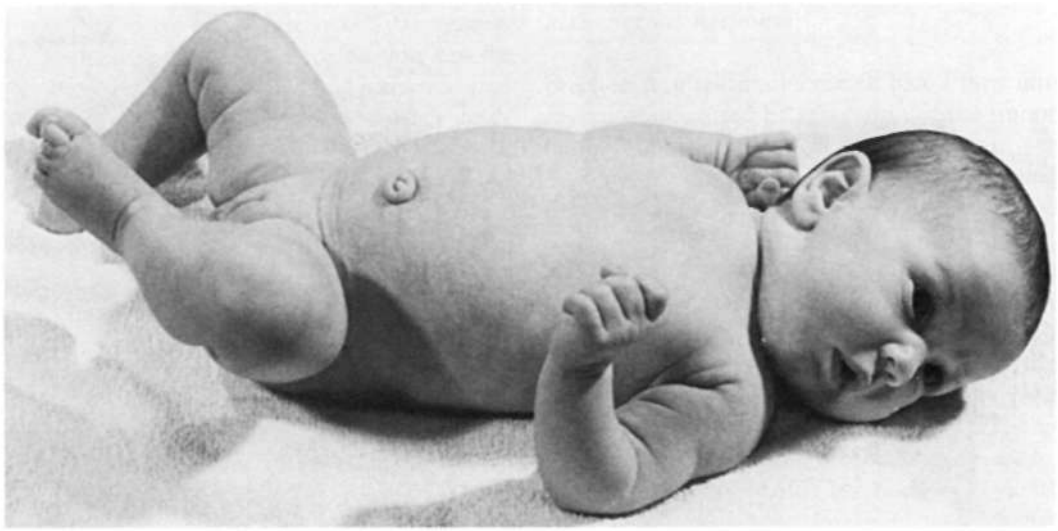

FIGURE 30.1 Normal resting tone. Note flexion at knees, hips, and elbows; hips are partially internally rotated to lift knees off of the surface and shoulders arc neutral to internal rotation.

CNS. Diminished muscle power (weakness) limits the appreciation of increased, normal, or diminished tone. Thus to the degree to which weakness is present, less can be inferred about motor pathways of the CNS.

Power

Muscle power (strength) is more easily defined than is muscle tone, and, in most cases, more easily evaluated. It is the maximum force that can be generated by any stimulus or provocation, whether voluntary or reflexive, normal or pathological. Attention is generally focused on states of diminished power, because increased muscle power is never pathological. Occasionally, infants and children with profound hypotonia cannot or will not express their available power by the usual examination methods but may do so duting phlebotomy or other painful procedures. Weakness in infants and children is usually best assessed in relation to develop mentally appropriate skills and behaviors, because maximum strength in isolated muscles may be difficult to elicit and grade according to the traditional five-point measures used in older children and adults. Certain skills that are often assessable and useful for the evaluation of infants and children are noted in Table 30.4, Diminished muscle power is substantial but not conclusive evidence of involvement of the motor unit; rare patients may have diminished muscle power on a central basis.

FIGURE 30.2 Abnormal traction response with a mixture of increased and decreased postural tone. The head sags, yet legs extend, manifesting a tendency to "pull to stand."

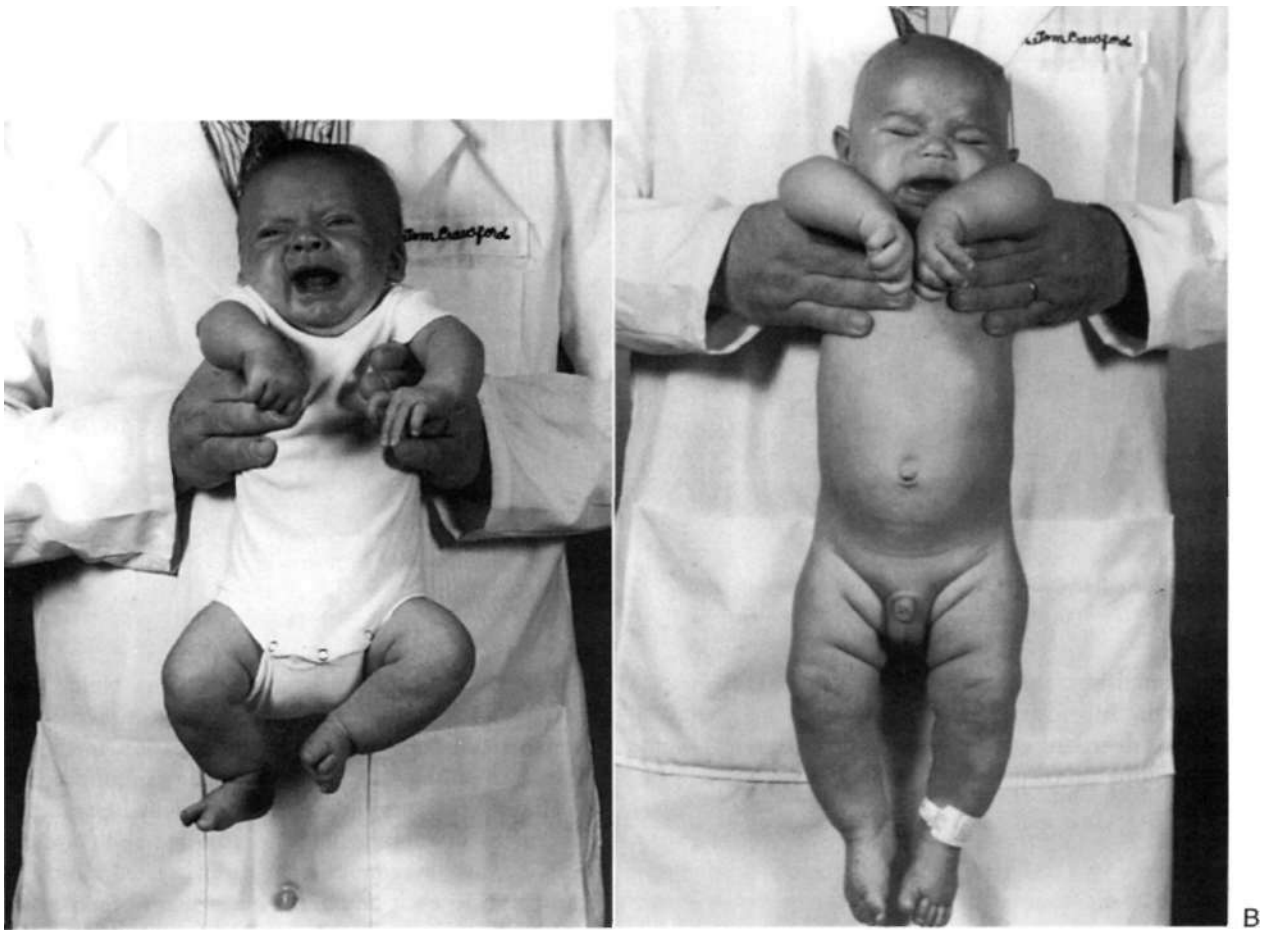

FIGURE .10.3 Vertical suspension: (A) Normal response. The head is erect, shouklers resist elevation, and arms remain adducted to counter slip-through while the legs are mostly flexed. (B) Abnormal response with a mixture of increased and decreased postural tone. Shoulders and arms elevate, requiring the examiner to clasp the chest to prevent slip-through. Legs are extended with a tendency for scissoring.

Range of Movement

Newborn infants often have an increased range of joint movement for a few days after delivery, the consequence of maternal hormone-mediated connective tissue relaxation to aid parturition. Premature infants have greater range of motion than do term infants. Infants and children with hypotonia or weakness have the appearance of joint laxity and may be referred for consultation with the presumptive diagnosis of a connective tissue disorder. However, children with isolated pathological joint laxity, such as those with the Ehlcrs-Danlos disorders, generally have normal strength and tone and thus appear quite different from children with primary disorders of the motor unit.

Joint range can be restricted by one or mure factors that include muscle fibrosis with an associated restriction of maximum length of the muscle tendon unit, ligamentous restrictions, and fibrosis of the joint capsule and associated structures. If acquired prenatally, a restriction of joint range is termed *arthrogryposis* and may be associated with underdevelopment of the joint itself. If acquired postnatally, a restriction in joint mobility is termed a *contracture.* Demonstration and measurement of a contracture require sufficient relaxation of the muscles surrounding a joint so that the connective tissue restrictions, and not active muscle tension, are the limiting factor being measured. With spasticity, contractures are often present but difficult to assess or measure because passive stretch stimulates muscle contraction.

Arthrogryposis is caused by a wide range of disorders and may affect a single joint or many joints. Multiple joint involvement is called *arthrogryposis congenita multiplex.* The least severe end of the arthrogryposis spectrum is the observation that main normal term or posi-tcrin infants can have mild and transitory restriction of full hip extension in the neonatal period. The most common pathologic expression of arthrogryposis is clubfoot, which may be unilateral or bilateral and usually involves multiple joints of the ankle and foot. The differential diagnosis

Tabic 30.3: Useful characteristics of tone at different stages of development

	Resting tune	*Static and passive tone*	*Postural and dynamic tone*
Premature	Increasing flexor tone associated with gestational age: lower extremities (30-32 wks), elbow flexion (34-36 wks), shoulder elevation (37-38 wks)*	Hypertonic states rarely expressed	Elastic recoil (36-40 wks)*; minimal postural reflexes
Neonate	Flexor tone prominent*	Hypertonic states rarely expressed	Traction response*; vertical suspension*; ventral suspension* ; head support emerges*
Infant	Decreasing resting tone; opisthotonus posture at rest	Emergence of spasticity with corticospinal tract injury; mixed tone; increased deep tendon reflexes	Traction response*; vertical suspension* ; luiri/nnial suspension '; good head support*; emergence of parachute responses**
Early childhood (approximately 15 yrs)	External rotation of hips and arms*; extensor posturing of lower extremities, flexor or extensor posturing of upper extremities**	Developing spasticity; increased deep tendon reflexes; rigidity (rare); dystonia	Gait analysis: symmetry, toe walking**; reciprocal upper extremity movements* ; spastic posturing of upper extremities*'
Adulthood	KM una I rotation tit hips and arms"; extensor posturing of lower extremities, flexor or extensor posturing of upper extremities**	Spasticity*; increased deep tendon reflexes ; rigidity ; dystonia	Gait analysis* : symmetry, toe walking*; reciprocal upper extremity movements* ; spastic posturing of upper extremities ; diminished checking with cerebellar disease*

* Features useful for assessment of decreased tone.
*Features useful for assessment of increased tone.

of arthrogryposis is summarized in Table 30.5. Many nongenetic and nonorthopedic causes of arthrogryposis are considered to be a nonspecific consequence of fetal immobility and may be the result of obstetrical complications such as uterine abnormalities, abnormal fetal positioning, diminished volume of amniotic fluid, or twinning, Curiously, among the several disorders that significantly decrease fetal movement, arthrogryposis is frequently associated with some but rarely so in others. In many cases in which arthrogryposis appears to be attributable to abnormal fetal development, a specific diagnosis cannot be made. One reason for this difficulty is found in the developmental interplay of trophic support between the fetal motor neuron and muscle; early injury to one or the other tissue may lead to resorption of both, thereby removing the evidence that can localize the primary insult.

Acquired contractures can be a consequence of either weakness or spasticity but are rarely seen in patients with primary central hypotonia. Although some association exists between the type and distribution of contractures and the underlying pathology, the overlap is sufficient to limit the usefulness of these distinctions to aid differential diagnosis.

Reflexes

Tendon reflexes involve a monosynaptic connection between afferent and efferent arms of the peripheral nervous system. The knee tendon reflexes usually can be elicited shortly after birth; ankle and biceps reflexes are more inconsistent but become more easily demonstrated with each succeeding month. Tendon reflexes are easiest to elicit when the limb is relaxed and are difficult to obtain in an agitated child. In younger infants, care should be taken to maintain the head in a midline position because of the asymmetrical effect of the tonic neck reflex (see discussion in this section of the chapter). Attention should be paid to the amount of stimulus necessary to evoke a reflex and to response symmetry and proportionality, comparing the vigor of reflexive responses between distal and proximal sites and between the arms and legs. Some overall change in the briskness of the tendon reflexes can be expected with change of state, but the relationships between body-locations should remain constant.

To produce a tendon reflex, the pulse of excitation elicited by tendon percussion must ascend the sensory nerve to the spinal cord in a coherent phasic pulse. Any neuropathy with

Tabic 30.4: Practical in-office measures of strength in infants and young children

! lend and mink
- Upright head stability
- Traction response
- Ability to recover head stability from progressively greater deflections laterally or anterior/posteriorly
- Independent sitting with or without hand propping, slumped or upright sitting posture
- Ability to reach overhead without lateral propping and tilting head back

Proximal arm strength
- Arms overhead *{"So* big")
- Reaching overhead to defined height (top of head, eye level, and so forth)
- Height of reach with arm outstretched at elbow
- Toy rings over post at defined heights
- Length of ball throw
- Combat crawling
- Wheelbarrow walk (with horizontal body position at defined level of support: hips, thighs, knees, ankles)

Distal arm strength
- Ability to grasp and elevate defined objects of various size and weight

Proximal leg strength
- Movement of legs against gravity while supine
- Kneeling, quadrupedal stance, or crawl
- Gower's maneuver (roll to prone, push to quadrupedal stance, walking up knees and trunk with hands to elevate torso)
- Stance
- Gait, Trendelenburg's waddle
- .Stoop and recover (squat stanee)
- Standing broad jump
- Time to run 30 yd

Distal leg strength
- Motion against gravity
- Steppage gait with slapping feet

associated abnormality of myelin spreads out arrival of the signal between different sensory nerve fibers, which in turn blunts the phasic motor response. The vigor of the reflexive response is related both to the phasic nature of this signal on arrival at the spinal cord as well as the excitability of the motor neuron pool. Chronic decreases in corticospinal tract input, inhibition of local inhibitory interncuronal circuits, isometric strain of other limbs (Jendrassik's maneuver), head position in infants (the tonic neck reflex), and some stimulatory drugs can increase motor neuronal excitability and increase the vigor of response. Acute inhibition of the corticospinal tract (spinal shock) and some other complex

- Congenital segmental spinal muscular atrophy (non-SMN)
- Congenital hypo myelinating polyneuropathy
- Genetic myasthenic syndromes
- Passive transfer of maternal acetylcholine receptor antibodies (neonatal myasthenia gravis)
- Fiber disproportion myopathics
- Neurogenic arthrogryposis (non-*SMN)*

central disorders can decrease motor neuron excitability and inhibit the tendon reflex,

The importance of the tendon reflexes is always related to context. Absent or increased reflexes with normal coordination and power are likely to be of little importance. Normal reflexes in the setting of hypotonia or weakness imply localization to the CNS. Decreases in the number of motor neurons or contractile ability of muscle generally decrease the reflexes commensurate with the loss of power. Increased ease of reflex elicitation with a normal or diminished response, for example, percussion below the tibial tuberosity provoking reflexive knee extension in a weak limb, suggests simultaneous CNS and motor unit involvement. Disorders of the neuromuscular junction usually spare tendon reflexes, at least early in the course, because the first impulse of a series of depolarizations is relatively unaffected. Slowing of nerve conduction with dispersion of the phasic afferent signal, even though all impulses arrive at the spinal cord and are sensed normally, blunts stimulation of the reflex, which is why demyelinating neuropathy diminishes reflexes out of proportion to clinical weakness or loss of sensation.

Extension of the great toe and flaring of the other toes with plantar stimulation, Babinski's response, is suggestive of CNS ilvstunction at any age. hi younger children, infants, and newborns, however, extension of the great toe in response to plantar stimulation is common and likely to be complicated by other responses; in the absence of other signs of central involvement the value of plantar stimulation as a diagnostic clinical test is probably not worth the infant's annoyance.

Certain postural responses elicited in infancy may have predictive value. The Moro reflex and tonic neck reflex may be elicited in newborns and infants with cerebral hypotonia even when there is a paucity of spontaneous movement (Fenichel 1993). Their presence shows that the motor unit is intact. The Moro reflex is elicited by startle and is normally present in its full expression up to 6 months, but can be seen in fragmentary form in adults. It allows for observation of coordination and symmetry of extension. The best stimulus for startle is the sensation of falling. With the child held in the supine position, the head is allowed to fall a few centimeters rapidly, but gently, into the examiner's hands. The first response is a spreading movement, with the arms abducted and extended and the hands open. This is followed by a clutching movement of the arms adducting and flexing over the torso with fists closed. Absence of a Moro reflex is always abnormal and suggests severe central or motor unit dysfunction. Asymmetry of the response also may be either central or peripheral in origin.

The tonic neck reflex is a primitive vestibular reflex that is present from birth to 3 months of age. It must be suppressed before the child can learn to turn over. In the supine position the normal resting position of arms and legs is in flexion. With head rotation to one side, the ipsilateral arm and leg extend and contralateral limbs remain flexed. The tonic neck reflex should be variable, unsustained, **and** nonobligatory, with other responses easily dominating. An asymmetrical tonic neck response suggests injury to the contralateral hemisphere; a persistent or obligatory tonic neck response bilaterally suggests bihemispheric injury. In some infants turning the head from one side to the other can alter the vigor of tendon reflexes on one and then the other side, likely by a means analogous to the effect of Jcndrassik's maneuver.

Endurance

The concept oi latiguc ⊱. at least as complicated, and as confusing, as that of muscle tone. Many different competing definitions of fatigue exist among neurologists as well as the lay public. One form of fatigue can be a result of central perception of mood, weariness, or sleepiness. At the other end of the neuraxis, a different form of fatigue is demonstrable in the progressive loss of contractile force to tetanic direct muscle stimulation. Muscle fibers fatigue at differing rates, depending on the type and concentration of contractile proteins, energy substrate and supply, gas exchange, and the clearance of toxic metabolites.

The form of fatigue that is of greatest interest to most neuromuscular clinicians is that associated with progressive conduction failure of the neuromuscular junction. This manifests as an abnormal diminution of power in a muscle under a continuous load; it requires that the subject sustain maximum effort despite the associated discomfort. The assessment that effort is indeed maximum requires clinical judgment and is a common source of error in mistaken diagnosis, both in the misdiagnosis of myasthenia as psychogenic weakness and the reverse.

Disorders of the neuromuscular junction are not common in infants, but the appreciation that weakness has a fatigable component may be even more difficult because infants do not ordinarily exercise to the point of mental or physical exhaustion, except possibly while crying vigorously. Thus neuromuscular junction fatigue is best appreciated in those with difficulty in sucking or possibly swallowing. An infant who appears alert and hungry and has normal oral motor coordination but only sucks briefly may have bulbar fatigue. When junctional function is severely compromised, fatigue is manifested as variable weakness without sustained effort. In infants with junctional disorders, this is most often exhibited in restricted extraocular movement, ptosis, and bulbar and facial weakness but can eventually also cause generalized weakness.

Bulk

Severe loss of muscle bulk follows denervation and is most extreme in spinal muscular atrophy. Diminished bulk

of muscle may be obscured in infants by abundant subcutaneous fat and is thus sometimes better appreciated by palpation of long bones rather than by inspection. With severe muscle atrophy it is possible to outline the bony contour in a way that is not possible when muscle mass is more normal. Chronic denervating weakness without loss of muscle bulk is a characteristic of chronic conduction block in adults, but there arc no descriptions of disorders specific to children with well-characterized and long-standing conduction block. Some congenital myopathies also manifest with significant loss of muscle mass. Commensurate decreases in muscle bulk and power occur in severe malnutrition and some poorly characterized developmental myopathies that mostly have stable function over time. Though muscle atrophy suggests motor unit disease, it also occurs infrequently with purely central disorders.

Sensation

The sensory examination is difficult to evaluate in infants. It requires a lot of time, and small differences in sensibility almost never have diagnostic value. Thus the general sensory examination is limited; more extensive probing is necessary and appropriate only when there is a specific question and the answer is important. The different modalities of sensory testing have differing value for answering specific questions (Table 30.6). In evaluating the floppy infant, the sensory examination is of greatest value in the evaluation of those with spinal injury or peripheral polyneuropathy, in which sensory and motor fibers are equally affected. In polyneuropathy, changes in sensibility are most apparent in long fibers to the distal portions of extremities. In children old enough to report their experience reliably, the appreciation of vibratory stimuli should be roughly equal between distal and proximal bony prominences of both the arms and the legs. It is not as easy to relate the degree of the impairment of joint position sense between distal and proximal sites unless the changes with location are more extreme. Pin sharpness and temperature should be equal at distal and proximal sites, although care should be taken to compare extensor surfaces with extensor surfaces and flexor surfaces with flexor surfaces of the limb.

Associated Features

Long-standing immobility in the fetus may produce a scries of deformations. Such infants may have, in addition to arthrogryposis, a narrow, high-arched palate with mandibular underdevelopment, a short umbilical cord, and demincralizariou of bones with thinning on ribs notable on chest radiography. In addition, the hip acetabulum may be shallow, with dislocated or easily dislocated hip joints. If there is difficulty with swallowing, polyhydramnios may ensue. Babies with significant weakness are more likely to be breech at presentation.

CLINICAL TESTS USEFUL IN THE EXAMINATION

Traction Response

The traction response is a sensitive measure of postural tone. The response is initiated by grasping the hands and pulling the child to a sitting position. Ry 1 month, normal infants lift the head immediately and maintain it in line with the trunk. When the sitting position is attained, the head is erect in the midline. During traction, the examiner should feel the child pulling back against traction, and there is flexion at the elbows, knees, and ankles. A traction response is not present in premature infants of less than 33 weeks' gestation. After 33 weeks, there is considerable head lag, but the neck flexors consistently respond to traction by lifting the head. At term, only minimal head lag is present, but when the sitting posture is attained, the head may continue to lag or may become erect momentarily before falling forward (see Figure 30.2). The presence of more than minimal head lag and failure to counter traction by flexion of the limbs is abnormal and indicates weakness or postural hypotonia in full-term newborns and infants.

Table 30.6: Modalities of sensation most useful in the evaluation of neuromotor disorders

Modality	*Central pathway*	*Transverse spinal level*	*Dorsal spinal cord defect*	*Ventral spina! cord defect*	*Unilateral spina! cord defect*	*Poly-neuro pathy*	*Radiculopathy/ plexopathyl mononeuropathy*

Temperature	Spinothalamic	t	—	ttt	ttt	ttt	—
Light touch	Spinothalamic and others	—	—				

t t t = very useful; ft = moderately useful; T = *ot* some value.

Vertical Suspension

To test vertical suspension, the examiner places both hands in the child's axillae and without grasping the thorax lifts straight up. Normal full-term newborns and infants respond with shoulder fixation sufficiently strong to suspend themselves vertically without falling through. With weakness or postural hypotonia, the infant needs to be grasped around the trunk to prevent falling, or the shoulders elevate excessively with internal rotation of the arms (see Figure 30.3). While the infant is in vertical suspension, the head is held erect in the midline and the legs are kept flexed at the knee, hip, and ankle. Sustained extension and adduction of the legs is abnormal and suggests regional hypertonicity (see Figure 30.2).

Horizontal Suspension

A normal infant suspended horizontally in the prone position keeps the head erect, maintains a straight back, and demonstrates flexion at the elbow, hip, knee, and ankle. A healthy term newborn makes intermittent efforts to maintain the head erect, the back straight, and the limbs flexed against gravity. Hypotonic and weak newborns and infants drape over the examiner's hands, with the head and legs hanging limply.

Fetal Posture

The favored posture that a fetus assumed in utero can often be inferred by the ease of folding of arms and legs into that position, a phenomenon that is generally observable for the first week or two of postnatal life. This natural asymmetry can at times be quite unusual, for example, a leg with extended knee across the chest, but is normal if the ease of folding into this posture diminishes steadily and quickly after release from the confinement of the womb.

Assessment of the Mother

In some disorders of the floppy infant, significant information can be discerned from a careful review of the mother (Table 30.7). Maternal percussion myotonia or the inability to relax quickly a tightly clenched fist might suggest the floppy infant has congenital myotonic dystrophy. Bulbar weakness, ptosis, or diplopia with sustained upgaze, or early arm ptosis with sustained forward arm abduction may suggest unappreciated maternal myasthenia, which can be transferred passively to an infant, producing more obvious signs and symptoms, l.ong-since resolved congenital limb deformities or a narrow, high-arched palate may suggest a dominantly inherited developmental anomaly of power or tone. The age of first walking of both parents, often remembered accurately by the newborn's grandparents, may be a clue to early dominantly inherited weakness.

CHARACTERISTIC SYNDROMES AND DIFFERENTIAL DIAGNOSIS

Injury to each portion of the motor unit produces a characteristic clinical syndrome that is often sufficiently-distinctive to have significant localizing value (Table 30.8, see also Table 30.1). Once a location is suspected a specific differential diagnosis often follows naturally.

Cerebral Disorder

Floppincss attributable to a cerebral cause is often marked by the prominence of hypotonia out of proportion to weakness. Many infants with hypotonia on a central hasis also have regional signs of hypertonia at the same time. One common combination of this mixture of increased and decreased tone is the infant with obligatory trapping of thumbs into the hand, excess pronator tone of the forearms, and excess extensor and adductor tone of the legs on vertical suspension (see Figure 30.3B), combined with axial and appendicular hypotonia at rest. Infants with a combination of increased and decreased tone likely will develop more diffuse spasticity later. Increased or "inappropriately normal" tendon reflexes in the setting of hypotonia have the same implication. Other features that indicate brain involvement are seizures, alterations in level of consciousness, or abnormalities of head size or shape. The appearance of other unexplained unusual physical features raises the concern about occult brain malformations, hut the potential for in utero deformation with long-standing weakness should not be overlooked. It is notable that many well-characterized syndromes combine central with peripheral weakness.

Chromosomal disorders associated with hypotonia usually are associated with other dysmorphtsms. Careful chromosomal studies are warranted in any floppy infant with dysmorphic features of hands or face or with other major organ malformation, but the yield is low in the absence of any of these abnormalities.

Table 30.8: Classic clinical syndromes that characterize the floppy infant

	Examples	*Characteristic features*
Corticospinal tract	.Stroke	Regional spasticity (diplegia, hemiplegia, quadriplegia)
Diffuse central nervous system	Down syndrome, Prader-Willi syndrome	Diffuse hypotonia more than weakness
High cervical spinal cord	Birth injury	Quadriplegia sparing the face, arms, and legs; impaired sphincter function; possible diaphragm weakness
Motor neuron	Spinal muscular atrophy	Diffuse weakness, legs > arms > diaphragm > face
Nerve	Congenital hypomyelmating neuropathy	Distal weakness of extremities, legs > arms; sensory impairment, distal I iinbs>proximal
Neuromuscular junction	Congenital myasthenic syndromes; infantile botulism	Prominent involvement of bulbar muscles with impaired suck and swallow; extraocular muscle weakness
Muscle	Congenital myopathy	Diffuse weakness including face, proximal limbs > distal

Chronic nonprogressive encephalopathy may be caused by genetic or acquired influences and may or may not be associated with anatomical deformations of the CNS. Known or unknown toxins may be responsible for cerebral dysgenesis, but the etiology of most cerebral palsy is unknown. Most cases of hypotonic cerebral palsy evolve to forms of increased tone, either with spasticity, dystonia, or a mixed hypertonic and hypotonic state.

Perinatal brain injury leading to a chronic encephalopathy and weakness is never an occult event. Seizures, coma, or other features of an acute encephalopathy shortly after birth suggest petinatal traumatic injury, hypoxia-ischemia, infection, or withdtawal from maternal placental "dialysis" of small toxic molecules that may build up after delivery as **a** consequence of an inborn error of metabolism. Perinatal asphyxia sufficient to cause brain injury leads to sustained very low Apgar scores and obvious signs of an acute encephalopathy or evidence ot other organ damage. All newborns with an acute encephalopathy should be evaluated immediately for sepsis or other occult infection and treated presumptively. In the absence of obvious infection or perinatal injury, however, the newborn who appears vigorous at birth but then becomes weak or encephalopathy should be assessed for inborn errors with blood tests for metabolic acidosis, glucose, electrolytes, serum lactate, and ammonia, and urine tests for reducing substances and abnormal amino acids. Feedings should be suspended temporarily until these studies are demonstrably normal. Because inborn errors are complex and rare, when they are suspected, early consultation with centers expert in their care is essential.

Chronic progressive encephalopathy may be caused by identifiable inborn errors of metabolism or unknown causes. In general, diagnosable conditions involve large insoluble molecules of peroxisomal metabolism or lysosomal storage disorders. In most of these disorders, hypotonia is less prominent as a presenting feature than is developmental regression. *Benign congenital hypotonia* is a term applied to a group of infants in whom early hypotonia gives way to more normal motor development, implying that there is a developmental anomaly of motor control. Family histories are often positive and reassuring, particularly if a similarly affected first-degree relative later did well. Most clinicians agree that cognitive impairment is common in this group, but the incidence is unknown because of the difficulties in case definition.

Combined cerebral and motor unit disorders may have features of both and can present especially challenging diagnostic problems. Degeneration of white matter of the brain and peripheral nerve myelin combined is a feature of Krabbe's and metachromatic leukodystrophies. Mitochondrial disorders may affect both cerebral and muscular metabolism. Congenital myotonic dystrophy produces an unusual developmental delay with both hypotonia and weakness but without myotonia until later years; school-aged children are often more impaired by mental subnormality than by weakness. Many children with hypotonia or weakness who have an abnormal muscle biopsy characterized by only a predominance of rype 1 fibers have associated cognitive subnormality manifest in later years (Kyriakidcs et al. 1993). Acid maltase deficiency (Pompc's disease) produces both an encephalopathy and a distinctive vacuolar myopathy, as well as congestive cardiac failure with cardiomegaly. Congenital muscular dystrophy now has four forms that include cerebral dysgenesis with myopathy. Various acquired insults, particularly hypoxia-ischcim.i, can injure brain and motor neurons within the spinal cord. Severe weakness from any defect in the motor unit can lead to perinatal asphyxia if respiration is impaired for too long. Finally, some patients have a combination of motor neuron or nerve disease with CNS dysfunction that has no other distinctive features and thus falls into an idiopathic group of ncurodysplasia or neurodegeneration.

High Cervical Spinal Cord

Fortunately, congenital or acquired high cervical myelopathies are now rare. Affected infants may have many features of motor unit dysfunction, especially before the

development of spasticity. Such miauls have an active facial expression and frog-leg posture of the body and limbs that resemble that seen with spinal muscular atrophy. Additional features may include diminished responsiveness to pin, weakness of sphincters with continuous urinary leakage or abnormal retention, variable diaphragmatic weakness and ventilatory dependence, and a different clinical course. Infants with a high cervical myelopathy often have prominent weakness at birth, whereas those with severe infantile spinal muscular atrophy are often progressively weaker over weeks or months.

Motor Neuron op athy

Infantile spinal muscular atrophy is the most common neuronopathy causing a floppy infant. It is characterized by an active face with diffuse weakness of legs more than arms, normal sphincter tone, and paradoxical breathing with a strong diaphragm but weak chest and abdominal wall musculature. Other motor neuronopathies are rare and generally have other associated features that are important to the diagnosis. Spinal muscular atrophy has traditionally been divided into several clinical subgroups ranging from the severe acute infantile to milder chronic forms appearing later in childhood (Crawford and Pardo 1996). Identification of the pathogenic survival motor neuron (.SMN) gene has now led to recognition of a broader expression of phenotypes, with a severe form associated with widespread neuron degeneration, arthrogryposis, and an early demise after birth. Spinal muscular atrophy affects approximately I in 10,000 infants. Most of those with the sevete form develop evident weakness before 6 months of age and succumb to respiratory insufficiency at a median of 8 months and *95%* mortality by the second birthday. However, the course of weakness is unusual for a degenerative disease, with the greatest losses occurring at the outset of the disease and increasingly slower loss of power with the passage of time. This course has led to speculation that the underlying defect is related to a distortion of naturally occurring motor neuron cell death (apoptosis). The pathogenic *SMN* gene appears lo k imolvi.\l in nuclear UNA processing; how ibis relates to motor neuron survival is at present beyond speculation.

Other motor neuronopathies of infancy are recognized usually by context. Vaccine-acquired poliomyelitis is rare but persists with a meningoencephalitic illness leading to characteristic regional weakness and paralysis and slow recovery. A predominantly cervical, nun .S'.U.V spinal muscular atrophy-like syndrome is now distinguished from the more common disorder by the unusual segmental distribution of weakness and a normal genetic test. A rare X-linked form of infantile spinal muscular atrophy also exists. Incontinentia pigmenti and GM2 gangliosidosis (Tay Sachs disease) have been associated with motor neuron dropout. Occult spinal cord deformities may be associated with segmental loss of motor neurons.

Infantile Polyneuropathy

Infantile polyneuropathy, a rare syndrome in infants, is characterized most often by weakness and insensibility concentrated distally in the limbs, combined with loss of deep tendon reflexes. The only specific neuropathies that may present in the first year as a floppy infant are congenital hypomyelinating neuropathy and Dejerine-Sottas syndrome (hereditary motor and sensory neuropathy, type III); others may have their onset in early childhood years or infancy (Ouvrier 1996). Polyneuropathies are divided into two categories: those in which the primary defect is in the myelin- forming cells, and those in which the primary defect is in the integrity of the axon (Table 30.9). In the very young, the demyelinating polyneuropathies also include those disorders that might be more properly termed *dysmyelinating* and *hypomyelinating polyneuropathies*^ in which myelin is abnormally formed or diminished in abundance as a developmental defect.

Disorders of the Neuromuscular Junction

Most congenital and acquired disorders of the neuromuscular disorders, including infantile botulism, are characterized by weakness of bulbar, facial, and oculomotor muscles, alone or in combination with weakness of the limbs. Abnormal fatigue with sustained maximum effort is difficult to discern in infants except when the severity is just sufficient to limit the duration of sucking followed by hungry irritabiliry and weak attachment to the nipple. In most cases, fatigue manifests as baseline weakness of swallowing, crying, or facial or extraocular movement. In some of the congenital myasthenic syndromes, particularly when myasthenia coexists with myopathy, appendicular weakness can exist independent of facial, ocular motor, or bulbar weakness.

The congenital myasthenic syndromes constitute a heterogeneous group of defined genetic disorders that have a common physiologic disturbance of the neuromuscular junction. They can be classed into disorders of presynaptic acetylcholine (ACh) release, receptor binding of ACh molecules, kinetics of receptor-mediated opening of the sodium channel (slow channel syndrome), and a disturbance of junctional acetylcholinesterase. Many patients who are not the product of a consanguineous relationship have a complex junctional physiology that results in a loss of safety factor for neuromuscular transmission that arises from a compounding of heterozygous mutations. Diagnosis can be suspected by fatigable weakness, responsiveness to cholincstcrasc-inhibiting drugs or a-adrencrgic agents, characteristic decremcntal responses to repetitive stimulation

Table 30.9: Named polyneuropathies with possible onset in infancy

Demyclinating

testing, or a "double hump" compound muscle action potential with single stimulation of a motor nerve, and absence of detectable ACh receptor antibodies. Diagnosis can be confirmed only with more sophisticated in vitro testing of the neuromuscular junction.

Passive transfer of maternal ACh receptor antibody may cause more profound weakness in the newborn infant than in the mother; this weakness improves with time, but rare infants are profoundly weak. Infantile onset of the adult form of autoimmune myasthenia gravis is at most very rare,

Infantile botulism can present as young as 2 weeks of age or as old as 1 year, with a median peak of onset in the second month, A history of decreased stooling frequency followed by decreasing feeding in a previously normal infant is common. Affected infants often have relative appendicular strength at a time of substantial bulbar, extraocular, and intraocular weakness, but may then progress to quadriparesis. Early diagnosis can be suspected with a characteristic EMG and incremental nerve conduction velocity responses to repetitive stimulation at high rates. Such infants should be watched carefully because respiratory failure caused by collapse of the airway can be seen at a time of relative appendicular strength. Full recovery is usual with only supportive therapy.

Myopathy

In infants, myopathic weakness often involves facial, appendicular, and axial muscles equally, although loss of strength is easier to demonstrate in the largest muscles proximally in the limbs. Many have an associated reduction in muscle mass, although this may not be apparent in the young infant with normally abundant baby fat. Severe facial and extraocular weakness can lead to the false impression of mental subnormality or inattentiveness; however, this distinction is both important and difficult to make because several congenital myopathies are associated with widespread cerebral disease.

The diagnosis of congenital myopathy depends on the muscle histology (Goebel 1996). However, some of the distinctive abnormalities of muscle histology are seen in a variety of clinical settings, which diminishes the predictive value of the histological diagnosis alone. Three disorders of infants are nosologically distinct. X-linked myotubular myopathy is associated with severe weakness, limitation of extraocular movements, respiratory insufficiency, and mental subnormality. Severe infantile nemaline myopathy is an autosomal recessive disorder associated with significant facial and axial weakness with a high-arched narrow palate. Both of these severe infantile disorders have a defined gene mutation, but the histologic features are shared with milder conditions that do not share the same mutation (Wallgren-Pettersson 1998). Central core disease is a dominantly inherited disorder involving mutation of the calcium-release channel of skeletal muscle sarcoplasmic reticulum, the ryanodine receptor. It is not clear how often a floppy baby's histological features of central core myopathy are attributable to mutation of the same gene. Abnormalities in the ryanodine receptor are present in less than one half of older individuals with a malignant hyperthermia response to anesthesia.

The congenital muscular dystrophies are characterized by severe weakness at birth, elevated levels of creatine kinase, and muscle biopsy features of a necrotizing myopathy with significant fibrosis and fatty replacement of muscle. Four nosologically distinct entities, each associated with abnormalities of the brain, have emerged in recent years (Voit 1998). The best understood of these involves mutation of the a2-laminin gene, also known as *tnerosin,* an extracellular constituent of the muscle basal lamina that is linked to dystrophin through a transmembrane dystroglycan. Infants with this form of congenital muscular dystrophy have associated profoundly abnormal white matter signal on magnetic resonance imaging (MRI), but have no important functional cerebral deficits. The Fukuyama form of congenital muscular dystrophy, mostly seen in Japan, is associated with cerebral and cerebellar micropolygyria and leptomeningeal fibrogliosis and severe cognitive subnormality. The responsible gene, fukutin, appears to be a secreted protein but its function is otherwise unknown. The Walker-Warburg syndrome, characterized by lissencephaly, hydrocephalus, microphthalmia, and retinal dysplasia may or may not be distinct from the Finnish muscle-eyc-brain syndrome, which is characterized by severe congenital myopia, retinal hypoplasia with congenital glaucoma, hydrocephalus, myoclonic jerks, and mental retardation.

LABORATORY TESTS

A limited number of confirmatory tests, or a screening test within a restricted range of differential possibilities, is generally possible in the final diagnostic steps of the

differential diagnosis. Laboratory diagnosis has changed significantly in the last decade because of specific DNA tests for several of the better characterized disorders that can obviate the need for biopsy; EMG and nerve conduction velocity studies; or other painful, expensive, or ambiguous tests (see Table 30.1). Because DNA test availability is likely to change rapidly between editions of this textbook, the reader is directed to the Web-based Online Mendclian Inheritance in Man for up-to-date information on specific disorders.

Neuroim aging

T1 -weighted MR! of the brain is useful for the detection and characterization of occult cerebral malformations. However, care should be taken with sedation for this or any other procedure in rhe floppy infant, because respiratory and airway muscles may be easily compromised because of weakness. If cerebral malformation is suspected, careful evaluation of skin and eyes may produce clues to the underlying diagnosis. T2-weightcd imaging best displays the abnormal white matter signal associated with *ot2*-laminin deficiency in congenital muscular dystrophy. More specialized MRI studies may demonstrate abnormal spectra associated with the mitochondrial encephalomyopathies.

Nerve Conduction Studies and Electromyography

Nerve conduction studies and EMG are most useful in focusing attention on a portion of the motor unit for further study. The value of the study is related directly to the skill and experience of the physician performing the test, the quality of the question being posed, the age of the infant being studied, the setting in which the study is performed, and the presence of a disorder of the motor unit. EMG is able to discern myopathic from neuropathic weakness in most cases in which one of the two is present. Nevertheless, profound hypotonia on a central basis, in very young infants, or studies taken in the neonatal intensive care unit with significant background electrical noise degrade the quality of information obtained. Specific studies with repetitive stimulation are especially valuable in the diagnosis of the myasthenic syndromes and infantile botulism (Jones, Bolton, and Harper 1996).

Muscle Biopsy

Muscle biopsy is essential to the diagnosis of congenital myopathies and muscular dystrophies, but like neurophysiological studies, biopsies are most useful when the question being asked is sharply focused and the center obtaining and interpreting the tissue is experienced, especially in the handling of infant muscle. Histochemical evaluation of quickly frozen muscle tissue is essential to diagnosis. If possible, delay of muscle biopsy beyond the newborn period or later improves sensitivity for a number of disorders in which the persistence of characteristic features of muscle immaturity is helpful to diagnosis. The best anatomical sites for biopsy are those muscles free of myotendinous insertions in which the histochemical fiber types ate normally equal in abundance. Muscles that best fit these criteria are the deltoid, biceps, triceps, and rectus femoris. The muscle selected for biopsy should be mild to moderately weak and not recently needled by EMG, Adequate tissue can be obtained either by needle biopsy or by open biopsy depending on physician experience, However, careful thought should be given prospectively to the amount of tissue that will be necessary for the potentially relevant histochemical, electron microscopic, enzymatic, or DNA tests.

Nerve Biopsy

Biopsy of the sural nerve is indicated in the setting of unexplained neuropathy when other tests for specific candidate neuropathies are either not available or are normal. Nerve biopsies should be done only in centers with significant experience, particularly because, if done poorly, they can be repeated only once. Nerve biopsies can reveal features of primary demyelination or axonal degeneration, the presence of abnormal abundant inflammation suggesting an acquired pathophysiology, and on occasion, specific features within myelin or axon that can have specific diagnostic import. Samples for electron microscopy should be obtained routinely. New techniques in the visualization of small myelinated and unmyelinated axons in skin biopsies may expand the role of nerve pathology in the evaluation of neurodegenerative disorders.

Edrophonium (Tensilon) Test

Edrophonium chloride (Tensilon) is a rapid-acting anticholinesterase that produces a temporary reversal of weakness in patients with many of the myasthenic syndromes. It is most useful when change can be assessed in a chronically weak muscle that is tonically activated. In practice, this is generally confined to eyelid ptosis or restriction of eye movement. A false impression of significantly increased appendicular muscle strength sometimes results from the limb movements generated by an uncomfortable feeling accompanying Tensilon infusion. Rare patients, especially those with a defect of the junctional acetylcholinesterase or vagal sensitivity, may be paralyzed or stop breathing with Tensilon infusion. Thus the test should only be done where defense of the airway, breathing, and circulation can be ensured. In newborns and infants the total dose is

0.15-0.20 mg/kg; one fourth of this dose is given intravenously each minute until a response is seen or the total dose is given,

Chapter 31
Sensory Abnormalities of the Limbs, Trunk, and Face

Karl E. Misulis

Clinical evaluation of sensory deficits is inherently more difficult than evaluation of motor deficits because of the subjective nature of the examination. Although we try to make the sensory examination as precise as possible, there is commonly inconsistency in reporting by the patient. Also, the types of sensory abnormality may differ greatly among patients. Nevertheless, identifying sensory deficits is of importance in localization of the lesion.

Accurate localization begins with a foundation of detailed anatomy. Of course, the presence or absence of motor deficits also aids with anatomical localization. Therefore the sensory data are always considered in association with other neurological functions.

ANATOMY

Sensory **Transduction**

Activation of sensory end organs produces a generator potential in the afferent neurons. If the generator potential reaches threshold, an action potential is produced. The action potential is conducted to the spinal cord by action-potential propagation.

Sensory transducers are seldom directly affected by neuropathic conditions, although peripheral vascular disease can produce dysfunction of the skin sensory axons, and systemic sclerosis can damage skin sufficiently to produce a primary deficit of sensory transduction {Table 31.1).

Sensory Afferents

The rate of action-potential propagation differs depending on the diameter of the axons, and whethet the fibers are myelinated or unmyelinated. In general, nociceptive afferents are small myelinated and unmyelinated axons. Non-nociccptivc afferents are large-diameter myelinated axons. Afferent fiber characteristics are shown in Table 31.2.

Spina! Cord Pathways

Sensory afferent information passes through the dorsal root ganglia to the dotsal horn of the spinal cord. Some of the axons pass through the dorsal horn without synapsing and ascend in the ipsilateral dorsal columns; these serve mainly joint position and touch sensations. Other axons synapse in the dorsal horns, and the second-order sensory neurons cross in the antetior white commissure of the spinal cord to ascend in the contralateral spinothalamic tract. Although this tract is best known for conduction of pain and temperature information, some non-nociceptive tactile sensation is conducted as well.

The dorsal column tracts ascend to the cervicomedullary junction where axons from the leg synapse in the nucleus gracilis and axons from the arms synapse in the nucleus cuneatus. Figure 31.1 shows the ascending pathways through the spinal cord to the brain.

Brain Pathways

Brainstem

Axons from the nucleus gracilis and cuneatus cross in the medulla and a seen d in the medial lemniscus (from a Greek word meaning *ribbon).* The spinothalamic tracts in the brainstem are continuations of the same tracts in the spinal cord and ascend lateral to the medial lemniscus in the brainstem.

Table 31.1: Sensory receptors

Receptor	? !•/><•	*Afferent axon*	*Modality*
Pacinian corpuscle	Multilayeted capsule around a nerve terminal, producing a rapidly adapting mecbanoreccptor	Large-diameter myelinated axons	Touch and vibration
Golgi's tendon organ	Specialized organs in the tendons near joints	Large-diameter myelinated axons	Joint position and rate of movement
Free nerve ending	Branched terminal endings of axons	Small myelinated and unmyelinated axons	Strong tactile and thermal stimuli, especially painful inputs
Me rk el's discs	Slowly adapting mcchanorcccptor	Large- to medium-diameter myelinated axons	Touch and pressure. Slowly adapting
Meissner's corpuscle	Specialized quickly adapting mechanorecepror	Myelinated axons	Touch
Krause's end bulbs	Specialized terminal axon ending	Small myelinated axons	Thermal sensation
Muscle spindles	Specialized organ involving intrafusal muscle fibers and the associated nerves	Large-diameter myelinated axons	Sensation of muscle length and contraction

Table 31.2: Sensory afferent axons

Class {older terminology)	*Diameter*	*Conduction velocity*	*Modalities*
la (Aa)	12-20 microns	70-100 m/sec	Proprioception (muscle spindles)
lb (Aa)	12-20 microns	70-100 m/sec	Proprioception (Golgi's tendon organs)
ii ***tm***	5-12 microns	30-70 m/sec	Touch and pressure from skin; proprioception from muscle spindles
III (AS)	2-5 microns	10-30 m/sec	Pain and temperature; sharp sensation; joint and muscle pain sensation
IV (C, unmyelinated)	0.5-2.0 micron	0.5-2.0 m/sec	Pain, temperature

Note: The terminology of sensory afferents has changed through the years. The older terminology *{Act,* A/J, *Ay, AS,* B, C) spans motor and sensory modalities, so the newer classification presented here for sensory fibers should be used nowadays. The corresponding older terms are placed in parentheses in the table for reference.

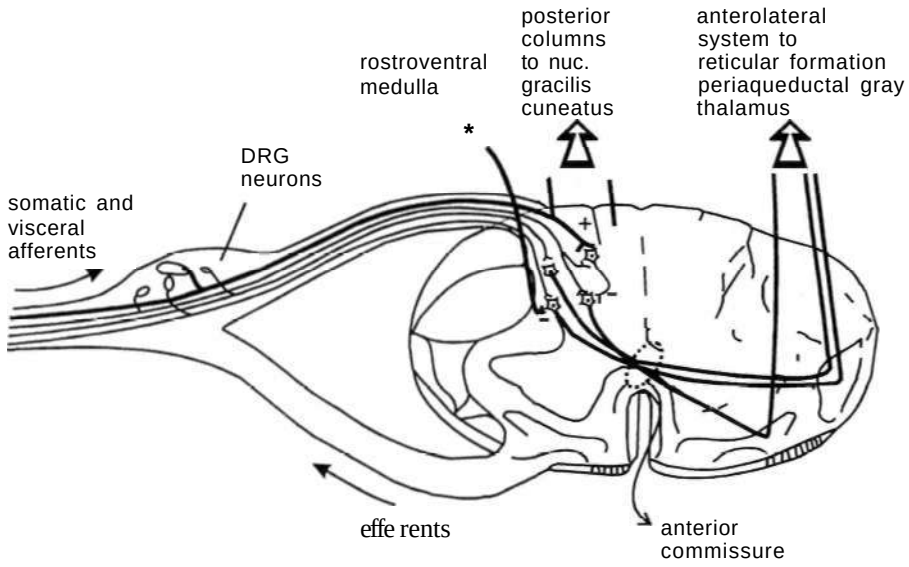

FIGURE 31.1 Axial section of the spinal cord showing dorsal and ventral roots forming a spinal nerve. Sensory afferents give rise to two major ascending pathways: the anterolateral system (nociceptive, thermal sensation primarily) and posterior columns (large-fiber modalities primarily, including touch, vibration, and proprioception). Inhibitory input derives from descending fibers as well as collaterals, via interneurons, from meehanoreceptive fibers. DRG = dorsal mot ganglion; dashed circle anterior white commissure. (Modified with permission from Rizzo, M. A., Kocsis, J. D. & Waxman, S. G. 19%, "Mechanisms of paresthesiae, dysesthesiae, and hypcresthesiac: Role of Na^+ channel heterogeneity," *Eur Neurol,* vol. 36, pp. 3-12.)

Thalamus

lesions of the thalamus rarely affect only a single region, but there is functional organization, which may affect clinical findings. The ventroposterior (VP) complex is the main somesthetic receiving area and includes the ventroposterior lateral nucleus, which receives information from the body, and the ventroposterior medial nucleus, which receives sensory input from the head and face. Projections are to the primary somatosensory cortex

on the postcentral gyrus. The posterior nuclear group receives nociceptive input from the spinothalamic tract and projects mainly to the secondary somesthetic region on the inner aspect of the postcentral gyrus, adjacent to the insula.

Cerebral Cortex

Classic neuroanatomical teaching presents a picture of the central sulcus hounded by the motor strip anteriorly and the sensory strip posteriorly. This division was derived largely from study of lower animals where the separation between these functions is marked. As we ascend the evolutionary ladder, this division becomes less prominent, and many of us refer to the entire region as the motor sensory strip. In general, sensory function is served prominently on the postcentral gyrus. The mapping of the cortex follows the same homunculus presented in Chapter 26, with the head and arm portions laterally on the hemisphere and the leg region superiorly near the midline and wrapping onto the parasagittal cortex.

SENSORY ABNORMALITIES

Sensory perception abnormalities are varied, and the pattern of symptoms is often a chic to diagnosis.

- Loss of sensation (numbness)
- Neuropathic pain
- Dysesthesia and paresthesia
- Sensory ataxia

Patients often use the term *numbness* to mean many different abnormalities, including weakness. Strictly speak ing, numbness is loss of sensation, usually manifest as decreased sensory discrimination and elevated sensory threshold; these are negative symptoms. Some patients use the term *numbness* to mean positive symptoms, such as dysesthesia and paresthesia.

Dysesthesia is an abnormal perception of a sensory stimulus, such as when pressure produces a feeling of tingling or pain. If large-diameter axons are mainly involved, the perception is typically tingling; if small-diameter axons are involved, the perception is commonly pain. *Paresthesia* is an abnormal spontaneous sensation of similar quality to dysesthesia. Dysesthesias and paresthesias are usually seen in localized regions of the skin affected by peripheral neuropathic processes, such as polyneuropathy or mononeuropathy. However, these can also be seen in patients with central conditions such as myelopathy or cerebral sensory tract dysfunction.

Neuropathic pain can result from damage to the sensory nerves of any cause. Peripheral neuropathic conditions result in failure of conduction of the sensory fibers giving decreased sensory function, plus pain from excessive electrical discharge. The pathophysiology of neuropathic pain is interesting. Part of its basis is lowering of the membrane potential of the axons so that minor deformation of the nerve can produce repetitive action-potential discharges. There also appears to be membrane potential instability with neuropathic conditions, so that the crests of the fluctuations of depolarization can produce action potentials. Lastly, cross talk *(epbaptic transmission)* between damaged axons allows an action potential in one nerve fiber to be abnormally transmitted to an adjacent nerve fiber. These pathophysiological changes produce exaggerated sensory symptoms including hyperesthesia and hyperpathia. *Hyperesthesia* is increased sensory experience with a stimulus. *Hyperpathia* is augmented painful sensation.

Sensory ataxia is the difficulty in coordination of a limb that results from loss of sensory input, particularly proprioceptive input. The resulting deficit may resemble cerebellar ataxia until detailed neurological examination is performed.

LOCALIZATION OF SENSORY ABNORMALITIES

A general guide to sensory localization is presented in Table 31.3. Guidelines for diagnoses of these sensory abnormalities are summarized in Tabic 31.4. Details of specific sensory levels of dysfunction are subsequently discussed.

Peripheral Sensory Lesions

Lesions of peripheral nerves and the plexuses produce sensory loss, which follows the peripheral anatomic distribution. Exact mapping of sensory deficit is commonly difficult because sensory testing is subjective. Also, there are differences between individuals in sensory peripheral anatomy, including distribution and overlap of sensory fields.

Peripheral sensory loss produces a multitude of potential complaints. Clues to localization are as follows:

- Distal sensory loss and/or pain in more than one limb suggests peripheral neuropathy.
- Sensory loss in a restricted portion of one limb suggests a peripheral nerve or plexus lesion, and mapping of the deficit should make the diagnosis.
- Sensory loss affecting an entire limb is rarely due to a peripheral lesion, because even proximal plexus lesions rarely affect the entire limb. A central lesion should be sought.

Unfortunately, there is often a discrepancy between the complaint and the examination, especially with peripheral lesions. The patient may complain of sensory loss affecting an entire limb, when the examination shows a median or

Table 31.3: General guidelines to sensory abnormality localization

Level of lesion	*Features and location of sensory loss*
Cortical	Sensory loss in contralateral body, restricted to the portion of the homunculus affected by the lesion. If the entire side is affected (with large lesions), either the face and arm or the leg tends to be affected to a greater extent.
Internal capsule	Sensory symptoms in contralateral body, which usually involve head, arm, and leg to an equal extent. Motor findings commonly present, though not always.
Thalamus	Sensory symptoms in contralateral body including head and may split the midline. Sensory loss without weakness highly suggestive of lesion here.
Spinal transection	Sensory loss at or below a segmental level, which may be slightly different for each side. Motor examination is also key for localization.
Spinal hemisection	Sensory loss ipsilateral for vibration and proprioception (dorsal columns), contralateral for pain and temperature (spinothalamic tract).
Nerve root	Sensory symptoms follow a dcrmatomal distribution.
Plexus	Sensory symptoms span two or more adjacent root distributions, corresponding to the anatomy of the plexus.
Peripheral nerve	Distribution follows peripheral nerve anatomy or involves nerves symmetrically.

ulnar distribution of sensory loss. Alternatively, the patient may complain of sensory loss when examination fails to reveal a sensory deficit. This is mote likely to be due to Iimirations on the examination than malingering. Also, patients may have significant sensory complaints as a result of dysfunction of the afferent axons when the conducting function is still intact, so the examination shows no loss of sensoty function. Figure 31.2 summarizes the peripheral nerve anatomy of the body. Figure -SI.} shows the detmatomal disttibution.

Table 31.4: Guidelines to diagnosis of sensory abnormalities

Abnormality	*Features*	*I .ftion*	*Cause*
Distal sensory deficit	Sensory luss with or without pain distal on the legs; arms may also be affected	Peripheral nerve	Peripheral neuropathy
Proximal sensory deficit	Sensory loss on the trunk without limb symptoms	Neuropathy with predominantly proximal involvement	Porphyria, diabetes, other plexopathics
Dcrmatomal distribution of pain and/or sensory loss	Pain or sensory loss in the distribution of a single nerve root	Nerve root	Radiculopathy due to disc, osteophyte, tumor, herpes zoster
Single-limb sensory deficit	Loss of sensation on one entire limb that spans neural and dermatomal distribution	Plexus or multiple single nerves	Autoimmune plexitis, hematoma, tumor compression or infiltration
Hemisensory deficit	Loss of sensation on one side of the body, may be associated with pain; face is involved in brain lesions but not with spinal lesions	Thalamus, cerebral cortex, or projections less likely to be brainstem lesion if face im ⊱K i'd; spinal cord it face not involved	Infarction, hemorrhage, demyelinating disease, tumor, infection
Crossed sensory deficit: unilateral facial and contralateral body	Unilateral loss of sensation on the face and contralateral body	Lesion of the uncrossed trigeminal fibers and the crossed spinothalamic fibers	Lateral medullary syndrome
Crossed sensory deficit: pain/temperature and vibrarion/proprioce prion on opposite sides	Loss of pain and temperature inivmon on one side and vibration and proprioception on the other	Spinal cord lesion ipsilatcral to the vibration and proprioception deficit and contralateral to the pain and temperature deficit	Disc protrusion, spinal stenosis, intraspinal tumor, transverse myelitis; intra parenchyma I lesions more likely to produce dissociated sensory loss
Dissociated suspended sensory deficit	Loss of pain and temperature sensation on one or both sides, with normal sensation above and below	Syringomyelia in cervical or thoracic spinal cord	Chiari malformation, hydromyelia, central spinal cord tumor, or hemorrhage
Sacral sparing	Preservation of perianal sensation with impaired sensation in the legs and trunk	I esion ot tin' cord with mainly central involvement, sparing the peripherally located sacral ascending fibers	Cord trauma, intrinsic tumors of the cord

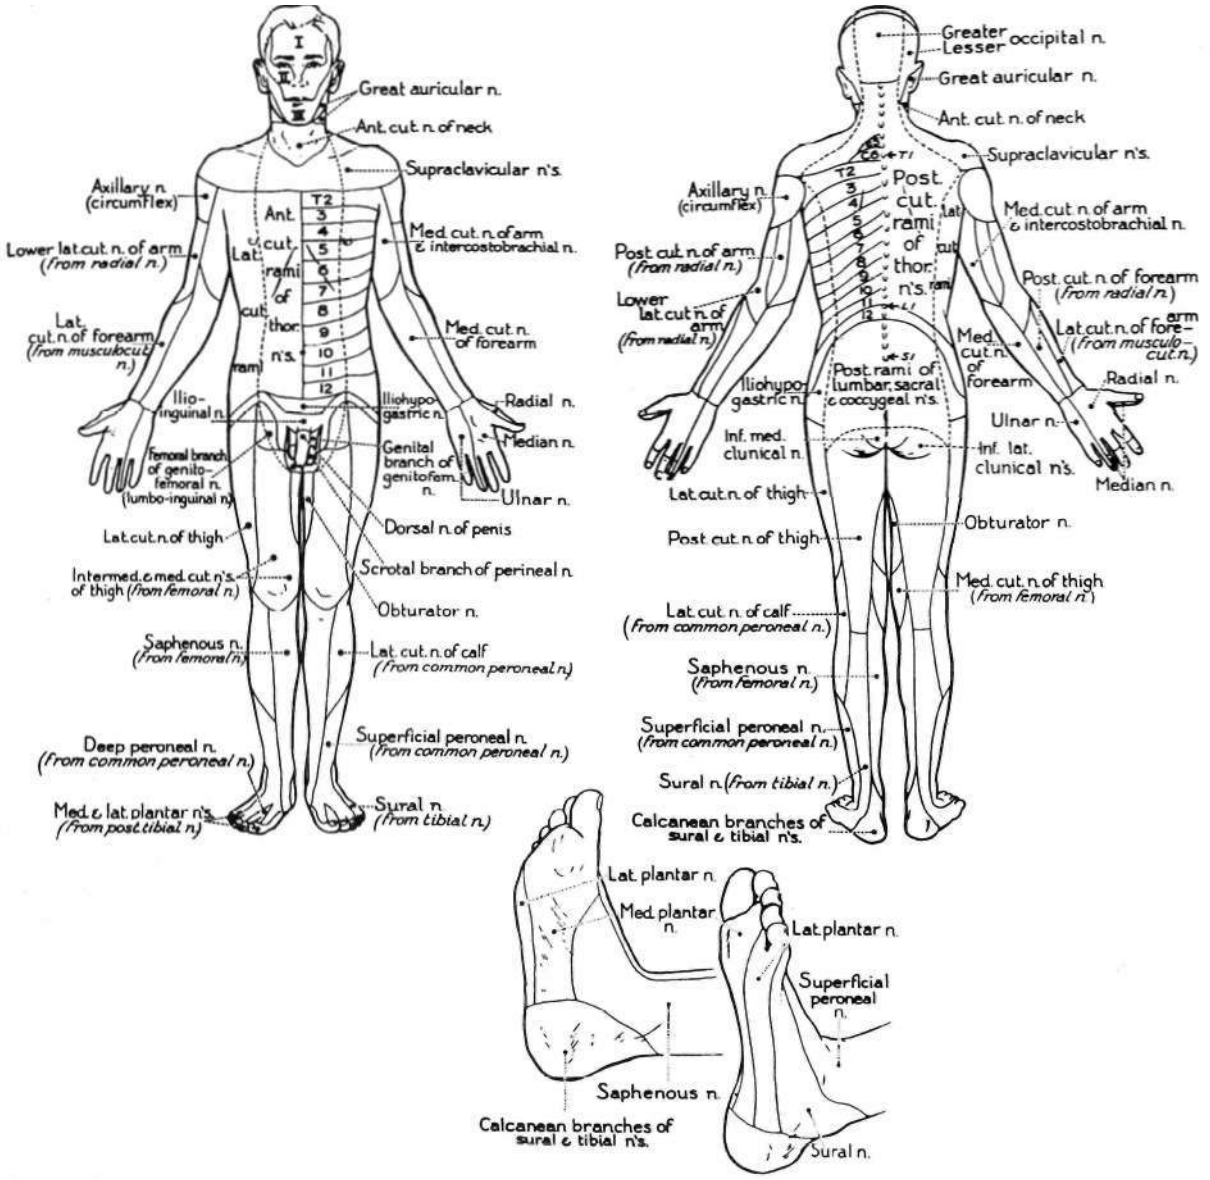

FIGURE 31.2 Cutaneous *(cut)* fields of peripheral nerves *(>:).* Note that the thoracic dermatomes are innervated by the primary anterior and posterior rami of the spinal nerves from the respective level. The spinous processes of T1, LI, and SI are indicated. Inf. = inferior; Lat. = lateral; Med. = median. (Reprinted with permission from Haymaker, W. & Woodall, B. 1953, *Peripheral Nerve Injuries: Principles of Diagnosis,* WB Saunders, Philadelphia.)

Spinal Sensory Lesions

Some sensory syndromes suggest a spinal lesion:

- Sensory level
- Dissociated sensory loss, sparing face
- Sacral sparing

Sensory Level

A spinal localization is suggested by loss of sensation below a certain spinal level (termed the *presence of a sensory level).* Loss of sensation in a myelopathic distribution without weakness and reflex abnormalities would be very unusual. Sensory symptoms with incipient myelopathy are more often positive than negative, with Lhcrmitte's sign being a common presentation of cervical myelopathy. Although we commonly think of Lhermitte's sign as being associated with inflammatory conditions such as multiple sclerosis, we more commonly see it with cervical spondylotic myelopathy.

Diagnosis of a spinal source of sensory abnormalities is suspected in a patient with a "sensory level." The level of the sensory loss may be slightly different between the two sides, and this should not suggest a functional sensory loss. Magnetic resonance imaging (MRI) is the best noninvasive

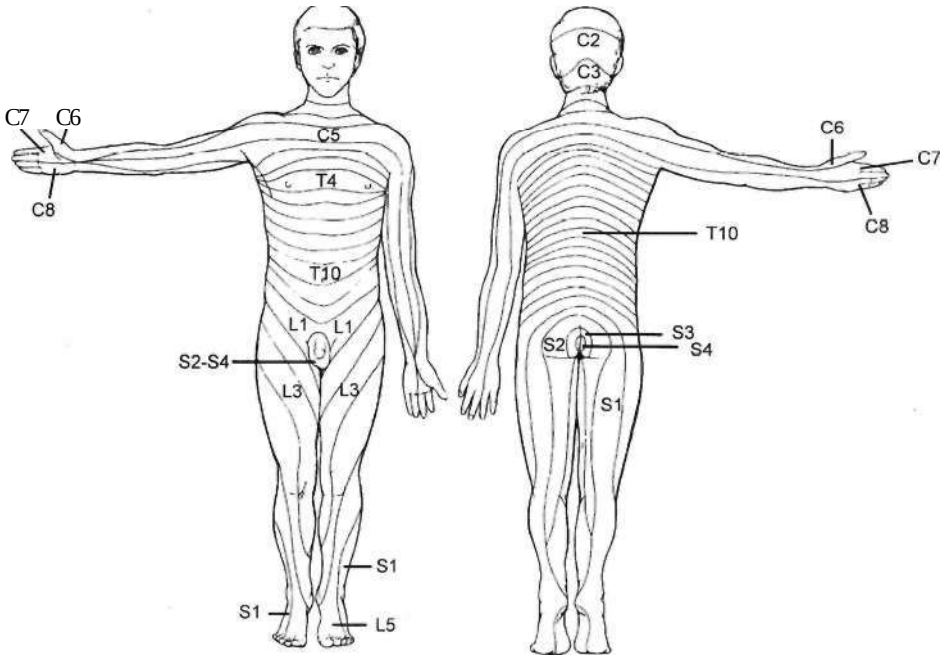

FIGURE 31.3 The dermatomes: (C) cervical, (T) thoracic, (L) lumbar, (S) sacral. The boundaries are not quite so distinct because of overlapping innervation and variability among individuals. (Reprinted with permission from Martin, J. H. & Jessell, T. M. 1991, "Anatomy of the somatic sensory system," in *Principles of Neural Science,* eds E. R. Kandcl et al, Appleton Sc Lange, Norwalk, Conn.)

test for sensory loss of spinal origin. Note that demyelinating disease and other inflammatory conditions of the spinal cord may not be visualized on MRI.

Dissociated Sensory Loss

Pain and temperature fibers cross shortly after entering the spinal cord and ascend contralaterally in the spinothalamic tract, whereas vibration and proprioception ascend uncrossed in the dorsal columns. Therefore unilateral lesions of the spinal cord can produce loss of vibration and proprioception ipsilateral to the lesion and loss of pain and temperature sensation contralateral to the lesion. This is most prominent with patients with intrinsic spinal cord lesions such as tumors but can also be seen with focal extrinsic compression. MRI usually shows the spinal lesion.

A second form of dissociated sensory loss can arise from selective lesion of the dorsal or ventral parts of the cord. Anterior spinal artery syndrome produces infarction sparing the dorsal columns, so there is deficit of pain and temperature below the level of the lesion but vibration and proprioception are spared. Selective lesion of the dorsal columns is less likely, but predominant dorsal column deficits can occur in patients with tabes dorsalis, multiple sclerosis, subacute combined degeneration, Friedreich's ataxia, and occasionally in focal spinal cord mass lesions.

A third form of dissociated sensory loss, with loss of pain and temperature sensation, sparing touch and joint position sensation, usually affecting the upper limbs with normal sensation above and below the lesion is seen in syringomyelia (see Syringomyelia, later in this chapter).

Sacral Sparing

Ascending spinal afferents are topographically organized, with caudal fibers peripheral to more tostral fibers. Therefore centtal cotd lesions can affect the higher fibers before the lower fibers, so that there may be sensory loss throughout the legs yet sparing of perianal sensation. In some patients with severe cord lesions, this may be the only neurological function below the level of the lesion. Cause is usually trauma, but intrinsic mass lesions can also produce this.

Brainstem Sensory Lesions

Brainstem lesions uncommonly affect sensory function without affecting motor function. The notable exception is *trigeminal neuralgia,* where there is characteristic lancinating pain without sensory loss in the distribution of a portion of the trigeminal nerve. Diagnosis is clinical, and studies serve to eliminate other possibilities,

Lateral medullary syndrome typically results from occlusion of the posterior inferior cerebellar artery, produces sensor) lus-. on the ipsilateral face from trigeminal involvement and loss of pain and temperature sensation from the contralateral body from damage to the ascending spinothalamic tract. However, the motor findings eclipse the sensory findings; these include ipsilateral ataxia, bulbar weakness giving dysarthria and dysphagia, and Horner's syndrome.

Medial medullary syndrome typically results from occlusion of a branch of the vertebral artery and is less common than lateral medullary syndrome. Patients have loss of contralateral position and vibration sensation, but again,

the motor findings predominate, including contralateral hemiparesis and ipsilateral paresis of the tongue.

Ascending damage in the brainstem from vascular and other causes can also produce contralateral sensory loss, but again, the sensory findings are trivial compared with the motor findings.

Cerebral Sensory Lesions

Thalamic Lesions

Pure sensory deficit of cerebral origin usually arises from damage to the thalamus. The thalamus receives vascular supply from the thalamoperforate arteries, branches of the posterior cerebral arteries, often with some contribution from the posterior communicating arteries. In some patients, both thalami are supplied by one posterior cerebral artery, so bilateral thalamic infarction can develop from unilateral arterial occlusion. Thalamic pain syndrome is an occasional sequela of a thalamic sensory stroke and is characterized by spontaneous pain localized to the distal arm and leg. exacerbated by contact and stress.

Cortical Lesions

Lesions of the postcentral gyrus produce more sensory symptoms than motor symptoms. Infarction of this region involving a branch of the middle cerebral artery can produce sensory loss with little or no motor loss. More posterior lesions may spare the primary modalities of sensation (pain, temperature, touch, and joint position) but instead impair higher sensory function, such as graphesthc-sia, two-point discrimination, and the perception of double simultaneous stimuli.

COMMON SENSORY SYNDROMES

Some common sensory syndromes are outlined in Table 31.5. Many of these have motor deficits as well.

Peripheral Syndromes

Sensory Polyneuropathy

The most common presenting complaint of a patient with distal symmetrica] peripheral polyneuropathy is sensory disturbance. The disturbance can be negative (decreased discrimination and increased threshold) and/or positive (neuropathic pain, paresthesias, dysesthesias}. Most neuropathies involve motor and sensory fibers, although the initial symptoms are usually sensory.

Nerve conduction studies can evaluate the status of the myelin sheath, thereby identifying patients with predominantly dcmyclinating polyneuropathies, including acute inflammatory dcmyclinating polyneuropathy (AIDP) and chronic inflammatory demyelinating polyneuropathy (CIDP). The electromyographic (EMG) study can identify denervation and hence axonal damage, thereby identifying the motor involvement of many neuropathies with predominantly axonal features. Cerebrospinal fluid (CSF) study is rarely performed for isolated neuropathy but when examined in patients with autoimmune demyelinating neuropathies shows increased protein. Increased cellularity suggests an inflammatory cause. Muscle biopsy is usually performed for evaluation of myopathy but in neuropathy may show denervation and reinnervation. Nerve biopsy can show several of the important causes of neuropathy, including inflammatory infiltrates, segmental demyelination, amyloid deposition, and axonal dropout. Nerve and muscle biopsy should be left to those who have expertise in the performance and interpretation of the data.

Diabetic Neuropathies. Diabetic sensory neuropathy-affects mainly small myelinated and unmyelinated axons, thereby producing disordered pain and temperature sensation. The findings often appear to be a paradox to the patients: loss of sensation yet with burning pain. Pathophysiological, this makes perfect sense. The damaged axons cannot carry the patterns of action potentials, which would give intact sensation, yet spontaneous action potentials from damaged nerve endings, plus increased susceptibility to discharge from mechanical stimuli, cause the perceived neuropathic pain.

Painful neuropathy in diabetics is so common that when present, other potential causes may be overlooked. When neuropathy is present, basic laboratory studies for other causes should be performed, even when the diagnosis is most likely diabetes.

Acquired Immunodeficiency Syndrome-Associated Neuropathies, Human immunodeficiency virus type 1 (HIV-1) infection can produce a variety of neuropathic presentations. One of the most common is a painful, predominantly sensory polyneuropathy. Diagnosis can be confirmed by nerve conduction studies, EMC, and the appropriate clinical setting. CSF analysis and biopsy are usually not necessary, unless there is an HlV-l-associated vasculitis or infection (such as cytomegalovirus).

Toxic Neuropathies. Some toxic neuropathies can be predominantly sensory. We see this most commonly in patients with chemotherapy-induced peripheral neuropathy. Although motor abnormalities do occur, the sensory symptoms eclipse the motor symptoms for most patients. Patients develop dysesthesias, burning, and loss of sensation. The neuropathy can be severe enough to be dose limiting for some patients. The neuropathy may continue to progress for a couple of months following the cessation of

Table 31.5: Common sensory syndromes

Syndrome	*Localization*	*Sensory features*	*Associated findings*
Acute inflammatory demyelinating polyneuropathy	Demyelinating lesion of peripheral nerves and roots	Dysesthesias and paresthesias, which may be painful, along with sensory loss	Areflexia is common early in the course; motor findings are predominant
Sensory polyneuropathy	Axonal or neuronal damage involving predominantly sensory axons	Burning pain, often with superimposed dysesthesias and paresthesias	Reflexes often suppressed distally early in the course
Carpal tunnel syndrome	Compression of the median nerve at the wrist	Numbness on the thumb, index and middle fingers	Weakness and wasting of the abductor pollicis brevis may develop in advanced cases
Ulnar neuropathy	Ulnar nerve compression is most likely near the elbow and at the wrist	Loss of sensation on the fourth and fifth digits	Weakness of the interossei is often evident with advanced cases
Syringomyelia	Fluid-filled cavity, which expands the spinal cord damaging segmental neurons and eventually also white matter tracts	Loss of pain and temperature at the levels of the lesion (capelike distribution; suspended sensory loss); dissociated sensory loss (i.e., affecting spinothalamic sensation and sparing posterior column sensation)	Weakness at the levels of the lesion can develop with motoneuron damage; spasticity below the lesion can develop in severe cases
Thalamic infarction	Infarction of the territory of the thalamoperforate arteries	Sensory loss and sensory ataxia involving the contralateral body	Weakness may develop; aphasia or neglect suggesting cortical damage can rarely develop with involvement of the thalamocortical connections
Thalamic pain syndrome	Previous sensory stroke in thalamus produces neuropathic pain of central origin	Burning dysesthetic pain in the contralateral body, especially distally in the limbs	Other signs of the thalamic damage are typical, including sensory loss
Trigeminal neuralgia	Dysfunction of the trigeminal nerve root	Paroxysms of lancinating electric shock–like neuropathic pain	No sensory loss or motor findings are seen; no other cranial nerve abnormality is seen

chemotherapy administration ("coasting"), after which time some recovery is expected.

Patients with neuropathy that develops during chemotherapy can be presumed to have toxic neuropathy. However, if the association is not clear, then other possibilities should be considered, including paraneoplastic and nutritional causes. Atypical features of chemotherapy-induced ncuropathy would be development of symptoms clearly after cessation of the administration or development of prominent neuropathy with administration of agents that are seldom neurotoxic.

Amyloid Neuropathy, Primary amyloidosis can produce 1 predominantly sensory neuropathy in about one third of patients. Familial amyloid polyneuropathy is a dominantly inherited condition. Patients present with painful dysesthesias, phis loss of pain and temperature sensation. Weakness develops later. Autonomic dysfunction is typical. Eventually, the sensory loss can be severe enough to make the affected extremities virtually anesthetic. Diagnosis can be suspected on clinical grounds, and confirmation requires nerve biopsy. Nerve conduction studies and LMG findings are not specific.

Proximal Sensory Loss. Proximal sensory loss involving the trunk and upper aspects of the arms and legs is uncommon but can be seen in patients with porphyria, diabetes, and with restricted distributions in some patients with proximal plexopathies. Other rare causes of proximal sensory loss include Tangier disease, Sjogren's syndrome, and paraneoplastic syndrome. These neuropathic processes can be associated with pain in addition to the sensory loss. Motor deficit is also common with weakness in a proximal distribution. Patients with thoracic sensory loss should also be evaluated for thoracic spinal cord lesion, which may not always be associated with corticospinal tract signs.

Temperature-Dependent Sensory Loss. Leprosy can produce sensory deficits that predominantly affect cooler

regions of the skin, including the fingers, toes, nose, and ears. Temperature sensation is initially impaired with subsequent involvement of pain and touch sensation in the cooler skin regions. The deficit gradually ascends to warmer areas. Distribution is typically in a stocking-glove distribution and with ftequent trigeminal and ulnar nerve involvement. Diagnosis is by suspicion and can be confirmed by additional testing including antibodies to phenolic glycolipid-I (PGL-I) and nerve biopsy.

Acute Inflammatory Demyelinating Polyradiculoneuropathy

AIDP (Guitlain-Barre syndrome) is an autoimmune process characterized by rapid progression of inflammatory demyelination of the nerve roots and peripheral nerves. Patients present with generalized weakness that may spread from the legs upwards or occasionally from cranial motor nerves downwards. Sensory symptoms are generally overshadowed by the motor loss. Tendon reflexes are lost as the weakness progresses.

Diagnosis is suspected in a patient who presents with progressive weakness with areflcxia. Nerve conduction studies can confirm slowing, especially proximally (F waves are particularly affected}. CSF analysis shows increased protein level without a prominent cellular response (albuminocytological dissociation).

Mononeuropathy

There are many mononeuropathies, the most common of which is carpal tunnel syndrome, with ulnar neuropathy being a close second. Although not classically considered a mononeuropathy, radiculopathy falls into this categoty, because one peripheral nerve unit is affected.

Carpal Tunnel Syndrome. Compression of the median nerve at the wrist produces sensory loss on the palmar aspects of the first thtough third digits. Motor symptoms and signs can develop with increasing severity of the mononeuropathy, but the sensory symptoms predominarc, especially early in the course. Weakness and wasting of the abductor pollicis brcvis can develop.

Nerve conduction studies usually show slowing of sensory and motor conduction of the median nerve through the carpal tunnel at the wrist. The slowing is ptcseut when conduction elsewhere is normal or at least when the distal slowing is far out of proportion to the slowing from neuropathy elsewhere. EMG is usually normal, bur denervation in the abductor pollicis brcvis may develop with severe disease.

Ulnar Neuropathy. Ulnar neuropathy is commonly due to compression in the region of the ulnar groove. Patients present with numbness in the ulnar two fingers (fourth and fifth digits). Weakness of the interossei develops, with advanced ulnar neuropathy of any location, but sensory symptoms predominate, especially early in the course.

Nerve conduction studies show slowing of motor conduction across the elbow or wrist—the two most common sites for ulnar entrapment. Sensory nerve conduction studies will also be abnormal if the lesion is at the wrist. EMG can show denervation in the ulnar-innervated intrinsic muscles of the hand; the muscle easiest to examine and study is the first dorsal interosseous muscle.

Radiculopathy. Radiculopathy commonly produces pain and/or sensory loss in the distribution of one or more nerve roots. Motor symptoms and signs develop with increasing severity, but sensory symptoms (usually pain) may be ptesent for years without motor symptoms.

Reflex abnormalities ate common in radiculopathy, but this should be considered a sensory finding, rather than a motor finding. Prominent weakness would need to be present to suppress a reflex, whereas mild sensory dysfunction may supptess or abolish the reflex.

Table 31.6 presents clinical features of common radiculopathies. Although cervical and lumbar radiculopathies are discussed here, any level can be affected. Diabetic tadiculopathy and herpes zoster commonly affect thoracic dermatomes, as well as cervical and thoracic dermatomes unaffected by spondylosis or disc disease.

Radiculopathy is best studied using MRL In patients younger than 45 years, the most common etiology is disc disease. In older patients, spondylosis and osteophyte formation predominate. The lattet is slower to progress

Table 31.6: Radiculopathies

Nerve root	*Sensory loss*	*Motor loss*	*Reflex abnormality*
C5	Radial forearm	Deltoid, biceps	None
C6	Digits 1 and 2	Biceps, brachioradialis	Biceps
C7	Digits 3 and 4	Wrist extensors, triceps	Triceps
C8	Digit 5	Intrinsic hand muscles	None
L2	Lateral and anterior upper thigh	Psoas, quadriceps	None
L3	Lower medial thigh	Psoas, quadriceps	Patellar (knee)
L4	Medial lower leg	Tibialis anterior, quadriceps	Patellar (knee)
L5	Lateral lower leg	Peronei, gluteus medius, tibialis anterior, toe extension	None
S1	Lateral foot, digits 4 and 5, outside of sole	Gastrocnemii, gluteus maximus	Achilles (ankle)

and less likely to have spontaneous remissions and exacerbations. EMG can be helpful to determine whether there has been any axonal damage from radiculopathy, which may help determine rhc need, location, and timing of decompressive surgery.

Spinal Syndromes

Myelopathy

Myelopathy typically produces sensory loss, although the motor and reflex findings eclipse the sensory findings for most patients. Nevertheless, when a patient presents with back pain with or without leg weakness, a sensory level should be sought. There are some basic pearls regarding sensory testing in patients with suspected myelopathy.

- A defined linclike level is not expected. The sensory mapping is not as precise as that shown on dermatome charts.
- The sensory loss is seldom absolute, which makes precise localization even more difficult.
- The sensory level may not be at the same level on the two sides of the body—a discrepancy of up to several levels can be seen.
- The sensory level may be much higher than might be expected from motor examination or pain. This is because the lesion may be much higher than the lower levels of clinical findings, reinforcing the pearl that one must start from the level of the symptoms and look up!

Syringomyelia

Syringomyelia is due to a syrinx, or fluid-filled space, in the spinal cord that extends over several to many segments. This is most commonly associated with a Chiari malformation. The theory is that partial obstruction to (:Sl flow plus pressure waves in the CSF produce rupture of the central canal into the parenchyma of the spinal cord, which then produces symptoms by mechanical effects. The mass effect of the syrinx produces damage to the fibers crossing in tlic anterior whin.- commissure and destined for die spinothalamic tract that convey pain and temperature sensation. With more severe enlargement of the syrinx, there can be damage to the surrounding ascending tracts affecting sensation below the level of thi[1] lesion, By the riuntil is develops, segmental motoneuron damage and descending corticospinal tract damage are almost always present, and clinical signs of these can be seen.

Spinal Hemisection

The spinal hemisection (Brown-Sequard) syndrome is classically described as the result of surgical or traumatic hemisection of the cord, but this presentation is rarely, if ever, encountered in clinical practice. Below the level of the lesion, there are ipsilateral deficits in vibration and proprioception from dysfunction of the dorsal columns, as well as contralateral deficits in pain and temperature from damage to the spinothalamic tracts. Ipsilateral weakness is also seen from damage to the corticospinal tracts.

Diagnosis is suspected by clinical presentation. This is a condition that can be easily missed if individual sensory modalities are not examined. Merely testing for pinprick will not identify this syndrome. V1R1 is usually performed to look for inflammatory or structural causes of the condition.

Tabes Dorsalis and Related Disorders

Tabes dorsalis is due to involvement of the dorsal roots by late neurosyphilis. Patients present with sensory ataxia, lightning pains, and often with a slapping gait. Tendon reflexes are depressed. Diagnosis is confirmed by serological testing.

Syphilitic myelitis is a rare complication of neurosyphilis, characterized by progressive weakness and spasticity. Moror symptoms dominate in this condition, with lesser sensory symptoms than with tabes dorsalis. MRI of the spine must be performed to look for other structural causes of myelopathy.

Brain Syndromes

Thalamic infarction and Hemorrhage

Thalamic infarction typically produces contralateral hemisensory loss and is the main cause of a pure sensory stroke. All modalities are affected to variable degrees. The thalamus and its vascular supply arc not organized so that specific portions of the sensory system are affected without dysfunction of other sensory systems and regions.

Emergent computed tomographic (CT) scanning is performed on patients with sudden onset of sensory symptoms. This can differentiate infarction from hemorrhage, which has implications for emergent medical management. CT may not show infarction early in stroke, so repeated scanning or MRI should be performed after 2-3 days.

Thalamic Pain Syndrome

Thalamic pain syndrome is an occasional sequela to thalamic infarction that usually affects the entire contralateral body, from face through arm, trunk, and leg. The pain is present mainly distal in the limbs at rest but is exacerbated by sensory stimulation. Sensory detection thresholds arc increased. Involvement of the posterior ventrobasal region is thought to be necessary for production of thalamic pain,

When the patient is known to have had a thalamic infarction, additional study is usually not needed when the patient develops thalamic pain. If the pain develops long after the infarction, then repeated scanning is warranted to look for new pathology, such as recurrent infarction, hemorrhage, or less likely tumot.

Trigeminal Neuralgia

Trigeminal neuralgia is a painful condition that produces lancinating pain in the distribution of part of the trigeminal nerve. This is prototypical neuropathic pain. Patients have paroxysms of pain, which last for seconds at the most. Sensory loss does not occur and when present encourages further search for other diagnoses. Imaging studies arc commonly performed in trigeminal neuralgia **but** are seldom revealing.

Cortical Infarction

Infarction of the sensoty cortex serving the face and arm is due to thromboembolism of branches of the middle cerebral artery. Infarction of the anterior cerebral artery produces sensory loss affecting the leg. Motor symptoms and signs are usually present, as well as the sensory findings; howevet, if the region of infarction is limited, the sensory findings may be much more prominent than the motor findings.

Functional (or Psychogenic) Sensory Loss

Functional sensory loss is less common than other positive functional neurological symptoms such as seizures or paralysis. In fact, it is easy to mistakenly ascribe a pattern of sensory loss as being nonanatomical, when in fact true disease damage is present. This is particularly common in thalamic infarction and plexus dysfunction. As one last precaution, embellished sensory and/or motor loss may be obvious to an examiner but may be superimposed on a real neurological deficit. The patient may be unintentionally helping the examiner and rather ruining the credibility of the report.

With these cautionaty notes, clinical presentations suggesting functional sensoty loss include the following:

- Sensory loss exactly splitting the midline, with a transition zone of millimeters
- Circumferential sensory loss around rhe body or an extremity
- Failure to perceive vibration with a precise demarkation
- Loss of vision ot hearing on the same side of the body as the cutaneous sensory deficit
- Total anesthesia

The discrepancies in total anesthesia can be failure to perceive any sensory stimulus on an extremity that moves perfectly well. This degree of sensory loss would be expected to produce sensory ataxia. Another trap for the patient with an anesthetic limb is movement of the limb when it is tapped while the eyes are closed. Third, if the anesthetic limb is an arm, asking the patient to fold the arms across the chest and then examining sensory abnormality can be confusing, especially if peiformed quickly.

Chapter 32
Neurological Causes of Bladder, Bowel, and Sexual Dysfunction

Clare J. Fowler

Because of their anatomical proximity and shared peripheral innervation, it might reasonably be assumed that the bladder, bowel, and organs of sexual function are neurological ly similar. Although the organs share the same nerve roots and have common peripheral nerves within the pelvis, each is controlled by its own unique set of central nervous system reflexes. In this chapter, a brief account ni the neurophysiological control of the bladder, bowel, and sexual responses is given, followed by a description of the functional consequences for each organ of neurological damage in different parts of the nervous system.

THE FUNCTION OF PELVIC ORGANS AND THEIR NEUROLOGICAL CONTROL

Bladder

The bladder performs only two functions: storage and emptying. The modern view of the control of these two mutually exclusive activities is that neural programs for each exist in centers in the dorsal tegmentum of the pons and that supra pontine influences switch from one state to the other (Morrison et al. 2002).

The frequency of micturition of a person with a bladder capacity of 400-600 mL is once every 3-4 hours, depending on fluid intake. Because voiding takes 2-3 minutes, this means that for more than 98% of life, the bladder is in storage mode. The decision as to when to switch to voiding is determined by the perceived state of bladder fullness and an assessment of the social appropriateness to do so. To effect both storage and voiding, connections between the pons and the sacral spinal cord must be intact, as must the peripheral innervation that originates from the most caudal segments of the cord.

During the storage phase, raised pressure in the bladder outlet is maintained by sympathetic influences on the smooth muscle of the detrusor in the bladder neck region and by pudendal nerve activation of the striated muscle of the urethral sphincter and the pelvic floor. Inhibition of the parasympathetic outflow prevents detrusor contraction. At the start of voiding, the reciprocal activation-inhibition of the sphincter-detrusor reverses. Relaxation of the striated muscle of the sphincter is followed seconds later by contraction of the smooth muscle of the detrusor, effecting bladder emptying.

Positron emission tomography (PET) studies of male and female subjects voiding have demonstrated that neurological control of the bladder in humans is essentially similar to that demonstrated in experimental animals (Blok et al. 1997, 1998). Right-handed volunteers were trained to void while lying in the scanner, but some subjects, botb male

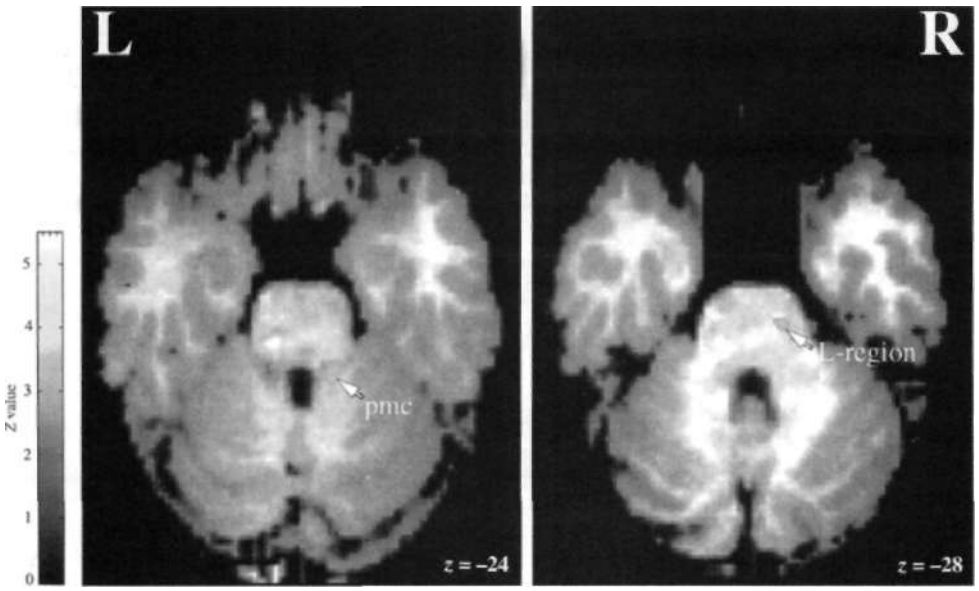

FIGURE **32.1** PET scanning images of the pontine region in subjects who could micturate in the scanner (left) and those who could not (right), compared with empty bladders. In those who could void, activation is seen in the pontine micturition center (pmc), whereas in those unable to void and still storing urine, activation is seen in a lateral part of the pons (L-region). (Reprinted with permission from lilok, P. I'., Sturm-,. [. M.. 8i Holstege, (I. 1998, "Brain activation during micturition in women," *Hmin,* vol. 121, pp. 2U33-2042.)

and female, were unable to do this. In successful voiders, activity was shown in a region of the medioposterior pons. In the unsuccessful voiders, when the subjects were attempting to void hut failing, a region in the ventrolateral pontine tegmentum was activated (Figure 32.1). It had been demonstrated in cats that separate pontine nuclei exist for the storage and voiding phases of bladder activity. In the cortex, the PET scans showed significant activity in the right inferior frontal gyrus and the right anterior cingulatc gyrus during voiding that was not present during the withholding phase.

A PET study of cortical activation with bladder filling showed increased brain activity with increasing bladder volume in the periaqueductal gray matter in the midline pons, in the mid-cingulate cortex, and bilaterally in frontal lobe area (Figure 32.2). Increased brain activity relating to decreased urge to void was seen in a different portion of the cingulate cortex, in the premotor cortex, and in the hypothalamus. These findings supported the hypothesis that the PAG receives information about bladder fullness and relays this information to areas involved in the control of bladder storage and that a network of brain regions is involved in modulating the perception of the urge to void that is distinct from that associated with the appreciation of bladder fullness (Athwal et al. 2001).

Bowel

Similarly, lower bowel function exists mostly in the storage mode. Continence is maintained by a combination of the acute anorectal angle, caused by puborectalis contraction,

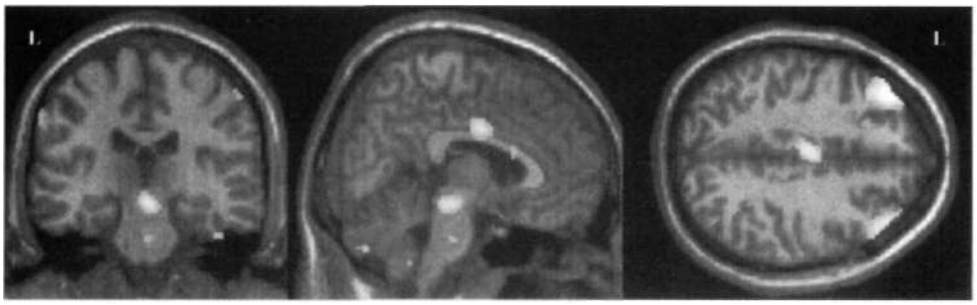

FIGURE 32.2 PET scanning images showing increasing activity in the periaqueductal gray, pons, and cingulate gyrus with increasing bladder volume in health; male volunteers. [Reprinted with permission hum Athwal, 11. S.. link lev, K. | , f lussam,]., el al. 2001, "Brain responses to changes in bladder volume and urge, to void in healthy men," Bram, vol. 124, pp. 369-377.)

and internal anal sphincter tone, determined by sympathetic activity. In neurological health, defecation can be delayed if necessary by contraction of the external anal sphincter and pelvic floor, which requires sensory feedback from the anorcctum. Functional imaging has shown differences between cortical processing of distention of the rectum and the anal canal, as would be expected because the former is a visceral structure and the latter receives somatic innervation (Hobday et al. 2001).

The process of defecation involves a series of neurologically controlled actions that begin in response to the conscious sensation of a full rectum. When this is perceived and if it is judged to be appropriate, defecation is initiated by raising the intra-abdominal pressure and by straining down, causing descent of the pelvic floor. The internal anal sphincter pressure falls due to the rectoanal inhibitory reflex, and the pubococcygeus and striated external sphincter muscles relax (Craggs and Vaizey 1999).

Sexual Function

Physiological sexual response in men and women has been divided into four phases: excitement, plateau, orgasm, and resolution (Masters and Johnson 1970). Excitation occurs in response to either physical or psychologic stimulation and results in clitoral or penile tumescence and erection and vaginal lubrication. The plateau phase is accompanied by the various physical changes of high sexual arousal in anticipation of orgasm. Orgasm, an intensely sensory event, is usually associated in women with rhythmic contraction of the pelvic floor and in men with ejaculation. During resolution, the increased genital blood flow resolves.

Much remains to be discovered about cortical control of sexual function. Although it is thought that cerebral processing determines libido and desire, the ability to effect a sexual response is determined by spinal, autonomic reflexes (Lundberg and Brattbcrg 1993). Libido is hormone dependent, with a major hypothalamic component, and loss of libido may be the earliest symptom of a pituitary tumor.

In experimental animals, the deep anterior midline structures that form the limbic system have been shown to be important for sexual responses, and the medial preoptic-anterior hypothalamic area has an integrating function (Andersson 2001), Electrical stimulation of the hypothalamic and limbic pathways in experimental animals results in erection. Brain stimulation in awake men has been carried out as part of various forms of stereotaxic neurosurgery, but there are no reliable reports of erection occurring during such surgery. Recent functional imaging experiments have demonstrated a number of areas of brain activation (Figure 32.3) with penile turgidity during sexual arousal in healthy men (Arnow et al. 2002).

Male Sexual Response

Erection results from increased blood flow into the corpus cavernosum caused by relaxation of the smooth muscle in the cavernosal arteries and a reduction in venous return. The major peripheral innervation determining this is the parasympathetic, which arises from the S2-S4 segments and travels to the genital region in the pelvic nerves **(Lue** and Tanagho 1987). Sympathetic input is also important: The sympathetic innervation of the genital region originates in the thoracolumbar chain (T11-L2) and rravels through the hypogastric nerves to the confluence of nerves that lies on either side of the rectum and the lower urinary tract: the pelvic plexus. The pelvis plexus also receives input from the pelvic nerves. It is from the pelvic plexus that the cavernous nerves pass to innervate the corpora cavernosa. Although erection is induced by-para sympathetic activiry, the effective neurotransmitter is not acetylcholine because erection in humans is not blocked by atropine. Nitric oxide has been identified as important in causing relaxation of the corporeal blood vessels and the increase in penile blood flow that causes erection,

Psychogenic erection requires cortical activation of erectogenic pathways via the spinal cord, and the preservation of this type of responsiveness in men with low spinal cord lesions suggests that sympathetic pathways can mediate it. Reflex erections occur as the result of cutaneous genital stimulation. Preservation of reflex erections in men with lesions above T i l indicates that the response is the result of spina! reflexes with afferent impulses conveyed in the pudendal nerve, the S2-S4 roots, and efferent traffic through the same sacral roots. In health, reflex and psychogenic responses are thought to reinforce one another. In men, orgasm and ejaculation arc not the same process: Ejaculation is the release of semen, and orgasm consists of the sensory changes accompanied by pelvic floor contractions. Ejaculation involves emission of semen from the vas and seminal vesicles into the posterior urethra and closure of the bladder neck. The latter processes are under sympathetic control, whereas the contraction of the pelvic-floor muscles is under somatic nerve control, innervation being from the perineal branch of the pudendal nerve. Afrer ejaculation, a period of resolution is necessary before sexual activity can be reinitiated.

Female Sexual Response

Lundberg (1999) has written a detailed account of the neurology of the female sexual response. The neurological control of sexual function in women is less well understood than that of men, but similarities exist: The main para-sympathetic innervation is from the pelvic nerves, the sympathetic innervation from the hypogastric nerves, and bilateral somatic innervation from the pudendal nerves. The finding of acetylcholincstcrasc-positivc nerves around

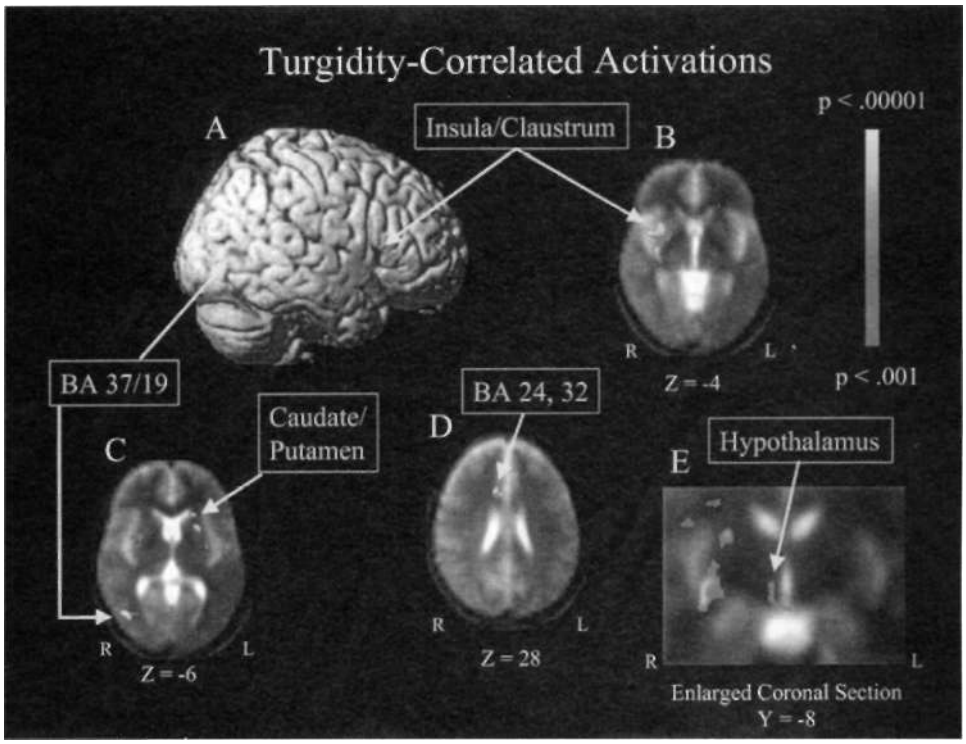

FIGURE 32.3 Magnetic resonance images showing brain activation correlated with penile turgidity in 11 subjects. E., Banner, L. L., ct al. 2002, "Brain activation and sexual arousal m healthy, heterosexual males," Brain, vol. 125, pp. 1014-1023.)

blood vessels in the vagina suggests that there is parasympathetic control of vaginal vasodilation secretomotor function. It seems likely that increased vaginal blood flow, erection of the cavernous tissue of the clitoris and around the outer part of the vagina, and lubrication are brought about through similar neural mechanisms to those that control erection in men.

The lubrication that occurs as part of sexual arousal results from transudation through the vaginal walls and fluid from Bartholin's glands. There are no actively secreting gland cells in the vaginal walls, and the formation of vaginal lubricant is thought to be the result of a nonsecretory process entirely dependent on increased vaginal blood flow, with the slippery quality of the vaginal fluid resulting from its sialoprotein content. Sexual arousal, either through direct stimulation of the genital region or through cerebral mechanisms, can result in very rapid vaginal lubrication (i.e., within 30 seconds). Normal lubrication depends on both intact innervation and normal estrogen levels.

During orgasm, there may be a scries of synchronous contractions of the sphincter and vaginal muscles. As many as 20 consecutive contractions have been registered, lasting for 10-50 seconds. The sensory changes generally are described as an intensely pleasurable pelvic event. Discussion continues as to whether there is any physiological difference between clitoral or vaginal orgasm. Unlike men, some women are able to have multiple orgasms without a resolution phase.

EFFECT OF CORTICAL LESIONS ON PELVIC ORGAN FUNCTION

Bladder Dysfunction

That anterior regions of the frontal lobes are critical for bladder control has been known since the 1960s. Series of patients with disturbed bladder control were reported with various frontal lobe disturbances, including intracranial tumors, damage after rupture of an aneurysm, penetrating brain wounds, and prefrontal lobotomy (leukotomy) subjects (Andrew and Nathan 1964). The typical clinical picture of frontal lobe incontinence is of a patient with severe urgency and frequency of micturition and urge incontinence but without dementia; the patient is socially aware and embarrassed by the incontinence. Micturition is normally coordinated, indicating that the disturbance is in the higher control of these processes. Urinary retention has also been described in patients with brain lesions. There are a small number of case histories of patients with right frontal lobe disorders who had urinary retention and

in whom there was restoration of voiding when the frontal lobe disorder was treated successfully (Fowler 1999).

After stroke, some patients develop urinary incontinence. This has been studied in two ways: with urodynamic studies and epidemiological^. Urodynamic studies of many incontinent patients have been carried out, and the general conclusion drawn from studying patients with disparate cortical lesions is that voiding is mostly normally coordinated, The most common cystometric finding is of detrusor hypcr-reflexia (Sakakibara et al. 1996). It has not been possible to demonstrate a correlation between any particular lesion site and urodynamic findings.

In terms of the epidemiological approach to stroke and urinary incontinence, the presence of urinary incontinence within 7 days after a stroke appears to be a more powerful prognostic indicator for poor survival and eventual functional dependence than does a depressed level of consciousness in this period. It was suggested that incontinence was the result of severe general loss of function or that those who were incontinent were less motivated to recover both continence and general function (Wade and Langton Hewer 1985).

The cause of urinary incontinence in dementia probably is multifactorial. Not all incontinent older adults are cognitively impaired, and not all cognitively impaired older adults are incontinent. In a study of patients with progressive cognitive decline, incontinence was associated with severe mental failure in pure Alzheimer's disease but was preceded by severe cognitive impairment in diffuse Lewy body disease {Del Ser, Munoz, and Hachinski *1996).*

A much less common cause of dementia is normal-pressure or low-pressure hydrocephalus, of which incontinence is a cardinal feature. Improvement in urodynamic function has been demonstrated within hours of lumbar puncture in patients with this disorder,

Bowel Dysfunction

Articles describing the effects of frontal lobe disorders on micturition note that defecation was generally affected much less often (Andrew and Nathan 1964). Cases of impaired defecation were always accompanied by urinary dysfunction. Only one study has concentrated primarily on the anorectal abnormalities of patients with frontal lobe damage of various types. The conclusion was that the frontal lobe is involved in neurological control of anorectal motility as it is for bladder function, but the lack of correlation between urinary and anorectal abnormality in individual cases suggests that these functions depend on distinct areas of the frontal lobes (Weber et al, 1990).

So far, PET studies of the areas of brain activation after rectal distention have compared responses in healthy control subjects with those of a group of patients with irritable bowel syndrome. It was hypothesized that hyperalgesia of visceral events would occur in the Iattet group. Using a balloon catheter inserted into the rectum, different degrees of distention were applied at timed intervals and the subjects asked to rate any discomfort. Differences between the control subjects and patients were found both on maximal filling and in anticipation of filling, but in healthy subjects activation of the anterior cingulate cortex could be demonstrated only on filling to pressures that were perceived as painful (Silverman et al, 1997).

Sc\ual Dysfunction

Before functional imaging experiments all that was known about human cerebral control and sexuality came from observations of patients with brain lesions, particularly those affecting temporal or frontal regions. These areas can be involved by disorders that cause epilepsy or by trauma, tumors, cerebrovascular disease, or encephalitis.

It has long been observed that sexual dysfunction is more common in men and women with epilepsy. Although various sexual perversions and occasionally hypersexuality have been described in patients with temporal lobe epilepsy, the picture most commonly seen is that of sexual apathy (Shukla, Srivastava, and Katiyar 1979). From studies comparing sexual dysfunction in generalized epilepsy with that in focal temporal lobe epilepsy, there is sufficient evidence to suggest that the deficit is a result of the specific temporal lobe involvement rather than a consequence of epilepsy, psychosocial factors, or antiepileptic medication. The problem is usually that of a low or absent libido, of which patients may not complain. The role of hormonal dysfunction has yet to be fully determined. Based on measurements of sex hormones and pituitary function, it has been suggested that the hyposexuality of temporal lobe epilepsy results from a subclinical hypogonadotropic hypogonadism and that dysfunction of medial temporal lobe structures may dysmodulate hypothaiamic-pituitary secretion (Murialdo et al. 1995).

Erectile dysfunction (ED) with preserved libido, of which some patients complain, can also occur in men with temporal lobe damage with and without epilepsy and may be characterized by loss of nocturnal penile tumescence. Surgery for epilepsy rarely restores erectile function, although a survey of operated patients showed a higher level of satisfaction with sexual function among those who were free of seizures. Sexual dysfunction is not uncommon after head injury, particularly if there has been cognitive damage. A study of people who were admitted to hospital for a minimum of 24 hours after a closed head injury found significant dysfunction in 50% during a 15-year follow-up period (O'Carroll, Woodrow, and Maroun 1991). Hypersexual behavior may occur after frontal lobe damage. Lesions of the frontal lobes, the basal-medial part in particular, may lead to loss of social control, which may also affect sexual behavior.

BASAL GANGLIA

Bladder Symptoms in Patients with Parkinsonism

There are several possible causes of urinary symptoms in a patient with parkinsonism, which include neurogenic causes as well as local urological problems. In Parkinson's disease (PD), bladder symptoms usually occur at an advanced stage of the disease (Araki and Kuno 2000), and prostatic outflow obstruction is a more common cause of problems in older men. In a patient with severe urinary symptoms but mild parkinsonism, a diagnosis of multiple-system atrophy (MSA) should he considered. The onset of urogenital symptoms in MSA may precede overt neurological involvement by years. A study that looked at the duration of symptoms before the diagnosis of MSA found that ED and bladder symptoms began 4-5 years before the diagnosis and, on average, 2 years before more specific neurological symptoms appeared. Almost half the male patients had had a transurethral prostatectomy, from which few benefited (beck, Herts, and bowler 19941.

The neuronal degeneration of MSA probably affects the central nervous system at several locations that are important for bladder control, which explains why urinary complaints occur early and are so severe. It is thought rh.ir detrusor hyper-reflexia is cruised bv neuronal loss in the pontine region, whereas incomplete bladder emptying is caused by loss of parasympathetic innervation of the detrusor after neuronal degeneration in the intermediolateral cell columns of the spinal cord. In addition, anterior horn cell loss in Onufs nucleus results in denervation of the urethral sphincter so that the patient has a combination of bladder overactivity, incomplete emptying, and a weak sphincter. Bladder dysfunction may change during the progression of MSA: Although patients often present with detrusor hypcr-rcflcxia, over the ensuing months or years, impaired bladder emptying may develop so that the postmicturition residual volume increases.

Bladder symptoms in other parkinsonian syndromes are less prominent than m MSA, and although they may occur as part of the patient's general disability, they are rarely so severe or occur at a stage of the disease when a neurological cause is not evident.

In patients with PD and urinary symptoms, it may be difficult to establish the exact cause of the bladder dysfunction, and its treatment often is problematic. Typically, patients present with advanced neurological disease and describe how the bladder symptoms came on many years after treatment for PD started (Chandiramani et al. 1997). They complain of urgency and frequency and urge incontinence if poor mobiliry complicates their bladder overactivity. Urodynamic studies in series of patients with PD have found that the most common urodynamic abnormality is detrusor hyper-reflexia (Araki et al. 2000). There arc several possible explanations for this. The hypothesis most often proposed is that in healthy individuals the basal ganglia have an inhibitory effect on the micturition reflex, and with neuronal loss in the substantia nigra, detrusor hyper-reflexia develops. Experimental data support this theory because marmosets with toxin-induced parkinsonism were found to have detrusor hyper-reflexia, and stimulation of the substantia nigra in cats inhibited distention-induced rhythmic contractions of the bladder. Additional studies on anesthetized cats demonstrated that rhythmic contractions were inhibited by inrracerebrovenrricular administration of a dopamine D| receptor agonist but were not affected by a D_2 receptor agonist. From this, it was concluded that the D, receptor is the main inhibitory influence on the micturition reflex in the cat. Studies in marmosets with toxin-induced parkinsonism confirmed that the same was true for the primate model {Yoshimura et al. 1992).

The results of clinical studies that have looked at the effect of i.-dop.i or apomorphinr on bladder behavior in patients with PD have produced conflicting results. In patients showing the on-off phenomenon, cystometry done in both states showed a lessening of hyper-reflexia with L-dopa in some patients and a worsening in others. A similar unpredictable effect was found on detrusor hyper-reflexia when subcutaneous apomorphine was given in one study, although in another series, all patients with detrusor hypcr-rcflcxia improved. From the results of the animal studies, it seems sensible to treat patients with bladder symptoms with a D] receptor agonist. Pergolide, with its dual D! and D_2 receptor activity, has been tried, with significant symptomatic and urodynamic improvement. The reputation for poor outcome after prostatic surgery in patients with PD may well have resulted from the inclusion of patients with MSA in some of the published studies of PD and the bladder. Nevertheless, if there is convincing evidence of an irreversible outflow obstruction presumed to be caused by prostatic enlargement {rather than a fluctuating, possibly neurogenic disorder), a prostatectomy should be considered.

Bowel Dysfunction

There are several possible causes for the constipation of which many patients with PD complain. A slow colonic transit time has been demonstrated in a number of studies, and it has been suggested that this is caused by a reduction in dopaminergic myenteric neurons, the colonic myenteric plexus being involved by the PD process. An abnormality of the defecation process has also been demonstrated in some patients with PD, with paradoxical contraction of the external anal sphincter and pubococcygcus causing outlet obstruction. This has been called *anismus* and is thought to be a form of focal dystonia.

Bowel dysfunction appears earlier and progresses faster in patients with MSA than in those with PD (Stocchi et al. 2000).

Sexual Dysfunction

Experimental animal and human evidence shows that dopaminergic mechanisms are involved in determining libido and inducing penile erection. In animal studies, the medial preoptic area of the hypothalamus has been shown to regulate sexual drive, and selective stimulation of D_2 dopaminergic receptors in this region increases sexual activity in rats (Andersson 2001). An increase in libido in some patients with PD treated with L-dopa is a well-known phenomenon, although its incidence is uncertain.

The cause of ED in PD is unclear, but it is a significant problem, affecting 60% of a group of men compared with 37.5% of an age-matched healthy nonparkinsonian group in one study. ED usually affects men with PD years after the neurological disease has been established. A survey of young patients with PD (mean age, 49.6 years) and their partners revealed a high level of sexual dysfunction, with the most severely affected couples being those in which the patient was male. ED and premature ejaculation were complaints in a significant proportion, although in general terms sexual dysfunction appeared to be multifactorial, with no single cause identified (Brown etal. 1990).

Dopaminergic agonists induce erection in rats and monkeys, and spontaneous erections have been reported in patients treated with L-dopa. Subcutaneous injections of apomorphine used to treat complicated motor fluctuations in patients with PD have been found to benefit sexual function in a small series (O'Sullivan and Hughes 1998), but sublingual apomorphine is now available to treat general patients with ED and is claimed to be particularly effective in men with mild dysfunction (Heaton 2001).

ED may be the first symptom in men with MSA, predating the onset of any other neurological symptoms by several years. The disorder appears chronologically to be distinct from the development of postural hypotension (Kirchhof et al, 2002). The reason for the apparently early selective involvement of neural mechanisms for erection is not known. Preserved erectile function strongly contradicts the diagnosis of MSA. Nothing yet is known about the sexual dysfunction of women with MSA.

BRAINSTEM

Pelvic Organ Dysfunction

Voiding difficulty is a rare but recognized symptom of a posterior fossa tumor and has been reported in series of patients with brainstem disorders (Fowler 1999). An analysis of urinary symptoms of 39 patients who had had brainstem strokes showed that lesions that resulted in micturition disturbance usually were dorsally situated (Sakakibara ct al. 1996), consistent with the known location of the brainstem centers involved with control of the bladder. The proximity of the pontine micturition center in the dorsal pons to the medial longitudinal fasciculus means that a disorder of eye movements, such as an internuclear ophthalmoplegia, is highly likely in patients with a pontine disorder causing a voiding difficulty.

There has been a single report suggesting that neurological control of anorectal reflexes can be affected by pontine disease, based on the observation of severe constipation in patients after brainstem strokes.

No isolated dysfunction of sexual response has been described specifically associated with brainstem disease.

SPINAL CORD

Bladder Dysfunction

Spinal cord disorders are the most common cause of neurogenic bladder dysfunction. Trans-spinal pathways connect the pontine micturition centers to the sacral cord. Intact connections are necessary to effect the reciprocal activity of the detrusor and sphincter needed to switch between storage and voiding. After disconnection from the pons, this synergistic activity is lost. The result is that the sphincter tends to contract when the detrusor is contracting, a condition known as *detrusar-sphmcter dyssynergia.* In addition, new reflexes emerge to drive bladder emptying and cause detrusor hyper-reflexia. Immediately after spinal cord transection and during the phase of spinal shock, the bladder is not contractile, but gradually over the course of weeks, reflex detrusor contractions develop in response to low filling volumes. The neurophysiology of this recovery has been studied in cats. It has been proposed that after spinal injury, C fibers emerge as the major afferents, forming a spinal segmental reflex that results in .uiiimutic voiding. It is assumed that the same pathophysiology occurs in humans. In support of this assumption is the observed response to intravesical capsaicin (a C-fiber neurotoxin) of patients with acute traumatic spinal cord injury (SCI) or chronically progressive spinal cord disease from multiple sclerosis (MS) (see Chapter 42).

The abnormally overactive, small-capacity bladder that characterizes spinal cord disease causes patients to experience urgency and frequency. If the detrusor hyper-reflexia is severe and if there is also a spastic paraparesis, urge incontinence is highly likely. Poor neural drive on the detrusor muscle during attempts to void, together with an element of demisor-splnncter dyssynergia, likely indicates incomplete bladder emptying. This may exacerbate the symptoms caused by detrusor hyper-reflexia. Although the neurological process of voiding may have been as severely disrupted as the process of storage, the symptoms of difficulty emptying can be minor compared with those of urge incontinence. Only on direct questioning might the patient admit to having difficulty initiating micturition,

an interrupted stream, or possibly a sensation of incomplete emptying.

Because bladder innervation arises more caudally than innervation of the lower limbs, any form of spinal cord disease that causes bladder dysfunction is likely to produce clinical signs in the lower limbs unless the lesion is limited to the conus. This rule is sufficiently reliable to be of great value when considering whether a patient has a neurogenic bladder caused by spinal cord disease.

Spinal Cord Injury

After SCI, detrusor hyper-reflexia, loss of compliance, and dctrusor-sphmcier dyssynergia can be of such severity as to cause ureteric reflux, hydronephrosis, and eventual upper renal tract damage. Before the introduction of modern treatments, renal failure was a common cause of death after SCI. The bladder problems of those with SCI therefore muse be managed aggressively to lessen the possibility of upper tract disease and to provide the patient with adequate bladder control for a fully rehabilitated life. Those with SCI often are young and otherwise fit, and it may be best for them to undetgo surgery on their lower urinary tract with a view to fulfilling these two aims father than to be treated medically.

Multiple Sclerosis

The pathophysiological consequences for the bladder of progressive MS affecting the spinal cord are similar to those of SCI, but the medical context of increasing disability is such rhat management must be quite different. The incidence of bladder dysfunction in MS is estimated to be approximately 75%, similar to the incidence of spinal cord involvement. There is a strong association between bladder symptoms and the presence of clinical spinal cord involvement, including paraparesis and upper motor neuron signs on examination of the lower limb in patients with MS (Betts, D'Mellow, and Fowler 1993). The most common urinary symptom is urgency. All series of urodynamic studies of patients with MS have shown that this is caused by underlying detrusor hyper-reflexia (Chancellor and Blaivas 1995). Patients may volunteer or admit on direct questioning to hesitancy of micturition, but the more disabled may find themselves unable to initiate micturition voluntarily, emptying their bladders only with an involuntary hypcr-rcflcxic contraction and an interrupted urinary flow. Evidence of incomplete emptying may come not from a sensation of continued fullness after voiding but rather from the need to pass urine again within 5-10 minutes.

As the neurological condition progresses, the bladder dysfunction may become more difficult to treat. This is caused by both worsening detrusor hyper-reflexia and decreasingly efficient emptying in the context of worsening paraparesis, spasticity, and general immobility and possibly also cognitive impairment. Unlike the bladder dysfunction that follows SCI, however, progressive neurological diseases very rarely cause upper urinary tract involvement. This is true even when long-standing MS has resulted in severe disability and spasticity. The reason for this is not known, but it means that in such patients, management must emphasize symptomatic relief.

Bladder Dysfunction in Other Nontraumatic Causes of Spinal Cord Disease

Various other forms of nontraumatic spinal cord disease are likely to cause bladder dysfunction, and a more detailed description of these is available (Fowler 1999). Early reviews stated that bladder disturbance was rare in patients with cervical spondylosis, but more recent studies have refuted this. A variable combination of detrusor hyper-reflexia and detrusor sphincter dyssynergia is the most common urodynamic finding, and the majority of patients with bladder dysfunction also have long-tract symptoms and signs.

A consistent feature of transverse myelitis is that although there may be an excellent clinical recovery from **a (.|uadnp:)ivsis of siieh** severity rhat at **its nadir** artificial ventilation was necessary, bladder dysfunction may be the sole residual neurological sequela (Sakakibara et al. 1996). The explanation for this is not known, but it may tclatc to the emergence of spinal segmental reflexes during the period of spinal shock, which then persist as a dominant functional mechanism.

Detrusor hyper-reflexia occurs as an early feature and may even be a presenting symptom in patients with tropical spastic paraparesis, the progressive myelopathy caused by infection by human T-cell lymphotropic virus 1.

Once a common cause of bladder dysfunction, neurosyphilis is now rare. Tabes dorsalis was classically said to result in an areflexic, hyposensitive bladder through involvement of the dorsal columns and roots. Studies of small groups of patients with tabes have demonstrated a variety of abnormal urodynamic findings.

Arteriovenous malformations of the spinal cord may be difficult to recognize clinically but common!) cause bladder disturbance as a prominent, early feature. Although the majority of arteriovenous malformations occur in the thoracolumbar tegion, alterations to cord blood flow and subsequent ischemia of the conus mean that the patient may present with what appears to be a conus or cauda equina lesion. Symptoms of voiding difficulty arc common at an early stage, followed by urinary retention.

A mixture of upper and lower motor neuron signs in the legs together with urinary symptoms is characterisric of a tethered spinal cord. Typically asymmetrical wasting of the calves and intrinsic muscles of the feet occurs, but the prominent bladder symptoms and possibly extensor plantar

responses suggest a diagnosis of a conus lesion rather than peripheral neuropathy or previous poliomyelitis. Although the majority of cases present in childhood, tethered spinal cord is a condition that should be considered in adults with the appropriate clinical features. Urodynamic studies show a mixed picture of detrusor hyper-reflexia and incomplete bladder emptying. Although an improvement in bladder function after a detethering procedure has been claimed, the operation usually is carried out to treat pain or prevent progression of neurological deficit.

Bowel Dysfunction

Only about one third of patients achieve fecal autonomy after SCI, and half of patients need help with bowel management. A questionnaire survey of patients with SCI found that bowel dysfunction was a major problem, rated as only slightly less serious than loss of mobility ((Hickman and Kamm 1996). Bowel management may be equally problematic for patients with progressive spinal cord disease, such as MS. The loss of rectal sensation and the normal desire to defecate mean that bowel emptying must be induced at a convenient time by digital anal stimulation, the use of suppositories or enemas, or manual evacuation (Norton and Henry 1999). The loss of ability to postpone bowel emptying, because of both impaired sensation of impending defecation and the inability to voluntarily contract the anal sphincter means that fecal incontinence is common.

Sexual Dysfunction

Male Sexual Dysfunction

The level and completeness of a lesion determine erectile and ejaculatory capability after SCI. With a complete cervical lesion, psychogenic erections are lost, but the capacity for spontaneous or reflex erections may be intact. In low spinal cord lesions, particularly if the Cauda equina is involved, there may be little or no erectile capacity (Bors and Comarr I960). Theoretically, a lesion below spinal level L2 leaves psychogenic erections intact, but in practice it is uncommon for men with such a lesion to have erections adequate for intercourse. Psychogenic erections arc more likely to be preserved in incomplete lesions. Preserved ejaculation function after a spinal cord lesion is unusual.

Studies of men who underwent bilateral anterolateral cordotomies for pain relief reported loss of orgasmic sensation, which suggests that erotica I ly colored sensation travels in close proximity to the spinothalamic tracts, and a study of patients with anorgasmia after an anterior cord syndrome demonstrated loss of small nerve fiber-media ted function, whereas large-fiber, dorsal column functions were preserved.

Although earlier studies indicated a much lower figure, 60-65% of men with MS have ED. ED usually occurs in men with urinary symptoms, the majority having urodynamically demonstrable hype r- re flex i a (Belts et al. 1994). Typically, in the early stages of MS, the chief complaint is of difficulty sustaining an erection for intercourse. Penile erections occurring during rhe night and on morning waking and normal nocturnal penile tumescence tests have been demonstrated in men with MS who complain of erectile difficulties. These features may have contributed in the past to a misapprehension that the problem was not organic. Wirh advancing neurological disability, erectile function may cease, and there may be difficulty with ejaculation. A study of the pudendal evoked potentials in men with MS found that those with a severe delay (i.e., those with more severe spinal cord disease) were more likely to be unable to ejaculate (Betts et al. 1994). It has been said that a diagnosis of MS should be considered in a young man presenting with impotence, but in the absence of clinical spinal cord disease, this seems unlikely. In one series only, a single patient had erectile difficulties in association with the firsr symptoms of MS, and no man presented with ED and then developed neurological disease.

Female Sexual Dysfunction

A remarkable recent study of female sexual function after SCI showed that a proportion of women, particularly with higher cord lesions, had preserved orgasmic capacity (Sipski, Alexander, and Rosen 2001). Sexual dysfunction in women with MS is common, affecting 50-60%, with the incidence increasing with increasing disability. Reduced sexual desire is the most common complaint. Presumed neurogenic problems with intercourse include decreased lubrication and reduced orgasmic capacity. In women with advanced disease, there may be additional problems of lower limb spasticity, loss of pelvic sensation, genital dysesthesia, and fear of incontinence (Hulter and Lundberg 1995). Little research has been done to date, although female sexual dysfunction is now being recognized as a significant problem and treatment trials of various therapies are in progress.

SYMPATHETIC THORACOLUMBAR OUTFLOW

The fibers that travel from the thoracolumbar sympathetic chain emerge from spinal levels T10-L2 and course rhrough the retroperitoneal space to the bifurcation of the aorta, from which they enter rhe pelvic plexus. Loss of sympathetic innervation of the genitalia causes disorders of ejaculation, with cither failure of emission or retrograde ejaculation; the ability to experience the sensation of orgasm may be retained. The sympathetic thoracolumbar fibers are particularly likely to be injured by the procedure

of retroperitoneal lymph node dissection, and complaints of loss of ejaculation are common after such surgery (Fowler 1998).

CONUS AND CAUDA EQUINA

The cauda equina contains the sacral parasympathetic outflow together with the somatic efferent and afferent fibers. Damage to the cauda equina therefore results in sensory loss as well as a parasympathetic defect. After such a lesion, both men and women complain of perineal sensory loss and loss of erotic genital sensation, for which there is no effective treatment. In men, ED is also a complaint.

Damage to the cauda equina leaves the detrusor decentralized rather than denervatcd because the postganglionic parasympathetic innervation is unaffected. This may explain why the bladder dysfunction after a cauda equina lesion is unpredictable and why even detrusor hyperrcflexia has been described. Inability to evacuate the bowel may be a severe problem, and manual evacuation may be necessary for the long term. Additional denervation of the anal sphincter can result in incontinence of flatus or liquid motions.

Loss of control over bladder and bowel and loss of sexual function are patticularly difficult for patients to bear psychologically when they are otherwise ambulant and mobile. Although there are a number of scries reporting the urodynamic changes that can occur after a cauda equina lesion, there has been no analysis of the effect a cauda equina lesion can have on the quality of life. The levels of compensation awarded in medicolegal cases reflect the fact that loss of control of the pelvic organs is a catastrophe.

Contact with other patients similarly affected may prove supportive (see www.caudaequina.com or www.cauda-cquina.org).

PERIPHERAL INNERVATION

Diabetic Neuropathy

Bladder involvement was once considered an uncommon complication of diabetes, but the greater use of techniques for studying bladder function has shown that the condition is common, although often asymptomatic. Bladder dysfunction does not occur in isolation, and other symptoms and signs of generalized neuropathy must be present in affected patients. The onset of the disorder is insidious, with progressive loss of bladder sensation and impairment of bladder emptying over years, eventually culminating in clironic low-pressure urinary retention (Frimodt-Moller 1980). Urodynamic studies demonstrate impaired detrusor contractility, reduced urine flow, increased postmicturition residual volume, and reduced bladder sensation (Kaplan, Alexis, and Blaivas 1995). It seems likely that vesicle afferent and efferent fibers are involved, causing reduced awareness of bladder filling and decreased bladder contractility.

Diabetes is the most common cause of ED. Surveys of andrology clinics have found that 20-31% of men attending arc diabetic. The prevalence of ED increases with age and duration of diabetes, and the problem is known to be associated with severe retinopathy, a history of peripheral neuropathy, amputation, cardiovascular disease, raised glycosylated hemoglobin, and the use of antihypertensives (Kolodny et al. 1974). A large population study of men with early-onset diabetes found that 20% had ED. Whether its pathogenesis in diabetic patients results mainly from neuropathy, there is a significant microvascular contribution, or rhe two processes are codependent is not yet resolved. At a cellular level, however, the evidence suggests a depletion of neurotransmitters.

Age-matched studies of women with and without diabetes suggest that diabetic women may also be affected by specific disorders of sexual function, including decreased vaginal lubrication and capacity for orgasm (Jensen 1986).

Amyloid Neuropathy

Autonomic involvement occurs early both in inherited familial amyloid polyneuropathy (FAP) and in amyloidosis secondary to myeloma or benign plasma cell dyscrasia. Typically, there are features of somatic sensory involvement, such as loss of pain and temperature sensation in the feet, by the time the disease has advanced to produce pelvic autonomic deficits. A study of the urogenital complaints of 12 patients with FAP type I amyloidosis showed reduced bladder contractility and a reduced flow rate in most of them, and two patients had a significant postmicturition residual. Five had ED, and one also had retrograde ejaculation (Villaplana et al. 1997). Although the patients in this series generally were at an advanced stage (undergoing liver transplantation), ED is often reported early in the course of FAP when fewer systemic symptoms are present.

Immune-Mediated Neuropathies

About one fourth of patients with Guillain-Barre syndrome have bladder symptoms. These symptoms usually occur in patients with more severe neuropathy and appear after limb weakness is established. Both detrusor areflexia and bladder overactivity have been described (Zochodne 1994).

It is likely that acute distal autonomic neuropathy is a form of Guillain-Barre syndrome, and there have been a

number of reports of distal autonomic neuropathy affecting both the sympathetic and parasympathetic systems. Painful urinary retention usually occurs in both cholinergic and pandysautonomia.

Injury to Pelvic Nerves

Extirpating pelvic surgery, such as resection of rectal carcinoma, radical prostatectomy, or radical hysterectomy, can damage the peripheral innervation of the pelvic organs. The dissection necessary for rectal cancer surgery is likely to damage the parasympathetic innervation to the bladder and genitalia because the pelvic nerves take a mediolateral course through the pelvis on either side of the rectum and the apex of the prostate. The nerves may be removed together with the fascia that covers the lower rectum or may be damaged by a traction injury as the rectum is mobilized before excision (Mundy 1982).

Urinary incontinence after a radical prostatectomy or a radical hysterectomy that includes the upper part of the vagina probably is also caused by damage to the parasympathetic innervation of the detrusor and, in the case of radical prostatectomy, direct damage to the innervation of the striated urethral sphincter. Much has been written about the importance of sparing nerves during a radical prostatectomy to preserve erectile function {Walsh and Donker 1982), but ED occurs in a significant proportion of patients postoperatively. Ejaculation can also be affected after this operation.

Myotonic Dystrophy

Although myotonic activity has not been found in the sphincter or pelvic floor of patients with myotonic dystrophy, bladder symptoms may be prominent and difficult to treat, presumably because bladder smooth muscle is involved. With advancing disease, megacolon and fecal incontinence may also become an intractable problem (Herbaut et al. 1992),

Urinary Retention in Young Women

Urinary retention or symptoms of obstructed voiding in young women in the absence of overt neurological disease have long puzzled urologists and neurologists alike, and in **the** absence of any convincing organic cause, the condition was often said to be hysterical. Typically, the clinical history is of a young woman aged 20-30 years who presents with retention and a bladder capacity greater than 1 liter. The history is often that over the preceding 12 hours she has found herself unable to void and, although by the time of presentation she may be very uncomfortable, she does not have the sensations of extreme urgency that might be expected. Many of the women have previously had an interrupted urinary stream but are unaware that this is abnormal; therefore, a voiding history can be misleading unless taken carefully (Swinn et al. 2002). There are no other clinical neurological features or laboratory investigations to support a diagnosis of MS, and magnetic resonance images of the brain, spinal cord, and cauda equina are normal. The lack of sacral anesthesia makes a cauda equina lesion improbable. In some young women with urinary retention, concentric needle electrode examination of the striated muscle of the urethral sphincter reveals a striking electromyographic abnormality (Fowler et al, 1988) (see Chapter 42). Until recently, management was symptomatic only, and patients had to perform intermittent self-catheterization indefinitely. However, it appears that these patients respond particularly favorably to sacral nerve stimulation. The mechanism of action of this therapeutic intervention is being researched (Swinn et al. 2000).

Chapter 33
Arm and Neck Pain

Michael Ronthal

The evaluation of the patient with arm or neck pain depends on a careful history and clinical examination. Almost always, the diagnosis of the common causes can be made in the office before seeking laboratory investigation, but these may be required if the patient fails to improve with treatment or has other specific indications for imaging or electrophysiological studies.

A useful approach is to consider the problem in terms of pain-sensitive structures in the neck and in the upper limb. These structures may be part of the nervous system (neurological) or part of the joints, ligaments, muscles, and so on (non-neurological). Neurological causes involve the innervation of the structures in the neck and arm, and non-neurological causes are based on dysfunction of other anatomical structures of the arm or neck. Nerve root irritation frequently generates neck muscle spasm, which is therefore classified in the "neurological" category. Some essentially non-neurological conditions have neurological complications and are grouped in this chapter as "in between" disorders.

CLINICAL ASSESSMENT

History

Neurological Causes of Pain

Muscle Spasm. Spasm of posterior cervical muscles causes local pain that is aggravated by neck movement. The diagnosis is supported by the finding of palpable spasm and tenderness of the neck and shoulder muscles. The pain may radiate upwards to the occipital region and over the top of the head to the bifrontal area. It is usually described as constant, aching, and bursting or as a tight band or pressure on top of the head. Pain with similar characteristics can be triggered by abnormalities of the facet joints of the cervical spine, of the vertebrae, and even of the intervertebral discs.

Neck mobility is restricted as a result of muscle spasm. It should be assessed by testing for movement in each of the main planes, flexion and extension, lateral flexion to the right and left, and rotation to right and left. Normally in flexion the chin can touch the sternum and in rotation the chin should be able to approximate the point of the shoulder.

Central Pain, Central dysfunction affecting sensory tracts in the spinal cord may generate pain or paresthesias in the arm or down the trunk and lower limbs. An electric-like sensation spreading to the arms, down the spine, and even into the legs that is provoked by neck flexion is thought to originate in the posterior columns of the cervical spinal cord (Lhermittc's sign). Although it is common in patients with multiple sclerosis, it is nonspecific and simply denotes a pathological process in the cervical cord. Sharp superficial burning or itching pain suggests dysfunction in the spinothalamic system, whereas deep aching boring pain with paresthesias and sensations of tightness, squeezing, or swelling suggest dysfunction in the posterior columns.

Nerve Root Pain. If the damage involves nerve roots, it is referred down the limb more or less in dermaromal distribution. Brachialgia (arm pain) aggravated by neck movement, coughing, or sneezing indicates a cervical radiculopathy, hut ihis pathognomonic symptom may not

he present. Nerve root pain is classically lancinating bur can be a dull ache in the arm,

Plexus Pain. Pain in the arm can result from damage to the brachial plexus or individual nerves in the arm. Infiltrative or inflammatory lesions of the brachial plexus produce severe brachialgia radiating down the arm and spreading also to the shoulder region. Radiation to the ulnar two fingers suggests origin in the lower brachial plexus, and radiation to the upper arm, forearm, and thumb suggests an upper brachial plexopathy. Patients with a thoracic outlet syndrome complain of brachialgia and numbness or tingling in the upper limb or hand when working with objects above the head.

Ulnar Nerve Pain. Ulnar nerve entrapment produces numbness or pain radiating down the medial aspect of the arm to the little and ring fingers. The symptoms are often worse at night when the patient sleeps with a flexed elbow and may be the cause of interrupted sleep. They are also worse when the patient rests the elbow on the arm of a chair or desk.

Median Nerve Pain, Median nerve entrapment in the carpal tunnel will often wake the patient from sleep with numbness and tingling in the thumb, index and middle fingers, which is relieved by "shaking out" the hand. Pain generated in the median nerve can be sharp and lancinating and radiates to the thumb and index and middle fingers.

Non-Neurological Causes of Neck Pain and Brachialgia

Pain arising in muscles is described as deep aching and boring. In the cervical region, it is localized to the shoulders and sometimes radiates down the arm. Patients with fibromyalgia ma] have pain in the neck, shoulders, and arms, with trigger spots that are exquisitely render even to light pressure.

Joint and tendon pain has the characteristic of being initiated and aggravated by movement of the joint involved or tension of a specific tendon. Particular attention should be paid to these precipitating factors. Pain on shoulder joint movement is unlikely to be neuropathic. Although the pain of epicondylitis may radiate down the forearm in a pseudoneuralgic fashion, precipitation of pain by movement at fingers or wrist generally indicates an arthropathy cause.

Examination

The physical examination is designed to localize a neurological deficit related to spinal cord, nerve roots, or peripheral nerves. At the same time, evaluation for non-neurological pathology is important because orthopedic and rheumatological problems often simulate or complicate neurological presentations. A detailed knowledge of motor and sensory neuroanatomy is required for accurate localization.

Motor Signs

The examination begins with inspection. Particular attention is paid to atrophy of the muscles of the shoulders and arms, as well as the small muscles of the hands. Fasciculations are often due to anterior horn cell disease, but they are not uncommon in patients with cervical spondylosis and radiculopathy. A good confirmatory sign of cervical radiculopathy is in the Spurling sign. The patient's head is inclined towards the painful side, and pressure is applied downwards from the crown. This may produce sharp pain radiating down the arm and forearm. Although the specificity for radiculopathy is in the range of 93%, sensitivity is only around 30% (Tong, Haig, and Yamakawa 2002).

Muscles in the various cervical and upper thoracic myotomes must be tested individually. When there is unilateral weakness, the contralateral side can act as a control. A standard measure of strength is necessary for accurate evaluation when bilateral weakness is present. If the examiner can overcome the action of a patient's muscle by resisting or opposing its action using an equivalent equipotcnt muscle (fingers test fingers, whole arm tests biceps), then that muscle in the patient is by definition weak. The amount of weakness present can be graded, and the 5-point Medical Research Council (MRC) grading scale is often used. Grade 5 represents normal strength. Grade 4 represents "weakness" somewhere between normal strength and the ability to move the limb only against gravity (grade 3). Grade 4 covers such a large range that it should be expanded. One simple expansion is into mild, moderate, or severe. When the muscle can move the joint with the effect of gravity eliminated, it is graded at 2, and grade 1 is just a flicker of contraction.

The distribution of weakness helps localize the problem to the nerve root, peripheral nerve, muscle, or even the upper motor neuron. It is useful to use a simplified schema of anatomical localization in the evaluation of weakness due to nerve root lesions because overlap of myotomes can complicate the analysis (Table 33.1}.

The lower limbs need to be examined even when the patient complains of symptoms only in the upper limbs, because evidence of a myelopathy and the finding of sensory or motor dysfunction in the lower limbs, when combined with the presence of radicular signs in the upper limbs, indicates a spinal cord lesion.

The thoracic outlet syndrome is an overdiagnosed condition. Maneuvers designed to test for compromise of the neurovascular structures passing through the thoracic outlet are often difficult to interpret. In these maneuvers, the arm is extended at the elbow, abducted at the shoulder, and then rotated posteriorly. The examiner palpates the radial

Table 33.1:

Segment level	*Muscle(s)*	*Action*
C4	Supraspinacus	First 10 degrees of shoulder abduction
C.5	Deltoid	Shoulder abduction
	Biceps/brachialis	Elbow flexion
C6	Extensor carpi radialis longus	Radial wrist extension
C7	Triceps	Elbow extension
C7	Extensor digitorum	Finger extension
C8	Flexor digitorum	Finger flexion
Tl	Interossei	Finger abduction and adduction
	Abductor digiti minimi	Little finger abduction

Nore: This is a somewhat schematic representation of the main segmental innervation of the muscles of the upper limbs. It is clinically useful in localizing a single radicular level and although not entirely correct, it usually "works," If we were to be absolutely anatomically correct, because virtually all muscles are of multisegmental innervation, clinical localization would be more complicated and imprecise.

pulse and listens over the proximal and distal brachial artery with a stethoscope. The patient takes a deep inspiration and turns the head to one and the other side. Many normal individuals lose the radial pulse with these maneuvers, but the development of a bruit does suggest the presence of at the least vascular entrapment (Adson's test). The patient then exercises the hands held above the bead with extended elbows; the development of numbness, pain, or paresthesias, often with pallor of the hand, supports the diagnosis of a thoracic outlet syndrome (Roos test).

Light tapping over an accessible plexus or peripheral nerve may elicit distal tingling in the distribution of the plexus or nerve {Tinel's sign). This may be positive over the brachial plexus in the supraclavicular fossa, the ulnar nerve at the elbow, or the median nerve at the wrist.

Sensory Signs

Sensation is tested in a standardized manner starting with pinprick appreciation at the back of the head (C2), followed by testing the cervical dermatomes proceeding stepwise down the shoulder, over the deltoid down the lateral aspect of the arm to the lateral fingers, and then proceeding to the medial fingers and up the medial aspect of the arm ifigure ,i.>. I I. The procedure is repeated with a wisp of cotton, and test tubes filled with cold and warm water to test temperature sensation. Vibration sense is tested in the fingers. Position sense in the distal phalanx of a finger is tested by immobilizing the proximal joint and supporting the distal phalanx on its medial and lateral sides. Then the terminal phalanx is moved up and down, and the patient reports movement and its direction. Loss of position sense in the fingers usually indicates a high cervical cord lesion.

Tendon Reflexes

Examination of the tendon reflexes helps localize segmental nerve root levels affected. An absent or decreased biceps reflex localizes the root level to C5, and an absent triceps reflex localizes the level to C6 or C7. In patients with cervical spondylosis who have both a radiculopathy and an associated myelopathy, the reflexes may be preserved or even increased despite the radiculopathy. The most common disc prolapse at C5-C6 may result in a radiculopathy and myelopathy at that level, which manifests with absent or decreased biceps and brachiuradialis reflexes, an increased triceps reflex, and spread of the brachioradiahs reflex to the finger flexors to produce a finger jerk. There may be a Hoffman reflex.

Non-Neurological Signs

The arm is passively abducted and internally and externally rotated at the shoulder. The complaint of pain on movement or at a point in the abductor arc indicates local shoulder joint pathology. This is usually due to shoulder tendonitis or pcricapsulitis. The tendons anteriorly and at the lateral point of the shoulder may be tender to pressure. More diffuse tenderness anterior to the shoulder joint indicates bursitis. Tenderness over the medial or lateral epicondyle at the elbow indicates local inflammation, and pain on active or passive wrist or finger joint movement suggests tendonitis or arthritis.

CLINICAL SYNDROMES AND DIFFERENTIAL DIAGNOSIS

Spinal Cord

Primary intramedullary spinal cord lesions may be neoplastic, inflammatory, or developmental. The most common presenting symptom of spinal cord tumor is pain that is present in about two thirds of patients, usually radicular in distribution, often aggravated by coughing or straining, and worse at night (Alter 1975), A minority of patients show dissociated sensory signs (segmental suspended [i.e., has an upper and lower border] loss of pinprick and temperature sensation with preserved

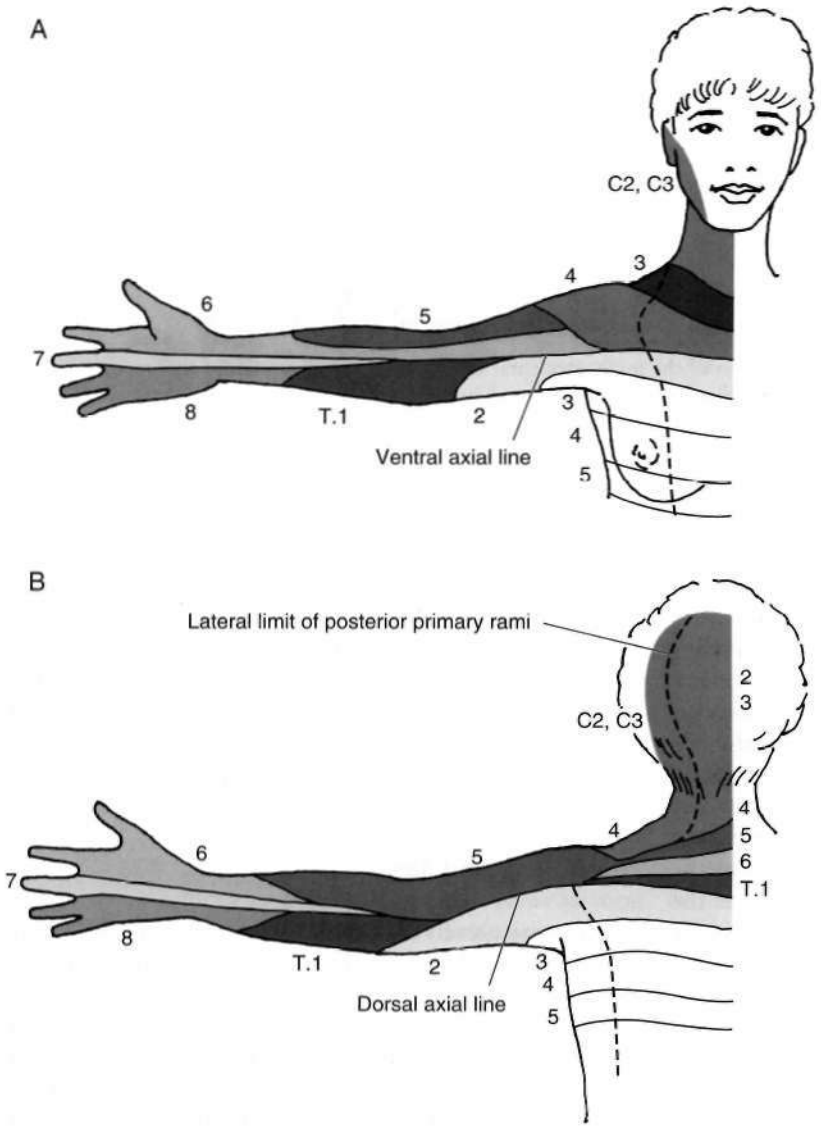

FIGURE 33.1 Diagram of the dermatomes in the upper limbs. (**A**) Anterior aspect. Although there is variability and overlap across the interrupted lines, there is little or no overlap across the continuous lines (i.e., the dorsal and ventral axial lines). The examiner should routinely choose one spot in the "middle" of a dermatome and test at that point in all patients. C4 usually terminates at the point of the shoulder, T3 is almost always in the axilla, and T4 spreads across the chest so that C4 abuts T4 approximately at the nipple line. (**B**) Posterior aspect.

light-touch, vibration, and position sense) in the upper limbs to suggest a central cord lesion. Long tract signs in the lower limbs will develop sooner or later. Imaging with magnetic resonance reveals swelling of the spinal cord. The most common tumors arc glioma, lymphoma, and ependymoma.

Cervical myelitis may sometimes present with rapid onset of radicular and long tract symptoms and signs, although commonly radicular signs are absent. This may be due to multiple sclerosis or postinfectious acute dcmyclinating encephalomyelitis, or it may be without clear cause (idiopathic).

Syringomyelia, a cystic intramedullary lesion of variable and unpredictable progression, may present with deep aching boring pain in the upper limb said to be characteristically referred to the ear. Asymmetrical lower motor neuron signs in the upper limbs with dissociated suspended sensory loss is very suggestive of a syrinx. However, the most common cause of intramedullary cord dysfunction is extrinsic spinal cord compression.

Extramedullar? Lesions

Extramedullar lesions may result in any combination of nerve root, central spinal cord, and long tract signs and symptoms. The most common cause of extrinsic nerve root and spinal cord compression is cervical spondylosis (Ronthal 2000). This is a degenerative disorder of the cervical spine characterized by disc degeneration with disc-space narrowing, bone overgrowth producing spurs and ridges, and hypertrophy of the facet joints, all of which can compress spinal cord or nerve roots. Hypertrophy of the spinal ligaments with or without calcification may contribute to compression. However, hypertrophic osteophytes

are present in approximately 30% of the population, and the incidence increases with age. Hence, the presence of such degenerative changes docs not indicate that the patient has symptoms caused by these changes and acumen is needed in the diagnosis to ensure that the abnormalities seen on imaging are responsible for the patient's signs and symptoms. The osteophyte is sometimes referred to as a "hard disc" as opposed to an acute disc herniation or "soft disc," in which the onset is acute with severe neck pain and brachialgia.

Patients with cervical spondylosis often awake in the morning with a painful stiff neck and diffuse nonpulsatile headache that settles in a few hours. Cervical spondylosis is most commonly found at C5-C6 and C6-C7, and focal signs are likely to be at these levels. Wasting and weakness of the small muscles of the hands may occasionally be seen in cervical spondylotic radiculomyelopathy with no observable anatomical change at the C8-T1 level, when it is referred to as a *fake localizing sign.* However, most commonly, the intrinsic muscle wasting in the hand is due to another disease, such as amyotrophic lateral sclerosis (ALS).

Restricted neck movement is always present with significant cervical spondylosis. Bladder dysfunction, indicated by frequency, urgency, and incontinence, ot the finding of long tract signs or symptoms indicate the need for imaging of the cervical spine both to exclude a disease othet than cervical spondylosis and to define the severity of the spinal cord compression. Immobilization in a cervical collar often helps with the symptoms and signs of cervical spondylosis. The role of surgery in treatment is discussed in Chapter 79.

Extramedullar compression, usually in the extradural space is usually due to primary or metastatic tumors. Of the primary tumors commonly encountered, a schwannoma produces signs and symptoms telatcd to the nerve root on which it arises, and as it enlarges a progressive myelopathy develops. X-rays of the cervical spine may demonstrate an enlarged intervertebral foramen at the level of the nerve root schwannoma, bur magnetic resonance imaging (MRI) is usually diagnostic. A meningioma may present in a somewhat similar fashion, but without foramina! enlargement; this is more common in the thoracic region.

Epidural spinal cord compression due to metastatic malignancy presents initially with spine pain in more than 90% of patients (Gilbert, Kim, and Posner 1978). Malignant bone pain is usually localized to the vertebra involved and percussion tenderness is a good localizing sign, even in the neck. As the metastasis spreads to the epidural space, radicular pain appears. X-rays of the cervical spine may show bony erosion with preservation of disc spaces, and the imaging modality of choice is MRI. The whole spinal column should be scanned because metastases are often at multiple sites, some of which may be subclinical (Chamberlain and Kormanik 1999). Spinal cord compression resulting from metastatic disease is a neurological emergency requiring treatment with immediate high-dose corticosteroids and local irradiation. Few patients arc referred for surgery.

Epidural infection (abscess) may be either acute and pyogenic or more chronic when the organism is likely to be mycobacterial or fungal (Mackenzie et al. 1998; Sampath and Rigamonti 1999). Pyogenic epidural abscess usually presents acutely with fever, severe pain localized to a rigid neck, radicular pain, and rapidly progressing nerve root and myelopathic signs. Sometimes the presentation is more subacute with less systemic evidence of infection. Imaging will usually reveal early destruction of the intervertebral disc with spread into the epidural space. Only later is there spread to bone with vertebtal collapse. Optimal therapy is surgical decompression and evacuation, combined with 6-12 weeks of appropriate antimicrobial therapy for pyogenic infections and more prolonged treatment for tuberculosis.

The differential diagnosis of a very rapidly progressing painful epidural lesion includes spinal epidural abscess and spinal subarachnoid, subdural or epidural hemorrhage (Henderson et al. 2001). The latter is usually associated with some form of coagulopathy, including iatrogenic anticoagulant therapy, and sometimes with vascular anomalies or trauma. The sudden onset of severe pain in the neck with or without radicular pain suggests the diagnosis of hemorrhage. Reversal of the coagulation deficit if present should be followed by decompression.

The sudden onset of pain at the back of the neck with associated posterior fossa signs suggests vertebral artery dissection {Caplan, Zarins, and Hemmati 1985). The diagnosis is nowadays easily made with MR] and fat suppression sequences.

Repetitive sudden shooting pains radiating from the occipital region to the temporal areas or vertex suggest the diagnosis of occipital neuralgia. There may be local tenderness over the greater or lesser occipital nerve, and a local injection of corticosteroid and local anesthetic is both diagnostic and therapeutic. Failure to respond suggests that the cranioverrebral junction area should be imaged.

Radiculitis

Herpes-zoster virus may infect cervical sensory root ganglia (Kleinschmidt-DcMastcrs and Gilden 2001). The pain is typically radicular and the diagnosis becomes clear when, after 2-10 days, the typical vesicular rash appears. Motor involvement occasionally occurs. Myelitis with long tract signs is seen in fewer than 1% of patients. If the pain lasts longer than 3 months after crusting of the skin lesions, postherpetic neuralgia has developed. The pain is described as constant nagging, burning, aching, tearing, and itching, upon which are superimposed electric shocks and jabs.

Treatment of postherpetic neuralgia pain (Bajwa and Ho 2001) is discussed in Chapters 50 and 81.

Brachial Plexopathy

Brachialgia and signs not respecting a single nerve root with tenderness to palpation in the supraclavicular fossa should arouse suspicion of a brachial plcxopathy.

Brachial Neuritis (Neuralgic amyotrophy, Parsonage-Turner syndrome)

Brachial neuritis is characterized by the abrupt onset of severe pain in one shoulder and arm, which is constant and unrelenting, worse at night, and rarely bilateral, and the syndrome afflicts mainly young adult men (Kim 1996). Within a week or so, muscle weakness atrophy and fasciculations are evident, mainly in the shoulder girdle but at times more distally and not in one particular myotome. There is usually little or no sensory loss despite the pain. The pathogenesis is thought to be autoimmune/ inflammatory and a number of antecedent inciting events have been described, including immunization, prior infections, and trauma. The syndrome is associated with autoimmune diseases and Hodgkin's disease. There is no proven specific treatment, but a short course of corticosteroid is usually given. Treatment should be directed to relief of pain, which often runs its course in 6-8 weeks. In some patients, paralysis can take up to 2 years to recover and occasionally there is some permanent weakness.

A subset of patients have a familial history of recurrent attacks. Hereditary neuralgic amyotrophy is an autosomal dominant trait, and many patients have deletions of the **PMP-22** gene on the distal long arm of chromosome 17 (Chance and Windcbank 1996).

Brachial Plexopathy in Cancer Patients

Plexopathy in patients with cancer, particularly those with breast cancer or lymphoma who have been irradiated poses a diagnostic problem: Is this radiation plexopathy or malignant infiltration of the brachial plexus? Malignant infiltration is more likely to trigger severe brachialgia and a Horner syndrome and to affect the lower plexus. Irradiation damage is less likely to cause severe pain and often affects the upper plexus. Both are slowly progressive, but radiation plexitis is more likely to be of longer duration. Electrophysiological studies (see Chapters 17B and 81) are helpful, because myokymia and fasciculations support the diagnosis of radiation plexitis (Harper ct al. 1989). MRI for infiltration with tumor has a sensitivity of *96%,* a specificity of 95%, and a positive predictive value of 95% (Qayyum ct al. 2000). Occasionally, a locally malignant, recurrent schwannoma occurs in a brachial plexus that has been irradiated many years before.

Thoracic Outlet Syndrome

Brachial plexus involvement as an entrapment syndrome in the thoracic outlet is rare. The very existence of this entrapment remains open to debate, partly because n is difficult to diagnose, and partly because it is often used in disability claims, often in the absence of proof. Consequently questions remain about diagnosis and the efficacy of surgical treatment (Landry et al. 2001). Entrapment may involve the brachial plexus, the subclavian artery, or both. Sagging musculature with postural abnormalities including droopy shoulders and a long neck contributes to the predisposition to develop the thoracic outlet syndrome.

A supernumerary cervical rib or simply an elongated transverse process of the seventh cervical vertebra may be seen on x-rays. The rib may articulate with superior surface of the first true rib or a fibrous band may extend from its tip or the tip of the abnormal transverse process connecting to the first true rib. The abnormal structure compresses the brachial plexus, particularly when the upper limb is elevated above head level. Pain and paresthesias radiate to the ulnar side of the hand and fingers, and weakness and wasting of the intrinsic muscles of the hand, secondary to lower plexus compression, may be evident. Thoracic outlet maneuvers described earlier are generally considered to be unreliable, but do raise suspicion of the presence of the syndrome. The examination may be normal, or there may be weakness of abductor digiti minimi and hypothenar sensory loss. Occasionally, the abductor pollicis brevis muscle is particularly atrophic and weak.

The diagnosis is often one of exclusion; imaging of the cervical spine is normal and nerve conduction studies below the clavicle are also normal. Venous and arterial anatomy can be studied by catheter angiography, Doppler flowmetry, or magnetic resonance angiography (Napoli et al. 1993; Dymarkowski et al. 1999). Electrophysiological studies that show partial denervation of the small muscles of the hand and a decreased sensory nerve action potential amplitude from the fifth digit are compatible with the diagnosis of thoracic outlet syndrome (Smith and Trojaborg 1987).

In all cases, a conservative approach should be tried initially. Postural exercises and thoracic outlet muscle strengthening exercises, instructions in proper sitting at work, and correction of unusual sleep positions should provide relief in 50-90% of patients, usually **within** 6 weeks (Tyson and Kaplan 1975). Failure of conservative treatment prompts consideration of a surgical opinion (Leffert, Perlmuttcr 1999; Sheth and Belzberg 2001).

Suprascapular Nerve Entrapment

The nerve may be entrapped or injured as it passes through the suprascapular notch (see Chapter 82). It is occasionally

cut in the process of lymph node biopsy. The branch to the infraspinatus muscle can be entrapped at the spinoglenoid notch by a hypertrophicd inferior transverse scapular ligament. The patient complains of deep pain at the upper border of the scapula aggravated by shoulder movement and there may be atrophy and weakness of the supraspinatus and more commonly the infraspinatus muscles. The supraspinatus muscle accounts for the first 10 degrees of shoulder abduction and the infraspinatus muscle externally rotates the arm.

Carpal Tunnel Syndrome

Carpal tunnel syndrome, the most common entrapment neuropathy, is more common in women (Atroshi et al. 1999). It is now an accepted occupational hazard secondary to repetitive stress and occasionally is the presenting symptom of underlying systemic disease. The nerve is entrapped in the bony confines of the carpal tunnel, which is roofed by the ttansverse carpal ligament. Pregnancy, diabetes, rheumatoid arthritis, hypothyroidism, sarcoidosis, acromegaly, and amyloid infiltration of the ligament are possible predisposing factors, and appropriate screening studies should be performed on all patients with a carpal tunnel syndrome. Numbness or pain radiating to the thumb, index, and middle fingers often wakes the patient at night. At times, there is diffuse brachialgia. Atrophy of the abductor pnllicis brcvis muscle may be marked, but the motor deficit is rarely the cause of disability. Significant sensory loss in the median nerve distribution can be a handicap because of poor feedback when using the hand out of sight.

Examination reveals, in advanced cases, atrophy of abductor pollicis brevis muscle, which produces a longitudinal furrow in the thenar eminence. There is weakness of thumb abduction. In theory there is also weakness of **the** opponens, but patients recruit the long flcxot tendons when testing opposition so that weakness is hard to define. The palmar cutaneous branch leaves the median nerve proximal to the flexor retinaculum and supplies the skin over the thenar eminence and proximal palm on the radial aspect of the hand. Hence, sensoty loss secondary to dysfunction of the median nerve in the carpal tunnel, if present, is likely to involve the distal thumb, index, and middle fingers but not the thenar eminence, a diagnostic point helpful in localization of the lesion. Phalen's test is performed by holding the wrist in complete flexion, when numbness or tingling in a median nerve distribution is seen within 20 seconds, but latency before the sensory symptoms occur can be up to a minute. Sensitivity is about 74% and the false-positive rate is about 25% (Salerno et al. 2000). The Tinel's sign may be elicited by producing distal tingling on tapping the median nerve at the wrist (Kuhlman and Hennessy 1997). Confirmation of the diagnosis is provided by nerve conduction studies and electromyography (EMG). Distal motor and sensory latencies are prolonged, and polyphasic reinnervation potentials are seen in the abductor pollicis brevis muscle (Kimura 1979), More extensive and expensive investigations are not warranted, but sonography and MR scanning have been utilized (Swen et al. 2001; Horch et al. 1997). **Initial** relief of the sensory symptoms can be obtained with the use of wrist splints, but patients with unremitting pain or significant motor and sensory signs, with confirmatory nerve conduction studies, should be offered decompressive surgery, which can now be undertaken using fiberoptic techniques. This can be curative. The surgeon should always send the flexor retinaculum for histopathological examination to search for amyloid deposition.

Occasionally carpal tunnel syndrome may be mimicked by entrapment of the median nerve more proximally at the elbow. Here, it passes beneath the thick fascial band between the biceps tendon and the forearm fascia and then between the two heads of the pronator teres muscle. As the nerve passes between the heads of the pronator teres, it supplies that muscle, as well as the flexor carpi radialis (which flexes and abducts the hand at the wrist) and the flexor digitorum superficialis (which flexes the fingers at the interphalangeal joints with the proximal phalanx fixed) muscles. After it passes between the two heads of the pronator teres muscle, it supplies the flexor pollicis longus muscle (which flexes the distal phalanx of the thumb with the proximal phalanx fixed), the flexor digitorum profundus muscle to the first and second digits (which flexes the distal phalanx with the middle phalanx fixed), and the pronator quadratus muscle (which pronates the forearm with the elbow completely flexed). Nerve conduction studies may localize the site of pathology and the EMG precisely defines which muscles are involved.

Ulnar Entrapment at the Elbow

The ulnar nerve may be entrapped proximal to the epicondylar notch or as it passes through tin- cubital tunnel at the elbow, a fibro-osseous canal formed by the medial condyle, ulnar collateral ligament, and flexor carpi ulnaris muscle (Campbell etal. 1991). Structural narrowing of the canal aggravated by occupational stress and a sustained flexion posture, especially when sleeping, as well as repetitive flexion-extension movements contribute to entrapment. Although numbness and tingling is more common than pain, both are referred to the hypothenar eminence and little and ring fingers. A positive Tinel's sign at the elbow over the ulnar nerve helps to localize the site. In severe cases, there is wasting and weakness of the small muscles of the hand (excluding the abductor pollicis brevis and opponens muscles, which are median nerve innervated). There is decreased sensation over the palmar aspect of the ring and little finger and there may be decreased sensation on the media] dorsal aspect of the hand and ulnar two fingers

because of involvement in the distribution of the dorsal branch of the ulnar nerve. In severe chronic cases, clawing of the fourth and fifth digits results from weakness of the third and fourth lumbrical muscles. Nerve conduction studies localize the area of entrapment, and if the symptoms do not settle by avoiding prolonged elbow flexion and the physical signs are significant, surgical decompression may be considered (see Chapter 82).

Radial Nerve and Posterior Interosseus Nerve Syndrome

Having passed round the spiral groove of the humerus, the radial nerve pierces the lateral intermuscular septum to lie in front of the lateral condyle of the humerus between the brachialis and brachioradialis muscles. There, it bifurcates to form the superficial branch, which is sensory to the lateral dorsal hand, and the deep branch, referred to as the *posterior interosseus nerve.* This branch supplies the finger and thumb extensors and the extensor carpi radialis brevis muscle, which is of lesser importance for radial wrist extension (extensor carpi radialis longus is dominant and its nerve supply comes off slightly more proximally, so radial wrist extension is spared in lesions of the posterior interosseus nerve). The deep branch passes through the fibrous edge of extensor carpi radialis muscle through a slit in the supinator muscle (arcade of Frohse |Papadopoulos, Paraschos, and Pelekis 1989]). Entrapment of the posterior interosseous nerve produces symptoms similar to those of lateral epicondylitis, namely lateral arm pain, or a dull ache in the deep extensor muscle area, which radiates proximally and distally and is increased with resisted active supination of the forearm. Extension of the elbow, wrist, and middle fingers against resistance increases the lateral elbow pain. Tenderness may be elicited over the posterior interosseous nerve just distal and medial to the radial head. Pain secondary to posterior interosseous entrapment is typically seen in manual laborers and occasionally in typists. The site of pathology is easily localized by EMG and nerve conduction studies, and surgical decompression is usually successful (Lawrence, Mobbs, and Forrcms 1995). Occasionally, a neoplasm of the nerve causes the same symptoms and some surgeons prefer MRI before surgery (Rosenberg, Bencardino, and Beltran 1997).

Complex Regional Pain Syndromes

Complex regional pain syndromes include syndromes previously called *reflex sympathetic dystrophy* (RSD), causalgia, shoulder-hand syndrome, Sudeck's atrophy, transient osteoporosis, and acute atrophy of bone (see Chapters 50, 82, and 83). By consensus, the syndrome requires the presence of regional pain and sensory changes following a noxious event (Stanton-Hicks et al. 1995). The pain is of a severity greater than that expected from the inciting injury and is associated with abnormal skin color or temperature change, abnormal sudomotor activity or edema. Type I refers to patients with RSD without a definable nerve lesion, and type II refers to patients in whom a definable nerve lesion is present and was formerly called *causalgia.*

A soft tissue injury is the inciting event in about 40% of patients, a fracture in 25%, and myocardial infarction in 12% (Paketal. 1970).

The pathophysiology is unclear, but because it used to be thought that many patients respond to sympathetic block and autonomic features are prominent, it has been suggested that there is an abnormal reflex arc that follows the routes of the sympathetic nervous system and is modulated by cortical centers. There is decreased sympathetic outflow to the affected limb and autonomic manifestations previously ascribed to sympathetic overactivity are now thought to be due to catecholamine hypersensitivity (Wasucr et al. 2001). Significant emotional disturbances at the time of onset occur in many patients and stress may be a precipitating factor (Geertzen et al. 1994).

Pain can be progressive and three stages of progression have been described (Veldman et al. 1993):

Stage I: There is diffuse burning, throbbing, aching sensations, sensitivity to touch or cold, and localized edema. Vasomotor disturbances produce altered skin color and temperature.

Stage II: There is progression of soft tissue edema with thickening of skin and articular soft tissues and muscle wasting. This may last 3-6 months.

Stage III: There is now limitation of movement, often with a frozen shoulder, contractures of the digits, waxy trophic skin changes, and brittle ridged nails. X-rays show severe demtneralization of the adjacent bones.

Motor impairment is not necessary to make the diagnosis, but weakness, tremor, or dystonia is sometimes present.

The diagnosis is essentially clinical. Diffuse severe nonsegmental pain with cyanosis, or mottling, increased sweating and shiny skin, swollen nonarticular tissue, and coldness are characteristic. Hypersensitivity to pinprick may preclude precise sensory testing. There may be associated myofascial trigger points and tendonitis around the shoulder,

Autonomic testing may help with the diagnosis; the resting sweat output and quantitative sudomotor axon reflex test used together are 94% sensitive and 98% specific and are excellent predictors of a response to sympathetic-block (Chelimsky et al. 1995). Bony changes including osteoporosis and joint destruction may be seen. Bone scintigraphy is more sensitive in stage I, though less useful in later stages (Lee and Weeks 1995). A stellate ganglion block may be useful both therapeutically and diagnostically (see Chapter 82).

These patients require a good deal of support, as well as trials of symptomatic medication. Drugs that sometimes work are prazosin, propranolol, nifedipine or verapamil, guancthidine or phenoxybenzamine, and antidepressants. Bisphosphonarcs may prevent bone resorption and are helpful with pain control. A trial of stellate ganglion block, which can be repeated if successful, is worthwhile. Sympathectomy has been used for progressive disease in patients who previously responded to sympathetic block.

"In Between" Neurogenic and Non-Neurogenic Pain Syndrome: Whiplash Injury

Whiplash is an acceleration-deceleration mechanism of energy transfer to the neck. It may result from rear-end, or side-impact motor vehicle collisions bur can also occur during diving or other mishaps. The impact may result in bony or soft tissue injuries (whiplash injury), which in turn may lead to various clinical manifestations (whiplash-associated disorders) (Spitzer et al. 1995). Rear-end motor vehicle collisions are responsible for 85% of whiplash injuries, and about one million such injuries occur in the United States every year. Severe injuries can cause rupture of ligaments, avulsion of vertebral endplates, vertebral fractures, and intervertebral disc herniations, sometimes associated with cervical nerve root or spinal cord damage.

The severity of injury can he graded:

- Grade I injuries: pain and stiffness and tenderness in the neck with no physical signs
- Grade II injuries: as noted above, together with physical signs of decreased range of movement and point tenderness
- Grade III injuries: neurological signs, including weakness, sensory loss, absent reflex, or long tract signs.

The prognosis is related to the severity of injury:

- Neck pain for more than 6 months after injury: grade I, 44%; grade II, 81%; grade III, up to 90%
- Headache for more than 6 months after injury: grade I, 37%; grade II, 37%; grade III, 70%.

In general about 40% of patients report complete recovery at 2 years, and about 45% continue to have major complaints more than 2 years after the collision.

The cause of persistent symptoms in patients with minor injuries is unknown and little evidence exists for a structural basis for chronic whiplash pain in this group. The difference between a trivial injury and one of more significance should be based on the presence or absence of neurological signs.

About 20% of patients complain of cognitive symptoms after whiplash, which is likely to be functional or malingering (Alexander 1998).

The influence of compensation and legal action in whiplash-associated disorders remains controversial. Two studies from Lithuania, where only a minority of car drivers are insured for personal injury, demonstrated both retrospectively and prospectively significantly less symptomatology than for similar accidents in the United States; at 1 year there was no significant difference between collision and control groups (Obelieniene et al. 1999). The Quebec Task Force emphasized that whiplash is essentially a benign condition with most patients recovering, but it is the refractory minority that accounts for an inordinate proportion of the costs (Spitzer et al. 1995).

Support, physical therapy, muscle relaxants, and antidepressants are the main therapeutic options, but if neurological signs are present, imaging of the cervical spine with magnetic resonance is indicated. Persistence of pain for more than 6 weeks should indicate referral to a more specialized center, and often a multidisciplinary team approach is best.

Rheumatoid Arthritis of the Spine

Rheumatoid arthritis in the cervical spine involves all the synovial joints but is particularly dangerous when it involves the atlantoaxial articulation. Local inflammation and pannus formation cause pain on neck movement and rupture of the transverse ligament, which holds the odontoid process in place. This may cause atlantoaxial subluxation. Pain is referred to the neck below the carlobe, and there may be a high myelopathy or even sudden death, Spine x-rays show excessive space between the anterior arch of the atlas and the odontoid process (Dreyer and Boden 1999).

Non-Neurological Neck/Arm Pain Syndromes

Patients with n on-neurological causes for acute, subacute, or chronic neck and arm pain are often referred for neurological opinion. They may have no focal neurological deficits, or they may have minor nerve root or peripheral nerve signs, which arc incidental to their main complaint. Usually, the clue to diagnosis is to be found in the history of movement aggravating or triggering the pain.

Fibromyalgia and Myofascial Syndrome

Within this group of rheu ma to logical disorders, fibromyalgia is considered the most common cause of gcnctalized musculoskeletal pain in women between the ages of 20 and 55 years; its prevalence is approximately 2% (Goldenberg 1999). The pain may be initially localized to the neck and shoulders but can spread diffusely over the body (see Chapter 79), It may follow an episode of physical or

emotional trauma or an influenza-like illness. It is associated with depression, which is present in more than 90% of cases, but chronic pain cannot be regarded as a manifestation of depression. Many patients have a sleep disorder. A host of somatic symptoms may accompany the pain: fatigue and a feeling of weakness, paresthesias, memory complaints, "allergies,'" palpitations, and irritable bowel syndrome.

The only physical sign is muscle tenderness and the finding of "trigger spots"—tender palpable nodules in the muscles. The diagnostic criteria are widespread musculoskeletal pain and excess tenderness in at least 11 of 18 predefined anatomic sites (Wolfe et al. 1990). Myofascial pain is considered a localized form of fibromyalgia with pain in one anatomic region such as in the right or left neck and shoulder with local tenderness.

Although litigation issues may drive the concept of causality and permanent tissue damage, there is no good evidence to support the notion that minor trauma induces a persistent source of noxious stimuli, and the 1994 Fibromyalgia Consensus Conference recommended that the terms *reactive* and *post-traumatic* fibromyalgia be eliminated.

The cause and pathology of the condition are unknown. Some evidence is accumulating to implicate stress as a mediator of disturbed hypotha la mic-pituitary-adrenocortical function in fibromyalgia and chronic pain. Neurally mediated postural hypotension is present in some patients. "Resetting" of central pain pathways has been postulated as a factor in increasing pain sensitivity and prolonging it. Maladaptive coping mechanisms certainly play ii role,

Adequate office management of the patient with fibromyalgia is time consuming and not cost effective for treating individual patients, so group clinics are often used. Lducniion of the patient is followed by recommendations for therapy. Most patients are tried on analgesics, muscle relaxants, and antidepressants, combined with a regimen of physical therapy and exercise. Low doses of fluoxetine and amitriptyline are more effective than either medication alone (Goldenberg ct al. 1996). If a sleep hygiene disorder is diagnosed, treatment of this can alleviate the symptoms of muscle pain. Failure to tespond suggests the need for a trial of trigger point injections of local anesthetic with or without corticosteroid.

Polymyalgia Rhcumatica

Usually seen in patients older than 50 years, severe aching pain and tenderness in the neck and shoulder-girdle muscles in association with a markedly elevated erythrocyte sedimentation rate responds dramatically to small doses of oral corticosteroid (Cohen and Abril 2001). Sometimes this is associated with temporal arteritis. If there is weakness, the diagnosis is more likely to be polymyositis and the serum creatine kinase concentration should be estimated,

Tendonitis, Bursitis, and Arthritis

Shoulder

Pain triggered by shoulder joint movement suggests tendonitis, peri capsulitis, or an internal derangement of the joint. Flexion and elevation of the shoulder, which evokes pain, is often called the *impingement sign.* Patients with a painful arc syndrome often respond to local corticosteroid injections into the tender tendons. Tenderness anterior to the shoulder joint suggests butsitis, which also will usually respond to local corticosteroid injections. Weakness is said to indicate a rotator cuff tear, but pain on movement makes evaluation difficult and MRI of the shoulder may be needed to establish the diagnosis. Acromioclavicular joint arthritis causes a more diffuse shoulder pain aggravated by arm elevation; diagnosis requires x-rays of the shoulder joint. Nonsteroidal anti-inflammatory medications help. In patients with such marked limitation of shoulder joint movement that the scapula moves en bloc with the humerus, together with movement-evoked pain, a diagnosis of "frozen shoulder" or adhesive capsulitis is made. Treatment of adhesive capsulitis is often unsatisfactory. Analgesics and physical therapy help in a limited way, but the course is likely to consist of many months of discomfort,

Elbow

Epicondylitis. Pain in the elbow region triggered by clenching the fist, which tenses the extensor muscles and irritates their points of origin, or pain that is increased with resisted finger and/or wrist extension and flexion suggests epicondylitis. Local tenderness will be found medially or laterally over the distal end of the humerus. Lateral epicondylitis is known as *tennis elbow,* and medial epicondylitis as *golfer's elbow.* F.xercises designed to strengthen the muscles that attach to these tendons arc helpful in many patients. Treatment with a firm elbow support can be supplemented by local corticosteroid injections. Occasionally these patients come to surgery.

Olecranon Bursitis. Local tenderness and swelling, which can be extreme (Popcye joint) at the point of the elbow, makes the diagnosis. The condition may follow local irritation but can be part of gout and occasionally represents a pyogenic infection. The bursa may need to be aspirated for diagnosis.

Wrist

Tendonitis. Wrist tendonitis is diagnosed by finding local tendon tenderness and by evoking the pain by stretching the tendon in question. Thus De Quervain's tenosynovitis is diagnosed by finding tenderness over the radial aspect of the wrist and by evoking pain by ulnar flexion with the thumb held in the closed fist (Finklestein test). Splinting or

casting and the use of local corticosteroid injections usually produce relief.

Hands

Arthritis of the fingers and hands leads to the complaint of pain on finger joint movement, and there may be swelling of the joints and inflammation as indicated by rubor. Pain and stiffness in the fingers, worse in the morning and not associated with numbness as in carpal tunnel syndrome, suggest rheumatoid arthritis. Spindling of the fingers or other joint deformity can often be seen. Distal arthritis in the terminal intcrphalangeal joints suggests osteoarthritis or psoriatic arthropathy. Bony swelling of the terminal phalanges (Hebcrden's nodes) is likely to be due to osteoarthritis, which can also cause local pain and tenderness.

Red, hot painful extremities, which are sensitive to heat, suggest the diagnosis of erythromelalgia. This may represent abnormal sensitization of thermal receptors or abnormal platelet function and is sometimes associated with blood dyscrasias. It responds, usually, to aspirin (Kalgaard, Seem, and Kvernebo 1997).
