Atelectasis also invariably accompanies pleural effusions and pneumothorax. With pleural effusions, atelectasis is greatest in the vicinity of the pleural effusion.

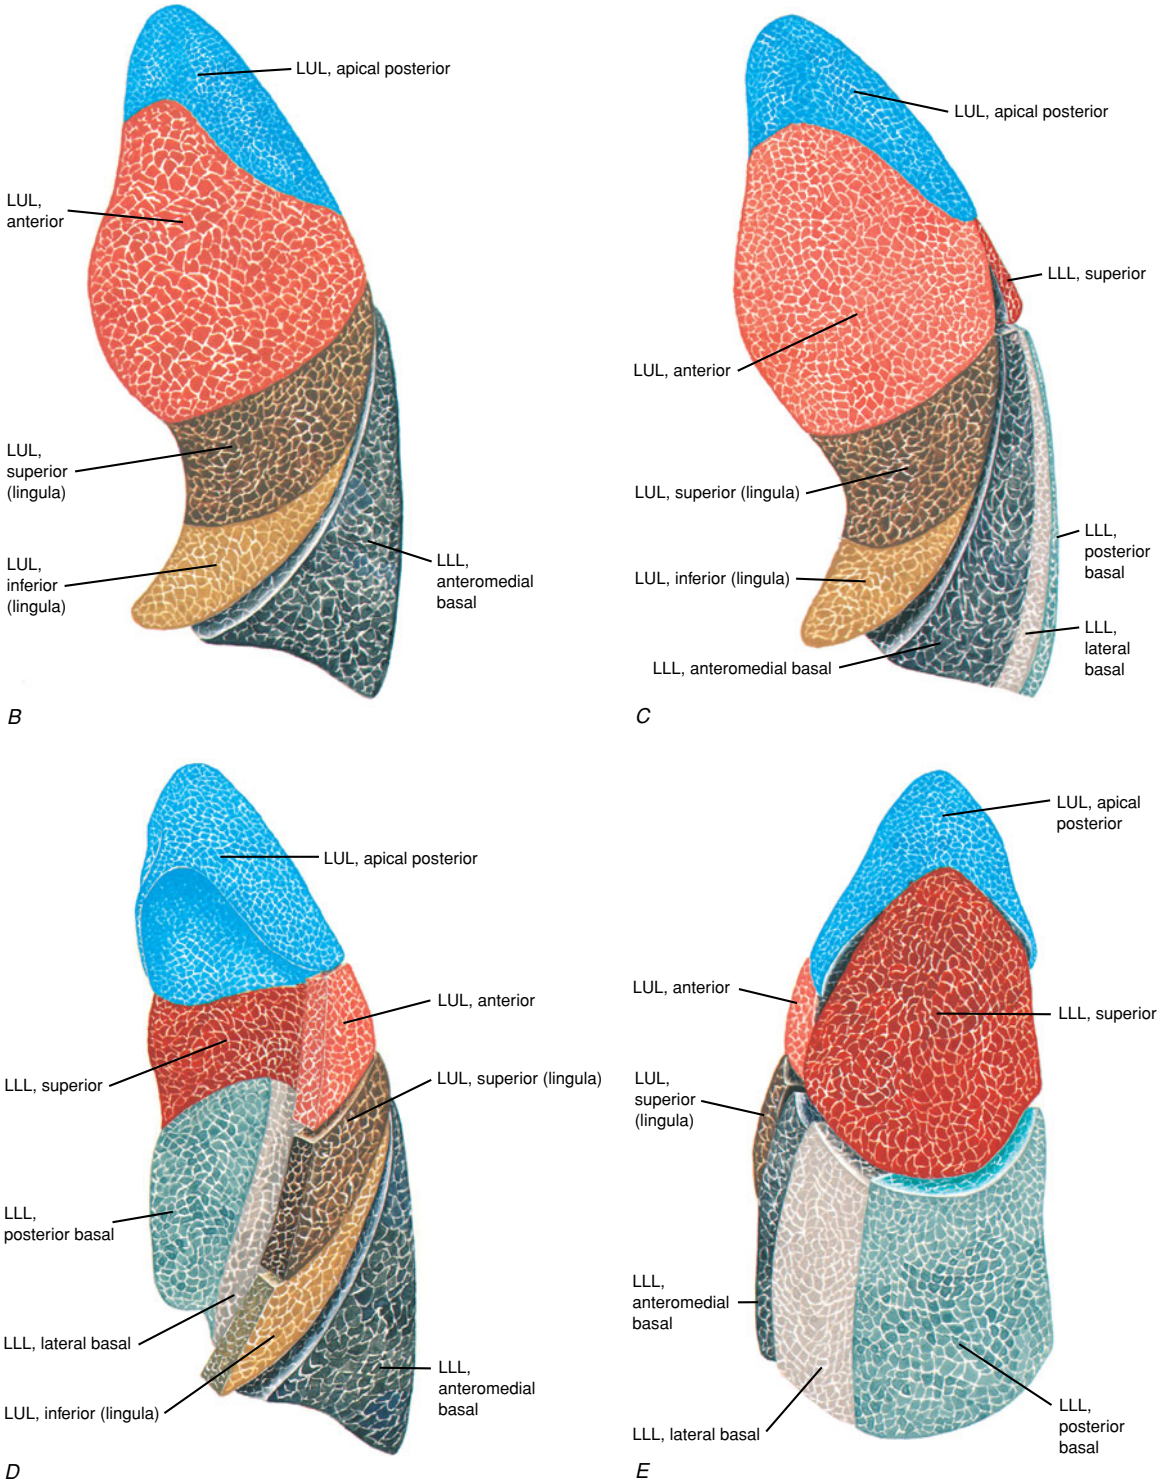

Figure 30-38 (*Continued*)

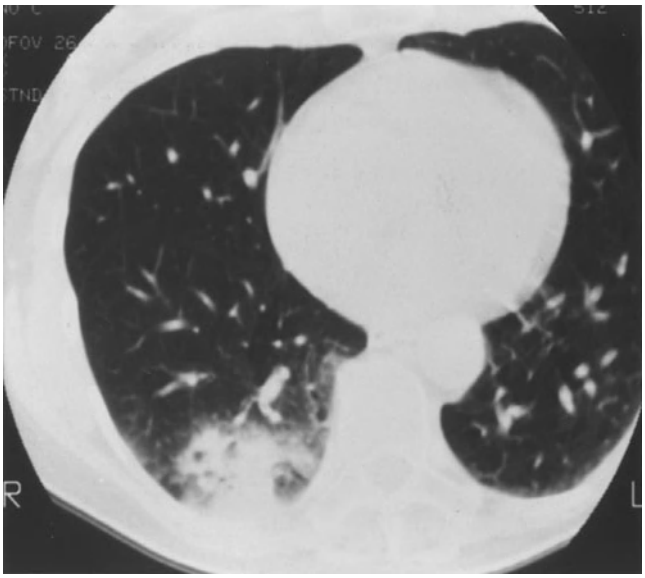

Figure 30-39 CT image of localized alveolar cell carcinoma. A patchy right lower lobe infiltrate is present. The characteristic alveolar infiltrate is most suggestive of pneumonia, but it is consistent with lobar-type alveolar cell carcinoma. The findings are not specific, and in this instance, CT adds little to the diagnosis.

CT may also suggest the diagnosis of rounded atelectasis (Fig. 30-47) and is particularly useful in demonstrating mediastinal adenopathy or the extent of a tumor that invades the mediastinum or great vessels. These findings reveal the anatomic basis for the atelectasis.

Diffuse Alveolar Disease

The prototype of a pathological process affecting the alveoli diffusely is pulmonary edema (Fig. 30-36). Most often, pulmonary edema is secondary to left ventricular failure. However, noncardiac pulmonary edema is common and may have a number of underlying causes, including hypersensitivity reactions to drugs or inhaled toxins, uremia, drug overdose, oxygen toxicity, near-drowning, and, especially adult respiratory distress syndrome (ARDS) (Chapter 145). Cardiogenic pulmonary edema characteristically clears rapidly after appropriate therapy, whereas noncardiogenic pulmonary edema often requires days or weeks to clear.

Other causes of diffuse alveolar disease may mimic pulmonary edema. Diffuse pneumonia and diffuse pulmonary hemorrhage may be indistinguishable and must be differentiated clinically.

If diffuse alveolar consolidation persists for weeks or months, chronic disorders, such as pulmonary alveolar proteinosis (Fig. 30-48*C*), alveolar cell carcinoma (Figs. 30-35 and 30-39), sarcoidosis, hypersensitivity pneumonitis, or desquamative interstitial pneumonitis should be considered.

As with localized disease, CT is often useful in distinguishing one type of diffuse alveolar disease from another. The distribution of the alveolar infiltrates may sometimes be helpful. Multifocal, patchy disease is typical of aspiration pneumonia. ARDS also appears patchy, but is typically less focal. Diffuse pneumonia, pulmonary hemorrhage, and pulmonary edema may be indistinguishable.

Diffuse alveolar disease or focal alveolar disease may be manifest on CT by "ground glass" changes. The term, ground glass opacification, refers to faint alveolar consolidation which is less dense than more extensive consolidation and has an appearance resembling ground glass. This finding is often not explained. If focal, it may be caused by pneumonia or aspiration, and if chronic, may be a manifestation of lung carcinoma or lymphoma. If more diffuse, pulmonary

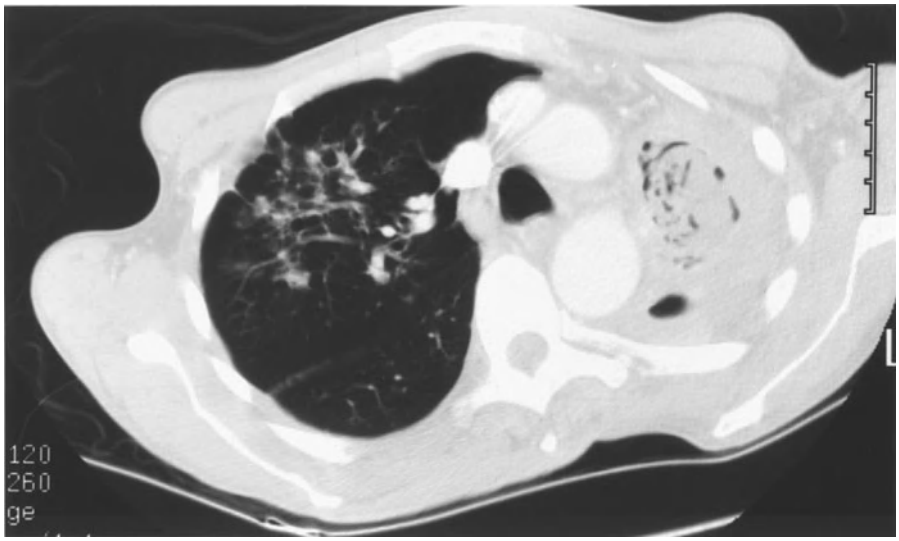

Figure 30-40 CT demonstrating characteristic crescent sign of aspergillosis. A right upper lobe infiltrate is seen that, in this case, was due to tuberculosis. In the left upper lobe, a crescent of air is seen around the matted mycelia of a fungus ball. The finding is characteristic of "noninvasive" aspergillosis.

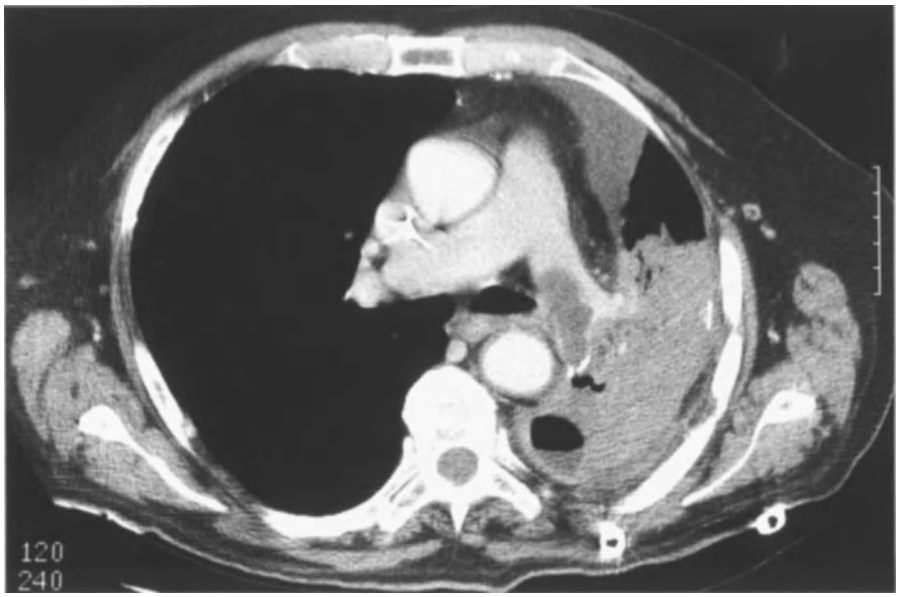

Figure 30-41 CT showing gangrene of the lung due to a pulmonary artery thrombus in the left main and lower lobe pulmonary artery. The patient had a prior left upper lobectomy; in the postoperative period, consolidation of the remaining left lung developed. The scan shows a lung cavity that was not previously suspected, as well as a thrombus in the left pulmonary artery. The cavity represents a rapidly developing lung abscess due to lung infarction (gangrene).

edema or patchy pneumonia may be the cause. Ground glass changes may also be seen in desquamative interstitial pneumonitis, lymphoid interstitial pneumonitis, or nonspecific interstitial pneumonitis.

Interstitial Lung Disease

The plain film features of interstitial lung disease differ from those of the alveolar disorders (Fig. 30-49). In interstitial disease, the pattern is discrete and sharp, rather than fluffy and irregular, and the lesions tend to be diffuse, rather than localized. In addition, coalescence is not a feature, and the small densities are characteristically nodular, reticular, or linear.

Pathological interstitial processes may be acute or chronic, although the chronic causes are more common. Within the acute category, a pattern changing over hours to days usually represents interstitial pulmonary edema. Occasionally, a rapidly changing interstitial pattern represents pneumonia due to *Pneumocystis carinii* or cytomegalovirus. The acute interstitial disorders typically cause a linear or reticular pattern, which is characterized by prominent Kerley's lines throughout the lung fields (Fig. 30-49 *A*).

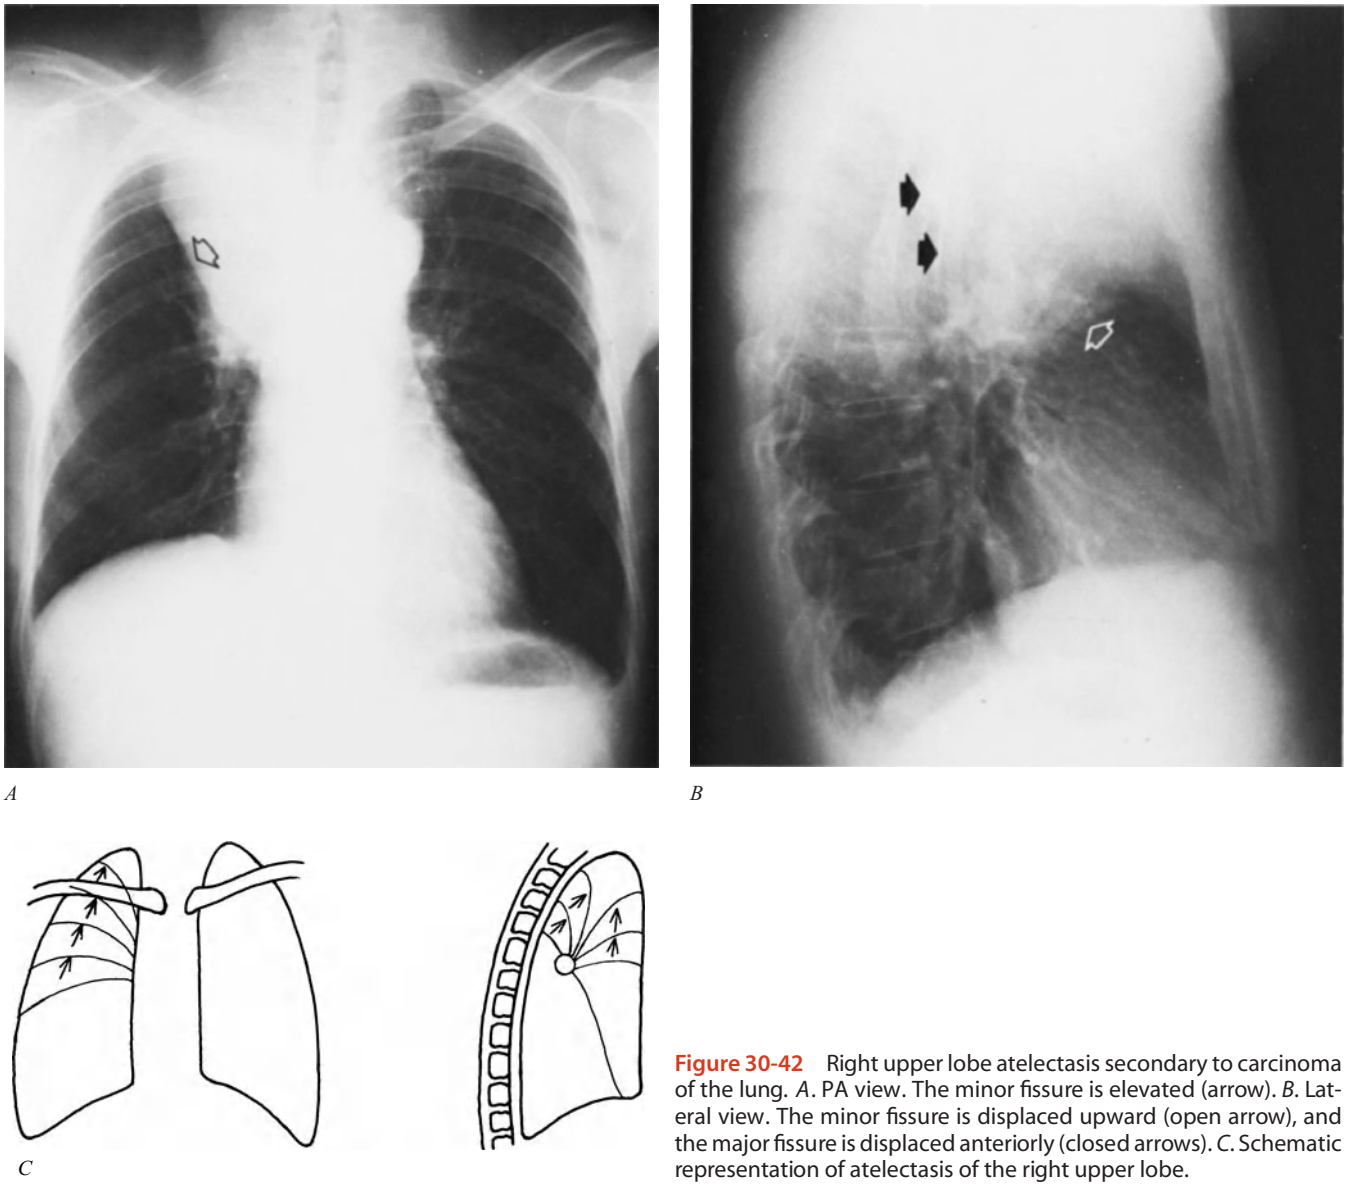
In his original description in 1951, Kerley associated thin, radiographic parenchymal opacities with left ventricular failure. At first, Kerley's lines were thought to represent swollen pulmonary lymphatics. It is now recognized that Kerley's lines usually represent edematous septa within the pulmonary interstitium. Three patterns exist. Kerley type B lines are the most familiar and are particularly prominent at the lung bases, where they appear as straight, thin lines approximately 1 cm long; they are oriented parallel to the diaphragm. Kerley type A lines represent septa deep within the substance of the lungs; they radiate from the hili. Kerley type C lines probably represent coalescence of A and B lines.

Chronic interstitial lung diseases may be caused by a wide variety of diseases (Figs. 30-49 and 30-50), including pneumoconioses; sarcoidosis; lymphangitic spread of tumors; infections, such as miliary tuberculosis, interstitial pneumonia, and fungal diseases; allergic lung disease; collagen vascular diseases; eosinophilic granuloma; and idiopathic interstitial fibrosis. Characterization of the pattern of interstitial disease as nodular, reticular, or linear on the plain film may help in differential diagnosis, since many of the interstitial lung diseases assume, almost exclusively, one of these three patterns.

Interstitial nodules range in size from minute to massive. Large nodules generally represent metastatic tumor (Fig. 30-51). Smaller nodules are found in pneumoconiosis or silicosis, miliary tuberculosis, sarcoidosis (Fig. 30-49 *B*), and allergic lung disease.

Linear densities, as noted previously, are more characteristic of acute lung disease (e.g., interstitial pulmonary edema [Fig. 30-49 *A*] or interstitial pneumonia). A similar, but chronic, pattern occurs in lymphangitic spread of metastatic tumor (Figs. 30-12 and 30-49 *C*).

A reticular pattern suggests collagen vascular disease when the reticular or cystic changes are tiny and are confined primarily to the lung bases (Fig. 30-49 *D*). Asbestosis and UIP also cause a basilar reticular pattern (Fig. 30-52 *A*). Eosinophilic granuloma of the lung sometimes causes



A *B* *C*

Figure 30-42 Right upper lobe atelectasis secondary to carcinoma of the lung. *A*. PA view. The minor fissure is elevated (arrow). *B*. Lateral view. The minor fissure is displaced upward (open arrow), and the major fissure is displaced anteriorly (closed arrows). *C*. Schematic representation of atelectasis of the right upper lobe.

a similar pattern at the lung apices. A larger reticular pattern suggests idiopathic pulmonary fibrosis (IPF) or the end-stage lung pattern that often represents the final common denominator of a variety of chronic interstitial lung diseases.

Most interstitial diseases cause loss of lung volume on the radiograph, since these disorders are restrictive in their pathophysiological effect. However, two interstitial diseases that produce diffuse, small bullous changes are characteristically associated with preserved lung volume: eosinophilic granuloma and lymphangioleiomyomatosis. These are relatively uncommon causes of interstitial lung disease. Notably, patients with interstitial lung disease may have concurrent chronic obstructive pulmonary disease, in which case lung volume may be preserved.

High-resolution CT has emerged as a powerful technique for evaluating interstitial lung diseases. CT can often identify interstitial disease that is not seen on the plain radiograph, and it may also identify the underlying cause. Major indications for high-resolution CT are identification of suspected alveolar or interstitial disease, which is not seen on the chest radiograph, and characterization of the disease (Fig. 30-52).

CT patterns of interstitial lung disease follow, to some degree, the patterns seen on the plain radiograph. Collagen vascular disease and IPF typically have reticular or cystic changes in the periphery of the lung and at the lung bases (Fig. 30-52 *A*). These changes are so characteristic that many authors believe that further diagnostic efforts, such as lung biopsy, are unnecessary. The changes of IPF are virtually impossible to distinguish from those of collagen vascular disease. In most, but not all instances, the presence of collagen vascular disease is recognized prior to discovery of the lung disease.

Asbestosis may also cause reticular and peripheral interstitial lung disease. However, invariably associated pleural plaques are noted, suggesting the diagnosis in a patient

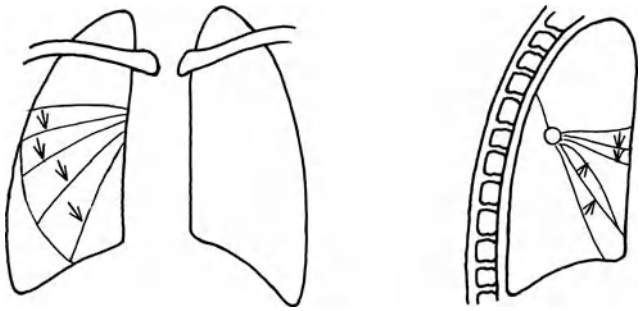
B



C

Figure 30-43 Right middle lobe atelectasis secondary to right middle lobe syndrome. *A*. PA view. The middle lobe is collapsed against the right side of the heart. *B*. Lateral view. The major and minor fissures are drawn together (arrows), creating a density that overlies the cardiac shadow. *C*. Schematic representation of right middle lobe atelectasis.

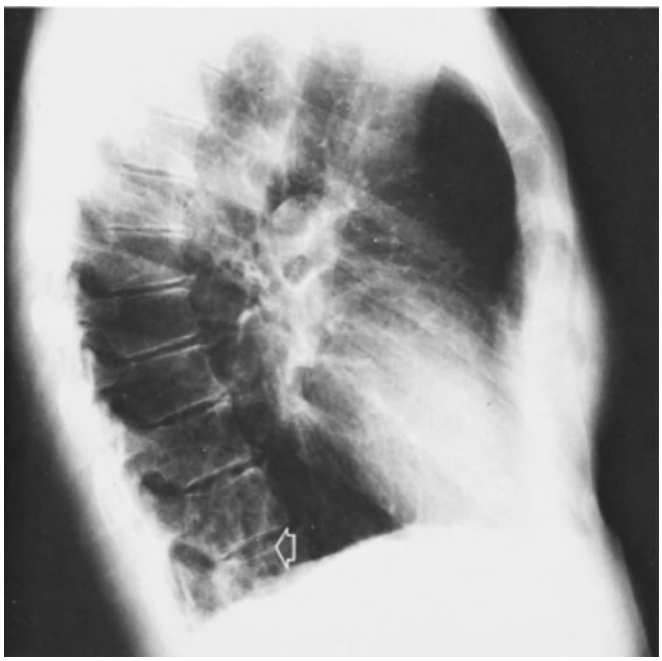
with a long history of asbestos exposure. Occasionally, pleural plaques and IPF can coexist. Asbestosis progresses very slowly; if progression is more rapid, IPF should be suspected.

Sarcoidosis, interstitial pulmonary edema (Fig. 30-52*B*), and lymphangitic spread of tumor (Fig. 30-12) demonstrate a bronchovascular (septal) distribution, with linear densities outlining the pulmonary lobule. This septal distribution is extremely characteristic of these three entities. Interstitial pulmonary edema is seen almost exclusively with heart failure or fluid overload and rapidly disappears with appropriate therapy.

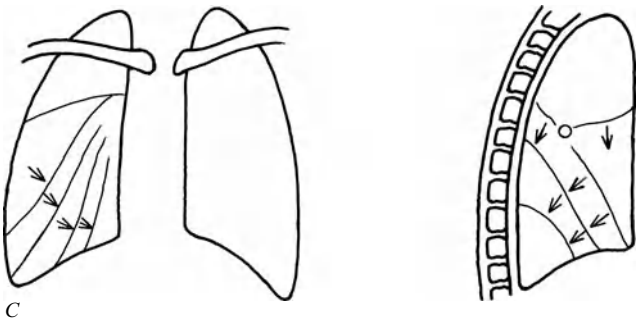
Lymphangitic spread of tumor improves only occasionally with chemotherapy and is usually progressive. While usually diffuse, the disorder is often unilateral when due to carcinoma of the lung, and it may occasionally be focal in lung cancer or when due to other tumors. The tumors that most frequently cause lymphangitic spread include carcinoma of the breast (the most common), lung, stomach, and pancreas, and, on occasion, other tumors.

Hypersensitivity pneumonitis frequently is associated with an alveolar or ground glass pattern, and commonly has a mosaic distribution (Fig. 30-52*C*). In addition, hypersensitivity pneumonitis may cause multiple tiny nodules. Several other diseases usually exhibit a nodular pattern. Large nodules are seen almost exclusively in metastatic tumor, but occasionally they are also seen in silicosis. On the other hand, carcinoma of the thyroid may be seen as multiple tiny nodules, although tiny nodules are usually indicative of another process. Miliary tuberculosis and miliary fungus diseases are among those that present with a fine nodular pattern. Sarcoidosis, which usually has a bronchovascular distribution and linear septal pattern, may also be seen as fine nodules. Silicosis also has a fine nodular pattern and invariably is more prominent in the upper lobes than elsewhere. Occasionally, the nodules of silicosis are somewhat larger and may be confused with metastatic tumor. Massive progressive fibrosis, also seen in silicosis, may also be confused with primary or metastatic tumor. Finally, metastatic tumor (Fig. 30-51) and miliary tuberculosis usually are characterized by fine nodules.

A



B



C

Figure 30-44 Atelectasis (severe) of the right lower lobe due to chronic inflammatory disease. *A*. PA view. Secondary signs of atelectasis are present in the right lung: small hemithorax, stretching of the pulmonary vessels, hyperlucent lung, and small hilus. In this instance, these secondary signs are important in suspecting atelectasis. In addition, there is downward displacement of the right hilus, and the collapsed lower lobe can be seen (poorly) through the right heart border (arrow). *B*. Lateral view. The entire right lower lobe appears only as a diffuse density overlying the spine (arrow). The posterior portion of the right hemidiaphragm cannot be identified (silhouette sign). *C*. Schematic representation of collapse of right lower lobe.

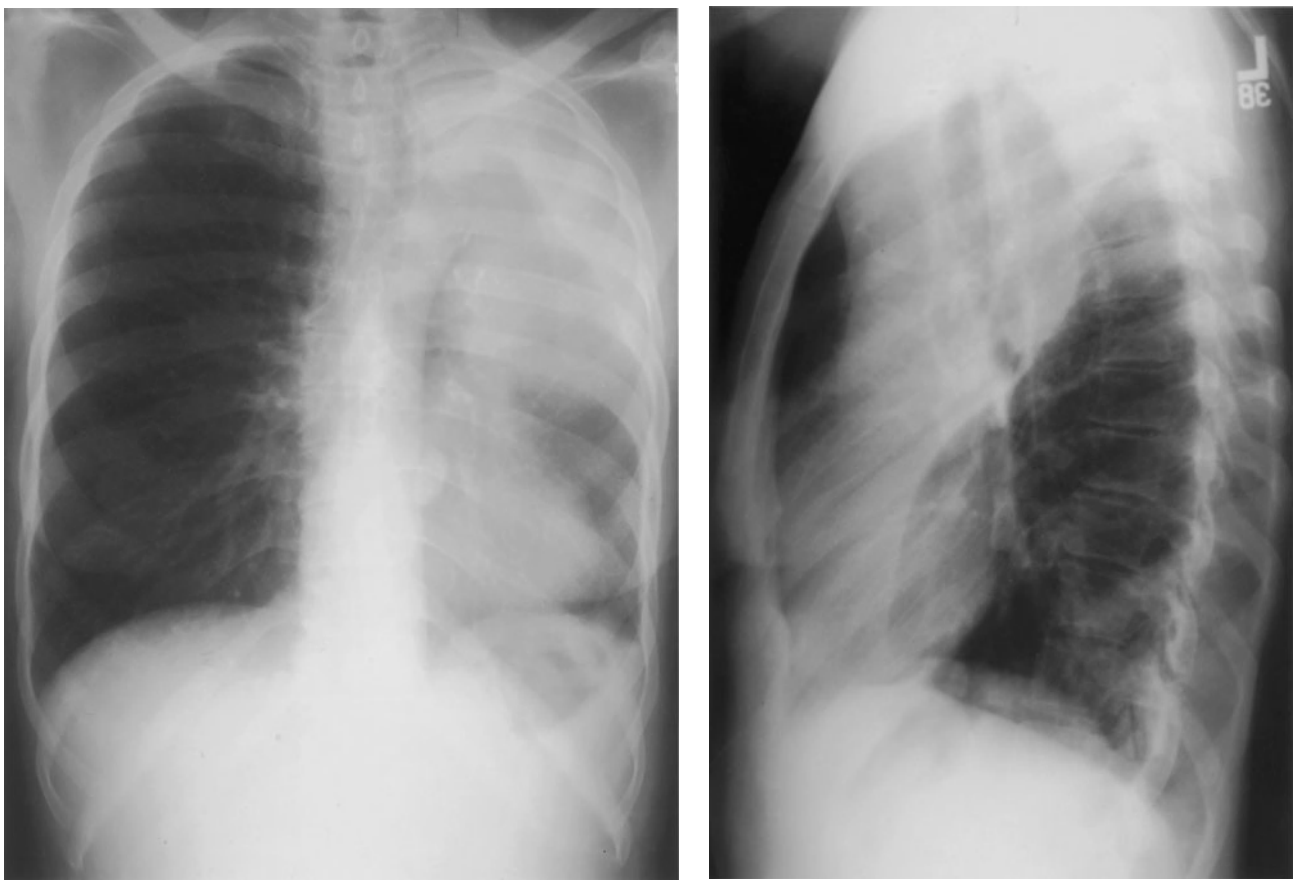
The Solitary Nodule

A wide variety of pathological processes appear on the chest radiograph as a solitary nodule (see Chapter 103). Among the most common are primary carcinoma of the lung, granulomas due to tuberculosis or fungal infection, metastatic carcinoma, and organizing pneumonia. Less common are hamartoma, bronchogenic cyst, bronchial adenoma, arteriovenous malformation, pulmonary sequestration, necrobiotic nodule due to rheumatoid arthritis, Wegener's granulomatosis, lymphoma, inflammatory pseudotumor, and lipoid granuloma. Although the radiograph is invaluable for detection of a pulmonary nodule, it is usually of little help in elucidating the underlying cause. Although certain radiographic aspects of a nodule may suggest its benign or malignant nature, in most instances, histological or cytological proof is required.

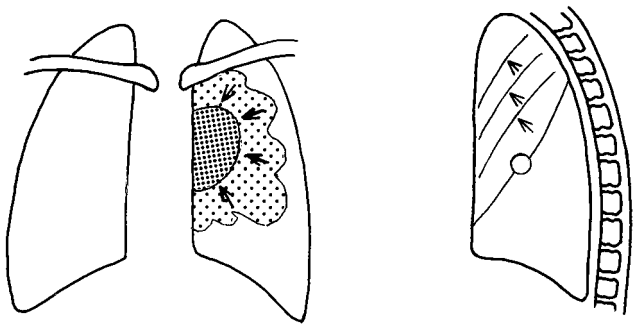
One radiologic clue to the origin of a pulmonary nodule is the character of its border. Ill-defined margins suggest an inflammatory lesion (e.g., tuberculosis or pneumonia) or primary lung carcinoma. A very sharply circumscribed pulmonary nodule with a regular contour is more likely to be a granuloma or hamartoma. However, metastatic tumor often presents with a sharply circumscribed edge, and primary lung neoplasms may present either as sharply circumscribed nodules or nodules with ill-defined margins.

The age of the patient is useful in stratification of the differential diagnosis of a solitary nodule. Primary carcinoma of the lung is extremely rare in patients under 30 years old, whereas in patients older than 50, more than half of solitary nodules on the plain film are primary carcinomas of the lung.

Occasionally, the radiograph may be sufficiently convincing of the benignity of a pulmonary nodule to preclude the need for diagnostic evaluation, including possible thoracoscopy or thoracotomy. Extensive calcification within the nodule suggests that the process is benign; CT may be helpful in demonstrating such calcification. Benignity is suggested by calcification that is central, concentric, diffuse, or punctate ("popcorn" calcification). On the other hand, eccentric calcification is of no diagnostic help, since it occurs in both benign and malignant disease, presumably as a consequence of envelopment of a preexisting benign calcified focus within an expanding neoplastic process.



A *B*



C

Figure 30-45 Left upper lobe atelectasis secondary to carcinoma of the lung. *A*. PA view. The left superior mediastinum and left side of the heart are indistinct, due to collapse of the left upper lobe medially. *B*. Lateral view. The collapsed lung is seen as a density anterior to the major fissure, which is displaced anteriorly. *C*. Schematic representation of collapse of left upper lobe.

Prominent vascular shadows extending from a nodule suggest that the nodule is an arteriovenous malformation; the shadows actually represent veins. Arteriography is useful in confirming the vascular nature of the lesion (Fig. 30-5*B*). CT and MRI are also helpful in diagnosing arteriovenous malformations and now constitute definitive imaging techniques. A basal lung nodule that is suggestive of a pulmonary sequestration can be definitively identified by CT, MRI, or arteriography if the study demonstrates that the mass is supplied by an anomalous artery arising from the abdominal aorta.

The lung is uniquely suited for serial chest radiographs or serial CT to estimate the size of a solitary pulmonary nodule. This feature has led to the practical concept of *doubling time*—the time required for a tumor to double in volume (not diameter). A previous radiograph in which the nodule was present, even if unrecognized, serves as a useful baseline for estimating the rate of nodule growth. If a nodule does not change in size for 2 years, it is likely that the process is benign. Conversely, any growth of the nodule within 1 year should raise suspicion of malignancy. Usually, malignant tumors grow quickly, with a doubling in volume between 1 and 15 months (Fig. 30-53*C* and *D*). Occasionally, a slowly growing nodule proves to be a primary carcinoma of the lung (Fig. 30-53*A* and *B*)—usually adenocarcinoma or localized alveolar cell carcinoma—or sometimes a carcinoid tumor.

The presence of cavitation within a pulmonary nodule is usually not helpful in determining whether the nodule is

C

Figure 30-46 Left lower lobe atelectasis (postoperative). *A*. PA view. The collapsed left lower lobe is seen as a straight line (arrow) behind the left heart border. No vasculature can be seen through the heart shadow, and the medial border of the left hemidiaphragm is obscured by the collapsed left lower lobe (arrow). *B*. Lateral view. Density over spine and absence of left posterior diaphragm. This is difficult to differentiate from a pleural effusion. *C*. Schematic representation of collapsed left lower lobe.

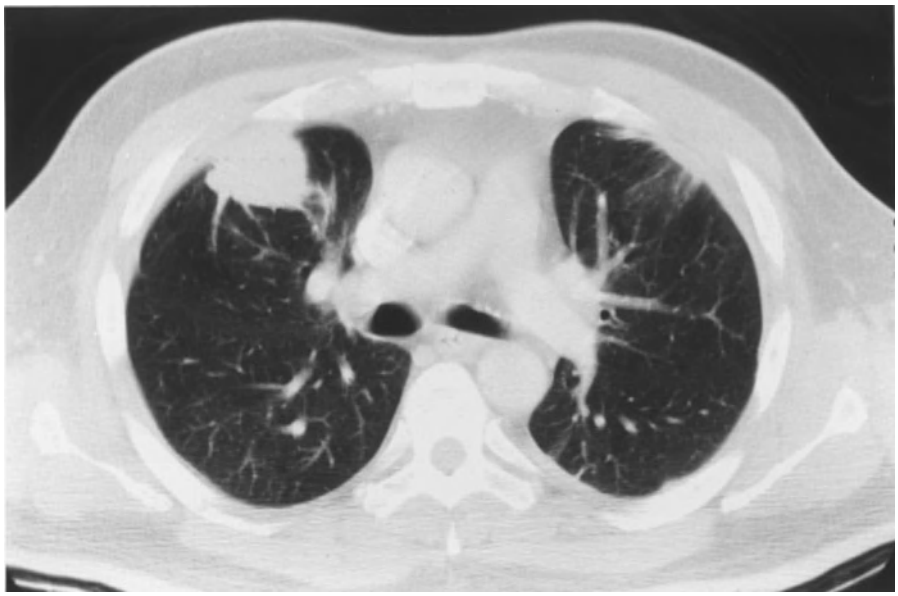

Figure 30-47 CT showing rounded atelectasis. A mass with a "tail" can be seen in the anterior segment of the right upper lobe. Pleural thickening is seen on the left side, with transpulmonary bands extending into the left upper lobe. The mass on the right represents rounded atelectasis, a finding usually associated with asbestos exposure. The changes on the right probably represent an early stage in the development of rounded atelectasis.

benign or malignant. Other radiographic features, including the presence of stranding, satellite lesions, or associated pleural disease, are seen in both benign and malignant processes and do not constitute bases for distinction.

A major use of CT is in determining whether a solitary nodule is, indeed, solitary. Many nodules that appear to be solitary on the plain radiograph are shown by CT to be multiple; many of these additional nodules are much smaller

The characteristic peripheral reticular pattern is from a patient with idiopathic pulmonary fibrosis. Collagen vascular disease causes an indistinguishable pattern. *B*. CT of interstitial pulmonary edema in congestive failure. Pleural effusions and prominent vessels are due to congestive heart failure. Linear densities are seen surrounding the lobules in the right lower lobe, adjacent to the right hemidiaphragm. These findings are characteristic of interstitial edema, but they might also be seen in lymphangitic spread of carcinoma. *C*. Chronic beryllium disease. CT shows ground glass changes in a mosaic distribution. *D*. Mosaic pattern due to small airways disease. This is frequently indistinguishable from hypersensitivity pneumonitis.

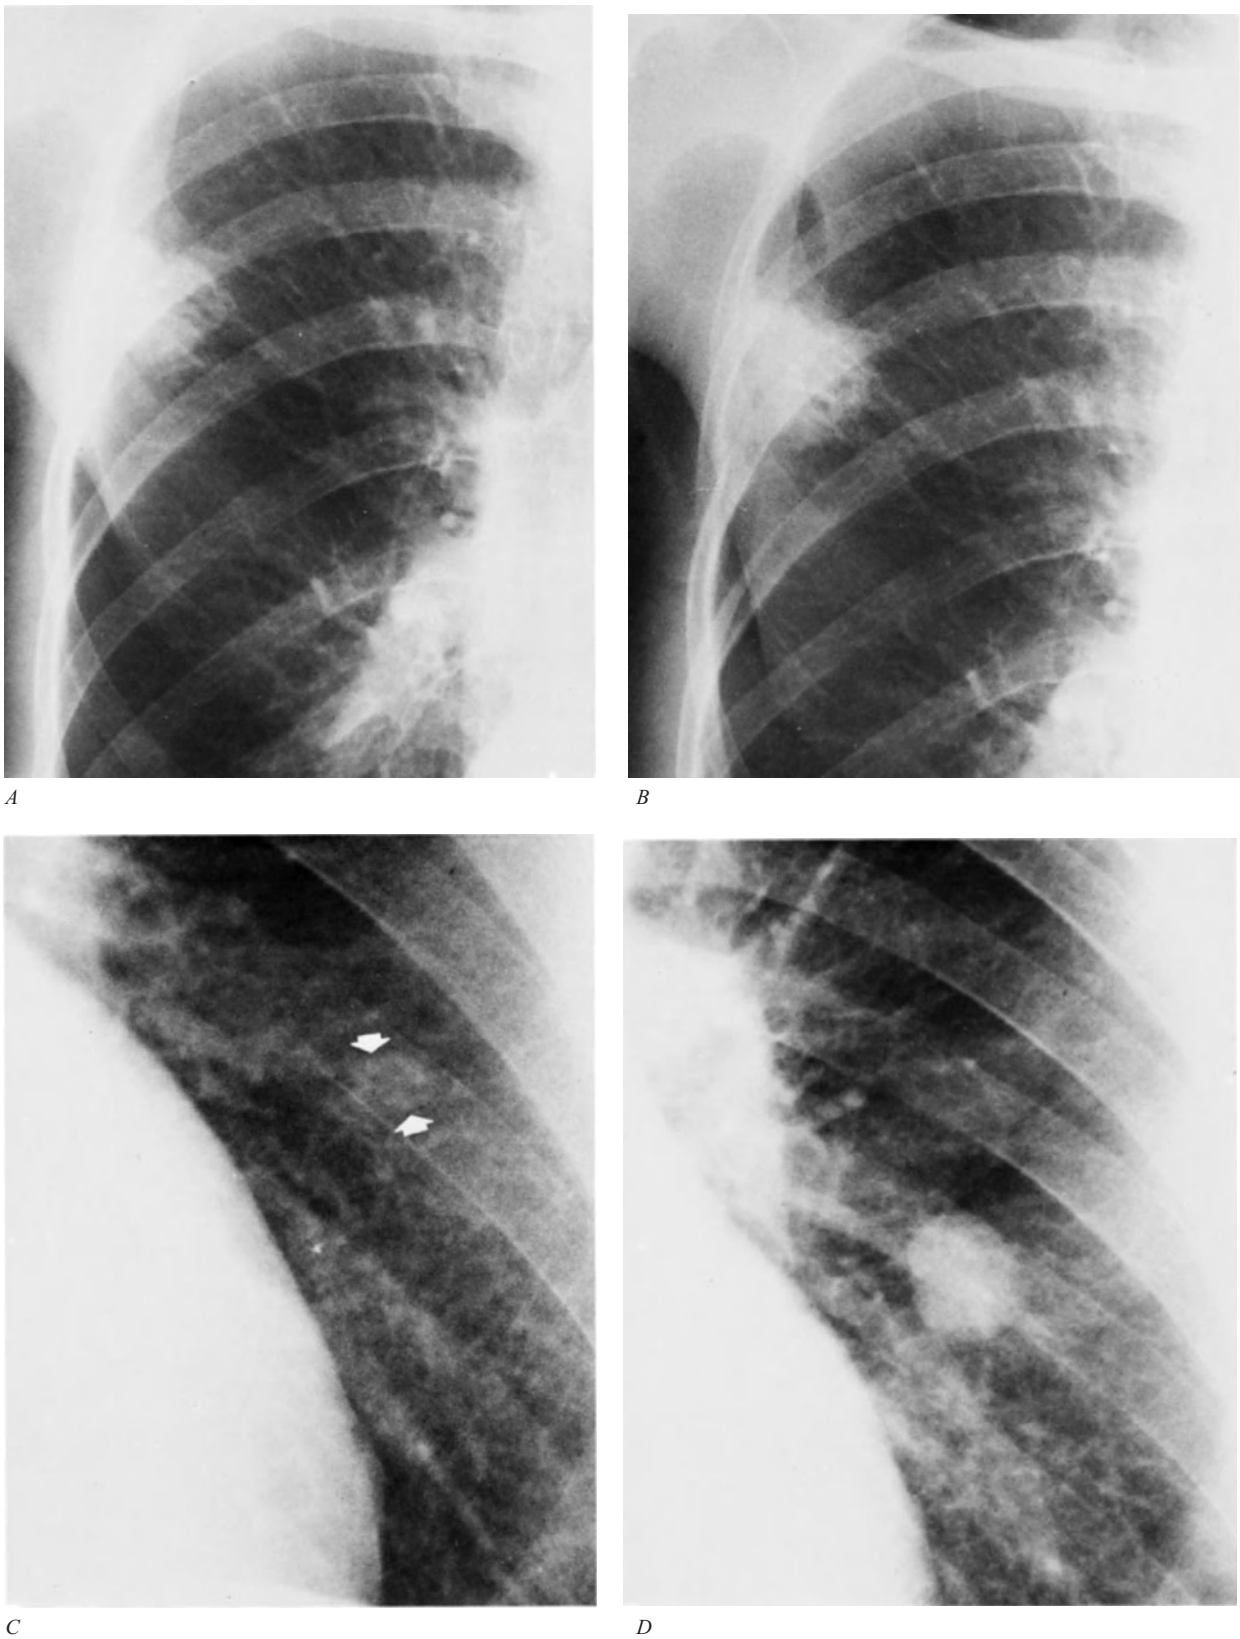

Figure 30-53 *Top:* Carcinoma of the lung with a long doubling time. An interval of 18 months elapsed between *A* and *B*. The right upper lobe lesion, which enlarged minimally during that time, proved to be squamous cell carcinoma of the lung. *Bottom:* Carcinoma of the lung with a short doubling time. An interval of 4 months elapsed between *C* and *D*. The nodule was not detected on the first radiograph (*C*). It proved to be a small cell carcinoma of the lung.

than the original nodule identified. The presence of multiple nodules suggests the diagnosis of metastatic tumor.

A major problem of chest CT is identification of one or several small nodules as an incidental finding. These nodules usually measure 5 mm or less in size and are almost always benign. Current thinking is that, in the absence of a known primary tumor, follow-up in 1 year is adequate to demonstrate stability of multiple nodules, and earlier follow-up is not necessary. However, with a solitary nodule, earlier follow-up (e.g., at 3 months) is prudent.

Like the plain film, CT is only marginally helpful in characterizing a pulmonary nodule. A "stellate" or "crablike" nodule is highly likely to be a primary lung carcinoma, although not invariably so. CT is excellent in demonstrating calcification in a nodule, usually indicative of a benign process (see above). CT may also demonstrate fat in a nodule, characteristic of a hamartoma. It may also demonstrate the draining vein of an arteriovenous malformation or the feeding artery of a sequestration.

Definitive diagnosis of the solitary pulmonary nodule is only rarely possible with radiographic techniques alone. Sputum cytology; bronchoscopy with bronchial washings, brushings, and biopsy; transthoracic lung aspiration or biopsy; thoracoscopic biopsy; or open lung biopsy may be necessary (see Chapters 36 and 37).

Multiple Pulmonary Nodules

Although a solitary pulmonary nodule that is seen on the plain film may be benign or malignant, the presence of multiple nodules strongly suggests metastatic tumor. Occasional exceptions to this rule include rheumatoid nodules (Fig. 30-54), fungal infections, alveolar sarcoidosis, and Wegener's granulomatosis. CT is often not very helpful when multiple pulmonary nodules have already been identified on the plain chest radiograph.

As previously noted, CT detects a large number of small pulmonary nodules which are not visible on the chest radiograph. If these are 5 mm or less and multiple, they are usually benign if the patient has no known primary tumor; radiographic follow-up is appropriate.

Left Ventricular Failure

Failure of the left ventricle is generally easy to recognize on the chest radiograph. The heart is enlarged, and the pulmonary vasculature is prominent. Changes in the size of the heart and central vessels are most evident on consecutive radiographs.

In chronic left ventricular failure, chronic dependent edema and interstitial fibrosis at the lung bases result in redirection of pulmonary blood flow from the bases to the apices; the vessels of the upper lobes become more prominent than those of the lower lobes, a finding referred to as *cephalization*. Interstitial edema often accompanies pulmonary venous congestion and is manifested by a diffuse increase in interstitial markings, usually in a linear distribution (Fig. 30-49*A*); Kerley's lines are characteristic features of interstitial edema.

Figure 30-54 Rheumatoid nodules. The nodules in the left lung of this patient with rheumatoid arthritis regressed 4 months later.

Alveolar edema may follow the development of interstitial edema and is characterized by diffuse bilateral consolidation (Fig. 30-36).

As on the plain film, heart failure on CT is first manifest as increased vascular markings. This is more easily recognized if a prior CT is available for comparison. As the heart failure progresses, interstitial pulmonary edema occurs, easily identified as increased interstitial markings with a septal pattern. Further progression leads to ground glass changes or frank alveolar edema.

Pleural effusions often accompany biventricular heart failure. At first, the pleural effusions are associated with prominence of the pulmonary vascular markings, cephalization, or both. However, while the pulmonary congestion clears in response to therapy, the pleural effusions often remain after the pulmonary vessels have returned to normal size. Pleural effusions in congestive heart failure may be unilateral or bilateral. If unilateral, the effusion most commonly occurs on the right side. As noted previously, recognition of left ventricular failure is difficult in the patient with obstructive lung disease because hyperinflated lungs and an elongated heart make it difficult to recognize cardiomegaly and pulmonary vascular engorgement. Comparison with previous films is paramount in recognizing subtle changes in cardiac size and in pulmonary vascular engorgement.

THE MEDIASTINUM

The anatomic delineations of "compartments" of the mediastinum are not defined consistently throughout the medical

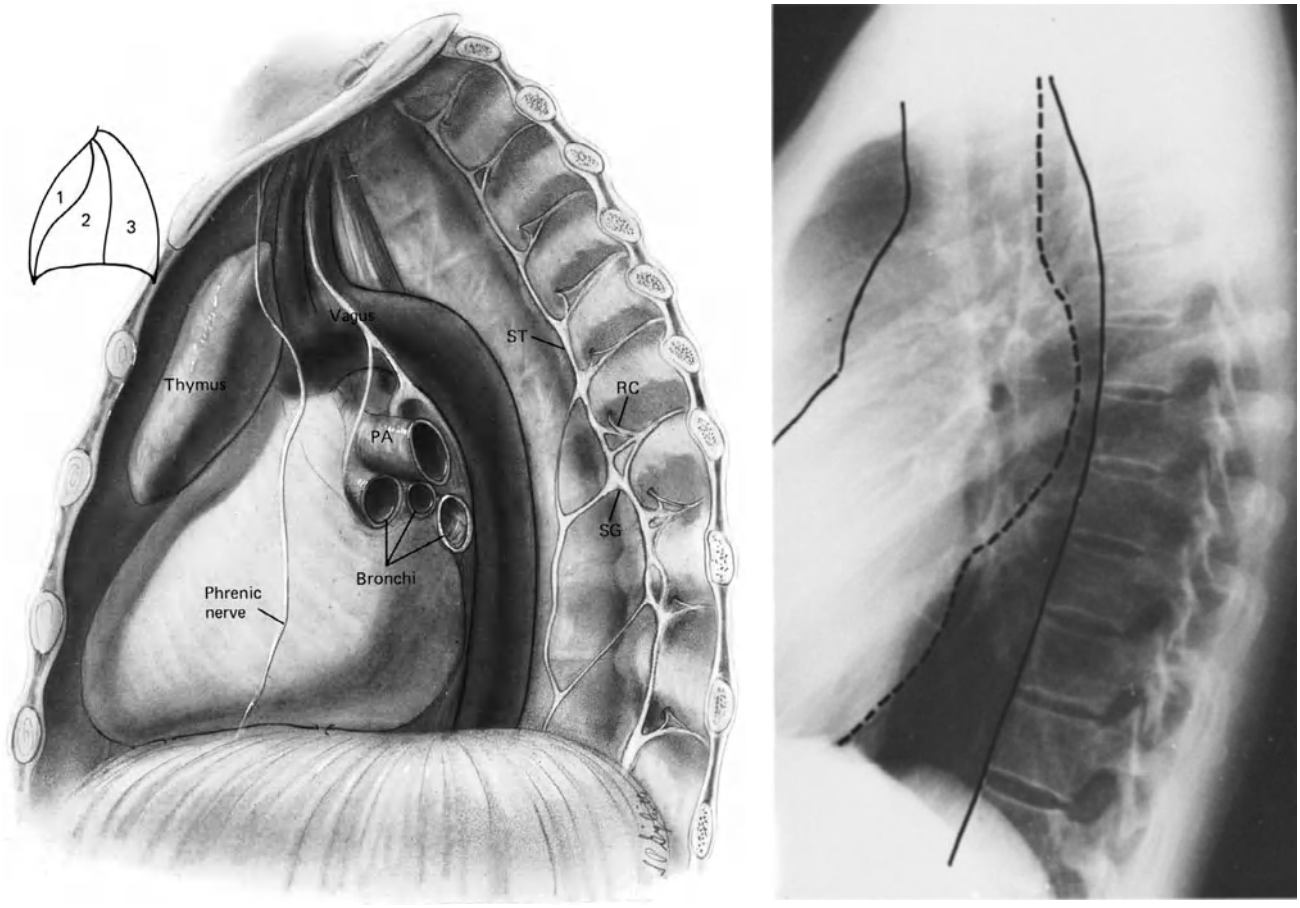

Figure 30-55 Compartments of the mediastinum. *A*. Anatomic view of the compartments of the mediastinum. The subdivisions in the small schematic (top left) correspond to those designated by the solid black lines in *B*. PA = pulmonary artery; ST = sympathetic trunk; SG = sympathetic ganglion; RC = ramus communicans. (*From Jones KW, Pietra GG, Sabiston DC: Primary Neoplasms and Cysts of the Mediastinum, in Fishman AP (ed), Pulmonary Diseases and Disorders, New York, McGraw-Hill, 1980, pp 1490–1521.) B*. Radiographic division of the mediastinum. The closed lines delineate the anterior, middle, and posterior compartments. The dashed line represents the division of the middle and posterior mediastinum that is conventionally used by anatomists.

literature. For radiographic diagnosis, a simple classification has been employed (Fig. 30-55): (1) The *anterior* compartment, which extends from the sternum anteriorly to the heart, aorta, and brachiocephalic vessels posteriorly, comprises only the thymus and a few lymph nodes. (2) The *middle*, or *visceral*, compartment contains the heart, great vessels, trachea and its branches, esophagus, and descending aorta. It extends from the posterior border of the anterior compartment to the anterior border of the vertebral column. These boundaries differ from the anatomist's classification (Fig. 30-55 *A*), which relegates portions of the esophagus and the descending aorta to the posterior mediastinum. (3) The *posterior* compartment contains the vertebrae and the paravertebral sulci. Applying this classification to the lateral chest radiograph, or to the CT, one may categorize mediastinal masses readily according to their position with the mediastinum.

Abnormalities in the anterior compartment include enlarged lymph nodes, substernal goiter, thymus and thymic tumors, and teratomas. Distinction among these can be made on the basis of their position within the anterior mediastinum and their appearance. Thyroid masses invariably lie high in the anterior mediastinum and displace the trachea and esophagus (Fig. 30-56 *A* and *B*). On CT, the thyroid has characteristic enhancement. Small thyroid nodules, usually a goiter, are frequently detected by CT as an incidental finding.

Benign, or minimally invasive, thymomas and teratomas generally lie below the aortic arch and present as single, well-demarcated masses (Fig. 30-56 *C* and *D*). If the outline of the mass is irregular by plain film or CT, the capsule likely has been breached and the thymoma or teratoma is invasive. However, invasive tumor may be present and not be recognized by radiographic means. In addition, invasive thymoma or teratoma may be indistinguishable from a lymphoma which is confined to the anterior mediastinum.

Lymph node enlargement is generally diffuse, often nodular or lumpy in character on the plain film (Figs. 30-57 and 30-58), and evident as a characteristic appearance on

A *B*

Figure 30-58 Sarcoidosis. *A*. PA view. A mass is present in the right paratracheal area, and both hili are enlarged. *B*. Lateral view. The hilar enlargement (arrows) is striking. Enlargement in these three node-bearing areas is characteristic of sarcoidosis.

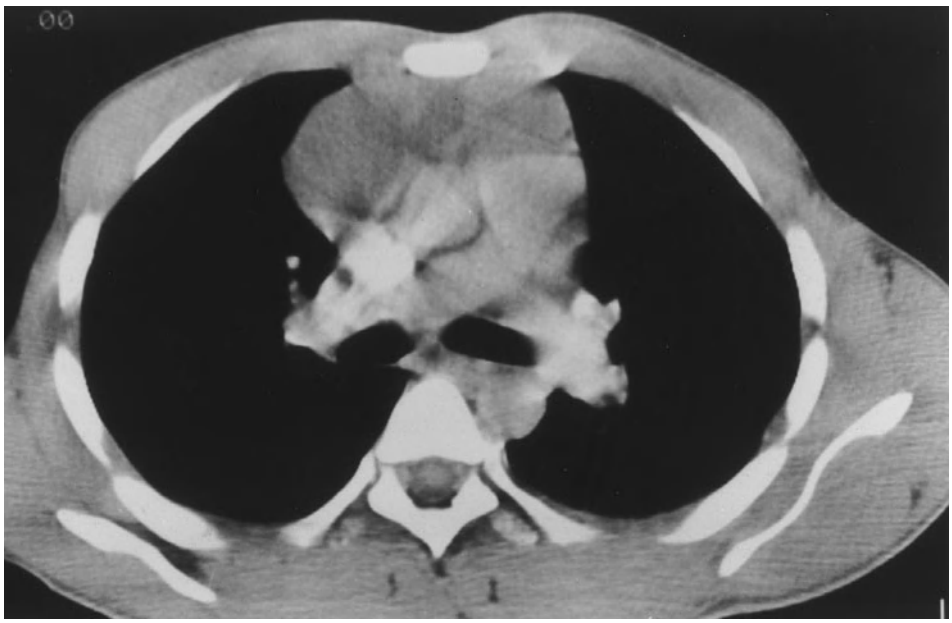

Figure 30-59 Malignant teratoma. A poorly circumscribed, diffuse mass can be seen anterior to the great vessels. Although the mass could represent lymphadenopathy from a number of causes, it is also consistent with malignant thymoma or teratoma. In this patient with AIDS, the mass was shown to be a teratoma.

CT. Enlarged anterior mediastinal lymph nodes are usually accompanied by enlarged lymph nodes in the middle mediastinum, making it easy to separate lymphoma from invasive thymoma or teratoma. Occasionally, differentiation may be impossible (Fig. 30-59).

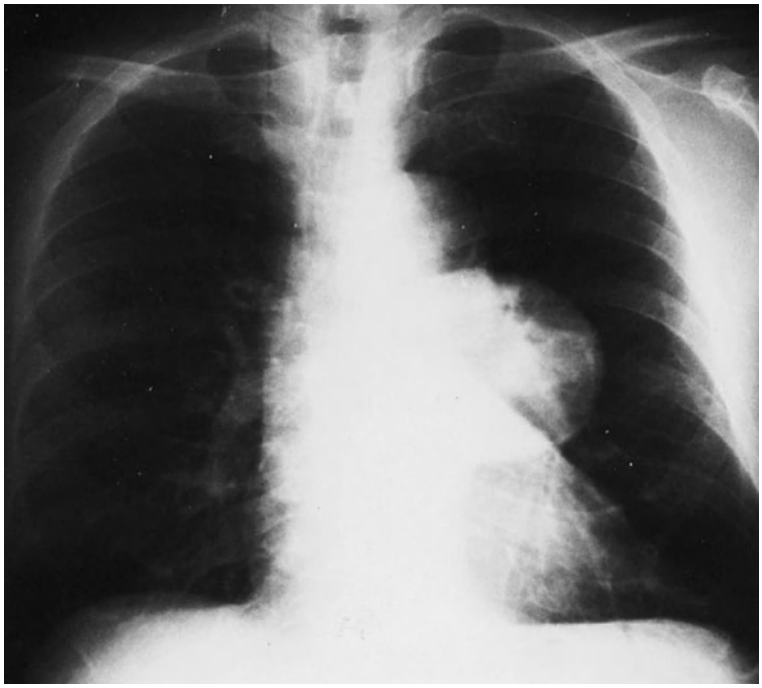
Lymph node enlargement may be produced by metastatic tumor, particularly from a primary neoplasm of the lung, or by sarcoidosis, lymphoma, or primary tuberculosis. Less common causes of mediastinal lymphadenopathy include other inflammatory processes, such as fungal infection or infectious mononucleosis.

The middle compartment of the mediastinum contains all of the mediastinal viscera, as well as lymph nodes. Lymphadenopathy in the middle compartment is quite common and is generally seen as a diffuse mass, often associated with enlargement of one or both hili (Fig. 30-58). CT often demonstrates mediastinal adenopathy which is not visible on the plain film (Fig 30-60).

A localized middle mediastinal mass may be caused by an aneurysm or other anomaly of the aorta or great vessels (Fig. 30-61). Its vascular nature is suggested by proximity to the aortic shadow and is readily confirmed by CT, MRI, or aortography (Figs. 30-62 and 30-66). Duplication cysts of the esophagus and the tracheobronchial tree are also common in the middle compartment. These localized masses are smooth and well circumscribed; generally, they do not contain air. Bronchogenic cysts commonly occur at the tracheal carina, whereas esophageal duplication cysts are characteristically located near the distal end of the esophagus (Fig. 30-63 *A* and *B*). However, esophageal and bronchogenic cysts may occur anywhere within the middle compartment. On CT, a duplication cyst often has a fluid density (as measured in Hounsfield units); however, not infrequently, fluid in the cyst is proteinaceous and of high density, erroneously suggesting that the cyst is a solid mass.

A dilated esophagus is sometimes seen on the chest radiograph as a long tubular mass in the middle compartment (Fig. 30-63 *C* and *D*) and is readily identified by CT. Tumors of the esophagus or trachea may also present as more localized mediastinal masses by chest radiograph; usually, CT is required for recognition. An esophageal tumor may involve primarily the mucosa and may not be well seen on the CT when it is clearly demonstrated on a swallowing study.

Figure 30-60 Mediastinal mass not seen on the routine chest radiograph. A large lymph node (arrow) is well seen on the CT scan lying just anterior to the descending aorta. This could not be seen on the routine chest radiograph. This node contained adenocarcinoma, and its presence on the scan was an important finding in staging a primary carcinoma of the left lower lobe.



A

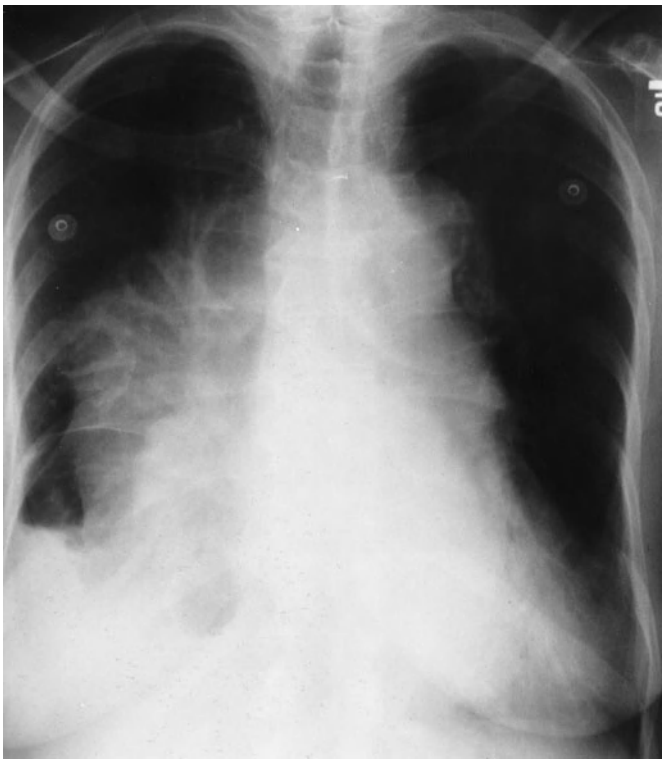
B

C

Figure 30-61 Mediastinal mass. *A*. Aortic aneurysm, PA view. A mass is seen to the left of the aorta. *B*. Aortic aneurysm, lateral view. The mass is also posterior to, and intimately associated with, the aorta. *C*. Aortic aneurysm, aortogram. An irregularity in the wall of the opacified aorta indicates the aneurysm. Most of the aneurysm is filled with clot. This type of mass may be mistaken for a neurogenic tumor in the posterior mediastinal compartment.

Radiographs taken with barium in the esophagus are particularly helpful in characterizing middle compartment masses on plain film and, occasionally, on CT.

In the posterior (paraspinal) compartment, the most common radiographic abnormalities are neurogenic tumors (Fig. 30-64). However, tumors or infections of the vertebral column may also present as masses in the posterior compartment (Fig. 30-65). CT or MRI usually distinguishes between a neurogenic tumor, which is unilateral and paraspinal in location, and lesions which erode or destroy the vertebrae and



A

A sagittal image is more graphic in its depiction of the huge ascending aortic aneurysm (arrows).

are generally present on both sides of the vertebral column. MRI findings are characteristic for neurogenic tumors.

A variety of radiographic lines or stripes seen in and around the mediastinum on the PA radiograph can be very useful diagnostically. Most useful among these is the *posterior paraspinal line,* which is a pleural reflection to the left of the thoracic spine (Figs. 30-5 and 30-65). The posterior paraspinal line is related to the descending aorta; it is seen on the right side if the descending aorta is on the right. Tumors or inflammatory diseases in the vertebral bodies displace the posterior paraspinal line to the left, creating a posterior paraspinal line on the right, where one is not ordinarily present. Large spurs arising from the vertebral body on the right also push out the pleura, creating a paraspinal line (Fig. 30-5*A*).

DIAPHRAGM AND CHEST WALL

The left hemidiaphragm is generally lower than the right; in only about 9 percent of subjects is the left hemidiaphragm

Figure 30-63 Esophageal duplication cyst. *A*, *B*. The small round mass behind the heart (arrows) has the characteristic location and appearance for an esophageal duplication cyst. Achalasia. *C*. PA view. The dilated esophagus is visible as a mass along the right mediastinum. Air outlines the wall of the upper esophagus above the aortic arch (arrow). *D*. Lateral view. The mass consists of an amorphous cluster of material lying posterior to the trachea and the heart (debris in the esophagus), displacing the trachea anteriorly.

A *B*

Figure 30-64 Neurogenic tumor (pheochromocytoma). *A*. PA view. A small mass (arrow) lies to the right side of the spine. *B*. Lateral view. The mass overlies the spine. The location is typical for a neurogenic tumor, usually a schwannoma or ganglioneuroma. This mass proved to be a thoracic pheochromocytoma.

higher. Variations in diaphragmatic contour are common. Most common is a localized eventration of the diaphragm (Fig. 30-6), in which a segment of diaphragmatic muscle is replaced by a thin fibrous membrane. The use of fluoroscopy in identifying local eventration of the diaphragm was described previously.

Foramina traverse the normal diaphragm to connect the thorax and abdomen. Sometimes the foramina enlarge sufficiently to allow herniation of abdominal viscera into the chest. The paired foramina of Morgagni lie anteriorly and medially; hernias through one of these foramina occur frequently on the right (Fig. 30-67 *A* and *B*), but rarely on the left. Generally, diaphragmatic hernias contain only omentum or fat, but they may sometimes contain colon. Hernias through the centrally placed esophageal hiatus (Fig. 30-67 *C–E*) are much more common than those through the foramina of Morgagni. The stomach is the usual herniating viscus; less often, the hernia contains colon or small bowel. Traversing the diaphragm posteriorly and slightly laterally are the paired foramina of Bochdalek. The massive congenital hernias occasionally seen in newborns generally occur through a large foramen of Bochdalek, usually on the left side. Hernias through these foramina are unusual in adults; when present, they may contain a kidney.

Traumatic diaphragmatic hernias occur secondary to traumatic rupture of the diaphragm, usually in the setting of a motor vehicle accident. Any viscus may protrude through the rupture; stomach and colon are common (Fig. 30-67 *F*). The actual herniation may occur days, weeks, or many months after the diaphragmatic injury. Delayed hernias often create a confusing radiographic picture. These hernias may be difficult to recognize on axial CT. Coronal reconstructions or MRI may be useful.

On the plain film, masses of the chest wall may cause bone destruction or erosion; if they do not, they may not be readily visualized. The masses also may be seen if they protrude into the lung as densities. Most lesions of the chest wall are metastatic tumors of the ribs, but primary tumors of the ribs and soft-tissue sarcomas also occur. Their encroachment into lung tissue causes a characteristic shadow that has smooth margins and tapering edges and is generally seen well in only one of the two standard views of the chest (Fig. 30-68 *A*). This characteristic configuration has been designated the *extrapleural sign.* Since many pleural lesions mimic the extrapleural sign, bone destruction is the key finding in accurate identification of an extrapleural mass. CT is extremely useful in the evaluation of chest wall lesions (Fig. 30-10), which often are not well seen or are poorly characterized on routine radiographs. CT readily shows bone destruction and the soft-tissue mass in the chest wall. Clinically palpable chest wall masses may not be visible on the plain film if they do not involve the ribs or protrude into the thoracic cage. In this instance, CT imaging is important. MRI also is an excellent technique for demonstrating chest wall masses.

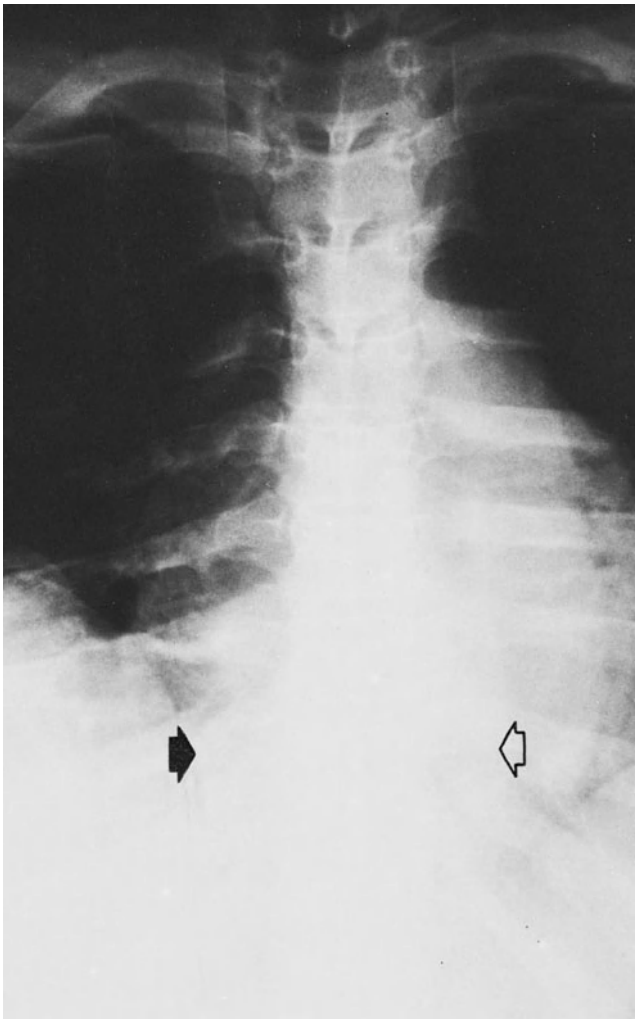

Figure 30-65 Tuberculosis. The normal left paraspinal line is displaced laterally (open arrow) by a paraspinal mass; the right paraspinal line, which is usually not seen, is present and displaced laterally (closed arrow). These findings are characteristic of infection involving the spine, in this case tuberculosis.

In addition to hernias through the diaphragm, tumors of the diaphragm occasionally present as masses seen on the chest radiograph. MRI is ideally suited to demonstration of diaphragmatic lesions, since coronal sections are much better than transaxial ones for this anatomic region. This is also true for pleural lesions, such as a pleural fibroma. With axial images, clear demonstration that a pleural lesion is in the chest (above the diaphragm), rather than in the abdomen, may be difficult. Coronal images will usually clearly demonstrate the location of the lesion.

PLEURA

The pleura and its disorders are considered in Chapters 85 through 88. Radiographic involvement of the pleura is generally manifested by pleural fluid, localized or diffuse pleural thickening, or pleural nodules.

A

B

Figure 30-66 Dissecting aortic aneurysm shown by CT. *A*. A sagittal image shows a dissecting aneurysm in the descending aorta; a prominent flap is seen medially, crossing the aortic lumen. *B*. An oblique sagittal reconstruction of the image shows the flap in the proximal descending aorta.

Pleural Effusions

Fluid in the pleural cavity appears radiographically as a homogeneous opacity that generally occupies a dependent position. A small pleural effusion that is barely perceptible or is overlooked on the PA view is often readily apparent on the lateral radiograph as blunting of the posterior costophrenic sulcus (Fig. 30-2). The best non-CT radiographic study for demonstrating small quantities of pleural fluid is the lateral decubitus film (Fig. 30-3*C*). Using this technique, as little as 25 ml of fluid can be detected. Larger pleural effusions usually blunt the lateral costophrenic sulcus on the PA radiograph as well (Fig. 30-68*B*).

Occasionally, pleural fluid remains between the diaphragm and the lung (i.e., is infrapulmonary or subpulmonic), displacing the lung upward, so that the lateral costophrenic angle remains sharp (Fig. 30-3). The presence of an infrapulmonary accumulation of fluid should be suspected if the diaphragm appears elevated, if the costophrenic sulcus is blunted posteriorly, or if the stomach bubble is separated from

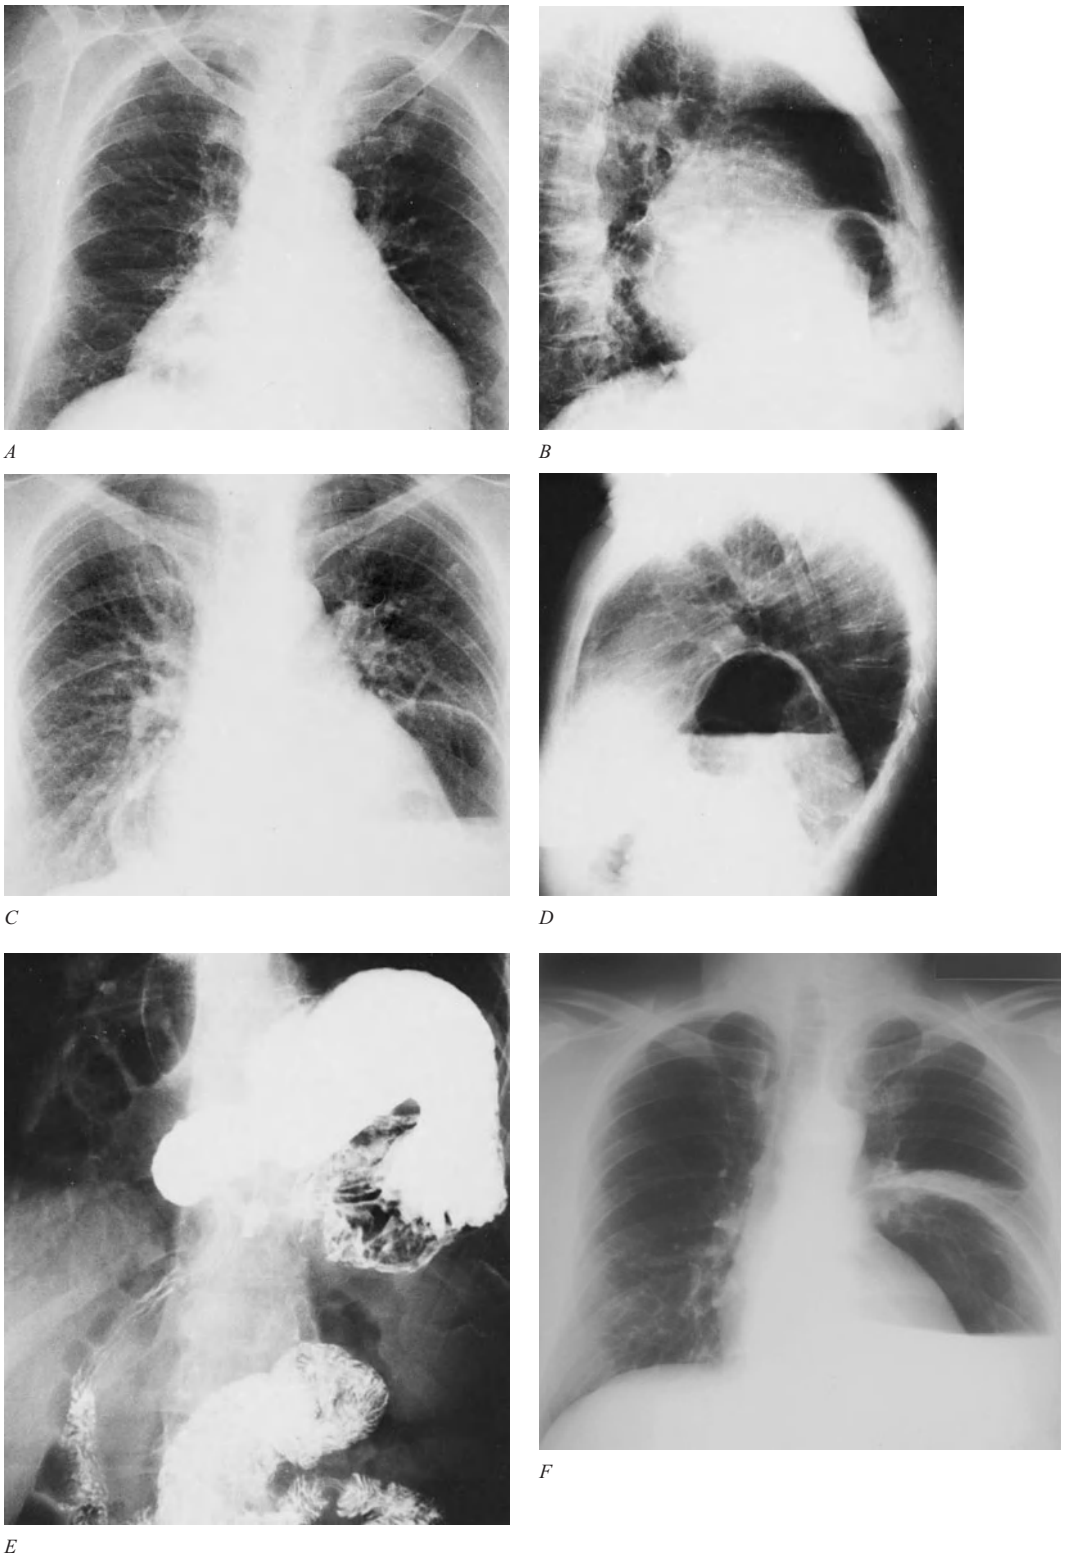

Figure 30-67 Foramen of Morgagni hernia. *A*. PA view. *A* mass containing a loop of bowel lies just to the right of the cardiac silhouette. *B*. Lateral view. The mass is also anterior to the cardiac silhouette. The location of the mass is characteristic for a foramen of Morgagni hernia. The hernia usually contains only omentum, but in this instance, it also contained a loop of colon. **Hiatus hernia**. *C*. PA view. An air-fluid level is present in the left chest and must be differentiated from an elevated diaphragm with underlying stomach. *D*. Lateral view. The mass is also posterior to the heart. *E*. An upper gastrointestinal series demonstrates the air-fluid level to be within the stomach, which has herniated into the chest and lies in an upside-down position. **Traumatic hernia**. *F*. PA film of the chest shows an air-fluid level in the left chest, quite similar to the above hiatal hernia. However, this was a traumatic hernia of the diaphragm with stomach herniated through the diaphragm and gangrenous at surgery.

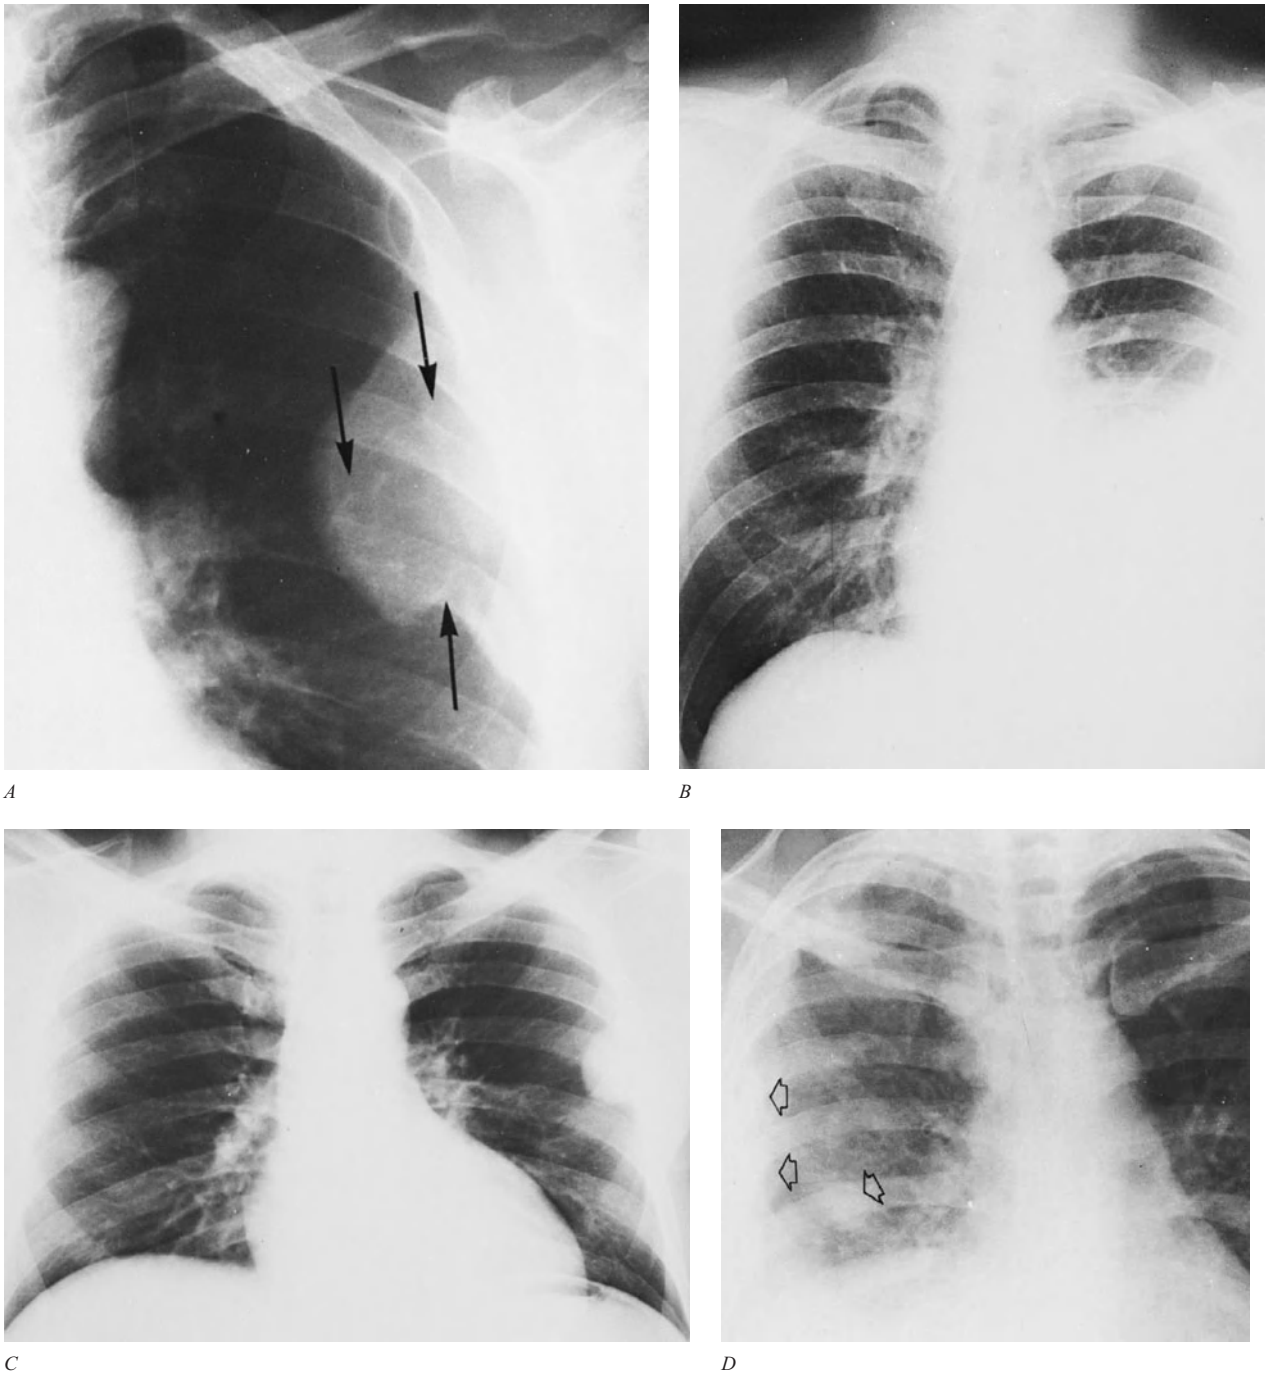

Figure 30-68 *A*. Rib metastasis (extrapleural sign). A smooth mass protrudes into the lung. This mass has tapering edges, characteristic of an extrapleural lesion. The destroyed anterior rib (arrows) is secondary to a metastatic tumor that is invading the rib. *B*. Rheumatoid effusion. The characteristic meniscus of a free pleural effusion is seen in the left hemithorax. This patient had rheumatoid arthritis. *C*. Pleural lipoma. A smooth mass along the left lateral chest wall proved to be a lipoma. *D*. Pleural metastases. A right pleural effusion, showing a meniscus, blunts the right costophrenic sulcus. The lobulation along the right lateral chest wall is characteristic of tumor nodulation (arrows).

the dome of the apparent hemidiaphragm by more than a few millimeters. CT is especially sensitive in identifying pleural effusions (Fig. 30-69). These effusions may be small and not visible on the plain film. In the intensive care unit, where most plain films are obtained in supine patients, CT imaging is helpful in the diagnosis of pleural effusions.

Pleural fluid sometimes is loculated and difficult to distinguish from localized pleural thickening. Loculated pleural fluid in an interlobar fissure assumes a cigar-shaped configuration on the lateral radiograph, and it sometimes simulates a mass. This mass, known as a "phantom tumor," disappears as the fluid is eliminated. CT readily recognizes these loculated

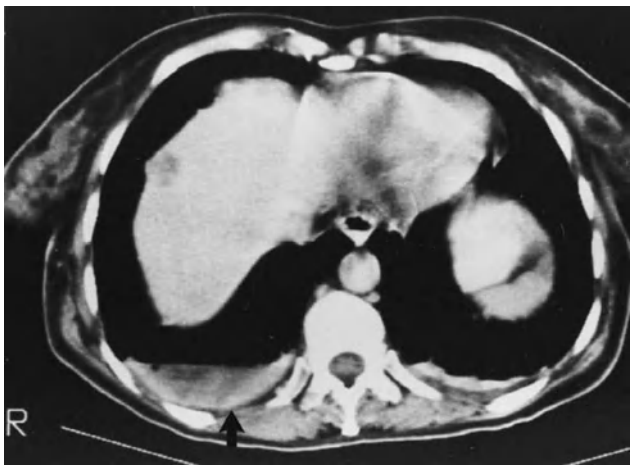

Figure 30-69 A small right pleural effusion (arrow) is identified by CT. This was not seen on the routine chest radiograph. Pleural thickening is seen in a similar location of the left side.

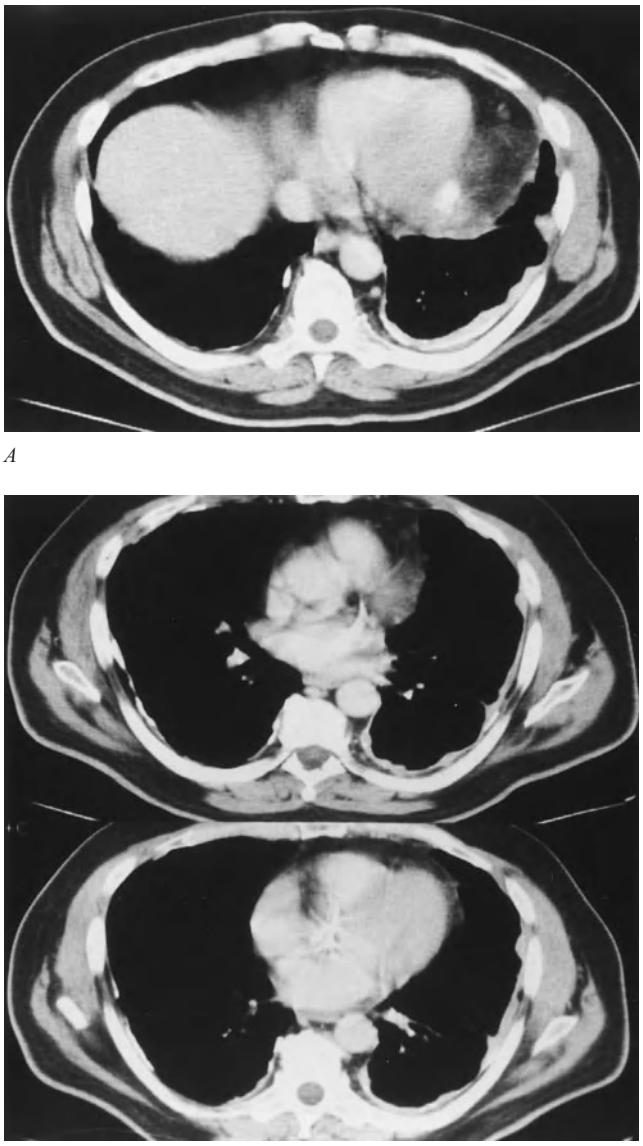
effusions. The loculation is usually indicative of a high concentration of protein in the fluid, frequently due to infection or tumor.

Bilateral pleural effusions are usually caused by heart failure or ascites. Occasionally, they are due to collagen vascular disease or metastatic tumor.

Common causes of unilateral pleural effusions include tuberculosis, pneumonia, pulmonary infarction, metastatic tumor, primary pleural tumor, lymphoma, collagen vascular disease, chest trauma, ascites, and intra-abdominal inflammatory processes, such as subphrenic abscess or pancreatitis. Thoracentesis and pleural biopsy may be necessary to establish the nature of a pleural effusion that has been recognized radiographically. CT and MRI are usually not useful in determining the exact cause of a pleural effusion. The lumpy, masslike character of a mesothelioma or metastatic tumor can be nicely demonstrated by CT (Figs. 30-68*D* and 30-70); such findings are often apparent on the plain chest radiograph. Many mesotheliomas demonstrate only a pleural effusion, without any specific findings to indicate the malignant nature of the process. CT or MRI may show associated mediastinal adenopathy that was not suspected on the plain radiograph.



A

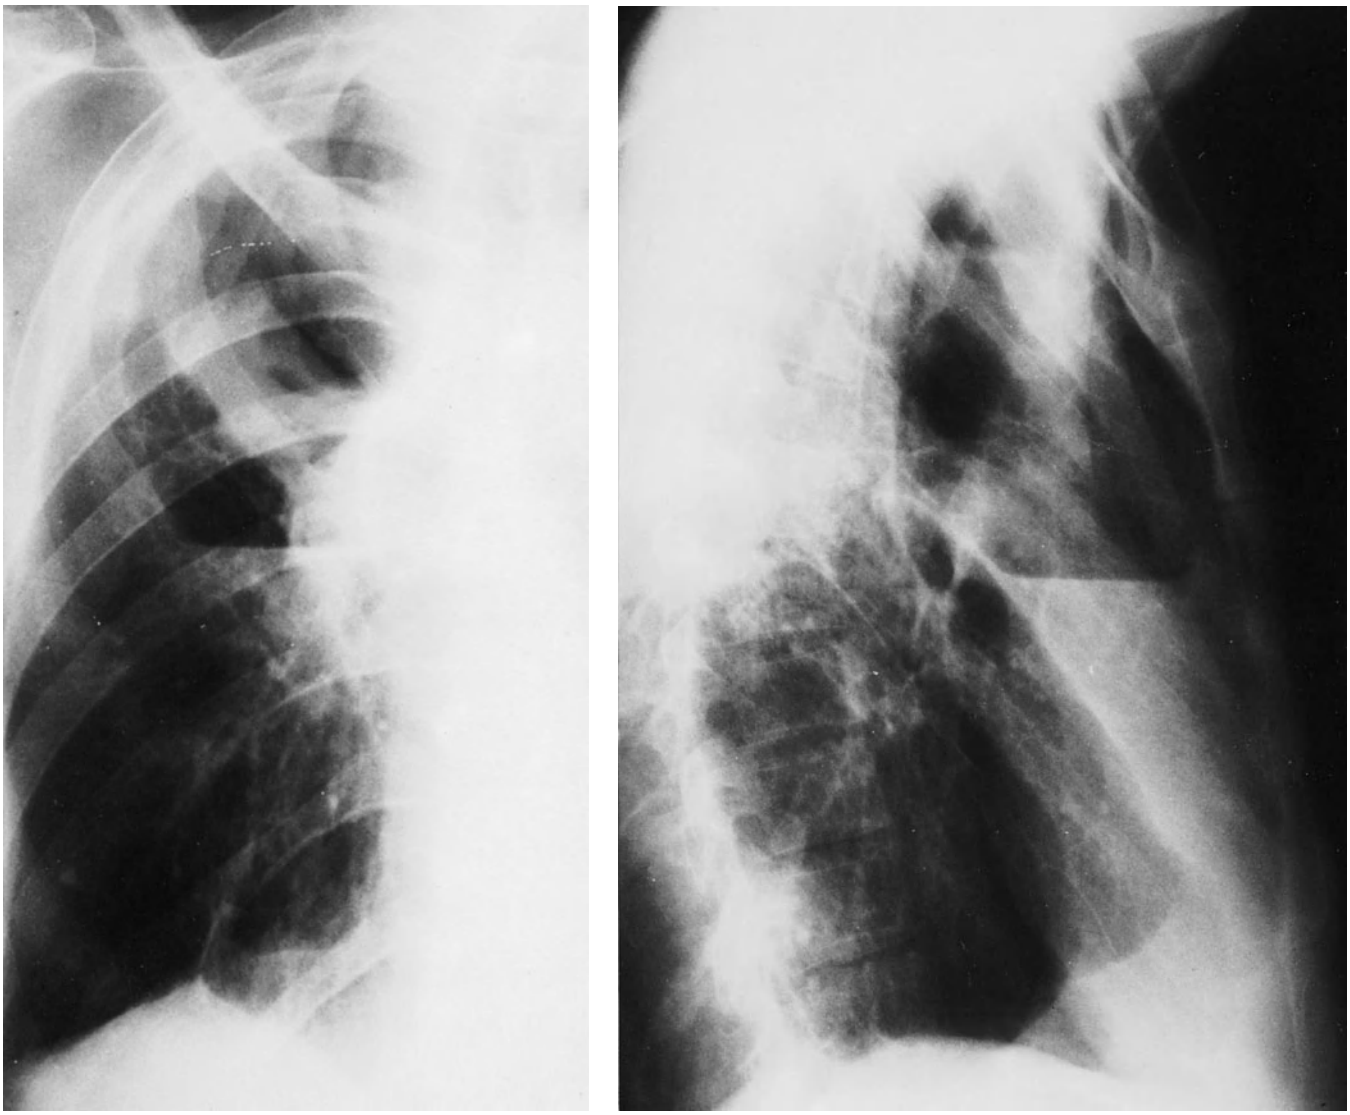
B

Figure 30-70 Pleural mesothelioma. Asbestos-related pleural plaques are seen in the right chest; pleural thickening and pleural calcification are present. On the left side, the pleura is thickened and quite lumpy. This is characteristic of mesothelioma, but the finding is not specific for this disorder and could be due to metastatic tumor. Mesothelioma might also present as a nonspecific pleural effusion.

Pleural Thickening

Fibrosis of the pleura may be localized or generalized. Localized pleural thickening is common at the lung apices and is suggestive of tuberculosis. Most often, however, apical scarring, commonly seen on CT, remains unexplained and is attributed to aging. Blunting of the costophrenic sulcus is occasionally the result of a previous pleural effusion. A costophrenic sulcus that appears to be blunted laterally on the PA radiograph, but not posteriorly on the lateral radiograph, usually represents pleural thickening, rather than pleural fluid.

Generalized pleural thickening confined to one hemithorax is usually secondary to previous tuberculosis, empyema, or hemothorax. Bilateral pleural thickening, either localized or generalized, is strongly suggestive of asbestos exposure. Although such thickening is sometimes accompanied by pleural calcification or interstitial lung disease, pleural thickening may be the sole radiographic manifestation of asbestos exposure. Pleural plaques are more commonly seen using CT imaging, and the associated calcification is more readily appreciated than on the plain film.



A *B*

Figure 30-71 Hydropneumothorax. *A*. Posteroanterior view. A distinct air-fluid level is seen overlying the left hilus. *B*. Lateral view. The fluid and air are anterior to the hilus. This is difficult to differentiate from a lung cavity, but the very thin edge suggests that this is in the pleural space. This was a hydropneumothorax and was secondary to a postoperative bronchopleural fistula.

Pleural Nodules

A localized pleural nodule suggests a benign pleural tumor, such as a fibrous tumor of the pleura or lipoma (Fig. 30-68*C*). The nodule may be difficult to distinguish from a localized area of pleural thickening, but generally it is larger and more symmetric in contour. On CT, these nodules generally have a characteristic appearance: the greatest diameter of the mass is in its center, and its edges are flat and tapering; the appearance is similar to the extrapleural sign, described previously.

Unilateral, diffuse pleural nodulation (Fig. 30-68*D*) usually indicates diffuse mesothelioma or metastatic malignancy, although empyema can sometimes be quite nodular in appearance. Mesotheliomas and pleural metastatic tumor are impossible to distinguish radiographically; they also may be difficult to distinguish histologically. Both are commonly associated with pleural effusion. As in the case of pleural effusions, CT is extremely useful in identifying localized or diffuse pleural abnormalities, but is somewhat limited in determining their cause.

Pneumothorax

In the conventional upright radiograph, air within the pleural cavity is best seen at the apices, where the thin line of visceral pleura surrounding the partially collapsed lung is easily identified. If doubt exists, a radiograph taken during expiration may make a pneumothorax more obvious. In supine patients, or in patients with pleural adhesions, pneumothorax may be

seen only at the bases, medially or laterally. CT is useful in demonstrating small pneumothoraces, which may not be appreciated on conventional radiographs.

Trauma, including that of iatrogenic origin, is the most common cause of pneumothorax. Spontaneous pneumothorax occurs in a variety of conditions. Most often the cause is unknown. On occasion, pneumothorax may be clearly attributed to a ruptured apical bleb. Diffuse lung disease, such as eosinophilic granuloma, is sometimes the cause of spontaneous pneumothorax.

Chronic pneumothoraces are almost invariably associated with pleural effusions. The interface of air and fluid in the pleural space causes the fluid to assume a flat line (Fig. 30-71), rather than the usual curved line configuration (meniscus) seen when air is absent. A pneumothorax is ordinarily rapidly reabsorbed or replaced by fluid in the pleural space. A chronic pneumothorax strongly suggests a bronchopleural fistula.

PORTABLE CHEST EXAMINATION

Use of portable radiographic studies in evaluation of seriously ill patients is routine. Interpretation of the portable radiograph is often difficult, since the film may be technically limited. Despite its problems, the portable radiograph usually provides useful information in postoperative patients, who may be difficult to examine clinically, and in mechanically ventilated, critically ill patients.

Localized pulmonary consolidation seen in the postoperative radiograph generally indicates one of three possibilities: pulmonary contusion, pneumonia, or atelectasis (segmental or lobar). Pulmonary contusion, common after thoracic surgery, is generally noted immediately after the surgery; it resolves gradually. In contrast, pneumonia usually occurs after the second or third postoperative day. Radiographic findings may be diffuse or localized: when localized they are difficult to distinguish from atelectasis; when diffuse, pneumonia may mimic pulmonary edema. Patchy multifocal pneumonia is common and frequently due to aspiration.

Atelectasis is a prevalent postoperative complication. It usually occurs in the lower lobes and is more common on the left. An increased density behind the cardiac shadow or obliteration of the diaphragmatic shadow behind the cardiac silhouette constitutes presumptive evidence of left lower lobe atelectasis. Frequently, distinction between atelectasis and pleural fluid based on a portable radiograph is difficult.

Basilar atelectasis, also known as platelike atelectasis, Fleischner's lines, or discoid atelectasis, frequently occurs in very ill patients, particularly after abdominal surgery. Manifestations include linear densities at the bases that generally are oriented parallel to the diaphragmatic surface; the densities do not follow the usual patterns of lobar collapse. Basilar atelectasis is considered an indication of poor diaphragmatic motion and often occurs with abdominal pain. Basilar atelectasis may be seen in patients who are obese or who have impaired diaphragm motion or diaphragm eventration (Fig. 30-72).

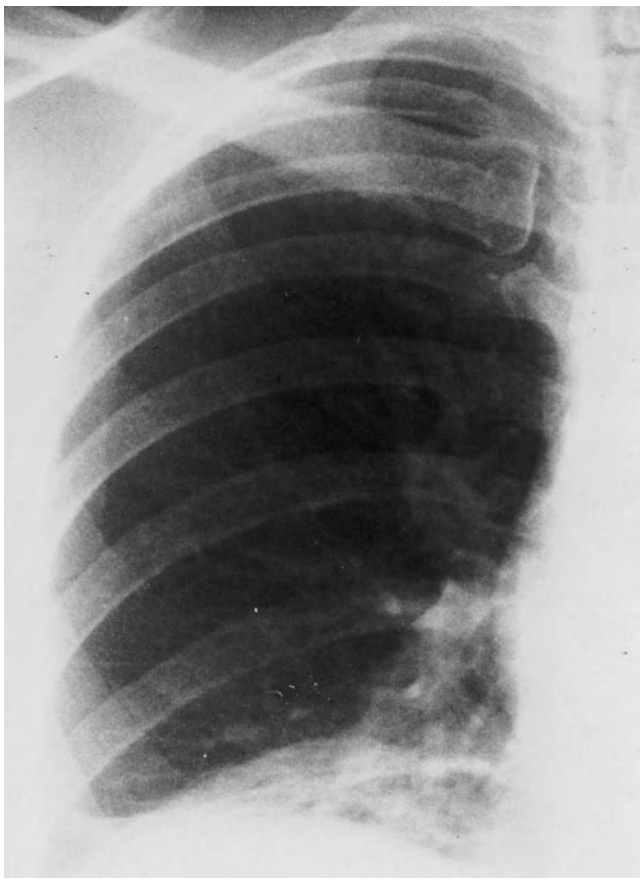


Figure 30-72 Platelike atelectasis. A linear density above the right hemidiaphragm in the postoperative patient represents platelike atelectasis. The configuration of this density does not correspond to that of a pulmonary subsegment, and it crosses segmental boundaries.

Pleural effusions are often difficult to identify in a portable examination, since the patient is rarely upright in bed or optimally positioned; a lateral radiograph is generally not available. On occasion, a large pleural effusion mimics lower lobe atelectasis. Although difficult to perform, portable decubitus radiographs can be useful in distinguishing a pleural effusion from atelectasis. Using CT imaging, pleural effusions, both large and small, are frequently seen, even when not suspected on the portable film.

In patients who have recently undergone thoracic surgery, fluid may accumulate in the extrapleural space in the area of the incision, simulating a loculated pleural effusion. With mediastinal incisions, mediastinal fluid accumulation is detected as diffuse widening of the mediastinal shadow. Comparison with earlier films is particularly useful in evaluating the process.

Left ventricular failure or fluid overload is another common clinical problem that is often difficult to recognize on the portable radiograph. Distortions in heart size produced

by inconsistent distances of the radiographic tube from the patient's chest complicate study interpretation. Enlargement of the pulmonary vessels is the most reliable sign of left-sided heart failure or fluid overload. The finding must be interpreted with care, however, since portable radiographs are often made while the patient is supine, resulting in redistribution of blood flow toward the apices. Pulmonary interstitial edema and alveolar edema are additional signs of left-sided heart failure that are generally recognizable in the portable radiograph. The presence of diffuse alveolar consolidation generally signifies pulmonary edema. In the critically ill patient, however, pulmonary edema is often noncardiac in origin (see Chapters 144 and 145). Massive aspiration or diffuse community-acquired or nosocomial pneumonia may also produce the radiographic picture of diffuse alveolar consolidation.

CT has become an indispensable tool in evaluating critically ill patients. Although significant challenges exist in transporting mechanically ventilated or hemodynamically unstable patients to the radiology department, the information gleaned may be critical to proper management. For example, CT imaging may elucidate an unexplained finding, or disclose a process not evident on the portable film. An unsuspected pneumonia or pleural effusion (perhaps, even a large effusion) may be demonstrated, or details, such as cavitation, may be appreciated. CT may be useful in helping elucidate the cause of diffuse alveolar consolidation by suggesting the presence of cardiogenic pulmonary edema, ARDS, or pneumonia, including that due to aspiration.

Finally, many institutions have incorporated into their routine critical care practices a daily multidisciplinary conference in which radiologists review current studies with clinicians managing the patients. The resultant clinical-radiographic correlation provides invaluable insight into the cause of the radiographic findings.

Pulmonary Cytopathology

Prabodh K. Gupta • Zubair W. Baloch

In his *Atlas of Exfoliative Cytology,* George N. Papanicolaou described the success and utility of cytopathology in detection and diagnosis of malignant lesions of the respiratory tract. Over the past 40 years, development of flexible fiberoptic bronchoscopy, transthoracic and transbronchial needle aspiration, and ultrasound-guided transesophageal and transbronchial fine-needle aspiration have broadened the methods by which cytological materials are obtained. These advances, coupled with refinements in specimen collection, cytopreparation, and ancillary laboratory diagnostic techniques, have established pulmonary cytopathology as an accurate, economical, safe, and rapid diagnostic procedure.

THE CYTOPATHOLOGY REPORT

A number of neoplastic and nonneoplastic pulmonary lesions can be accurately diagnosed with cytological techniques. For a valid and reliable diagnosis, the specimen must be satisfactory—that is, representative of the lesion(s) under investigation, adequate in cellular quantity and preservation,

and prepared and examined by experienced and qualified laboratory professionals. A cytopathology report should carry the same clinical and diagnostic significance as does a report from a representative histological study. The value of collaborative interaction between the clinician and laboratory personnel cannot be overemphasized. Relevant clinical information must be furnished to, and reviewed by, the cytopathologist. While cytological findings, at times, may be nonspecific, consultation between clinician and cytopathologist can help with patient management.

PULMONARY SAMPLES

A wide variety of pulmonary specimens may be examined cytologically; the most commonly employed are described below.

Spontaneously Produced Sputum

Spontaneously expectorated sputum has been a mainstay in the diagnosis of pulmonary lesions. While some patients readily produce a representative sputum sample, the collection procedure can be time consuming, uneconomical, and inefficient. Typically, three to five deep-cough specimens are obtained on consecutive days after the patient is instructed in the proper technique for providing a satisfactory specimen: after mouth rinsing and throat cleaning, the patient takes a deep breath, holds it for up to 20 seconds, and then coughs. With this method, material is forcefully expectorated from the airways. The procedure should be repeated for up to 30 min to produce a sufficient quantity of a representative specimen.

In addition to mucus and mature and immature squamous cells exfoliated from the oral cavity, the specimen may contain lymphoid cells from the tonsils and adenoids. A satisfactory specimen is one that is representative of the bronchial mucosa and pulmonary parenchyma and contains macrophages (generally, carbon-bearing) derived from the alveolar spaces. Inspissated mucus from the terminal airways (Curschmann's spirals) and columnar cells from the bronchial tree and nasopharynx can also be seen (Fig. 31-1). The presence of only squamous cells indicates an unsatisfactory sample. However, exfoliated cells from upper airway epithelial lesions may be seen in such samples.

Induced Sputum

Many patients, particularly those who are asymptomatic, generally are unable to spontaneously produce a satisfactory sputum specimen by deep coughing. These patients may be "induced" to produce a diagnostic sample representing the respiratory mucosal surface and associated lesions. Induction techniques vary, but generally they involve inhalation of a preheated (37°C) hypertonic saline solution or mucolytic agent (Mucomyst) for 10 to 15 min. The patient is asked to cough for up to an additional 20 min; a pooled sputum sample is then collected and submitted for examination. Following initial sample procurement, the patient is instructed to collect more specimens for 2 to 3 days. The additional specimens, which are valuable diagnostically, should be pooled and preserved in a polyethylene glycol-alcohol mixture according to Saccamanno's technique (see below) or in commercially available preservatives following the vendor's recommendations.

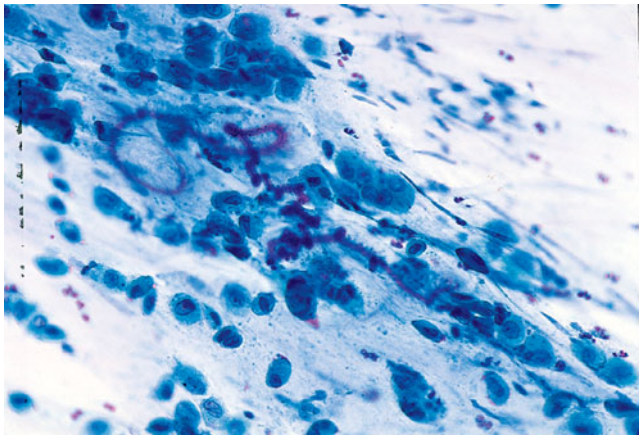

Figure 31-1 A satisfactory pulmonary cytology specimen (bronchial washing). Note the presence of macrophages, a Curschmann's spiral, and a few macrophages, indicative of a deep cough and pulmonary contents. Squamous cells most often indicate oral material. (Papanicolaou stain, ×105.)

Bronchial Washings

Cytological examination of bronchial washings has been in use for many years. While normal saline may be used to obtain bronchial washings, use of a physiological solution, such as Normosol or Plasmalyte, is preferable. Fresh specimens should be submitted to the laboratory. Fresh smears may be made on-site and fixed immediately in 95 percent ethyl alcohol for at least 20 min; alternatively, spray fixation (Surgipath cytology fixative) may be employed. Such preparations are diagnostically inferior to fresh specimens processed using cellulosic (Millipore) filters or other concentration techniques.

Segmental sampling of the bronchial tree (while taking adequate precautions against contamination of the specimen) may be useful in lesion localization. When delays are expected in specimen submission and processing, the material may be fixed by mixing the specimen with an equal volume of 50 percent ethyl alcohol or liquid-based cytology preservative, as specified by the vendor (ThinPrep or SurePath).

Bronchoalveolar Lavage

Bronchoalveolar lavage (BAL) consists of instillation of a physiological solution (normal saline, Normosol, or Plasmalyte) into a specified area of the pulmonary parenchyma, followed by aspiration (Chapter 36). The material obtained represents sampling of 1 to 3 million alveoli (about 1 percent of all alveoli).

BAL samples are most useful in investigating diffuse alveolar processes, such as *Pneumocystis carinii* pneumonia, viral infections, chemotherapy- or radiation-related changes, or lesions with transalveolar spread, such as alveolar proteinosis and bronchoalveolar cell carcinoma. Additionally, BAL has been used in the study of various immunologic, inflammatory, and infectious processes occurring within the alveolar spaces, including lymphomas, post-transplant lymphoproliferative disorders (PTLD), interstitial lung diseases, and inhalation-related disorders. Notably, only rarely are interstitial lung diseases diagnosed using BAL. However, the specimens obtained may be useful for differential cell counts and special ancillary investigations, including flow cytometry or immunohistochemical studies. BAL specimens must be differentiated from bronchial washings, as the cellular contents and diagnostic yields of the two specimens are different; while the bronchial wash represents the mucosal surface, BAL contains material from alveolar spaces.

Bronchial Brushings

Bronchial brushings represent material obtained though catheter-based brushing of airway mucosa or lesions under direct visualization or fluoroscopic guidance. The specimens are particularly useful because morphologic details are usually well preserved and representative of mucosal lesions. Fresh specimens should be submitted to the laboratory. Alternatively, the saline-immersed brush can be mixed with an equal volume of 50 percent ethanol or proprietary collection fluid for concentration methods when a delay in specimen delivery is expected.

Direct smears are prepared by rolling the brush on a clean glass slide, followed by immediate fixation using 95 percent ethanol. Caution must be exercised in their evaluation, since poorly preserved cells may appear hyperchromatic, have altered nucleocytoplasmic (N:C) ratios, and mimic undifferentiated tumors. Bronchial reserve cells, often seen in such specimens, may be mistaken for small-cell neoplasms.

In hypersensitivity and inflammatory processes, proliferative goblet cells and columnar cells are commonly seen and may be associated with eosinophils and Curschmann's spirals. Ciliocytophthoria (CCP), another manifestation of hypersensitivity reactions or viral infections, also may be observed in bronchial specimens. Proliferative mucosal cells may appear as cohesive aggregates; the cilia, which can be located centrally, may be inconspicuous. These so-called "creola bodies" may be mistaken for well-differentiated adenocarcinoma.

Postbronchoscopy Sputum

Cytological analysis of postbronchoscopy sputum specimens may be of diagnostic value. The patient is directed to collect morning sputum specimens for 2 to 3 days following bronchoscopy. These samples are more cellular and may be representative of the underlying pathology. Caution in interpretation is necessary, however, since extremely reactive and bizarre bronchial cells may be seen. An adequate clinical history and communication between bronchoscopist and cytopathologist are necessary for proper interpretation of post-bronchoscopy specimens. The technique may be of particular value in patients who are unwilling or unable to undergo additional diagnostic procedures. Specimens can be pool-collected in 50 percent ethanol or a proprietary preservative.

Transbronchial Aspiration

Transbronchial aspiration of pulmonary masses and intrathoracic and mediastinal lymph nodes is generally used to evaluate peritracheal, peribronchial, and, occasionally, anterior mediastinal lesions. An aspirating needle is introduced through the bronchoscope and directed to the area of interest. Considerable experience is needed for specimen collection and interpretation. On-site evaluation of specimens improves diagnostic accuracy and reduces the number of passes necessary. In situations where on-site evaluation is not available, specimens can be submitted to the laboratory in 50 percent ethanol or a proprietary preservative.

Percutaneous Transthoracic Fine-Needle Aspiration

Localized pulmonary parenchymal abnormalities are frequently evaluated using transthoracic fine-needle aspiration (FNA) under imaging guidance. The technique is extremely accurate, rapid, and cost-effective; results are comparable to those from tissue biopsies. Diagnostic sensitivity ranges from 75 to 95 percent and specificity from 95 to 100 percent. Complications include bleeding and pneumothorax. The incidence of tumor cells seeding along the needle track is extremely low. While on-site cytological evaluation is valuable and preferred, specimens may be submitted to the laboratory in appropriate transport media. Use of a large-bore needle during aspiration may result in excessive bleeding, rendering on-site specimen preparation and evaluation difficult.

Endobronchial and Endoscopic Ultrasound-Guided Fine-Needle Aspiration

Ultrasound-guided transbronchial and transesophageal fine-needle aspiration (FNA) are useful procedures in the evaluation of peripheral lung and mediastinal lesions, respectively. Radiation exposure is diminished, and a high degree of diagnostic accuracy is provided.

SPECIMEN PROCESSING

A variety of techniques are employed in the cytopreparations of pulmonary specimens.

Direct Smears

Direct smears, prepared by trained laboratory personnel using the "pick and choose" technique, are best made from fresh, unfixed specimens. A biologic hood and necessary infectious precautions are employed. Any thick, pink, or dark suspicious areas are transferred to clear, prelabeled slides for preparation of smears. At least four smears should be made from each sample and fixed immediately in 95 percent ethanol or spray-fixed for Papanicolaou stain. The remaining material may be processed as described below.

Saccamanno's Fixative

Saccamanno's fixative is used in a popular technique in which a mixture of 50 percent ethyl alcohol and polyethylene glycol (Carbowax 1540) is added to the specimen. The specimen is either smeared directly on glass slides or used to prepare a slurry after mixing in a blender and subsequent centrifugation. However, alcohol causes coagulation of proteinaceous material, making direct smearing of the specimen difficult. Furthermore, blending may result in fraying of the delicate cell cytoplasm and cilia. This technique is useful in detection of squamous carcinoma, other large-cell tumors, and certain infections; it is less valuable for the diagnosis of tumors with neuroendocrine differentiation.

Cytospin Preparations

Cytospin preparations can be prepared from either fixed or fresh specimens. At least four slides should be examined from each specimen when the technique is used exclusively for specimen evaluation.

Liquid-based preparations (ThinPrep or SurePath) are popular cell concentration techniques and are superior to cytospin slides. Pulmonary specimens are collected and preserved in a vendor-provided solution and are submitted to the laboratory. The preparation background is clean, and cytological examination is easier. In addition, slide preparations can be used for other special investigations, such as morphometry or immunocytochemistry. However, cells may clump together and appear hyperchromatic. In addition, delicate morphologic and background features, such as necrosis and inflammation, are often lost, limiting evaluation and diagnosis.

Cellulosic (Millipore) Filters

Cellulosic (Millipore) filters are used in processing fresh pulmonary specimens. An 8-nm pore filter is employed in the collection of cells; fixation artifacts are minimal. Adequate sampling, maintenance of intercellular relationships, and background features are facilitated using this technique. In addition, morphologic details and cellular preservation are excellent. However, the procedure is expensive and time-consuming, and it requires a special setup and experienced technicians.

Cell Block

Slides prepared using the cell block technique may permit accurate diagnosis when specimens contain abundant abnormalities. However, when cells of interest are limited, cell block preparations are suboptimal for diagnosis. In symptomatic patients, cell blocks have been found to improve cancer diagnosis by at least 50 percent compared with direct-smear slides prepared from induced sputum. In addition, cell blocks can be used for a variety of histochemical and immunocytological studies.

Ancillary Laboratory Diagnostic Techniques

Specialized investigations, such as immunocytochemistry, electron microscopy, flow cytology, or microbial cultures may be undertaken in evaluating selected cytology specimens. Based upon the on-site evaluation of fine-needle aspirates and cytological findings, specimens for these special studies can be appropriately collected and processed. The techniques are especially useful in differentiation of adenocarcinoma from mesothelioma, diagnosis of bronchoalveolar carcinoma, elucidation of specific microbial infections, and further characterization of poorly differentiated tumors and lymphomas. In addition, molecular diagnostic procedures may be applied in the diagnosis of pulmonary infections.

NORMAL BRONCHOPULMONARY CYTOLOGY

A variety of cells representing tracheobronchial tree and pulmonary parenchyma are seen in a pulmonary specimen that has been obtained using the previously described techniques. Notably, heavy oropharyngeal contamination can occur in sputum specimens obtained spontaneously or following induction, and in bronchial washings.

Squamous Cells

Squamous cells are seen commonly in expectorated specimens as uniform, flat cells with pyknotic nuclei; sometimes the nuclei are vesicular and enlarged. Most cells are large and keratinized and vary minimally in size. Atypical pleomorphic, small, hyperkeratinized cells with altered N:C ratios and hyperchromasia (dysplastic squamous cells) may be observed with oropharyngeal and laryngeal squamous lesions. The presence of abnormally shaped keratinized cells, with little inflammation and background necrosis, should prompt examination of the upper airway (Fig. 31-2).

Mechanical irritation in the oral cavity, generally by ill-fitting dentures or other prosthetic devices, can cause exfoliation of bizarrely shaped keratinized cells noted in small tissue fragments. Small, dense, keratinized metaplastic cells may be seen in patients who are endotracheally intubated or who have undergone tracheostomy. Chronic pulmonary diseases can often lead to squamous metaplasia and atypical cell

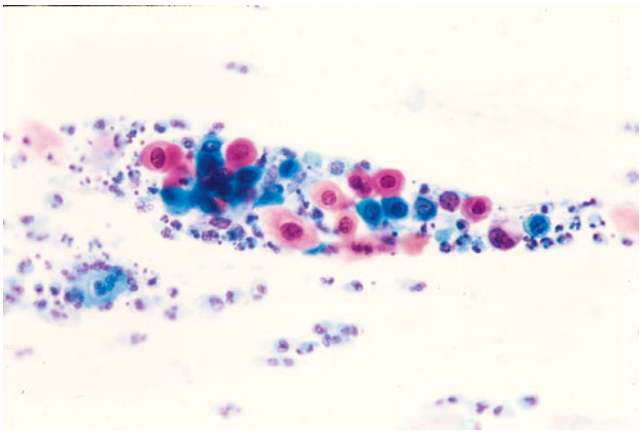

Figure 31-2 Upper airway brush specimen showing squamous cell carcinoma of the larynx. Note the group of small abnormal, keratinized cells occurring in a necrotic background. The patient had a normal chest radiograph. (Papanicolaou stain, ×166.)

morphology, causing concern about underlying malignancy. Finally, oropharyngeal contamination is extremely common in bronchial washings. The presence of fungal organisms (e.g., *Candida*) does not necessarily represent pulmonary infection. These observations must be interpreted in light of clinical features (Fig. 31-3).

Ciliated Bronchial Columnar Cells

Ciliated bronchial columnar cells may occur singly and in small tissue fragments. These columnar cells contain basally located, vesicular nuclei and pale cytoplasm. The cells have cilia of uniform length; they exhibit periodicity and attach at right angles to the terminal plates. The cilia must be accurately identified because, almost always, true cilia, which are visible by light microscopy, do not occur on malignant cells. Cellular degeneration and trapped mucus can be a source of error in

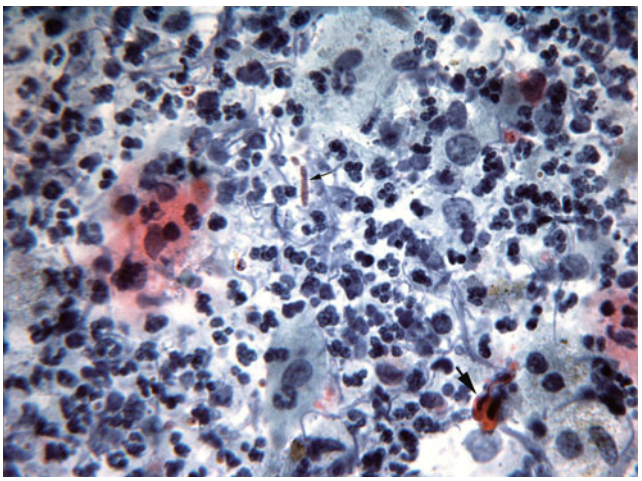

Figure 31-3 Bronchial wash specimen. Note intense, acute inflammatory exudate and filament of *Candida* organisms (arrow). The findings are common and represent oral contamination. (Papanicolaou stain, ×166.)

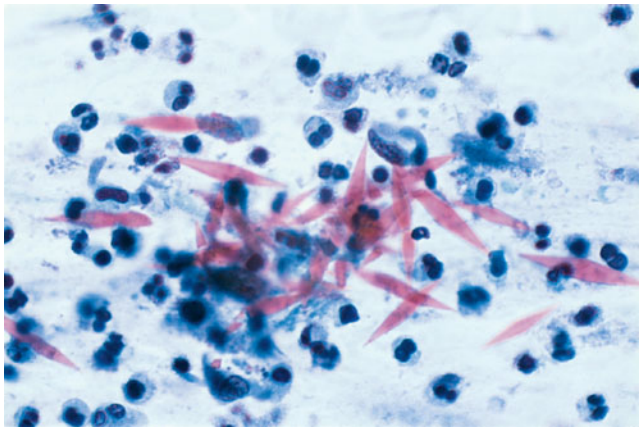

Figure 31-4 Bronchial washing showing Charcot-Leyden crystal in a patient with bronchial asthma. Note the numerous needle-shaped crystals occurring in an acute inflammatory background. The crystals are organophilic with the Papanicolaou method. (Papanicolaou stain, × 166.)

the proper identification of cilia. Fragmented ciliated cells (CCP) may occur in hypersensitivity and reactive conditions, as well as viral infection of the respiratory tract (as discussed below).

Goblet Cells

Goblet cells are recognized less commonly in normal pulmonary specimens. When present, they appear as swollen, pale cells. In general, goblet cells possess a single large vacuole or multiple small vacuoles that may contain mucus. Hyperplastic columnar and goblet cells may be seen in chronic pulmonary diseases, such as bronchitis or bronchial asthma, and in allergic conditions. In bronchial asthma, Curschmann's spirals may also be observed in cytological specimens. These are composed of a mucus shroud with numerous neutrophils and some eosinophils. Occasionally, needle-shaped Charcot-Leyden crystals, which appear orangophilic with Papanicolaou staining, may be seen (Fig. 31-4).

Hyperplastic bronchial columnar cells may appear quite bizarrely. They occur in tight tissue fragments with overlapping, hyperchromatic and enlarged, reactive nuclei that contain prominent nucleoli. On careful examination, such structures, known as creola bodies, reveal cilia on the edge or cell surface (Fig. 31-5). Creola bodies are a common cause of a false-positive diagnosis of adenocarcinoma. Similar hyperplastic structures can be seen in postbronchoscopy sputum specimens. The occurrence of large numbers of mucus-producing columnar cells without discernable cilia in tissue fragments obtained by FNA may be indicative of well-differentiated, mucin-producing adenocarcinoma.

Alveolar Macrophages

The presence of alveolar macrophages and type II pneumocytes in a pulmonary specimen are excellent criteria for specimen adequacy. These cells occur singly and are round or

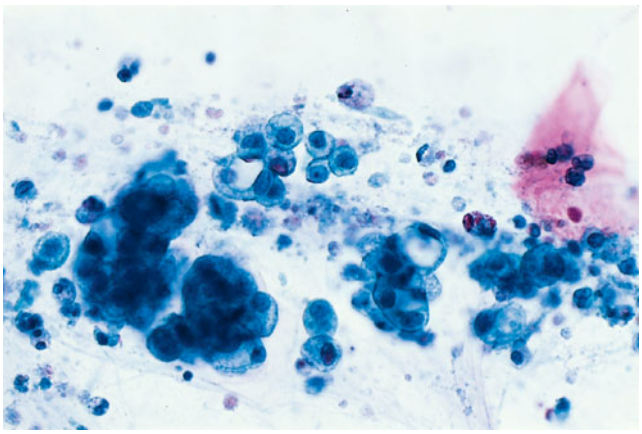

Figure 31-5 Bronchial washing showing creola bodies. Note the numerous glandular structures. Cells have prominent nucleoli, hyperchromasia, and evidence of mucus production. Some cells reveal terminal plates and cilia. Cilia may be few, poorly stained, and difficult to recognize. (Papanicolaou stain, ×208.)

cuboidal; typically, they have a kidney-shaped, vesicular nucleus which may contain a single, prominent nucleolus. Cell cytoplasm is pale and demonstrates fine vacuolation. Occasionally, ingested foreign material (carbon) or blood products (e.g., hemosiderin) may be observed in the cytoplasm. Multinucleated forms may occur in bronchoalveolar specimens obtained from patients who have pulmonary alveolar proteinosis or granulomatous diseases, or who have been exposed to pollutants (Fig. 31-6).

Alveolar macrophages must be examined in the context of the specimen background. Whereas evidence of old hemorrhage and necrosis may suggest a neoplasm, acute inflammation may signify an inflammatory process. Pulmonary infarcts, organizing pneumonia, prior chemotherapy, and other factors produce atypical cellular changes in macrophages and epithelial cells. The cytopathologist must be provided with proper clinical information in evaluating these specimens.

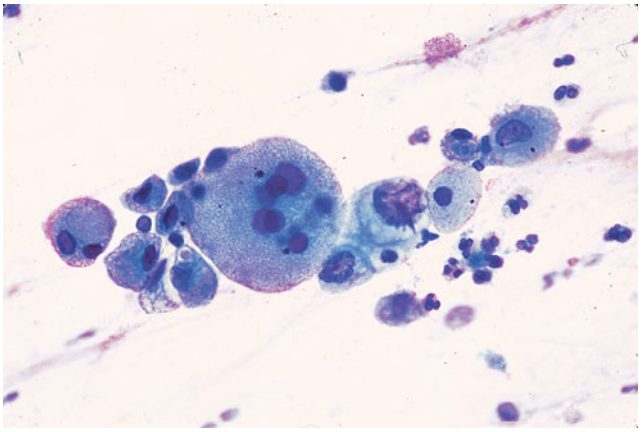

Figure 31-6 Bronchial washing showing multinucleated giant cell in pulmonary specimen from a cigarette smoker. Note the acute inflammatory background, mucus, and foreign body–type giant cell. (Papanicolaou stain, ×208.)

Pulmonary macrophages can be stained with CD68 immunochemical antibodies. Such immunocytochemical studies can be diagnostically useful in establishing the precise nature of atypical or other questionable cells.

TOXIC ENVIRONMENTAL INHALATION EFFECTS

Respiratory squamous and columnar cells and alveolar macrophages react to various environmental pollutants. As examples, the cytological responses of these cells to cigarette smoke, asbestos, beryllium, and "crack" cocaine are described briefly below.

Cigarette Smoke

Exposure of the respiratory system to cigarette smoke leads to accumulation of a golden-brown, refractile pigment within pulmonary macrophages. The pigment may be indistinguishable from carbon and hemosiderin particles. Alveolar macrophages may be ringed by material composed of α_1-antitrypsin, which stains orange-red with Papanicolaou stain. This material has been further investigated using appropriate immunocytochemical procedures. Intracellular α_1-antitrypsin may be tapered at one or both ends of the macrophage, creating a "tailed" appearance. Affected cells have been termed "pink-tailed" macrophages (Fig. 31-7).

Asbestosis

Asbestosis generally arises from exposure to dust containing mainly chrysolite and other forms of asbestos fibers. Elongated asbestos bodies, also referred to as ferruginous bodies, may be observed in pulmonary specimens from subjects exposed to asbestos. Ferruginous bodies vary in size from 4 to 5 nm to over 200 nm. They are commonly dumbbell-shaped; a central translucent fiber core is surrounded by layers of a material containing minerals (iron, calcium) and mucopolysaccharide. The color of ferruginous bodies is variable, from a pale golden yellow to dark brown or black. The outer coat tends to be segmented and oriented at right angle to the long axis of the fiber. Ferruginous bodies are generally accompanied by a tissue reaction comprised of macrophages and giant cells (Fig. 31-8). On rare occasions, needle-shaped asbestos fibers without any surrounding deposits are observed within the macrophages. Besides asbestos exposure, ferruginous bodies are also observed following inhalation of other minerals and fibers. No definitive correlation between the presence of ferruginous/asbestos bodies and occupational exposure to asbestos fibers has been observed. Although large numbers of ferruginous bodies may be seen after massive exposure to asbestos, occasional ferruginous bodies are observed as a nonspecific finding. Prussian blue staining for iron compounds helps further identify ferruginous bodies.

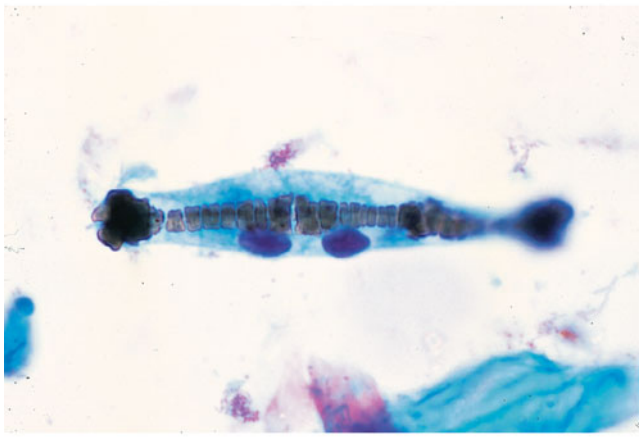
Figure 31-7 *A.* Bronchial washing showing "pink-tailed" macrophages in pulmonary specimen from a patient with a 15 pack-years cigarette-smoking history. *B.* Even distribution of α_1-antitrypsin around macrophages. While α_1-antitrypsin is distributed in the "points" in *A,* it is seen in close apposition to the cell in *B.* (Papanicolaou stain, ×330.)

A



B

Figure 31-8 Induced sputum showing ferruginous bodies in pulmonary specimens from a shipyard worker. *A.* Details of the central fiber core are visible. *B.* The surrounding core with segmented appearance is evident. (Papanicolaou stain, ×330.)

Berylliosis

Chronic exposure to beryllium and certain other heavy metals may result in profound pneumocyte proliferation and giant-cell formation. Multinucleated giant cells tend to be syncytial and often occur as large tissue fragments (Fig. 31-9). Variable numbers of lymphocytes may be present in the background. Clinical correlation is necessary before the cytopathologist can establish such a diagnosis.

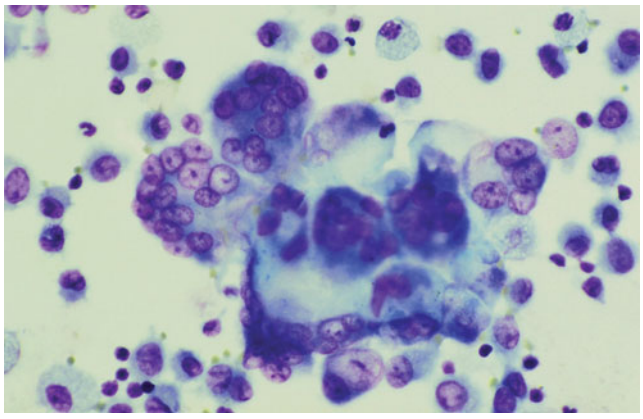


Figure 31-9 Bronchoalveolar lavage specimen showing multinucleated giant cell in beryllium exposure. Note the extremely large foreign body–type giant cell and alveolar macrophages (Diff-Quik stain, ×208.)

Crack Cocaine Inhalation

Repeated inhalation of recreational drugs may result in accumulation of large quantities of "black soot" within the alveoli and pulmonary macrophages (Fig. 31-10). The occurrence of large amounts of carbonaceous material within macrophages obtained by BAL appears to be unique to this patient population. The finding of similar pigmented macrophages within pleural fluid cells has been reported.

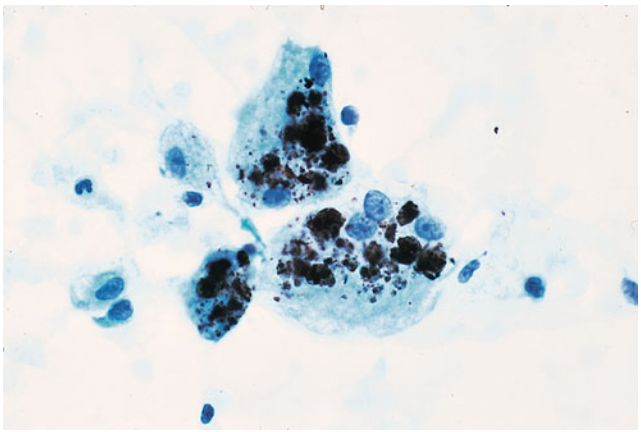

Figure 31-10 Bronchoalveolar lavage specimen showing pulmonary macrophages in a crack cocaine user. Note the abundant pigmented material in the cytoplasm of the cells, some of which appear reactive. Occurrence of pigment, per se, is a nonspecific finding. (Papanicolaou stain, ×208.)

INFECTIONS

A variety of infections of the respiratory tract result in cytopathological changes seen in specimens obtained by the aforementioned methods. The following sections outline changes that may be observed in pulmonary specimens obtained from patients with common bacterial, fungal, viral, or parasitic respiratory infections.

Bacterial Infections

Although bacterial infections of the respiratory tract are extremely common, cytopathology does not offer much help in their diagnosis or management. In selected cases, cytopathology may be useful.

Actinomycosis

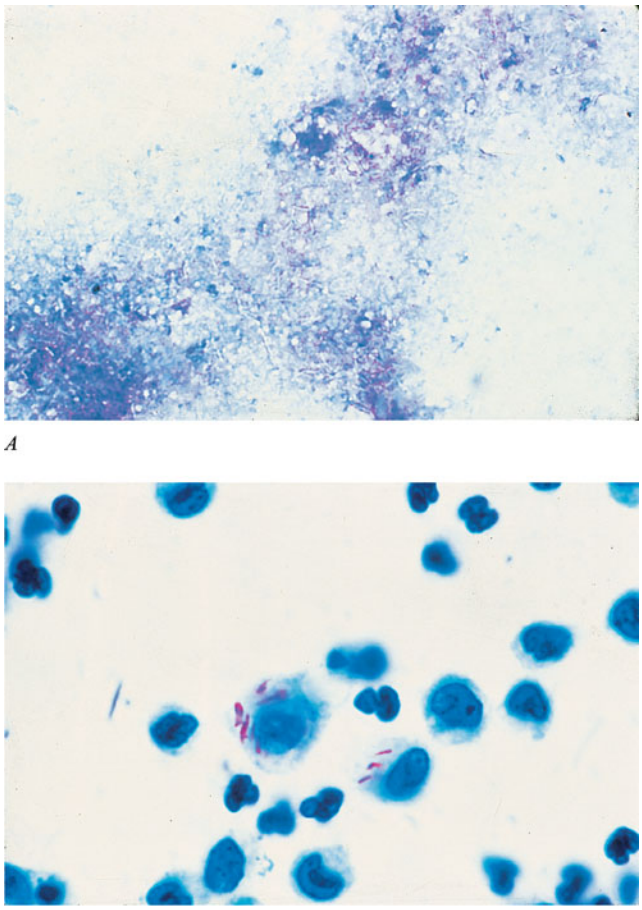
In patients with infection caused by species of *Actinomycetes*, pulmonary specimens generally contain large aggregates of filamentous, branching, thin organisms seen as tight, "woolly" clumps in an acute inflammatory background. The organisms are easily recognized in routine preparations and are correctly identified using appropriate immunohistochemical techniques. Diagnostic interpretation is made in view of the clinical and radiographic features. The constellation of these findings is important, since occurrence of actinomycetes in the oral cavity is extremely common, and morphologic detection may not indicate pulmonary infection.

Nocardiosis

Nocardia may be associated with pneumonia and cavitary pulmonary lesions. The organisms are visualized as delicate, nonseptate, filamentous, branching structures. The diagnosis can be made on specimens obtained from FNA or bronchoscopy. Generally, a histochemical (modified acid-fast) stain is used for further identification.

Mycobacteriosis

Acid-fast organisms may be detected in a variety of pulmonary specimens from patients with mycobacterial infections. Both tuberculous and nontuberculous mycobacterial infections are seen in immunocompetent and immunosuppressed patients. In immunosuppressed patients (e.g., those with human immunodeficiency virus [HIV] infection), the sample background is variable and may not be diagnostically helpful; only foamy macrophages, neutrophils, and a few lymphocytes may be seen (Fig. 31-11). While infection with *Mycobacterium tuberculosis* may yield only a few organisms in respiratory samples, specimens obtained from patients with atypical mycobacterial infections may yield numerous organisms that are identified easily by histochemical stains. Appropriate cultures should be performed in all such cases for a specific microbiologic diagnosis.



A

B

Figure 31-11 Fine-needle aspirate of the lung, atypical mycobacterial infection. *A.* Note the necrotic background, lack of inflammatory cells, and "ghost" forms of bacillary organisms. These can be seen in air-dried smears using Romanovsky's stain (Diff-Quik stain, ×330). *B.* Induced sputum specimen showing acid-fast, intracellular, atypical mycobacterium organisms. (Ziehl-Neelsen stain, ×330.)

Fungal Infections

A number of fungal organisms can be easily recognized in pulmonary specimens using the Papanicolaou stain. These include both true pathogens and a number of contaminants. Appropriate mycobial cultures should be performed if clinicopathological correlation is lacking and a specific diagnosis of the fungal type is important.

Candidiasis

Candida albicans may be seen as budding yeast forms in many specimens that are not freshly prepared and that have been stored at room temperature before fixation. This finding is of little clinical significance and is generally not reported by the cytology laboratory. In contrast, the occurrence of filamentous *Candida* forms, especially in specimens obtained by FNA, may be clinically important and should be reported. Such findings are seen in patients who are immunocompromised or suffer from diabetes or other disabling conditions. A laboratory report of *Candida* organisms in pulmonary specimens such as spontaneous or induced sputum or bronchial washings should be correlated with clinical and radiographic observations.

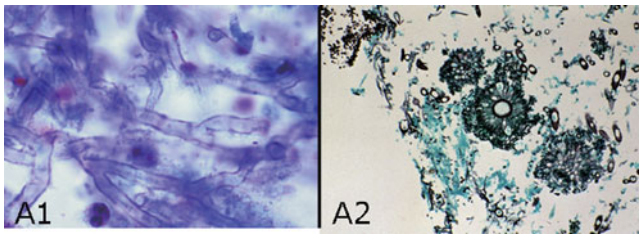
Aspergillosis

Aspergillus-related pulmonary disorders are quite varied in their clinical presentation. While establishing the presence of true tissue invasion may be difficult, the presence of the organism in pneumonic or cavitary lesions can be diagnosed cytologically. Most parenchymal infections are caused by *A. fumigatus,* although infections with *A. niger* and *A. flavus* also occur. Sputum specimens, bronchial washings, bronchial brushings, and FNAs can be diagnostic.

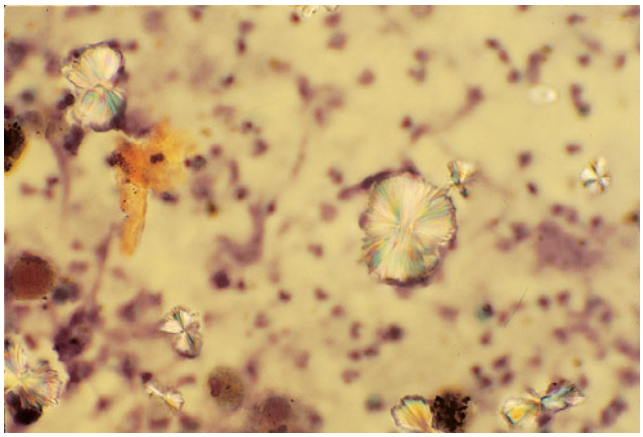
Since *Aspergillus* is an opportunistic airborne organism that sometimes contaminates pulmonary specimens, care should be exercised in reporting infection with *Aspergillus* if it is seen only on one slide or one set of slides. The presence of an acute inflammatory background and clinical and radiologic correlation are necessary for accurate diagnosis. The organisms are seen as broad, filamentous structures that branch at acute angles. In immunosuppressed patients with overwhelming infections, "fruiting bodies" (conidiospores) can be seen. Birefringent calcium oxalate crystals may occur in specimens containing *Aspergillus;* they are more commonly observed with *A. niger* (Fig. 31-12). Epithelial cells may show metaplastic and atypical morphologic features.

Cryptococcosis

Patients with cryptococcosis may be asymptomatic. Organisms can be visualized in sputum, bronchial washings, bronchial brushings, or FNA specimens. Most commonly, narrow-necked, budding yeast forms are observed; they demonstrate marked variation in size (5 to 40 nm) (Fig. 31-13). The organism has a surrounding mucopolysaccharide-rich capsule that can be stained with mucicarmine or other histochemical agents (Fig. 31-14). In fresh, unfixed specimens, an India-ink preparation outlines the organisms quite well.



A



B

Figure 31-12 *A1.* Bronchoalveolar lavage (BAL) specimen showing broad filamentous forms and acute angle branching of *Aspergillus. A2.* BAL specimen showing fruiting bodies (conidiospores). *B.* Bronchial washing specimen. Calcium oxalate crystals in association with *Aspergillus* infection seen with partially polarized light. (*A1.*, Papanicolaou stain, ×260; *A2.*, Papanicolaou stain ×160; *B.*, Papanicolaou stain, ×208.)

Occasionally, broad filamentous forms are observed (Fig. 31-15). Infection may present as noncaseating granulomas with multinucleated giant cells and macrophages.

Histoplasmosis

Pulmonary infection with *Histoplasma capsulatum* may be asymptomatic or associated with signs and symptoms that

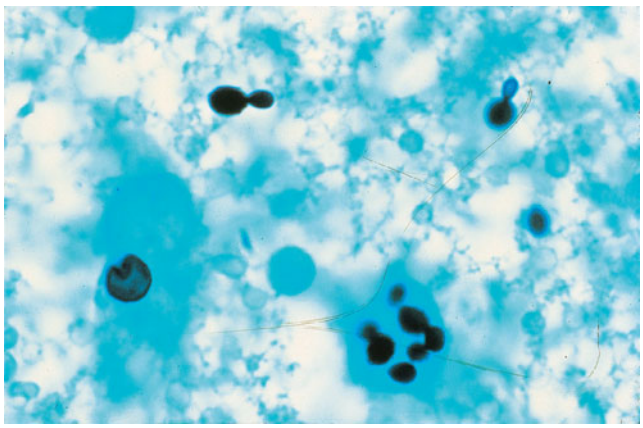


Figure 31-13 Bronchial washing showing *Cryptococcus.* Note the numerous budding organisms. Budding is narrow, and organisms show variation in size. (Silver methenamine stain, ×260.)

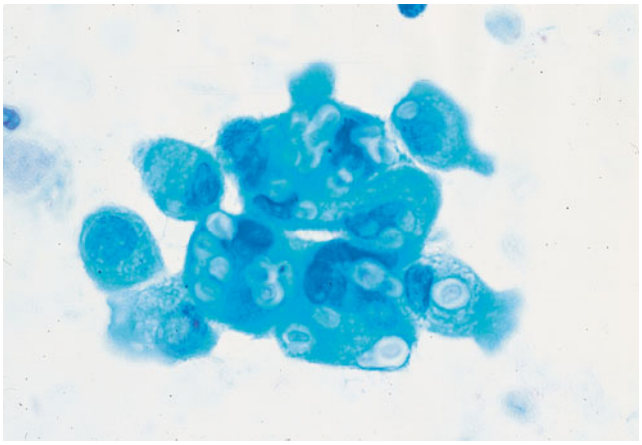

Figure 31-14 Bronchial washing showing *Cryptococcus*. Intracytoplasmic organisms show variation in size and a pale thick capsule. (Papanicolaou stain, ×330.)

mimic tuberculosis. The organisms are small, budding yeast forms, (2 to 4 nm) and are generally intracellular, occurring within the pulmonary macrophages, the bronchial epithelial cells, or neutrophils. Organisms are best identified using a silver-methenamine technique (Fig. 31-16).

Blastomycosis

Patients with respiratory infection caused by *Blastomyces dermatididis* may be asymptomatic or have signs and symptoms of chronic suppurative pulmonary disease. A clinical history demonstrating exposure in an endemic area (e.g., Ohio, Mississippi River Valley, or southeastern U.S.) is usually helpful. The organism is seen as a budding yeast, generally with single, broad-based refractile walls. The budding form has a short neck, and the daughter bud is found in close apposition to the mother bud.

Coccidioidomycosis

Patients with coccidioidomycosis generally present with features of a respiratory tract infection, including productive

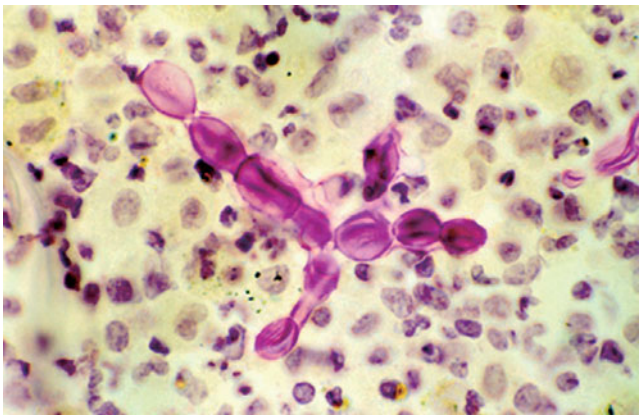

Figure 31-15 Bronchoalveolar lavage showing *Cryptococcus*. Note the broad, filamentous forms. Budding organisms are seen at the tips of the filaments. (Mucicarmine stain, ×330.)

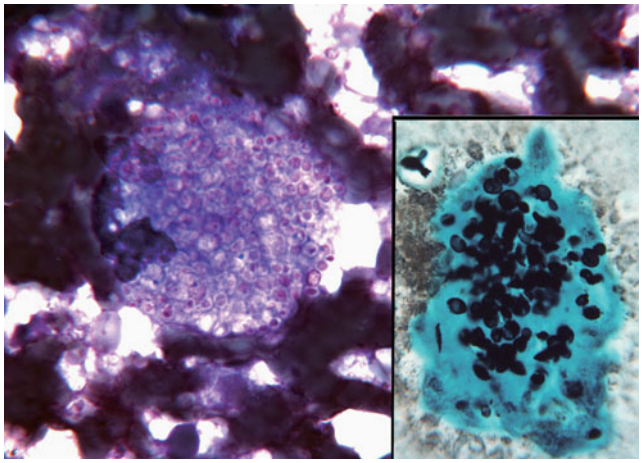

Figure 31-16 Fine-needle aspiration lung. *Histoplasma capsulatum* within the macrophages. Insert shows details and budding fungal forms. (Diff-Quik stain, ×260; *insert*, silver methenamine stain, ×330.)

cough; alternatively, the principal clinical finding may be a solitary pulmonary mass. *Coccidioides immitis* is found in dry, sandy areas of the southwestern U.S. (e.g., California, Arizona, New Mexico, and Texas). The organism is large (20 to 60 nm) and occurs as a nonbudding spherical structure. Spherules have a distinct thick wall and contain a variable number of endospores. The endospores are small (1 to 3 nm), round, and nonbudding. With most specimens, the background examination reveals a heavy acute inflammatory exudate that obscures the faintly stained organisms. Pulmonary fine-needle aspirates can be helpful in the diagnostic evaluation of solitary pulmonary nodules caused by coccidioidomycosis (Fig. 31-17).

Pneumocystis Pneumonia (PCP)

Pneumocystis carinii infection was originally described by Carlos Chagas in 1909 and confirmed a year later by Antonio

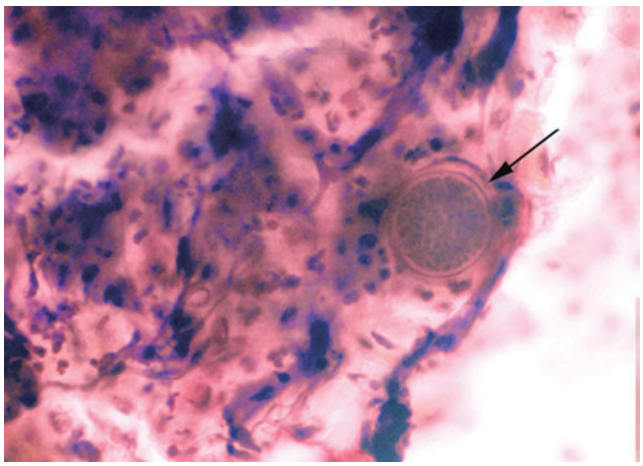

Figure 31-17 Fine-needle aspiration of lung. Coccidiodomycosis infection. Fungal spherule containing endospores (arrow). (Papanicolaou stain, ×330; case courtesy of Dr. Tunda Farkas.)

Carinii. Recently, *Pneumocystis jiroveci* was proposed as the organism's new name.

Infection with *P. carinii* has been most commonly reported among patients with underlying neoplastic or immunodeficiency diseases, particularly the acquired immunodeficiency syndrome (AIDS). Systemic chemotherapy for neoplastic diseases and transplantation also may result in immunosupression and subsequent infection.

Initially regarded as a parasite, *P. carinii* is now considered a fungus, based on ribosomal RNA studies. Attempts to culture the organism have been unsuccessful. *P. carinii* occurs in zygote or sporocyte forms, which are 1 to 5 nm in diameter and have a distinct nucleus. Up to eight spores may occur within the cyst, which measures 6 to 8 nm in diameter—roughly the size of a red blood cell. Organisms infect adjacent tissue after being liberated from the ruptured cysts. *P. carinii* infects alveolar macrophages; in rare instances, the organism may be seen in macrophages in pleural fluid, lymph nodes, or other reticuloendothelial cells.

Although, historically, PCP was often diagnosed from examination of tissue obtained by surgical lung biopsy, carefully collected cytology specimens obtained by fiberoptic bronchoscopy give comparable or better results with minimal patient risk. The technique is sensitive, rapid, and economical. While early reports on the diagnostic yield from examination of induced sputum specimens were encouraging, the findings have not been uniformly confirmed. The best results are obtained using BAL. *P. carinii* infection may be suspected upon inspection of routine Papanicolaou stains, as well as hematoxylin-and-eosin–stained pulmonary specimens. For a definitive diagnosis, a variety of histochemical, immunologic techniques are routinely used. Recently, molecular procedures have been used in identification of PCP. Zygote forms can be visualized using selected stains (e.g., Romanovsky's); basic dye (crystal violet, toluidine blue); and periodic acid-Schiff (PAS), Papanicolaou, and Gram-Weigert's stains. The most commonly used histochemical procedure, the silver-methenamine (Grocott) stain, outlines the cyst wall. Immunocytochemical and monoclonal antibody techniques can be used to identify the organisms, as well as the cyst walls.

Cytomorphology

In air-dried specimens prepared using the Romanovsky's, Papanicolaou, or hematoxylin-eosin methods, *P. carinii* appears within the alveolar material or foamy "coagulum" (Fig. 31-18). The fungal organisms occur in cyst forms that may contain sporocytes (see above). In silver-methenamine (Grocott) and Gram-Weigert's stained preparations, the cysts frequently collapse, giving a crescent or "poached egg" appearance (Fig. 31-19).

The sensitivity of the staining techniques varies according to the quality of preparation, content of pulmonary material, and duration of therapy before the diagnostic procedure is performed. Silver-methenamine and some of the immunologic techniques may give negative results in specimens collected from patients who have received prior therapy. After treatment, the cysts undergo lyses, with fragmentation of the walls, necrosis, and ingestion of the organisms by pulmonary macrophages (Fig. 31-20). Among commonly used histochemical stains, Gram-Weigert's appears slightly more sensitive and specific than silver-methenamine; Giemsa's stain is the least sensitive technique.

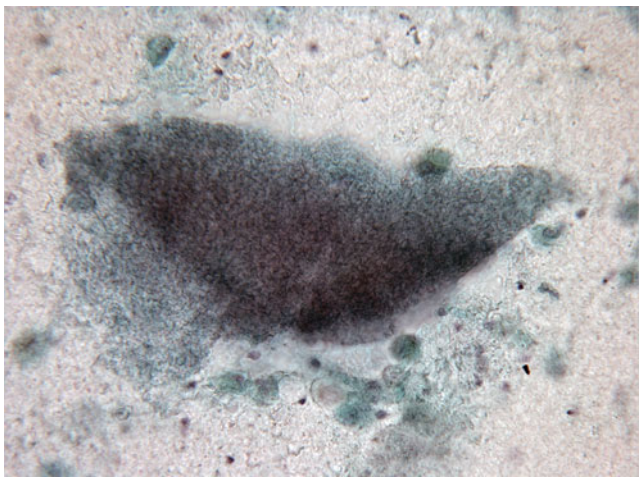

Figure 31-18 Bronchial washing specimen. *Pneumocystis carinii* occurring as intra-alveolar cast "coagulum". (Papanicolaou stain, ×260, Millipore preparation.)

Great care must be exercised in interpretation of silver and special stains for *P. carinii.* Yeast forms of *Candida* arising from oral contamination of sputum and other specimens may resemble *P. carinii* cysts. However, these yeast forms lack the soft, wrinkled, "poached egg" appearance. In addition, they occur in oral mucoid material, not in the proteinaceous, granular alveolar contents or coagulum. In situ hybridization and molecular techniques provide results similar to other diagnostic procedures; however, quantitative differences exist.

Other fungi, including *Paracoccidioides, Mucor,* and *Sporothrix,* are seen occasionally in pulmonary specimens.

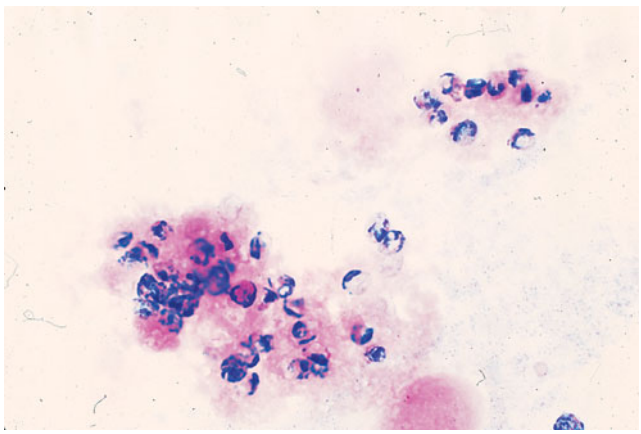

Figure 31-19 Bronchoalveolar lavage showing *Pneumocystis carinii.* Note the cluster of organisms with collapsed cyst walls and central clearing. These forms should be distinguished from the yeast form of *Candida*, which is commonly seen in pulmonary specimens. (Gram-Weigert's stain, ×260.)

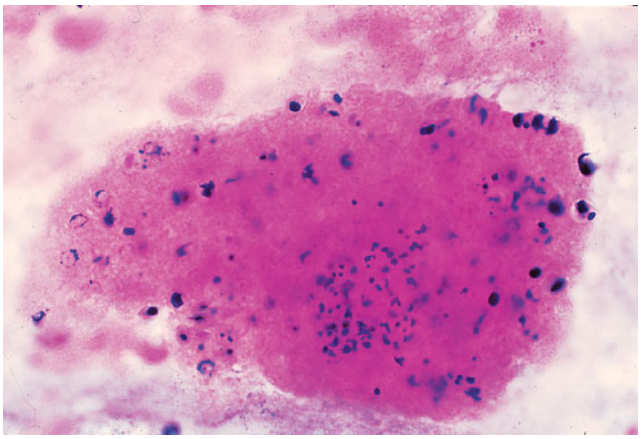

Figure 31-20 Bronchoalveolar lavage showing *Pneumocystis carinii* infection after therapy. Note the degenerated and ghost forms of the organisms in the alveolar cast material. (Gram-Weigert's stain, ×330.)

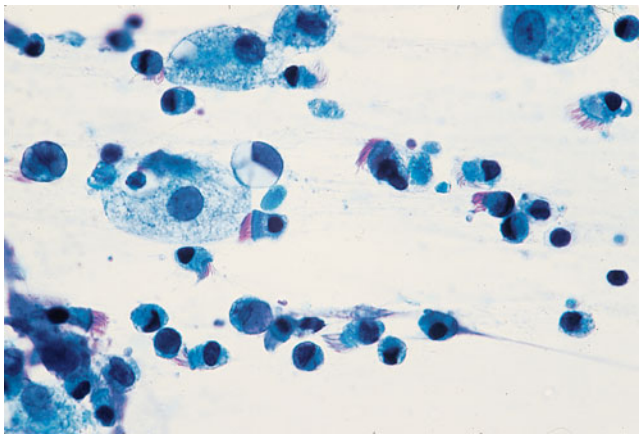
Viral Infections

Pulmonary specimens may reveal specific or nonspecific viral effects on cell components. When infected, bronchial epithelial cells may demonstrate CCP, noted previously. In CCP the cells degenerate when the cytoplasmic tip and attached cilia are exfoliated. The basal portion of the cell shows a pyknotic, degenerated nucleus (Fig. 31-21). Specimens generally have an acute inflammatory background and may contain numerous reactive bronchial cells that can be mistaken for neoplasm. CCP also may be observed in some pulmonary hypersensitivity states.

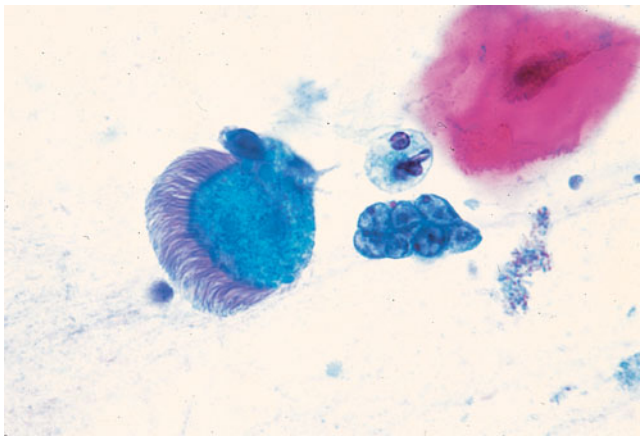
Herpes Simplex Virus

Herpes simplex virus (HSV) may infect the oral mucosa, tracheobronchial tree, or pulmonary parenchyma. The finding of HSV in a pulmonary cytological specimen is useful in localizing infection to the lower respiratory tract only when the specimen is "uncontaminated," (i.e., is obtained by FNA, tracheal aspiration, bronchial washing, or BAL). Clinical-radiologic correlation is necessary in most cases. When pulmonary parenchymal infection is present, the specimen background is extremely inflammatory, showing numerous neutrophils, abundant mucus, and cellular degeneration. Unless adequate pulmonary material is carefully examined, pulmonary HSV infection can be easily overlooked.

The infected cells may be small (10 to 15 nm) and round and contain intranuclear evidence of the virus as a "ground glass" appearance. This pattern is commonly seen with tracheobronchial infection or in specimens obtained from aspiration of material through a tracheotomy tube. In cases of severe pulmonary infection, multinucleated giant cells demonstrating internuclear molding, intranuclear acidophilic inclusions, or a gelatin chromatin pattern may be seen (Fig. 31-22). Care should be exercised in distinguishing HSV inclusions and prominent nucleoli within bronchial cells.



A



B

Figure 31-21 *A.* Bronchial washing specimen showing ciliocytophthoria (CCP) in a case with pulmonary viral infection. Note numerous fragmented, ciliated columnar cells and macrophages. *B.* Details of CCP. Note the cilia in a degenerated cell. (Papanicolaou stain: *A.,* ×208; *B.,* ×330.)

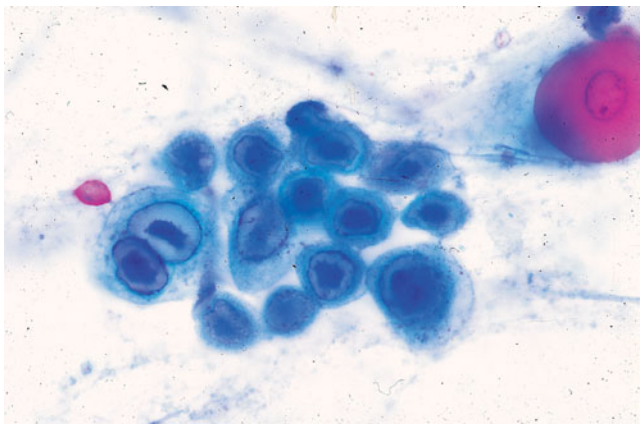


Figure 31-22 Bronchial washing showing herpes simplex virus (HSV). Note the large single cells with prominent intranuclear inclusions and gelatinous nuclear chromatin. (Papanicolaou stain, ×260.)

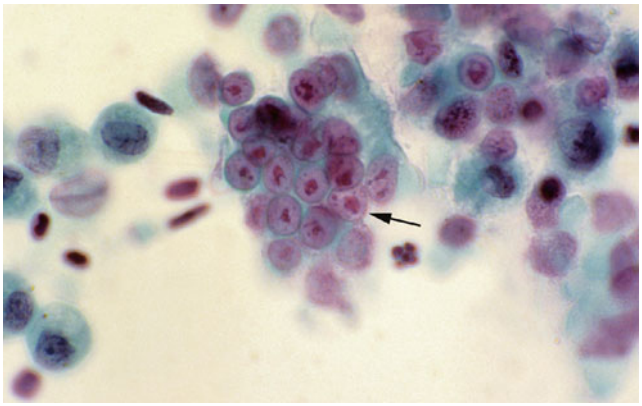

Figure 31-23 Bronchial brush from a patient with lung transplant showing cytomegalovirus (CMV). Note the large, intranuclear acidophilic inclusions with radiating chromatin threads. (Papanicolaou stain, ×330; Millipore preparation.)

Cytomegalovirus

A member of the herpes virus family, cytomegalovirus (CMV) may infect the bronchial epithelium and alveolar lining cells. Infection is common among immunocompromised patients. Infected cells show cytomegaly and large, generally distinct acidophilic intranuclear inclusions. Thin strands of nuclear chromatin bridge the space between the inclusion and the nuclear envelope (Fig. 31-23). Occasionally, the inclusions are basophilic and intracytoplasmic. In rare instances, CMV-infected cells may show multinucleation. Pulmonary HSV infection may occur concurrently with CMV. Viral infection may occur in a polymicrobial environment. CMV can occur with pneumocystis, HSV, and other pulmonary infections.

Respiratory Syncytial Virus

Respiratory syncytial virus (RSV) is often not recognized in routine cytological specimens. The virus produces two types of inclusions within bronchial and alveolar lining cells: (1) dense acidophilic inclusions with clear halos around them, and (2) "smudge" cells, which contain a basophilic nucleus with obliteration of chromatic details.

Para-influenza Virus

Para-influenza infection in the upper respiratory tract produces a variable number of infected columnar cells, which demonstrate eosinophilic degeneration and cytoplasmic inclusions. The inclusions are considered degenerative, rather than viral, particles (Fig. 31-24).

Adenovirus

Although more common in children and infants, adenovirus infection can also occur in adults. Depending upon the duration of the disease, intranuclear inclusions can be seen in bronchial columnar cells (Fig. 31-25).

Other Viruses

Multinucleation and eosinophilic cellular inclusions may be observed in measles infection. Human papillomavirus (HPV)

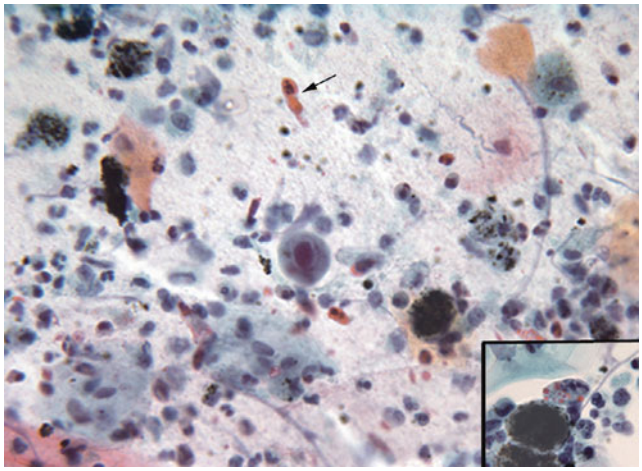

Figure 31-24 Bronchial washing in para-influenza viral infection. Note organophilic cytoplasmic changes affecting columnar cells (arrow). Insert shows multiple cytoplasmic inclusions. (Papanicolaou stain, ×260; *insert,* ×330.)

may cause tracheal papillomatosis and produce fragments of squamous epithelium containing typical koilocytes, which are squamous cells with eccentric, vesicular nuclei and a distinct cytoplasmic halo or cavity. The cells contain intranuclear HPV antigens, which can be demonstrated by use of various tissue and molecular techniques. Most airway HPV infections are caused by viral types 6 and 11.

Parasitic Infections

A number of parasitic infections may occur in the lung. They are seen almost exclusively in either endemic areas or among immunosuppressed patients.

Strongyloidosis

Pulmonary infection with *Strongyloides stercoralis* may be seen in patients with AIDS or those who are iatrogenically immunosuppressed (e.g., by prolonged corticosteroid

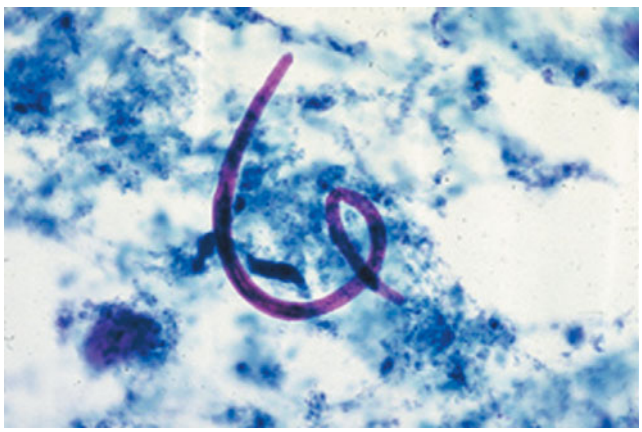

Figure 31-25 Bronchial brush specimen in adenovirus infection. Numerous intranuclear eosinophilic inclusions (arrow) are seen infecting the bronchial cells. (Papanicolaou stain, ×330.)

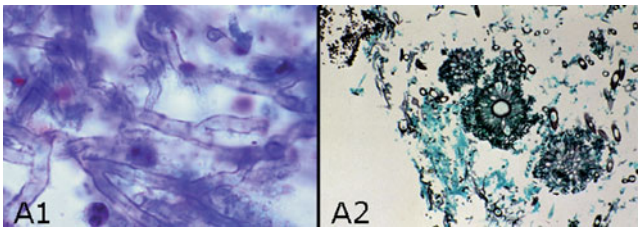

Figure 31-26 Spontaneously produced sputum specimen from a patient with AIDS. Strongyloides filariform larva present in a necrotic background. (Papanicolaou stain, ×110.)

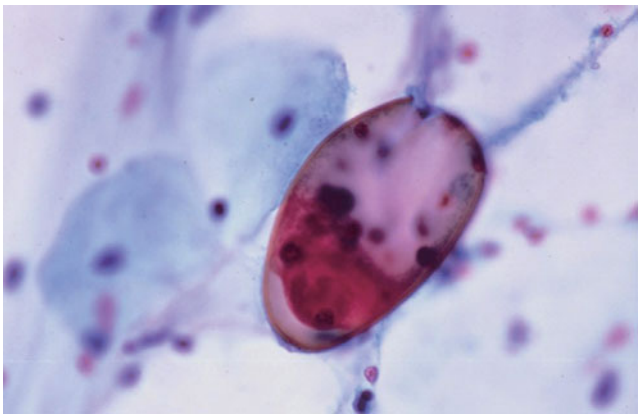

Figure 31-27 Induced sputum specimen showing *Paragonimus* egg. (Papanicolaou stain, ×110.)

administration). Filariform larvae, which are easily identifiable, may be seen in bloody sputum specimens. The larvae measure up to 500 nm in length and contain a gullet and notched tail. Ova may be observed in some sputum specimens (Fig. 31-26).

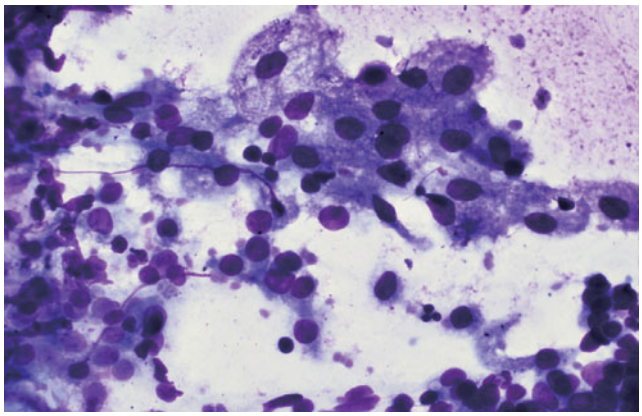
Uncommonly, other parasites, including *Echinococcus, Entamoeba,* microfilaria, *Toxoplasma* and *Paragonimus* (Fig. 31-27), may infect pulmonary tissues and be diagnosed cytologically. *Trichomonas* infection also has been identified in pulmonary specimens obtained from immunosuppressed patients.

OTHER NON-NEOPLASTIC CONDITIONS

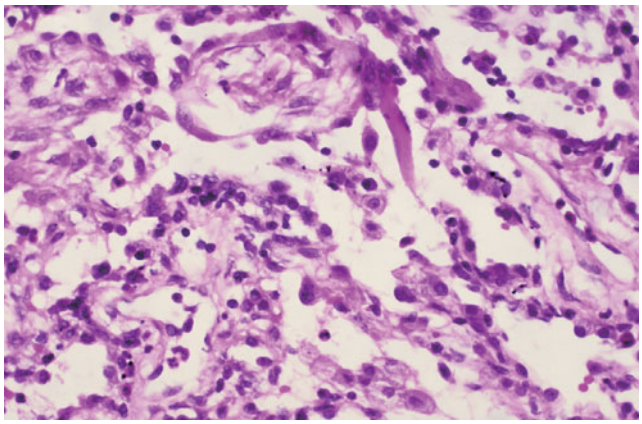
Cytopathological findings may be observed in a number of other non-neoplastic conditions. Some of the common ones that can be detected in pulmonary specimens are described below.

Aspiration Pneumonia

Generally, both severe acute inflammation and foreign-body giant-cell reactions may be observed in pulmonary specimens obtained from patients with aspiration pneumonia. The latter reaction is related to the duration of the disease. Often the aspirated material can be recognized in pulmonary specimens.



A



B

Figure 31-28 Fine-needle aspiration of lung showing organizing pneumonia. *A.* Note the hyperchromatic, atypical alveolar cells (Diff-Quik, ×260). *B.* Pulmonary core biopsy showing similar cells lining the alveolar spaces (H&E, ×166).

Organizing pneumonia can produce both radiographic and cytological changes affecting the alveolar lining cells that may mimic a neoplastic process (Fig. 31-28).

Lipid Pneumonia

Lipids may enter the respiratory system through exogenous sources (e.g., by ingestion, aspiration, or use of nasal sprays containing emollient particles) or through endogenous routes (e.g., from the bone marrow after injury—fat embolism). Cytologically, large foamy cells with small vesicular nuclei may be seen, either singly or in small tissue fragments (Fig. 31-29). The presence of endogenous or exogenous fats can be confirmed by appropriate histochemical stains. Differentiation and diagnosis can be valuable for infants and children with pneumonia.

Pulmonary Infarction and Intra-alveolar Hemorrhage

A radiographic lesion due to pulmonary infarction may be aspirated on clinical and/or radiographic suspicion

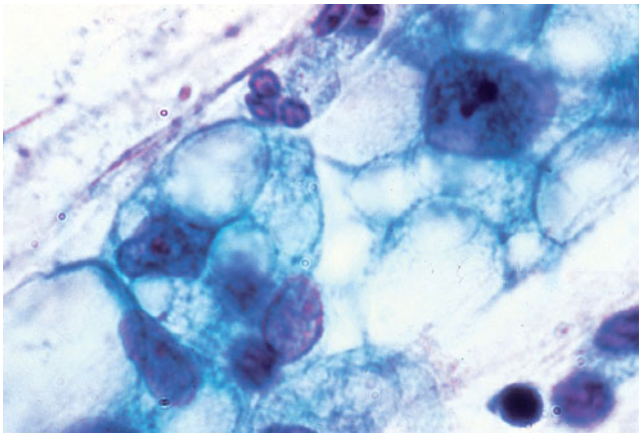


Figure 31-29 Bronchial washing showing lipid pneumonia. Note the large vacuolated cells with hyperchromatic nuclei and prominent nucleoli. Such cells can be mistaken for adenocarcinoma. (Papanicolaou stain, ×260.)

of malignancy. These specimens often contain numerous macrophages containing ingested hemosiderin. The hemoglobin metabolite occurs as dark green or brown intracellular clumps that can be stained histochemically. Extremely bizarre, reactive bronchial cells may accompany such macrophages and pose a diagnostic challenge (Fig. 31-30).

Bronchoalveolar lavage or bronchial washing performed following lung transplantation or in the setting of a number of autoimmune or other disorders may contain numerous alveolar macrophages which contain golden-brown, fine intracytoplasmic pigment (Fig. 31-31). Pigmented macrophages occur in a background of fresh hemorrhage and reactive bronchial epithelial cells in specimens obtained from patients with acute intra-alveolar hemorrhage, such as that which occurs in Goodpasture's syndrome (Fig. 31-32).

Sarcoidosis

Cytological diagnosis of sarcoidosis is considered accurate and cost-effective. Pulmonary specimens (especially BAL) obtained from patients with suspected parenchymal involvement with sarcoidosis, may reveal diagnostic cytological changes. Typical findings include a clean background, a few lymphocytes, Langhans'-type multinucleated giant cells, and syncytial forms of histiocytic cells. Giant cells often have a clear cytoplasm and vesicular or pyknotic nuclei (Fig. 31-33). These giant cells should be distinguished from the multinucleated cells associated with cigarette smoking, bronchial irritation, or pneumonia. The multinucleated giant cells from cigarette smokers often contain golden-brown pigment; numerous reactive columnar cells characterize the irritative processes; the pneumonic processes commonly include an inflammatory background. Concentrically laminated Schumann's bodies or spiderlike asteroid bodies may be observed in pulmonary specimens. Important to note is that these findings are uncommon and not specific for sarcoidosis.

Sarcoidosis is usually diagnosed by the finding of noncaseating granulomas within lung tissue or lymph nodes in

the absence of an alternative explanation for granulomatous inflammation (Fig. 31-33*B*). Additional studies for acid-fast and fungal organisms should be performed in all cases in which noncaseating granulomas are found.

Radiation and Chemotherapy Effects

Some of the most bizarre and atypical cytological changes can be seen in pulmonary specimens obtained after radiation or chemotherapy. The value of obtaining a proper clinical history in this regard cannot be overemphasized. Radiation may affect squamous, bronchial, and alveolar lining cells. The effect is long-term and dose-dependent. General features include cytomegaly and karyomegaly; N:C ratios are unaltered. Irradiated nuclei are generally pale and have a finely divided, evenly distributed chromatin (Fig. 31-34). Cells reveal minimum pleomorphism and contain prominent acidophilic inclusions. The cytoplasm may be variable, dense, or vacuolated.

Chemotherapeutic agents, including alkylating drugs (e.g., busulfan and cyclophosphamide) and antimetabolites

(e.g., methotrexate and azathioprine), generally produce changes that affect bronchial epithelial cells and type II pneumocytes. These cells enlarge and become hyperchromatic, although the chromatin remains uniform and generally does not show abnormal clumping and clearing. Nucleoli are single or multiple and appear prominent. The nuclei may appear smudged, with loss of chromatin granularity and nuclear detail (Fig. 31-35). Great care should be exercised in diagnosing neoplasm in such cases. A proper history, comparison of cells with the original tumor, and familiarity of cytomorphologic changes are useful adjuncts to correct diagnosis. Similar cellular changes may be associated with amiodarone therapy.

PULMONARY NEOPLASMS

In the United States in 2005, lung cancer will have accounted for approximately 163,000 deaths; 172,000 new cases will have been diagnosed. Only 16 percent of lung cancers are detected when the disease is localized, with an associated 5-year survival rate exceeding 60 percent. Regional and distant metastases are present in over 70 percent of cases at time of diagnosis; overall 5-year survival in this group is under 20 percent.

Early Lung Cancer Detection

In some lung cancers (e.g., squamous cell carcinoma), precursor lesions, including squamous dysplasia and in situ changes, precede development of invasive cancer. Early detection of this tumor type may improve survival. However, the multicentric origin of tumors, along with coexisting illnesses, contributes to mortality. Furthermore, moderate, atypical squamous metaplasia of the bronchial epithelium represents a lesion that, in a significant number of cases, may develop into squamous carcinoma. Application of molecular techniques to analysis of sputum specimens can detect moderately and markedly atypical metaplastic cells in patients at risk of subsequent lung cancer, a second primary tumor, or recurrent tumor. Attempts to identify the "at-risk" population using immunocytochemical techniques have been only partly successful. The labor and costs associated with sputum collection, sampling, and cell concentration have contributed to limited use of these techniques. Molecular methods are currently being evaluated for early lung cancer detection.

Based on experience from an early Veterans Administration study, and using the evolution of cervical cancer as a model, a multi-institutional, early lung cancer detection project was launched by the National Cancer Institute in the early 1970s. Guidelines were outlined for early lung cancer detection using chest radiographs, sputum cytology, and, when indicated, fiberoptic bronchoscopy. In addition, treatment methods were delineated for "early" cancer, which was defined as an unsuspected, asymptomatic tumor detected by cytological or imaging techniques.

Nearly 30,000 high-risk participants were screened using sputum cytology or chest radiographs (or both) at three participating centers. Cases were followed for up to 15 years. While sputum cytology and chest radiography detected a number of presymptomatic, early-stage lung cancers (especially squamous cell carcinomas), higher resectability and survival rates among the study group did not result in a lower overall mortality.

Established Lung Cancer

Although pulmonary cytology in its present form has been used for detection and diagnosis of lung cancer for about 50 years, the earliest description of the technique dates back to 1767, when exfoliated respiratory cells were first described. In patients with suspected pulmonary malignancies, examination of a single, expectorated sputum has a low diagnostic yield of nearly 20 percent; when five early-morning, deep-cough specimens are examined, the yield is as high as 90 percent. The type of pulmonary specimen (random, early-morning, induced, pooled, bronchial washing, bronchial brushing, transbronchial aspiration, or transthoracic needle

aspiration), technique of collection (fresh or fixed), quantity of specimen examined, and technique of specimen preparation have bearing on the value of pulmonary cytology in cancer detection. Additionally, the location of the lesion, associated pathology, and sampling techniques may contribute to the number of diagnostic tumor cells present in a specimen.

The two most important issues addressed in the diagnosis of pulmonary neoplasm are whether the tumor is primary or metastatic and, if primary, whether the cell type is small cell or non–small cell. The World Health Organization (WHO) classification of lung tumors is summarized in Table 31-1.

Non–Small-Cell Lung Carcinoma

Squamous Cell Carcinoma

Squamous cell carcinoma accounts for almost one-third of all primary pulmonary malignancies. The cytomorphologic diagnosis of squamous cell cancer is highly accurate and approaches 100 percent. Tumor cells detected in expectorated sputum or bronchial washings generally are more keratinized and poorly preserved than those obtained using bronchial brushing or FNA.

From a cytology perspective, early squamous cell carcinoma is the best-studied lung tumor; definitive precursor (dysplastic) and early (in situ) lesions have been documented. In situ tumor cells are recognizable as single cells with a high N:C ratio, hyperchromatic nuclei with no nucleoli, and an even chromatin pattern with some chromatin clumping and clearing. Cytoplasm is frequently keratinized (Fig. 31-36). The dysplastic cells can occur in small tissue fragments, especially in bronchial brush specimens. The metaplastic bronchial lining cells associated with mechanical irritation (e.g., tracheal intubation), infections (e.g., bronchitis, bronchiectasis, abscess, viral infection), or prior radiation or chemotherapy can mimic dysplastic squamous cells.

Invasive squamous cell carcinoma often leads to a mass or cavitary lesion with tumor necrosis and secondary

B

Figure 31-36 Bronchial washing showing "early" lung cancer. The cells in *(A)* and *(B)* represent nuclear and cytoplasmic features that are indicative of early squamous cell carcinoma. (Papanicolaou stain: *A.,* ×260; *B.,* ×330.)

infection. The background of such specimens may display acute inflammation, necrotic debris with numerous infarcted, necrotic cells lacking nuclear detail, and malignant features. The well-preserved tumor cells are pleomorphic and may appear as "tadpole" or fiber forms. Bizarre, irregularly shaped cells with obvious malignant features (nuclear membrane irregularities, abnormal chromatin clearing and clumping, and prominent nucleoli) can occur. Squamous differentiation of the cytoplasm is variable (Fig. 31-37). Examination of cells for intercellular bridges or keratohyaline granules is necessary before a definitive diagnosis of squamous cell carcinoma can be established. However, these cytoplasmic features are almost always absent in cases of poorly differentiated squamous cell carcinoma.

Adenocarcinoma

Pulmonary adenocarcinoma can be diagnosed relatively easily in bronchial washings and brushings when the tumor is located within central airways; however, diagnosis is extremely difficult with peripheral tumors or scar-associated malignancies. The latter require direct sampling by FNA under radiologic guidance.

The cells from adenocarcinoma generally occur in tissue fragments, which may appear as acinic and papillary

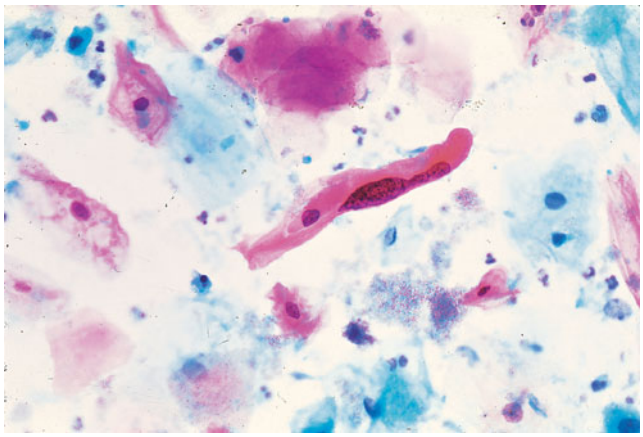

Figure 31-37 Induced sputum showing invasive squamous cell carcinoma. Note an obvious malignant cell with necrotic background and numerous squamous cells. (Papanicolaou stain, ×208.)

structures (Fig. 31-38). Cells have a soft cytoplasm that may contain evidence of mucin secretion. Tumor cells may exhibit bizarre, malignant nuclei with obvious nuclear membrane and chromatin abnormalities and prominent nucleoli. Nucleoli can be variable in number and are usually large and abnormally shaped. Shedded cells obtained from postbronchoscopy specimens, following viral infections, or during pulmonary infarction can be mistaken for tumor cells.

Bronchoalveolar Cell Carcinoma

The cytological diagnosis of bronchoalveolar cell carcinoma can be problematic due to lack of obvious malignant features. The key diagnostic features include presence of a monotonous tumor cell population arranged in papillary and acinic formations. The individual tumor cells show a prominent single

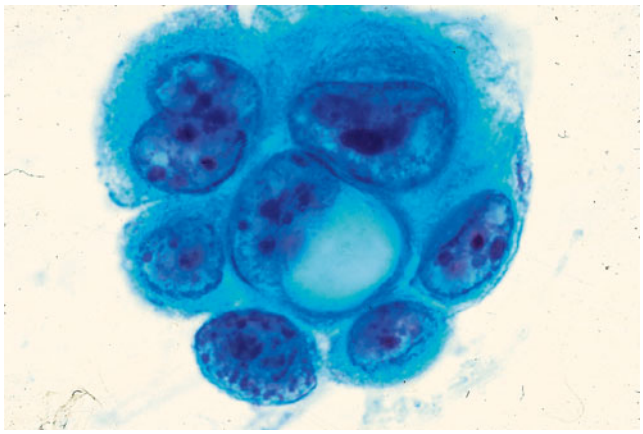

Figure 31-38 Bronchial washing showing adenocarcinoma of the lung. Note glandular features with nuclear chromatin and nucleolar variability. Evidence of mucus secretion is present in the cell in the center of the field. (Papanicolaou stain, ×330.)

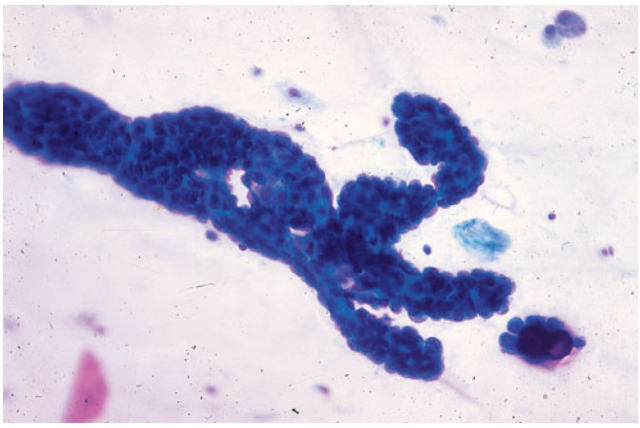
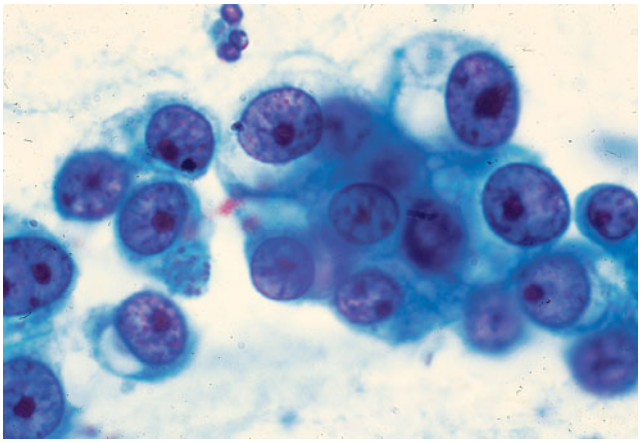


A



B

nucleolus and cuboidal or columnar cell forms, with or without intracytoplasmic mucus (Fig. 31-39). Occasionally, calcified psammoma bodies may be seen; tumor cells may display intranuclear grooves or inclusions. Under these circumstances, in patients with a history of papillary thyroid carcinoma, immunohistochemical stains for thyroglobulin are necessary to differentiate between a primary lung tumor and metastatic thyroid cancer. Tenacious intracytoplasmic connections, when present, are helpful diagnostically. Cytological diagnosis can be extremely accurate (60 to 80 percent). Bronchoalveolar tumor cells can often be confused with reactive bronchial cells, which may be seen with inflammation or after instrumentation or treatment.

Large-Cell Undifferentiated Carcinoma

Large-cell undifferentiated carcinoma represents a group of tumors that cannot be easily subclassified. Cells occur in tissue fragments. They show marked pleomorphism and classic malignant features (Fig. 31-40). These tumors can demonstrate features of both squamous cell and adenocarcinoma.

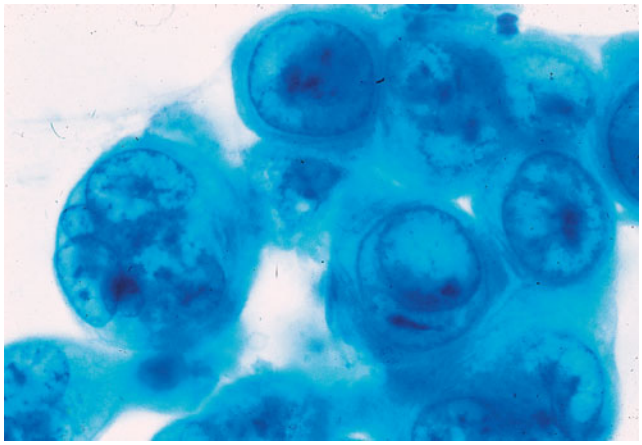

Figure 31-40 Bronchial washing showing large-cell undifferentiated carcinoma. Note that the malignant cells lack any obvious differentiation. (Papanicolaou stain, ×330.)

Small-Cell Undifferentiated Carcinoma

Small-cell undifferentiated carcinoma is relatively easy to diagnose when the specimen is of good technical quality. Well-preserved cells are an absolute requirement for cytological diagnosis of small-cell undifferentiated carcinoma. In fresh smears or monolayer preparations, tumor cells are seen in syncytial groups and as singly scattered cells. The cells have a high N:C ratio and uniformly distributed chromatin. Nuclei are absent or inconspicuous, intercellular molding is prominent, and cytoplasm is delicate and scant (Fig. 31-41). Individual tumor-cell necrosis or apoptosis is common. The background usually shows extensive tumor necrosis and strands of basophilic material representing DNA from fragmented fragile tumor nuclei. However, these cytological findings may not be prominent in the new monolayer cytological preparations. Subclassification of the tumors as oat cell or intermediate varieties may be possible, but this distinction is generally impossible on the basis of cytological preparations.

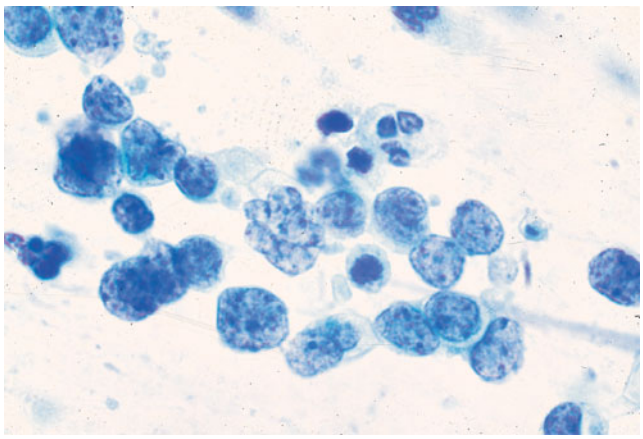

Figure 31-41 Bronchial washing showing small-cell undifferentiated carcinoma. Note the soft cells with uniformly granular chromatin, intercellular molding, and scant cytoplasm. (Papanicolaou stain, ×330.)

Great care needs to be exercised in the proper diagnosis of small-cell undifferentiated tumors. Lymphoid cells from tonsils and adenoids, reserve cells, degenerated bronchial columnar cells, or lymphoma may resemble small-cell carcinoma of the lung. Diagnostic accuracy with this tumor type approaches 100 percent in certain laboratories; most centers report 70 to 80 percent predictability of cytological diagnosis.

Not all small-cell tumors possess typical morphologic features. The tumors may contain a few prominent nucleoli, coarser chromatin, and a variable amount of cytoplasm. Such tumors are best classified as "undifferentiated tumors with neuroendocrine features." Immunocytochemical stains for chromogranin and neuron-specific enolase and ultrastructural studies are helpful in diagnosis.

Other Neuroendocrine Tumors

Carcinoid

A majority of pulmonary carcinoid tumors occur submucosally and do not exfoliate diagnostic cells. Diagnostic cells can, however, be obtained by bronchial brush and FNA techniques. When present, the cells are small and round or oval; they possess scant, delicate cytoplasm and contain one or two nucleoli. The cells exist in microacinic formations or in trabecular and papillary structures. Intercellular molding, pleomorphism, or necrosis are usually not observed.

Atypical Carcinoid

Atypical carcinoid tumors are classified morphologically as midway along the pathological spectrum between carcinoids and small-cell undifferentiated carcinomas. These tumors show neuroendocrine differentiation on the basis of morphology and immunohistochemistry. Although cells may not have the nuclear features typical of a small-cell carcinoma or the microacinic and trabecular pattern of a carcinoid, they can reveal occasional mitoses and focal necrosis.

Lymphoma

A diagnosis of lymphoma may be made from pulmonary specimens. A proper clinical history and use of marker studies are necessary for accurate diagnosis. Hodgkin's disease can be diagnosed by recognition of typical Reed-Sternberg cells in a variety of pulmonary specimens.

Metastatic Tumors

Malignant melanoma and breast, prostate, kidney, and gastrointestinal tumors commonly metastasize to the lungs. Knowledge of the patient's history, coupled with typical morphologic changes and immunohistochemical studies, is often helpful. Patients with an extrapulmonary primary tumor may develop a primary pulmonary malignancy; concurrent or sequential development of malignancies is common in cigarette smokers, particularly laryngeal and pulmonary squamous cell tumors.

Immunocytochemistry of Lung Tumors

Immunocytochemistry can often be used as an adjunct in the morphologic diagnosis of lung tumors. The technique is often needed to differentiate between primary and metastatic tumors and between and small-cell and non–small-cell carcinoma.

Primary pulmonary tumors, including small-cell cancers and adenocarcinomas, express thyroid transcription factor (TTF-1) and cytokeratin-7; rarely, they are positive for cytokeratin-20. TTF-1 can also be seen in primary thyroid tumors, although primary lung tumors do not express thyroglobulin. Carcinoembryonic antigen (CEA) is seen in lung adenocarcinoma; however, it can also be seen in adenocarcinoma of pancreas, colon, breast, or other organs.

Pulmonary neuroendocrine tumors, both benign and malignant, express neuroendocrine markers, chromgranin-A, synaptophysin, neuron-specific enolase, and CD56. These tumors also express cytokeratin-7 and TTF-1. Interestingly, small-cell carcinomas may also express calcitonin.

CONCLUSIONS

Cytology is an accurate, economical, rapid technique that can be useful in diagnosing a large number of nonneoplastic and neoplastic pulmonary lesions. Proper sampling, procurement of high-quality specimens, adequate specimen preparation, careful examination of material, and correlation with clinical and radiographic features are essential for accurate diagnosis.

Interventional Radiology in the Thorax: Nonvascular and Vascular Applications

Aalpen A. Patel • Scott O. Trerotola

Over the last few decades, medicine has seen the birth and growth of the field of interventional radiology (IR). IR complements various diagnostic and therapeutic surgeries or replaces them entirely. IR techniques are image-guided, minimally invasive methods that usually carry less morbidity compared to their surgical counterparts.

From a historical perspective, the first percutaneous needle biopsy of the lung was performed (without image guidance) in 1882. Thereafter, lung biopsy was used mainly for determining the microbial agent(s) causing lobar pneumonia. Due to high complication rates with early techniques, percutaneous biopsies fell out of favor until fine needles were developed. When computed tomography became available, image-guided transthoracic lung, pleural, and mediastinal diagnostic interventions became more widely adopted, especially for percutaneous drainage of pleural, lung, and mediastinal collections.

Additional radiography-based interventions were developed through application of vascular approaches in the 1960s, including bronchial arteriography. Subsequently, embolotherapy of the bronchial arteries for hemoptysis was described in the 1970s. Thereafter, refinements in catheter technology and techniques established bronchial artery embolization as an accepted component of the management of patients with hemoptysis. Embolotherapy has also been used in the pulmonary arterial circulation to treat pulmonary arteriovenous fistulae.

Endovascular techniques have also proved useful in foreign body retrieval from the heart and pulmonary arteries. With the advent of intravascular stents, surgical conditions, such as superior vena cava syndrome, can be treated using endovascular techniques. Modification of prior designs and introduction of new vena cava filters that have small introduction sheaths have also made percutaneous caval interruption routine for interventional radiologists.

As IR develops into an evidence-based practice, its techniques will become more widely accepted and adopted by other specialties as their own. IR has now become a full-fledged clinical specialty, providing outpatient and inpatient consultation and follow-up.

This chapter focuses on the most common and pertinent techniques and presents them as either nonvascular or vascular interventions. Adjunctive imaging modalities employed include ultrasound (percutaneous or intraluminal), fluoroscopy, computed tomography (CT), and magnetic resonance imaging (MRI). Each modality has its advantages and disadvantages; the first three modalities are most commonly used; MRI holds much promise.

Although some interventional radiologists are actively involved in procedures such as thoracic aortic endograft placement for aneurysmal disease, these procedures will not be discussed in this chapter. Likewise, treatment of peripheral vascular disease of the thoracic vessels using balloon angioplasty or stents is commonplace in IR, but is beyond the scope of this chapter. Bronchial and esophageal stent placement is often performed by interventional radiologists, but these topics are covered in Chapter 36.

IMAGE-GUIDED NEEDLE PROCEDURES IN THE THORAX

Appropriate use of image-guided, needle-based procedures in diagnosing chest lesions entails consideration of indications for the procedure, expected results, recognized complications, and post-procedure management.

Application of Diagnostic Methods

As with any procedure or test, image-guided sampling of thoracic structures is performed when a clinical or therapeutic decision rests upon it (e.g., when the histology of a lung nodule needs to be established prior to treatment), or when pleural fluid requires sampling for determining whether infection, malignancy, or other processes are present. CT and ultrasound are the most commonly used adjunctive imaging modalities employed for this procedure, especially when collections are too small to be reliably accessed using bedside techniques. Ultrasound is useful when a pleural fluid collection requires aspiration or when a tissue mass is in contact with the parietal pleura and intervening air is absent.

Needle aspiration or biopsy may be used to evaluate any lesion in the lung, pleura, or mediastinum, especially if it is not visible bronchoscopically and if it is safely accessible using a needle. Clinical circumstances in which needle aspiration or biopsy is commonly used include: (1) a new or enlarging lung nodule seen on chest radiograph or CT scan; (2) multiple nodules noted in a patient with known prior or current malignancy; (3) persistent pulmonary infiltrates or consolidation of unknown cause; (4) a hilar mass with nondiagnostic results on bronchoscopy; and (5) a suspected, but unconfirmed empyema or malignant pleural effusion.

Several relative contraindications to lung biopsy or aspiration are recognized. As with any procedure, risks must be weighed in relation to benefits. The risk of complications is obviously increased in the presence of baseline lung function abnormalities or coagulation defects. Furthermore, patients who plan air travel within 6 weeks of the procedure (possibly increased risk of delayed pneumothorax), prior pneumonectomy, presence of pulmonary arterial or venous hypertension (possibly increased bleeding risk), and lack of patient cooperation (despite administration of conscious sedation) increase the risk. Finally, one absolute contraindication to needle biopsy is a vascular lesion, such as aneurysm or arteriovenous malformation—entities that are usually recognized by careful review of preprocedural imaging studies.

Tools and Techniques

Patient evaluation prior to the biopsy is essential. Published recommendations include that the INR be less than 1.4, platelets greater than 100,000, and recent FEV_1 greater than 35 percent predicted. At our institution, less stringent guidelines for coagulation parameters are used: INR less than 1.5 and platelets greater than 50,000.

The biopsy may be performed using a fine needle (cytopathological evaluation) and/or a cutting needle, the choice of which is based upon operator expertise, availability and expertise of a cytopathologist, and suspicion as to whether the mass is malignant or benign (requiring a confirmatory diagnosis). Coaxial techniques traverse the pleura fewer times than non-coaxial techniques; they may be faster and may carry less risk of pneumothorax.

Results

Fine-needle biopsy has a diagnostic accuracy of 64 to 97 percent. Accuracy is a function of the size of the lesion and on-site availability of a cytopathologist. Sensitivity of a cutting needle biopsy ranges from 74 to 95 percent, and accuracy of a benign diagnosis is improved with use of a cutting, rather than fine, needle. For suspected, but unproved, infections in immunocompromised patients, the diagnostic yield ranges from 73 to 79 percent.

Complications

The most common complications of needle biopsy of thoracic lesions are pneumothorax and hemoptysis. The pneumothorax rate is a function of chest wall thickness, lesion size, and depth of the lesion below the chest wall surface, among other factors. Whether obstructive lung disease affects the risk of pneumothorax is controversial. In one study, patients whose lesions were $\leq$2 cm in diameter had a rate of pneumothorax that was eleven times greater than those whose lesions were >4 cm. Patients with subpleural lesions had four times the rate of pneumothorax as those whose lesions were deeper than 2 cm.

The incidence of pneumothorax ranges from 0 to 60 percent for a fine-needle biopsy (average, 20 percent), with 1.6 to 18 percent (average, 5 percent) requiring a chest tube; the

incidence of pneumothorax is 26 to 54 percent for a cutting needle biopsy, with 3.3 to 15 percent requiring chest tube insertion. Hemorrhage, with or without hemoptysis, occurs in fewer than 10 percent of patients. The risk of bleeding may be ten times higher for lesions deeper than 2 cm from the pleura compared to more superficial abnormalities. Most biopsy-related complications do not have secondary adverse consequences. The death rate from needle biopsy is very low (estimated at 0.02 percent).

Postprocedural Care

The patient should be placed such that the biopsy entry site is in a dependent position for 2 hours, thereby decreasing air leakage as the weight of the lung helps to appose the two pleural layers. A chest radiograph with the patient in an erect position is obtained immediately and 2 hours after the procedure. If no pneumothorax is present, the patient is discharged. If after 2 hours a pneumothorax is present, the chest radiograph is repeated at 4 hours; if the pneumothorax is resolved, or is small and stable, the patient is discharged and asked to return the next day for repeat chest radiography. If the patient is symptomatic, or the pneumothorax is moderate or large or enlarging, a small catheter with a one-way (Heimlich) valve is inserted. The patient may be discharged to return the next day for a chest radiograph and clinical evaluation in which the catheter is clamped for 2 hours. If the pneumothorax has resolved and does not recur after the clamping, the chest tube may be removed.

DRAINAGE OF THORACIC COLLECTIONS

Since the advent of CT, image-guided drainage or aspiration of air or fluid collections in the thorax (lung parenchyma or pleural space) has become increasingly popular. The documented safety and effectiveness of this intervention have made it an alternative to surgical options in many patients. Image-guided aspiration or drainage may be performed for virtually any collection in the thorax.

Empyema and Other Pleural Collections

Annually, approximately 65,000 patients in the United States and United Kingdom (combined) develop empyemas or complicated parapneumonic effusions. Twenty percent of these patients die; the associated health care costs are estimated to approach $500 million.

The early stage of an evolving empyema (stage I), the so-called exudative phase, can usually be treated using medical therapy. The intermediate stage (stage II), or fibrinopurulent phase, requires catheter drainage. The late stage (stage III), or organizing phase, responds less favorably to catheter drainage alone and usually requires lung decortication. In fact, some thoracic surgeons recommend early decortication as initial therapy for stage III empyema.

A comprehensive description of drainage technique is beyond the scope of this chapter, but an initial aggressive approach is recommended. Some investigators recommend early aggressive management of complex empyema with multiple catheter placements (if needed for multiple loculations) and use of fibrinolytic agents (to allow complete drainage of locules and partial debridement of the pleural surface).

Technical success is virtually 100 percent. Clinical success is 70 to 89 percent in previously unviolated empyemas, and 80 percent in those who have had a prior surgically placed chest tube. Most failures occur in stage III empyema (range of success, 11 to 30 percent). Formation of an extensive pleural peel may prevent catheter insertion or cavity collapse. Instillation of fibrinolytics into the pleural cavity may help prevent fibrin deposits and loculations. Clinical success rate ranges from 62 to 100 percent. In one recent, randomized, placebo-controlled trial, the clinical success rate was 82 percent for streptokinase-treated patients (250,000 IU daily) vs. 48 percent for those receiving placebo ($p = 0.01$). In addition, fewer referrals for surgery (9 percent vs. 45 percent; $p = 0.02$) were noted in the treatment group.

Although allergic reactions (nonanaphylactic) to streptokinase have been reported, and concern exists over a potential systemic thrombolytic effect, up to 1.5 million units of streptokinase have been used safely. In addition, urokinase is also effective when compared to saline alone for intrapleural treatment of loculated parapneumonic effusions. Compared with placebo, intrapleural instillation of urokinase is effective in improving chest-tube drainage and the radiographic appearance of the chest; early use of urokinase may be more effective than late use when catheter drainage alone has failed. Comparison of urokinase with streptokinase shows no difference in effectiveness.

Since urokinase is no longer available in the United States, alternative agents have been sought. Tissue plasminogen activator (t-PA) has been shown to be effective in reducing the duration of required chest tube placement in children with complicated parapneumonic effusions (using 4 mg of t-PA in 30 to 50 ml of saline instilled through the chest tube, which is clamped for 1 hour before applying suction to the tube). No adverse events have been noted. One retrospective study suggests that t-PA may be even more effective than urokinase in improving the early radiographic appearance of the chest. In our practice, 10 mg of t-PA in 50 ml of saline is instilled through the chest catheter, followed by 20 ml of a saline "flush." If possible, the patient's position is rotated every 10 min for 1 h before the catheter is connected to suction.

Some theoretical and observed complications of intrapleural fibrinolysis include hemorrhage, allergic reactions, transient chest pain, and promotion of bronchopleural fistula formation. Although, in theory, intrapleural instillation of thrombolytic agents may alter systemic coagulation parameters, many studies have shown that this effect does not

occur. Furthermore, although hemorrhage is also possible, it is rarely observed.

Lung Abscess

Most lung abscesses are successfully treated using medical therapy. However, the mortality rate associated with lung abscess remains high, and ranges from 15 to 20 percent. In 10 to 20 percent of pyogenic lung abscesses, a conservative approach fails, and surgical management (e.g., lobectomy) may be considered. Less invasive approaches, including endoscopic or percutaneous drainage, have been used successfully.

Percutaneous management of lung abscess remains somewhat controversial. In one comprehensive review, the success rate was about 85 percent. The causes for failure included multi-loculation and presence of a thick abscess wall. The procedure complication rate was just under 10 percent. Overall mortality rate related to the abscess was about 5 percent.

Additional studies are needed to establish percutaneous catheter drainage as the standard of care in patients who fail medical therapy. However, the technique is appealing because it results in immediate external drainage of pus without the need for thoracotomy, and it reduces the risk of aspiration of purulent material into the airways. For patients who fail medical therapy (e.g., after 10 to 14 days of treatment) or who have abscesses greater than 4 cm in diameter, and who are not fit for surgical intervention, percutaneous catheter drainage should be considered. Complications of the procedure include empyema, bronchopleural fistula, pneumothorax, hemothorax, intrabronchial hemorrhage, and catheter occlusion.

Lung Cancer

Since the introduction in 1990 of ultrasound-guided thermal ablation of malignant hepatic lesions using radiofrequency electrode needles, open radiofrequency ablation (RFA) and percutaneous RFA under imaging guidance have been increasingly employed. Use of RFA in treatment of renal cell carcinoma and bone and lung tumors has been described more recently, and results are promising. Other thermal ablation methods, including cryoablation and microwave ablation, may also have a future role in management of lung tumors. Adjunctive use of radiotherapy or chemotherapy with RFA is also being explored.

As pulmonary RFA is still considered investigational, delineation of indications for its use is difficult. An "ideal" candidate for RFA is a patient without underlying lung disease whose pulmonary lesion is small (2 to 3 cm), peripheral, and distant from vital intrathoracic structures. However, until evidence supports use of RFA as a primary treatment modality, its value currently lies in treatment of patients who are inoperable because of severe underlying lung disease.

As with many IR-based procedures, application of RFA in treating lung tumors is performed with the patient under moderate sedation. When the patient's cardiopulmonary status is questionable, an anesthesiologist may be consulted to provide a greater level of anesthesia oversight.

Many RFA probes of differing size and design are available (e.g., water-cooled, monopolar, bipolar, or expandable [umbrella-like]) (Fig. 32-1). Each delivers an alternating current, which agitates tissue ions and generates frictional heat, leading to cell death. Any cross-sectional imaging modality may be used in conjunction with RFA; however, due to limitations of ultrasound in imaging air-filled structures, CT is the preferred modality in treatment of lung tumors; MRI may have a niche role.

Depending on the tumor size and its proximity to vascular structures, more than one probe or more than one treatment (after probe repositioning) may be needed to achieve complete tumor ablation. The end point for a treatment session may be impedance-based or temperature-based. Although few data about ablation size in human lung cancer are available, some guidance may be derived from extrapolation of findings from a study in which a mean tumor size of 2.2 $\pm$ 0.6 cm was associated with a mean RFA time of 12 min, 9 sec.

According to a recent review of prior studies using RFA in treating primary and secondary lung tumors ranging in size from 0.7 to 12 cm (mean range, 2.7 to 5.2 cm), complete ablation was achieved in 38 to 91 percent. The highest rates of complete ablation were achieved in treatment of small tumors (mean size, 2.0 cm). In a study of 30 patients, most of whom had primary bronchogenic carcinoma, complete ablation was achieved using RFA in all tumors that were less than 3 cm in diameter; mean survival in this group was 19.7 months, more than twice that for tumors greater than 3 cm in diameter, in whom mean survival was 8.7 months.

The complication rate for RFA is similar to that for percutaneous lung biopsy. The rate of pneumothorax is 20 to 40 percent; 10 to 15 percent of patients sustaining a pneumothorax require a chest tube. Other complications include pleurisy, pleural effusion, pulmonary hemorrhage, and productive cough; death has been reported. In patients with large tumors, tumor cavitation and formation of a bronchopulmonary fistula have been reported.

Aspergilloma

Although surgical resection of a symptomatic aspergilloma is definitive, not all affected patients are surgical candidates. Indeed, aspergilloma formation is frequently associated with underlying lung disease, such as chronic obstructive pulmonary disease (COPD), sarcoidosis, lung abscess, tuberculosis, or pulmonary complications related to chronic immunosuppression. In this context, embolization of bronchial arteries has been used as a temporizing measure to control massive hemoptysis (see below). Unfortunately, in the absence of definitive treatment of the aspergilloma, recurrent bleeding is likely. Furthermore, systemic antifungal agents have a limited role in the primary treatment, as they are unable to penetrate the fungal mass. Consequently, intracavitary instillation of antifungal agents has been performed.

Images are courtesy of Jeffrey Solomon, M.D.

Typically, the cavity is accessed under imaging guidance (usually CT imaging), and the antifungal agent (e.g., amphotericin B) is instilled. Liquid-, gelatin-, and paste-based formulations of the agent have been employed. A relative contraindication to performing the technique is endotracheal intubation and limited ability to reposition the patient—circumstances that put the patient at risk for spillage of the therapeutic agent into the airways and related complications.

In one study of 40 patients with aspergillomas who were treated using amphotericin paste to completely fill the cavities, hemoptysis stopped in all; however, adjunctive bronchial artery embolization was required in six. The aspergillomas

resolved and serum tests for *Aspergillus* became negative in 65 percent, although complete disappearance of both the aspergillomas and cavities was observed in only 7.5 percent. In a smaller series, which used a liquid mixture of amphotericin and gelatin that solidified rapidly at body temperature when injected into the cavities, resolution of the aspergillomas was observed in 3 out of 4 patients. In the fourth patient, the aspergilloma decreased in size, but pneumonectomy was required for recurrent hemoptysis.

BRONCHIAL ARTERY EMBOLIZATION

Massive hemoptysis (300 to 600 ml or greater per 24 h) may be due to a wide variety of causes (among the more common are tuberculosis, aspergilloma, bronchiectasis, lung cancer, and a variety of chronic infectious or inflammatory processes) and carries a significant mortality rate (50 to 85 percent) when treated conservatively. Even when pulmonary resectional surgery is undertaken emergently, the mortality rate is 35 to 40 percent. Although definitive therapy is surgical resection of the bleeding source, not all patients are surgical candidates, due to severe underlying lung disease. In these patients, therapeutic arterial embolization plays an important role in mitigating the hemoptysis.

The two major indications for bronchial artery embolization include: (1) palliative therapy for patients who have acute, massive hemoptysis and who are not surgical candidates; and (2) preoperative intervention to stop active bleeding, thereby allowing definitive surgical therapy to be performed electively. A less common, and more controversial, indication is recurrent, moderate hemoptysis for which conservative management in the nonsurgical candidate has clearly failed.

A preoperative chest CT and bronchoscopic evaluation help with lateralization and further localization of the source, which has obvious therapeutic implications. An initial descending thoracic aortogram may also provide useful information. Knowledge of whether nonbronchial arteries supply the region is helpful, particularly in the setting of hemoptysis due to inflammatory processes. In this regard, CT arteriography has recently been shown to be helpful in planning bronchial artery embolization. Failure to embolize these additional vessels may be responsible for early treatment failure. The embolic agent of choice is polyvinyl alcohol particles (usually, 350 to 500 microns in diameter). Use of other microembolic agents has also been described. Although true contrast extravasation at the bleeding site is frequently not observed, detection of abnormal vascularity in an area localized by direct visualization or by imaging should prompt embolization of the branch (Fig. 32-2).

Since the anterior and posterior spinal arteries receive branches from bronchial arteries and some nonbronchial arteries (e.g., intercostals and cervical and thyrocervical trunks), care must be taken to avoid embolization of these branches. An absolute contraindication to performance of the procedure is inability to avoid embolization of these branches, as this may lead to transverse myelitis (see below).

Bronchial artery embolization is initially effective (i.e., during the first month following the procedure) in controlling massive hemoptysis in over 75 percent of patients. However, the long-term success rate is less favorable: 10 to 50 percent of patients experience a recurrence months to years later. If the underlying disease process is not addressed, recurrence of bleeding is not unexpected. Recruitment of additional vessels, recanalization of occluded vessels, incomplete therapeutic embolization, and new bleeding from pulmonary arterial sources (5 percent) contribute to the recurrences.

The most feared complication of bronchial artery embolization is transverse myelitis due to nontarget occlusion of radiculomedullary branches. Transverse myelitis occurs in 1.4 to 6.5 percent of patients undergoing the procedure. Other complications include chest pain (24 to 91 percent), transient dysphagia (0.7 to 18.2 percent), and, rarely, bronchial necrosis, nontarget embolization of abdominal viscera leading to ischemia, pulmonary infarction, and transient cortical blindness due to occipital cortex embolization.

EMBOLIZATION OF PULMONARY ARTERIOVENOUS MALFORMATIONS

Pulmonary arteriovenous malformations (PAVM) are dilated vascular shunts that connect directly the pulmonary artery and pulmonary vein. PAVM occur most often in patients with hereditary hemorrhagic telangiectasia (HHT), a genetic disorder with an autosomal-dominant pattern of inheritance. While the effects of the resultant right-to-left shunt may be transparent and well compensated, paradoxical embolization and vascular rupture are possible. Hence, accurate diagnosis and appropriate treatment are warranted.

Patients who have PAVM identified serendipitously (e.g., during whole-body CT screening or imaging performed for other reasons) should proceed directly to embolization. In addition, they should also be evaluated for HHT, ideally in a center with expertise in the disorder. Patients with HHT and their first-order family members should be screened using contrast (bubble) echocardiography. Those with a positive study should proceed to CT scanning. We prefer high-resolution pulmonary CT angiography with intravenous contrast; however, care must be taken with any intravenous injection in these patients, because of the potential risk of paradoxical embolization of an air bubble through these right-to-left shunts. All patients with identified PAVM should proceed to treatment to prevent the risk of paradoxical emboli, which can result in brain abscess and cerebrovascular events, as well as less common complications, such as hemoptysis. Ideally, PAVM embolization should be performed in centers that regularly perform large numbers of the procedure. Centers devoted to the diagnosis and management of HHT are located

throughout the world; 10 such centers are located in North America.

A long-standing recommendation has been to treat only those PAVM with feeding arteries 3 mm and larger in diameter. However, improvements in catheter and imaging technology, coupled with emerging evidence that paradoxical emboli can occur in patients with feeding arteries much smaller than 3 mm, have prompted us to undertake treatment of any readily accessible vessel, including those as small as 1.5 mm in diameter (Fig. 32-3).

Although some interventional radiologists perform the procedure on an inpatient basis, we treat patients on an outpatient basis. Bilateral pulmonary arteriography using digital subtraction technique is performed to create a "roadmap" and to identify PAVM undetected by CT. However, in the era of multislice CT scanning, use of digital subtraction is becoming far less important. After identifying the vessel(s) supplying the PAVM, each lesion is treated by embolization of the feeding artery, usually using stainless steel or platinum coils, although many other devices have been described, including detachable balloons and nitinol plugs (Fig. 32-4).

The technical success rate for the procedure is 88 to 100 percent. Although shunt fraction remains abnormal in 60 to 100 percent of patients, improvement in dyspnea (in previously symptomatic patients) or hypoxia is frequently noted. Small lesions have a potential for growth and should be evaluated by CT scanning every 5 years. Despite embolization of visible PAVM in patients with HHT, other subclinical lesions account for persistent right-to-left shunting; the contrast echocardiogram remains positive in most patients following PAVM embolization. Thus, patients should receive prophylaxis for endocarditis for life. In patients without HHT who have a solitary PAVM, follow-up CT scanning and endocarditis prophylaxis may not be necessary.

Although bronchial artery embolization is safe, complications can arise, including pleurisy (with fever and occasional pulmonary infarction), nontarget embolization, and stroke. Pleurisy is noted in 3 to 16 percent of patients within the first few days following the procedure. Delayed pleurisy is noted in up to 5 percent of patients; it responds well to nonsteroidal anti-inflammatory agents. If a superimposed infection is suspected, a course of antibiotics may be needed. The most feared complications of PAVM embolization are nontarget embolization and stroke; fortunately, these are rare (less than 1 percent) when the procedure is performed by experienced interventional radiologists.

VENOUS PERCUTANEOUS TRANSLUMINAL ANGIOPLASTY AND STENTING

Obstruction of the superior vena cava (SVC), brachiocephalic vein, or subclavian vein may be caused by benign or malignant conditions. Inflammatory lesions, radiation, and trauma sometimes result in scarring, causing venous obstruction. Chronic central venous access devices also may lead to thrombosis or occlusion. Tumors may cause obstruction via direct invasion or external compression. Since the surgery required for symptomatic central venous obstruction is very invasive and, at times, not possible, endovascular management using stent placement or percutaneous transluminal angioplasty (PTA) has become a standard mode of treatment. (The treatment of benign venous stenosis or occlusion is not discussed here.)

In the case of malignant obstruction of the SVC and its tributaries, treatment using endovascular techniques, in particular stent placement coupled with balloon angioplasty, is commonly employed. In SVC or brachiocephalic vein occlusion due to primary or metastatic malignant tumors (e.g., primary lung cancer, lymphoma, or malignant adenopathy), the vessel should be stented primarily and angioplasty performed. Increasing evidence supports the use of early stenting in symptomatic malignant occlusion of the SVC as safe and effective in achieving rapid improvement in symptoms.

Relative contraindications to performing the procedure are extensive peripheral thrombosis and low cardiopulmonary reserve. Patients must be able to lie flat, and in patients with SVC syndrome, this occasionally precludes percutaneous management or creates the need for general anesthesia. Preoperative imaging using magnetic resonance venography (MRV) or CT venography of the central veins may be used to plan the approach and technique. Ultrasound imaging is not adequate for evaluation of the central veins.

The clinical success rate after recanalization of central veins is 68 to 100 percent. Most symptoms, including face, neck, and upper limb edema, resolve in 1 to 4 days—far faster than with radiation therapy. A small retrospective study in patients with non–small-cell lung cancer showed that stent placement achieved more rapid symptomatic relief and more frequent complete resolution of SVC obstruction than did radiation therapy.

Compared to alternatives such as no treatment, radiation, or chemotherapy, complications of stent placement and PTA are relatively uncommon and minor. Major complications, such as stent misplacement or migration, transient cardiac arrhythmias, pulmonary embolization, venous rupture, hemomediastinum, and pulmonary edema, are uncommon.

INTRAVASCULAR FOREIGN BODY RETRIEVAL

For decades, interventional radiologists have employed techniques for intravascular foreign body retrieval. A variety of instruments, including catheters, tip-deflecting wires, snares, baskets, and forceps, used alone or in combination, has been

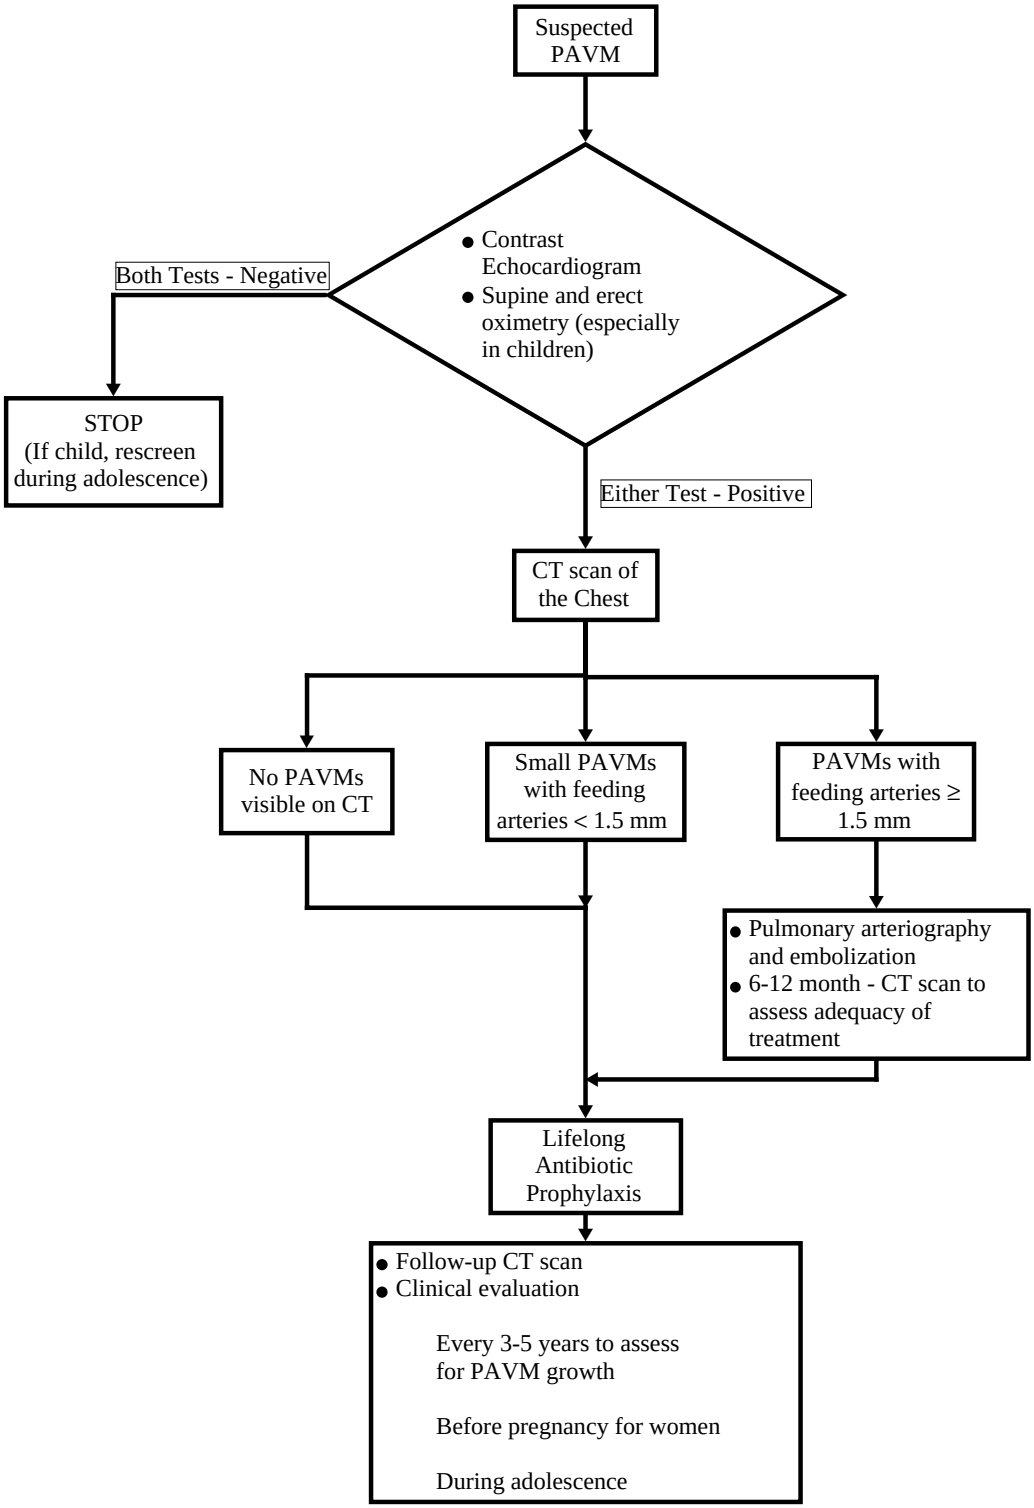

Figure 32-3 Management algorithm for patients with suspected pulmonary arteriovenous malformations (PAVM). (*Modified version of the algorithm from Pollack JS, White RI, Jr: Pulmonary arteriovenous malformation, in Baum S, Pentecost MJ (eds): Abrams Angiography, Interventional Radiology, 2nd ed. Philadelphia, Lippincott Williams & Wilkins, 2006, p 935.*)

applied to percutaneous foreign body retrieval from the venous system and hollow organs. These procedures constitute the standard of care for most intravascular foreign body retrievals (Fig. 32-5).

THORACIC DUCT EMBOLIZATION

Iatrogenic chylothorax (incidence, 0.1 to 0.4 percent), in which the daily output of chyle may exceed 1000 ml, is a serious complication of thoracic surgery. The problem can be controlled by direct ligation of the thoracic duct (TD). However, since surgical intervention carries a significant mortality rate (11.8 to 16 percent), application of percutaneous methods has been sought.

TD ligation is commonly used to treat high-output chylothorax or chylous pleural effusions if there is no improvement after 1 to 2 weeks of conservative management, including implementation of a low-fat diet or total parenteral nutrition, administration of somatostatin, and chest tube drainage. As patients lose chyle over this time, the combined loss of fluid, proteins, lipids, electrolytes, and T lymphocytes leads to malnutrition, increased susceptibility to infection, and increased operative risk. Under these circumstances, TD embolization should be considered as an initial alternative to surgical TD ligation.

Percutaneous transabdominal catheter-directed embolization or needle disruption of retroperitoneal lymphatics is effective and minimally invasive. In one series of 42 patients with chylothorax due to a variety of etiologies, treatment with percutaneous TD embolization using microcoils, particles, glue, or lymphatic collateral disruption resulted in a partial or complete response rate in 3 to 6 weeks of 74 percent. The procedure carries a minimal risk of serious complication or death; however, as the frequency with which the procedure is performed increases, the complication rate will likely grow (Fig. 32-6). The technique is not suitable for treating chylothorax resulting from malignancy.

PULMONARY ARTERY THROMBECTOMY

Traditional therapies for pulmonary embolism include anticoagulation, systemic thrombolysis, and surgical thrombectomy. More recently, endovascular techniques, such as catheter-directed thrombolysis, mechanical thrombolysis (clot fragmentation), and embolectomy have been described. These may be used in conjunction with pulmonary artery stent placement. However, the precise role of these more aggressive approaches is very controversial.

Use of a Greenfield thrombectomy device in major pulmonary embolism has been shown to improve cardiac output and carries a success rate of 91 percent. Although small, nonrandomized trials and case reports have described the utility of catheter-directed mechanical clot fragmentation or extraction, no randomized trials of systemic thrombolysis vs. surgical or catheter-based techniques for treatment of pulmonary embolism have been published.

In a small, multicenter trial of 34 patients with pulmonary embolism who were given either intravenous or intrapulmonary t-PA infusions, neither approach demonstrated a clear advantage over the other. Frequently, comorbid conditions make open surgical thrombectomy or thrombolytic therapy in these usually critically ill patients untenable. Under the circumstances, percutaneous thrombectomy and thrombolysis remain options. Treatment of pulmonary embolism is discussed in detail in Chapter 82.

Scintigraphic Evaluation of Pulmonary Disease

Abass Alavi • Daniel Worsley • Ghassan El-Haddad

Use of radiopharmaceuticals has made it possible to assess regional pulmonary function in a variety of pulmonary disorders. In 1955, ^{133}Xe was introduced for the study of regional ventilation. Shortly thereafter, it became possible to evaluate regional pulmonary blood flow using $^{15}CO_2$ by inspiration or ^{135}Xe by injection. In 1964, intravenous injection of ^{133}I-macroaggregated albumin made it feasible to obtain perfusion scans of the lungs. Although these techniques rapidly gained wide acceptance as tests of regional abnormalities in ventilation and pulmonary blood flow, the main practical application has been in the diagnostic evaluation of patients with suspected pulmonary embolism. Increasingly, the role of nuclear medicine in respiratory medicine has been expanded to include disorders such as preoperative assessment of lung function, inflammatory lung disease, and lung cancer. The more widespread availability of positron emission tomography (PET) and integrated PET/CT (computed tomography) has provided powerful tools to aid in the

diagnosis, staging, and management of patients with lung cancer.

RADIOPHARMACEUTICALS AND TECHNIQUES IN VENTILATION-PERFUSION LUNG SCANNING

Clinical application of perfusion lung scanning was first described in 1964, when iodine 131–labeled macroaggregates of albumin was utilized in the evaluation of pulmonary perfusion. Currently, the agents of choice for pulmonary perfusion imaging are technetium 99m–labeled human albumin microspheres (^{99m}Tc HAM) and macroaggregated albumin (^{99m}Tc MAA). ^{99m}Tc MAA particles range in size from 10 to 150 μm; however, more than 90 percent of injected particles measure between 10 and 90 μm. ^{99m}Tc HAM particles are relatively uniform in size and range between 35 and 60 μm. However, ^{99m}Tc MAA is considered the agent of choice for routine perfusion lung scanning because of its availability, short residence time in the lungs, and relatively low cost.

Radiolabeled particles are injected intravenously while the patient is in the supine position, thereby limiting the effect of gravity on regional pulmonary arterial blood flow. Following the administration of ^{99m}Tc MAA, particles are mixed uniformly with the blood that is flowing to the heart; the particles then lodge in precapillary arterioles in the lungs. The usual administered dose of radioactivity is between 74 and 148 MBq (2 to 4 mCi).

The distribution of particles in the lungs is proportional to regional pulmonary blood flow at the time of injection. Approximately 200,000 to 500,000 particles are injected during a routine clinical perfusion lung scan. The normal adult human lung contains approximately 300 million precapillary arterioles and 300 billion capillaries. Therefore, only about 0.1 percent of precapillary arterioles are blocked following the procedure. In addition, the blockage of pulmonary precapillary arterioles by ^{99m}Tc MAA is transient; the biologic half-life in the lung ranges between 2 and 6 h. In pediatric patients and patients with suspected or known right-to-left shunts, pulmonary hypertension, prior pneumonectomy, or a single lung transplant, the number of particles injected should be reduced. A minimum of 60,000 particles is required to obtain an even distribution of activity within the pulmonary arterial circulation and avoid potential false-positive interpretations. We routinely inject 100,000 and 200,000 particles of Tc-99m MAA when performing perfusion scintigraphy in patients with known pulmonary hypertension or in patients who have undergone single lung transplantation. Animal studies have demonstrated that perfusion imaging will detect greater than 95 percent of emboli that completely occlude pulmonary arterial vessels greater than 2 mm in diameter. A routine perfusion scan should include at least six views of the lungs; anterior, posterior, right and left lateral, and right and left posterior oblique views (Fig. 33-1). Right and left anterior oblique views may be helpful in selected cases. In spite of imaging in multiple projections, the perfusion scan may underestimate perfusion abnormalities. A solitary segmental perfusion defect within the medial basal segment of the

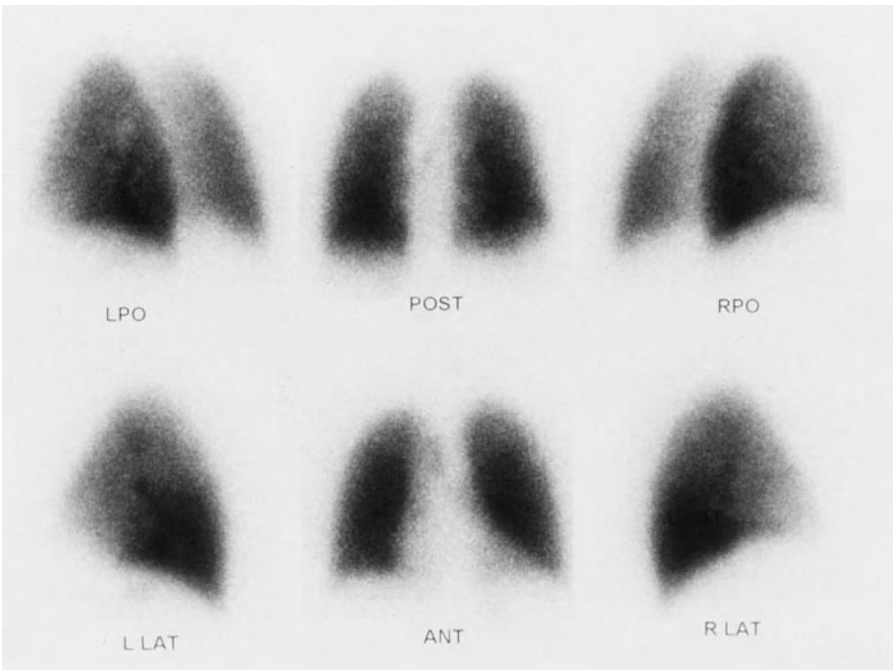

Figure 33-1 Normal perfusion scan using ^{99m}Tc MAA. The distribution of particles is uniform, with a minimum gradient of activity from lung apex to base. The six views (left posterior oblique, posterior, right posterior oblique, right anterior oblique, anterior, left anterior oblique) shown correspond to those shown in subsequent figures.

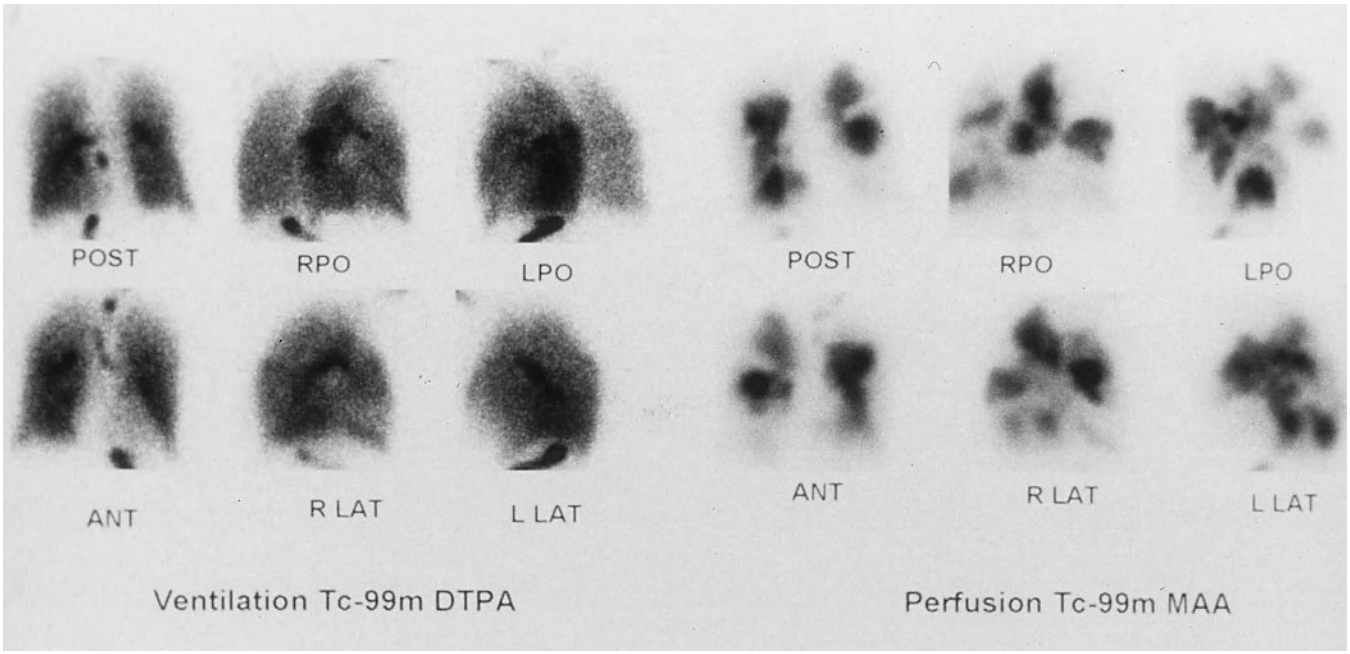

Figure 33-2 High-probability scan for pulmonary embolism. Ventilation scan utilizing ^{99m}Tc DTPA aerosol is within normal limits. Perfusion scan shows large segmental defects in both lungs. This combination of findings is most consistent with pulmonary embolism.

right lower lobe is completely surrounded by normal lung. Consequently, a perfusion defect in this segment will not be detected on planar perfusion imaging.

Perfusion lung scans are routinely utilized to examine patients with suspected pulmonary embolism. Unfortunately, perfusion imaging is sensitive, but not specific, for diagnosing pulmonary embolism. Virtually all lung diseases (including tumors, infections, asthma, and chronic obstructive pulmonary disease) may cause decreased pulmonary arterial blood flow in the affected lung zones. Therefore, combined use of perfusion and ventilation studies can improve the diagnostic specificity of lung scanning for pulmonary embolism. Pulmonary embolism almost always causes abnormal perfusion, while ventilation is preserved *(mismatched defects)* (Fig. 33-2). In contrast, in parenchymal pulmonary disorders, decreased ventilation and perfusion are noted in the same lung region *(matched defects)*. Conditions in which the ventilation abnormality may appear larger than the perfusion abnormality *(reverse mismatch)* include airway obstruction, mucus plug, atelectasis, and pneumonia (Fig. 33-3). Patients with metabolic alkalosis or patients treated with inhaled albuterol fail to respond to hypoxic insults by vasoconstriction and may demonstrate reverse mismatch (perfusion of poorly ventilated sites) on ventilation-perfusion scans.

^{133}Xe has been widely used to determine regional ventilation in the lungs. However, other tracers, such as xenon 127, krypton 81m, and, recently, the technetium 99m–labeled aerosols—Technegas and Pertechnegas—are utilized for this purpose. Studies that compare various ventilation agents are limited; however, based on the data available, there appear to be no major differences with regard to diagnostic yield among various radiopharmaceuticals.

Utilizing a closed breathing system and ^{133}Xe, the first inspiration image demonstrates regional ventilation in major airway systems (Fig. 33-4). Equilibrium images are obtained while the patient rebreathes the gas for several minutes. Regions of the lung that appear to ventilate poorly in the initial

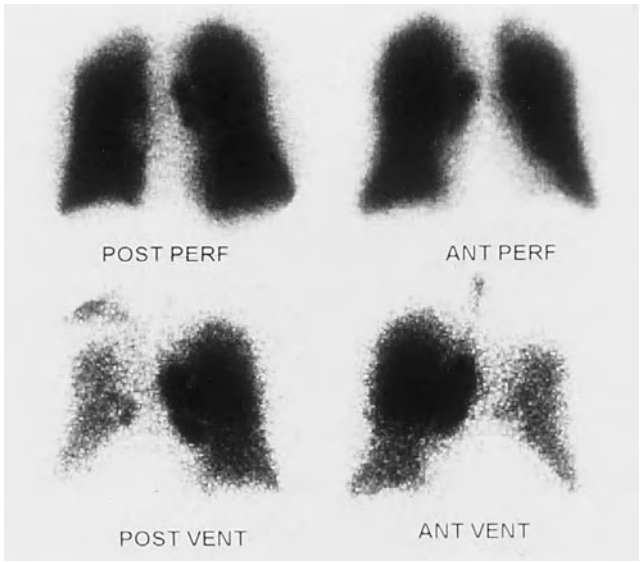

Figure 33-3 Reverse ventilation-perfusion mismatch. Posterior and anterior perfusion scans appear within normal limits (upper row). Posterior and anterior aerosol ventilation scans show significantly reduced perfusion in the left lung.

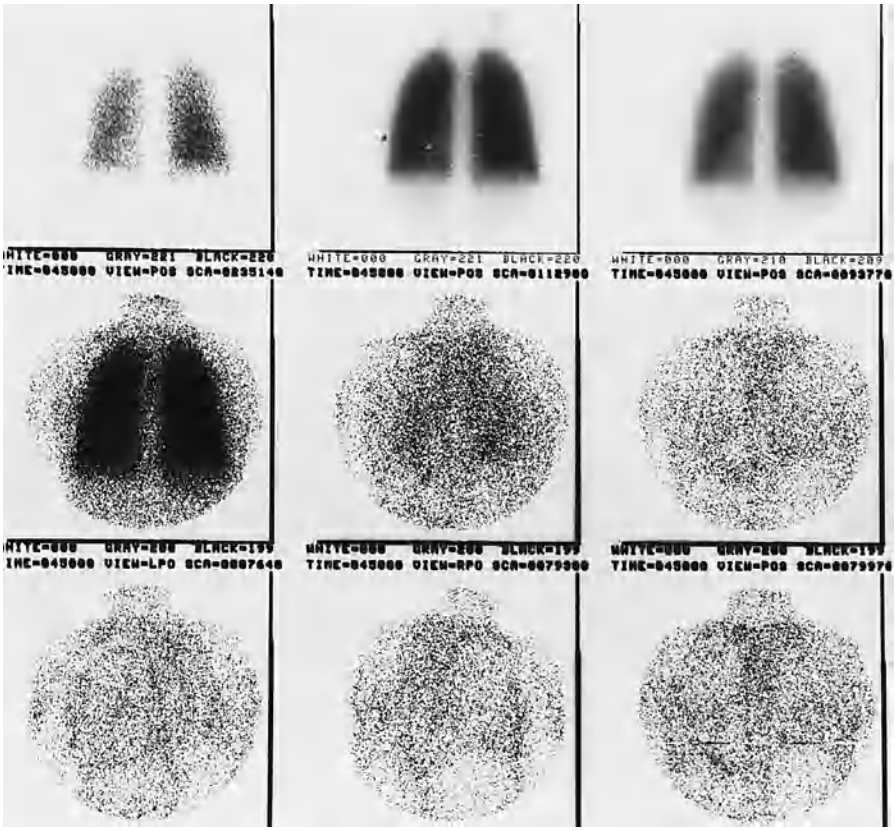

Figure 33-4 Normal ventilation scan using ^{133}Xe. The distribution of gas is uniform during the wash-in and equilibrium-phase images (left to right in upper row). During the washout phase, the radioisotope is rapidly cleared from both lungs (lower-row images). Ventilation images were obtained in the posterior projection.

image may fill in the equilibrium phase of the study because of collateral air drift. During the washout phase, while the patient inspires room air, areas of poor ventilation are detected as focal spots of gas retention on the image. Diagnostic yield from the ventilation-perfusion scan is significantly higher if studies are performed in the erect, rather than supine, position. Generally, for technical reasons (lower energy of gamma radiation of ^{133}Xe compared to ^{99m}Tc), ventilation images with ^{133}Xe are obtained before perfusion imaging.

The imaging technique for ^{127}Xe is similar to that for ^{133}Xe. However, because ^{127}Xe has a higher energy than ^{99m}Tc, ventilation scanning with ^{127}Xe can be performed following perfusion imaging. The advantages of acquiring ventilation imaging following perfusion studies are that the patient can be positioned so ventilation to the areas of the lungs that reveal the greatest perfusion abnormality can be imaged with optimal detail and ventilation imaging may be avoided altogether in selected cases when the perfusion lung scan appears normal.

However, ^{127}Xe scanning has several disadvantages. It is more costly than ^{133}Xe and requires medium energy collimation, which degrades image resolution. With either ^{133}Xe or ^{127}Xe, images can be obtained only in a limited number of views—in contrast to perfusion images, which are obtained in multiple projections.

Krypton 81m is a noble gas that can be used to evaluate regional ventilation. This radioactive gas has a very short physical half-life (13 s), and images acquired with this agent reveal ventilation to major airway systems only. However, the short physical half-life of ^{81m}Kr allows generation of images of the lungs in multiple projections. ^{81m}Kr is produced from a rubidium 81 generator. The parent radionuclide has a physical half-life of 4.7 h, which limits the useful lifetime of the generator to only 1 day. As with ^{127}Xe ventilation studies, imaging with ^{81m}Kr is generally performed following the perfusion scan.

Technetium-labeled aerosol studies can be performed following the inhalation of several preparations, including ^{99m}Tc DTPA (diethylene triamine penta-acetic acid), ^{99m}Tc sulfur colloid, ^{99m}Tc pyrophosphate, ^{99m}Tc MDP (methylene diphosphate), and ^{99m}Tc glucoheptanate. The most popular is ^{99m}Tc DTPA. However, this agent has a relatively short residence time within the lung, especially in smokers. In such patients, use of ^{99m}Tc-labeled sulfur colloid or pyrophosphate may be more appropriate. ^{99m}Tc-labeled radioaerosols have particles between 0.5 and 3 μm in size and are produced by utilizing commercially available nebulizers. The patient generally breathes from the nebulizer for 3 to 5 min or until 37 MBq (1 mCi) of radioactivity is deposited in the lungs. The regional distribution of radioactivity in the lungs is

proportional to local ventilation. ^{99m}Tc-labeled radioaerosol studies are generally performed before perfusion imaging. The lungs are imaged in multiple projections, which correspond to those obtained during the subsequent perfusion study. Ventilation studies using ^{99m}Tc-labeled radioaerosols require minimal patient cooperation and can be performed at the bedside and on patients who are on ventilators. Disadvantages of ^{99m}Tc-labeled radioaerosols include the central deposition of radioactivity in patients with chronic obstructive pulmonary disease (COPD) or airway obstruction and the need to dispose of the substantial unused amount of radioactivity that is deposited in the nebulizer.

Central deposition of ^{99m}Tc-labeled radioaerosol in patients with COPD is a major drawback to the use of aerosol agents, and newer agents have been developed to overcome this deficiency, including ^{99m}Tc Technegas and ^{99m}Tc Pertechnegas. These agents are generated by burning ^{99m}Tc pertechnetate in a carbon crucible at very high temperatures, which produces an ultrafine radiolabeled aerosol (particle size, 0.02 to 0.2 μm). Pertechnegas is purged with 5 percent oxygen and 95 percent argon; Technegas is purged with 100 percent argon. This relatively minor change in production of the final preparation causes profound differences in the biologic behavior of particles generated. When inhaled, both agents distribute homogeneously in the lung in proportion to regional ventilation and with very minimal central deposition, even in patients with COPD. Pertechnegas readily penetrates the alveolar epithelial membrane; therefore, its biologic half-life in the lungs is quite short (approximately 6 to 10 min). On the other hand, very little transalveolar or mucociliary clearance is seen with Technegas; thus, residence time in the lung is approximately equal to the physical half-life of ^{99m}Tc (6 h). Both agents require minimal patient cooperation, and only two or three breaths are required to obtain sufficient deposition in the lungs for optimal ventilation imaging. In general, ventilation imaging with both Technegas and Pertechnegas is performed before perfusion imaging. As with ^{99m}Tc-radiolabeled aerosols, multiple views of the lungs corresponding to those acquired during perfusion imaging can be generated with these preparations.

More recently, considerable interest has arisen in imaging based upon antibody fragments and radiolabeled peptides directed against GP IIb/IIIa receptors on the surface of activated platelets. Tc-99m Acutetec, a labeled synthetic peptide which binds to the GP IIb/IIIa receptors, has been used for evaluation of patients with suspected deep venous thrombosis (DVT). The main advantage of the agent is its ability to distinguish between acute and chronic DVT.

Several ^{99m}Tc labeled peptides directed against activated platelets are currently under investigation in evaluation of patients with suspected pulmonary embolism. Radiolabeled peptide imaging has the potential to serve as a single, comprehensive modality in the evaluation of patients with venous thromboembolism. However, at the current time, further studies and development of newer radiopharmaceuticals are required to fully realize this potential.

LUNG SCANNING IN THE DIAGNOSIS OF ACUTE PULMONARY EMBOLISM

Pulmonary embolism (PE) is a common and potentially fatal disorder for which treatment is highly effective in decreasing mortality and morbidity if initiated soon after the event. The accurate and expeditious diagnosis of acute PE can be difficult because of the nonspecificity of clinical, laboratory, and radiographic findings. Approximately 10 percent of patients with PE die within 1 h of the event. For patients who survive beyond the first hour, anticoagulation with heparin or thrombolysis with thrombolytic agents is effective therapy. The mortality in patients with PE who are not treated is as high as 30 percent. In contrast, correct diagnosis and appropriate therapy significantly lower mortality to between 1 and 10 percent.

Although anticoagulant therapy is effective in treating PE and reducing mortality, it is not without risks. The prevalence of major hemorrhagic complications among patients receiving anticoagulant therapy has been reported to be as high as 10 to 15 percent. Therefore, accurate diagnosis of PE is essential, not only to prevent death from recurrent embolism, but also to avoid complications related to unnecessary anticoagulant therapy.

Ventilation-perfusion lung imaging has been shown to be a safe, noninvasive technique in evaluating regional pulmonary function undertaken for a variety of purposes. The technique has been widely used in the assessment of patients with suspected PE. In spite of its proven value in the management of patients with PE and availability of studies suggesting the underdiagnosis of PE, critics have suggested that this powerful method has been overutilized and that it has had a minimal impact on patient outcome.

The first major study that utilized perfusion lung scanning as a screening test for the diagnosis of PE was the Urokinase Pulmonary Embolism Trial (UPET). In more than 90 percent of patients enrolled in the trial, perfusion lung scanning was performed following intravenous administration of ^{131}I-labeled MAA. Since lung imaging was carried out using rectilinear scanners, ventilation studies were not performed during the study. Despite utilizing a suboptimal radiopharmaceutical and imaging equipment, the UPET study established perfusion lung scanning as an effective technique in both screening for PE and assessing restoration of pulmonary blood flow following an embolic event.

Most patients with acute PE either completely lyse the thrombi or partly recanalize the pulmonary artery clots. In UPET, approximately 75 to 80 percent of perfusion defects resolved by 3 months, and those that did not remained largely persistent when followed for 1 year. The degree of clot resolution observed in UPET may represent an underestimate, since ventilation scanning was not performed, and many of the unresolved perfusion defects might have been due to preexisting chronic obstructive pulmonary disease. The defect size at 7 to 10 days following the initiation of therapy was a good predictor of defect size at 6 months. In an American College

of Chest Physicians consensus statement, the recommendation is performance of a follow-up ventilation-perfusion lung scan at 3 months following the initial diagnosis to evaluate clot resolution and serve as a baseline for future comparisons. If patients are unable to return in 3 months, a scan at discharge or 7 days following initiation of anticoagulant therapy may also be useful.

Data from multiple prospective and large, outcome-based studies have reported on the efficacy of ventilation-perfusion scanning in patients suspected of having acute PE and have been recently reviewed.

One prospective study, designed to determine if anticoagulation could be safely withheld in patients with adequate cardiorespiratory reserve who did not have high probability ventilation-perfusion scans or proximal venous thrombosis (as determined by serial impedance plethysmography [IPG]), underscored the pathophysiological concept that venous thromboembolism is a systemic disease, and that pulmonary embolism is merely the respiratory manifestation of the disorder. A total of 874 patients suspected of having PE were enrolled. Ventilation-perfusion lung scan interpretations were classified as normal (36 percent), non–high probability (56 percent), or high probability (8 percent) studies. Forty-seven percent had non–high probability scans and adequate cardiorespiratory reserve, while nine percent had non–high probability scans and inadequate cardiorespiratory reserve (pulmonary edema, right ventricular failure, systolic blood pressure less than 90 mmHg, syncope, acute tachyarrhythmia, or severely abnormal spirometry or arterial blood gases). During a 3-month follow-up period in which patients with non-high probability lung scans, adequate cardiorespiratory reserve, and negative serial IPG studies had anticoagulants withheld, only 2.7 percent had evidence of venous thromboembolism. The conclusion was that selected patients could be managed safely without anticoagulation, confirming findings from previous studies suggesting that the incidence of recurrent PE is very low in the absence of proximal lower extremity venous thrombus. Unfortunately, the criteria used to categorize the probability of PE (normal, nondiagnostic, or high) were different than those used in the Prospective Investigation of Pulmonary Embolism Diagnosis (PIOPED) study, and direct comparison of the two studies is not possible.

In another prospective study of over 1500 consecutive patients with suspected pulmonary embolism who underwent ventilation-perfusion scanning and IPG of the lower extremities, 40 percent had nondiagnostic scans and negative serial IPG studies. All had adequate cardiorespiratory reserve and were managed without anticoagulation. Only 1.9 percent had evidence of DVT or PE on follow-up. The findings suggest that a combination of ventilation-perfusion scanning and IPG can be useful in supporting a decision to withhold anticoagulation in patients who have not had clinically significant PE and who do not have evidence for proximal, lower extremity DVT.

Similarly, in another prospective study of over 1200 patients categorized as having a pretest probability of PE as low, moderate, or high, ventilation-perfusion lung scanning and bilateral lower extremity ultrasound revealed that only 0.5 percent (3 of 665) with low or moderate pretest probability and a non-high probability scan had PE or DVT during the 90-day follow-up period. The authors concluded that patients with clinically suspected pulmonary embolism could be managed safely based on pretest probability and results of a ventilation-perfusion scan. The findings are similar to those from another study of over 1000 patients with suspected PE, 22 percent of whom had a low clinical probability of PE, nondiagnostic lung scan, and negative venous study of the legs. These patients were not treated with anticoagulants, and in follow-up, the prevalence of DVT or PE was only 1.7 percent.

Finally, in the Prospective Investigative Study of Acute Pulmonary Embolism Diagnosis (PISAPED), which utilized perfusion scanning alone in conjunction with the chest radiograph, the sensitivity and specificity of scintigraphy were 92 percent and 87 percent, respectively. The prevalence of PE was high (39 percent). When considered in conjunction with clinical assessment of the likelihood of PE (very likely, possible, or unlikely), the positive predictive value (PPV) of a perfusion scan was 99 percent; the combination of a near-normal or abnormal perfusion scan without segmental defects and low clinical likelihood of PE had a negative predictive value (NPV) of 97 percent. Using standardized clinical assessment and perfusion lung scanning, the authors were able to accurately diagnose or exclude PE (PPV, 96 percent; NPV, 98 percent). CT angiography was required in only a minority of cases having discordant clinical and scintigraphic findings (see below).

Prospective Investigation of Pulmonary Embolism Diagnosis Study

To date, the most comprehensive prospective investigation addressing the role of ventilation-perfusion scanning in the diagnosis of PE has been the PIOPED study. This multiinstitutional study was designed to evaluate the efficacy of various conventional methods for diagnosing acute PE. In particular, PIOPED focused on the sensitivity and specificity of lung scans in the diagnosis of acute PE.

Although the clinical diagnosis of PE is not definitive, results from PIOPED emphasize the importance of incorporating clinical assessment in evaluating patients suspected of having acute PE. As expected, combining clinical assessment with lung scan interpretation improves diagnostic accuracy of the imaging technique. Similarly, although chest radiographic findings alone are not sensitive or specific for PE, they are essential for diagnosing conditions that can mimic PE clinically. Furthermore, chest radiographic findings heavily influence the criteria utilized for estimating the probability of PE based on lung scan patterns.

The sensitivity, specificity, and positive predictive value of ventilation-perfusion lung scans in detecting acute PE are presented in Table 33-1.

One of the limitations of ventilation-perfusion scanning is interobserver variability in scan interpretation. While

Table 33-1

Sensitivity, Specificity, and Positive Predictive Value of Lung Scans in Detecting Pulmonary Embolism in Patients Enrolled in PIOPED

Lung Scan Interpretation (Probability)	Sensitivity	Specificity	Positive Predictive Value
High	40%	98%	87%
High, intermediate	82%	64%	49%
High, intermediate, low	98%	12%	32%

there is generally excellent agreement in categorizing scans as normal or consistent with very low or high probability of PE, interobserver agreement on low-probability and intermediate-probability lung scans is not as good. Use of anatomic lung segment reference charts has been shown to reduce interobserver disagreement when interpreting scans.

Other interpretative pitfalls include false-negative and -positive readings. False-negative interpretations (i.e., low probability read with PE present) do occur, and patients who have a recent history of immobilization (bed rest for 3 days), recent surgery, trauma to the lower extremities, or central venous instrumentation are particularly at risk. In patients with low or very low probability scans who have none of the aforementioned risk factors, the prevalence of PE is only 4.5 percent. Conversely, in patients with low or very low probability scans and one or more of the risk factors, the prevalence of PE is 12 percent and 21 percent, respectively (Table 33-2).

Patients with false-negative lung scans tend to have nonocclusive subsegmental thrombi and a low pulmonary clot burden. In recent years, concern has arisen that a low probability scan may be misleading, resulting in unnecessary mortality in patients who have PE and are not anticoagulated. The prognostic value of a low probability scan is excellent, particularly in patients with a low clinical pretest likelihood of disease or negative lower leg ultrasound. In a series of 536 consecutive patients with these findings, evidence that PE caused or contributed to death within 6 months of imaging was absent.

The most common cause of ventilation-perfusion mismatch in patients who do not have acute PE is chronic or unresolved PE. Other causes include compression of the pulmonary vasculature (e.g., from mass lesions, lymphadenopathy, or mediastinal fibrosis), vessel wall abnormalities (e.g., pulmonary artery tumors or vasculitis), nonthrombembolic intraluminal obstruction (e.g., tumor emboli or foreign body emboli), and congenital vascular abnormalities (e.g., pulmonary artery agenesis or hypoplasia). In patients who have unilateral ventilation-perfusion mismatch (hypoperfusion or absent perfusion) within an entire lung or in multiple contiguous segments and normal perfusion in the contralateral lung, extrinsic compression of the pulmonary vasculature, congenital abnormalities, or proximal PE should be considered. Patients with a suspected false-positive scan or unilateral ventilation-perfusion mismatch often require further imaging using CT angiography.

Table 33-2

Risk Factors and Prevalence of Pulmonary Embolism in Patients with Low Probability and Very Low Probability Lung Scans Enrolled in PIOPED

	Patients with 0 Risk Factors (%)*	Patients with 1 Risk Factor (%)*	Patients with ≥2 Risk Factors (%)*	Total
PE positive	14 (2.2%)	19 (2.9%)	37 (5.7%)	70
PE negative	301 (46.4%)	136 (21.0%)	142 (21.9%)	579
Prevalence of PE	4.5%	12.2%	20.7%	10.8%

** Risk factors include immobilization, trauma to lower extremities, surgery, and central venous instrumentation within 3 months of enrollment.*

Table 33-3

Revised PIOPED Criteria for Interpretation of Lung Scans*

High probability
≥2 Large segmental perfusion defects (>75% of a segment) without corresponding ventilation or radiographic abnormalities
1 Large segmental perfusion defect and ≥2 moderate segmental perfusion defects (25%–75% of a segment) without corresponding ventilation or radiographic abnormalities
≥4 Moderate segmental perfusion defects without corresponding ventilation or radiographic abnormalities
Intermediate probability
1 Moderate to <2 large segmental perfusion defects without corresponding ventilation or radiographic abnormalities
Corresponding ventilation-perfusion defects and radiographic parenchymal opacity in lower lung zone
Single, moderate, matched ventilation-perfusion defects with normal radiographic findings
Corresponding ventilation-perfusion defects and small pleural effusion
Difficult to categorize as normal, low, or high probability
Low probability
Multiple matched ventilation-perfusion defects, regardless of size, with normal radiographic findings
Corresponding ventilation-perfusion defects and radiographic parenchymal opacity in upper or middle lung zone
Corresponding ventilation-perfusion defects and large pleural effusion
Any perfusion defects with substantially larger radiographic abnormality
Defects surrounded by normally perfused lung (stripe sign)
>3 Small segmental perfusion defects (<25% of a segment) with a normal radiograph
Nonsegmental perfusion defects (cardiomegaly, aortic impression, enlarged hila)
Very low probability
≤3 Small segmental perfusion defects (<25% of a segment) with a normal radiograph
Normal probability
No perfusion defects; perfusion outlines the shape of the lung seen on the radiograph

** Criteria generated after completion of prospective study.*

Interpretation Criteria and Amendments to Original PIOPED Criteria

Several diagnostic schemes have been suggested for interpretation of ventilation-perfusion scans. The original PIOPED criteria were developed to interpret the scans generated from the study based upon experience gathered over the preceding decade. However, several revisions of the original PIOPED criteria have been made since its original introduction (Table 33-3). It is now possible to decrease the number of intermediate scan readings and correctly interpret the scans as low probability. Use of revised PIOPED criteria has already been shown to provide a more accurate assessment of angiographically proven PE than the original criteria.

Another now-recognized interpretation nuance is based upon the so-called *stripe sign*, defined as a rim of perfused lung tissue between the perfusion defect and the adjacent pleural surface (Fig. 33-5). In the PIOPED study, the presence of the sign excluded the diagnosis of PE within the affected zone in 93 percent of cases. Therefore, perfusion defects that demonstrate a stripe sign are unlikely to be due to PE, and in the absence of perfusion defects elsewhere, such findings should be interpreted as representing a low probability of PE. The nuclear medicine physician's subjective estimate of the likelihood of PE (without using specific interpretation criteria) correlated well with the fraction of patients with angiographic evidence of PE in the PIOPED study. When interpreting lung scans, experienced nuclear medicine physicians often rely on a complex interaction between information derived from clinical presentation, chest radiographic findings, published criteria, and ancillary findings. Thus, experienced readers (such as the PIOPED investigators) can provide an accurate estimate of the probability of PE based on clinical, radiographic, and scintigraphic findings.

CT Angiography in the Diagnosis of Pulmonary Embolism

More recently, clinicians have employed spiral or helical CT angiography and electron beam computed tomography as an alternative to scintigraphy in the diagnosis of PE.

With CT angiography, acute PE appears as an intraluminal filling defect, which partially or completely occludes

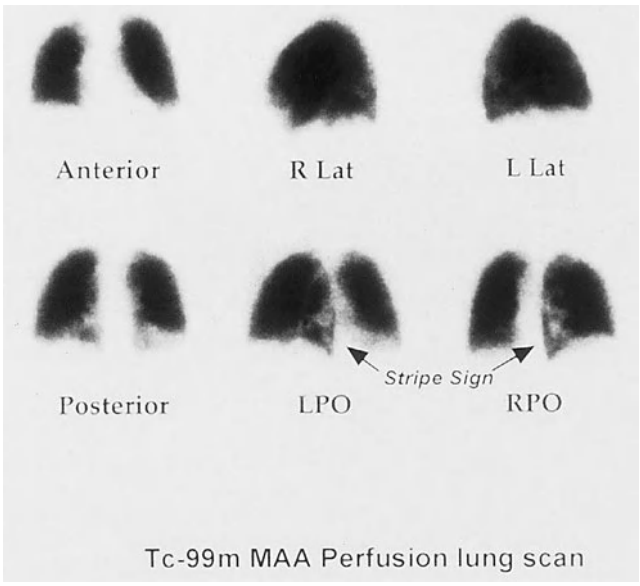

Figure 33-5 Stripe sign. Both left posterior and right posterior oblique views (lower row) demonstrate a defect surrounded by perfused lung. This pattern is very rarely seen in pulmonary embolism.

the pulmonary artery, or as an abrupt vessel cut-off. Commonly, mild vascular distension at the site of the thrombus is present within the affected vessel. Other indirect signs that suggest PE include a dilated central pulmonary artery, dilated right ventricle, or wedge-shaped parenchymal consolidation. In animal models, CT angiography has been shown to detect thrombi in vessels as distal as the fourth division (segmental) pulmonary arteries.

The performance of CT angiography for detection of PE is technically demanding. The sensitivity and specificity of CT angiography for detecting PE range from 53 percent to 100 percent and 75 percent to 100 percent, respectively. The diagnostic performance of CT angiography for detecting subsegmental thrombi is lower than for central PE.

In one prospective study comparing spiral CT angiography and ventilation-perfusion lung scanning, CT angiography had a higher sensitivity than a high-probability ventilation-perfusion scan. The specificity, PPV, and NPV were similar between the two modalities. A more recent study reported a higher sensitivity and specificity for CT angiography than ventilation-perfusion scanning. Spiral CT angiography also provides for higher interobserver agreement and the ability to elucidate an alternative diagnosis for patients with suspected PE.

Limitations of CT angiography include technical failures and incomplete examinations. Patient-related factors which can result in incomplete or suboptimal examinations include orthopnea, poor intravenous access, and inability to breath-hold because of dyspnea. In patients who are unable to breath-hold, respiratory misregistration may occur, degrading image quality. A poor signal-to-noise ratio or vascular enhancement may occur in patients with right heart failure, large right-to-left shunts, or extravasated intravenous lines. Intravenous contrast must be used cautiously, particularly in patients with renal insufficiency. The prevalence of suboptimal CT angiography examinations depends on the technique used and the population examined. In selected patients, technically inadequate studies occur in about 2 to 4 percent . In spite of its technical demands, CT angiography can provide a prompt and accurate diagnosis of PE in most patients.

Studies evaluating the safety of withholding anticoagulation in patients with a negative CT angiogram suggest that in selected patient populations, CT angiography has a high NPV and that anticoagulant therapy may be safely withheld. A meta-analysis of 3500 patients reported that CT angiography is equivalent to convential angiography in ruling-out clinically significant PE. In the authors' opinion, use of spiral CT in the diagnosis of PE has not yet been adequately evaluated, and further prospective studies are required to determine the sensitivity, specificity, and safety of the technique.

PIOPED II, a multicentered, prospective, outcome-based study supported by the National Heart, Lung, and Blood Institute, is designed to assess the accuracy of CT angiography in the evaluation of acute PE. Preliminary data indicate that the sensitivity, specificity, PPV, and NPV of the technique are 83, 96, 86, and 95 percent, respectively.

Recommendations Regarding Use of Ventilation-Perfusion Lung Scans and CT Angiography in Evaluating Suspected Pulmonary Embolism

Proponents of CT angiography suggest that it should be used as the first-line study in patients with suspected PE. Others suggest that ventilation-perfusion lung scanning should remain the first-line test, with CT angiography used in those patients in whom the diagnosis remains uncertain. In patients with a normal chest radiograph, the ventilation-perfusion lung scan is an effective, noninvasive initial study. However, in patients with significant chest radiographic abnormalities, CT angiography is more likely to provide a definitive diagnosis of PE or an alternative diagnosis. Furthermore, the combination of CT angiography and CT venography has the potential to provide a single, comprehensive evaluation of patients with suspected venous thromboembolism.

In summary, based upon results from prospective and outcome-based studies conducted over the last few years, the following conclusions can be drawn regarding use of radionuclide and CT imaging in evaluating patients with suspected PE: (a) A normal ventilation-perfusion scan excludes the diagnosis of clinically significant PE (Fig. 33-6). (b) Patients with very low or low probability scans and a low clinical likelihood of PE have a low (<5 percent) prevalence of PE and generally do not require pulmonary angiography or anticoagulation. (c) Patients with very low or low probability scan, intermediate or high clinical likelihood of PE, and negative serial noninvasive venous studies of the lower extremities generally do not require anticoagulation. In selected cases, CT angiography is helpful in excluding PE and providing an alternative diagnosis. (d) Clinically stable patients with an intermediate

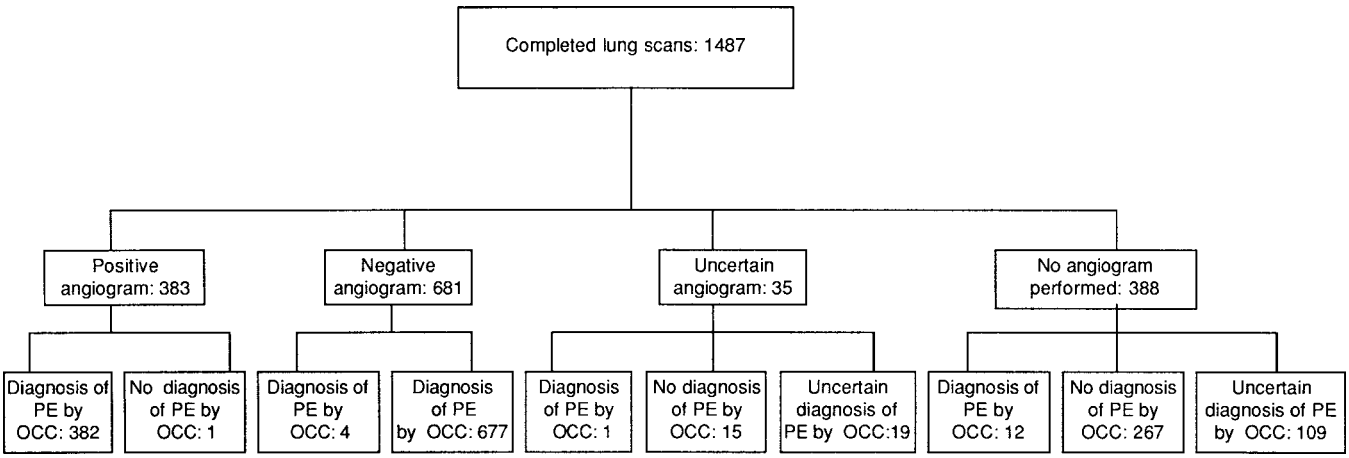

Figure 33-6 Outcome classification of patients enrolled in PIOPED. Data are from patients who completed ventilation-perfusion scans. See text for details. PE = pulmonary embolism; OCC = Outcome Classification Committee.

probability scan require noninvasive venous studies of the legs; if negative, CT angiography is required for definite diagnosis of PE. (e) A clinically stable patient with a high probability scan and high clinical likelihood of PE, or a patient suspected of having a false-positive scan requires treatment; no further diagnostic tests are required to confirm the diagnosis. (f) Clinically stable patients with a high probability scan and a low clinical likelihood of PE require noninvasive venous studies of the legs; if negative, CT angiography may be required for definitive diagnosis.

EVALUATION OF PULMONARY HYPERTENSION

Pulmonary hypertension (PH) as a consequence of chronic pulmonary thromboembolism is a serious and potentially surgically treatable disease. Estimates are that between 0.5 and 4 percent of patients with acute pulmonary emboli eventually develop chronic thromboembolic PH. Unfortunately, the clinical features, laboratory studies, and other noninvasive assessments employed are often unreliable in distinguishing chronic thromboembolic PH from primary and nonthromboembolic secondary PH. Pulmonary angiography is usually required to confirm the diagnosis and determine whether surgical intervention is indicated. Although there have been reports that pulmonary angiography may be performed safely in patients with severe PH, others have documented a high frequency of complications, including death.

Ventilation-perfusion lung scanning is a safe, noninvasive technique that facilitates selection of patients with PH for pulmonary angiography to confirm the diagnosis of chronic PE. In order to prevent potential adverse hemodynamic effects when performing ventilation-perfusion lung scans in patients with PH, the number of ^{99m}Tc MAA particles administered should be reduced. Both ventilation-perfusion lung scanning and pulmonary angiography may produce underestimations of the magnitude of vascular occlusion by chronic emboli, as determined at thromboendarterectomy.

In one study of 25 patients with chronic thromboembolic PH, 96 percent of ventilation-perfusion lung scans were interpreted as high probability for PE; in one patient, the scan was interpreted as intermediate probability. The findings suggest that in chronic PH, CT angiography or pulmonary angiography should be performed in those patients with intermediate or high-probability ventilation-perfusion scans in order to confirm the diagnosis of chronic PE.

Most patients with primary PH or secondary, nonthromboembolic PH have low-probability scans. The distribution of ^{99m}Tc MAA particles within the lungs is diffuse and nonhomogeneous. Patients with PH rarely, if ever, have normal or very-low-probability scans. Thus, a low-probability ventilation-perfusion scan effectively excludes chronic thromboembolism as the cause of PH.

QUANTITATIVE VENTILATION-PERFUSION LUNG SCANNING

In patients undergoing pulmonary resection or lung transplantation, quantitative ventilation-perfusion lung scanning is a useful method for determining regional lung function. The major use of the technique is prediction of postoperative pulmonary function following lung volume reduction for chronic obstructive pulmonary disease or pneumonectomy for other reasons.

Peripheral lung carcinomas are associated with ventilation and perfusion defects that correspond to abnormalities noted on the chest radiograph. In patients with central bronchogenic carcinomas, mismatches between ventilation and perfusion patterns may be noted. In these cases, either the primary lung tumor or adenopathy may compress the main pulmonary artery or vein, which, in turn, may result in decreased perfusion to affected areas. When the airway is

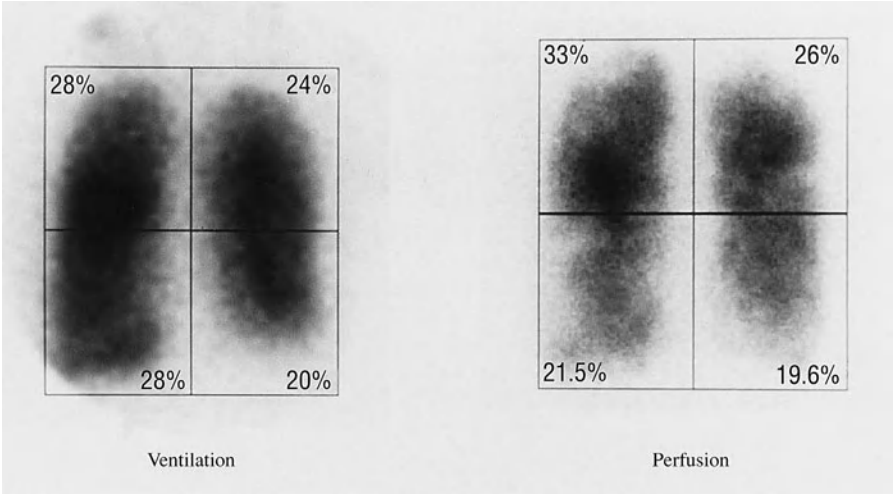

Figure 33-7 Quantitative ventilation-perfusion lung scan. Regional ventilation and perfusion can be quantified by outlining regular or irregular regions of interest and generating ratios that correspond to percent of total pulmonary function. Images shown were analyzed by dividing each lung into two equal rectangles.

partly or totally occluded by cancer, a matching ventilation-perfusion pattern is seen in affected lung zones.

In patients with central tumors, regional perfusion values correlate well with regional lung physiology and can be utilized to predict postoperative pulmonary function. The postoperative FEV_1 is calculated by multiplying the preoperative value by the ratio of the counts in the remaining lung to total lung activity (Fig. 33-7).

ASSESSMENT OF INFLAMMATORY AND GRANULOMATOUS LUNG DISEASE

Gallium-67 citrate and labeled white blood cells are the radiopharmaceuticals of choice for imaging pulmonary infection and inflammation. Gallium-67, which has a physical half-life of 78 h, is an iron analog. Following intravenous administration, approximately 90 percent of the dose injected is bound to transferrin. The kidneys excrete only 25 percent of the administered preparation during the first 24 h after injection. Another 10 percent of the injected activity is excreted in stool over the next several days. The remaining 65 percent is distributed within the body. Typically, gallium is taken up in the liver, skeleton, bone marrow, spleen, nasopharynx, lacrimal and salivary glands, and external genitalia. The precise mechanism of gallium localization at sites of inflammation or infection is not completely understood. Increased vascular permeability, direct bacterial uptake (binding to siderophores), binding to lactoferrin (which is secreted by activated leukocytes), and direct binding to circulating leukocytes have been postulated.

The optimal time for imaging the thorax is at least 48 to 72 h following the administration of gallium. Increased gallium activity in the lungs is a sensitive, but relatively nonspecific, indicator of pulmonary infection or inflammation. A variety of conditions, including acute respiratory distress syndrome, pneumonia, drug reactions (e.g., those due to busulfan, cyclophosphamide, amiodarone, or contrast agent following lymphangiography), pneumoconiosis, idiopathic pulmonary fibrosis, and sarcoidosis may cause increased radiogallium accumulation in the lungs. The intensity and distribution of the pulmonary accumulation can be quantified to determine the degree of parenchymal inflammation. Malignant processes, such as lymphoma, leukemia, mesothelioma, and lung metastases may also result in increased radiogallium uptake when there is focal disease activity.

Gallium-67 Citrate Imaging of the Thorax in the Immunocompromised Host

Diffuse gallium uptake in the lungs of HIV-infected patients who have normal chest radiographs is highly suggestive of *Pneumocystis carinii* pneumonia (PCP) (Fig. 33-8). The sensitivity of gallium scanning for detecting PCP is approximately 95 percent, and when gallium uptake in the lungs is intense (greater than the liver), the specificity also approaches 95 percent.

Other conditions associated with diffuse lung uptake in immunocompromised patients are cytomegalovirus pneumonitis, cryptococcal infections, and lymphoma. Although localized lung uptake may be associated with PCP, particularly in patients treated with prophylactic aerosolized pentamidine, focal accumulation is often secondary to bacterial pneumonia or immunoblastic lymphoma. Focal activity in the lung and corresponding regional lymph nodes is typical for infection with *M. avium-intracellulare* or *M. tuberculosis.* Kaposi's sarcoma does not accumulate radiogallium, but the lesions are clearly visualized following the administration of thallium-201 chloride. Combined imaging with gallium-67 citrate and thallium-201 chloride has been suggested as a way to distinguish Kaposi's sarcoma from PCP and lymphoma in HIV-infected patients.

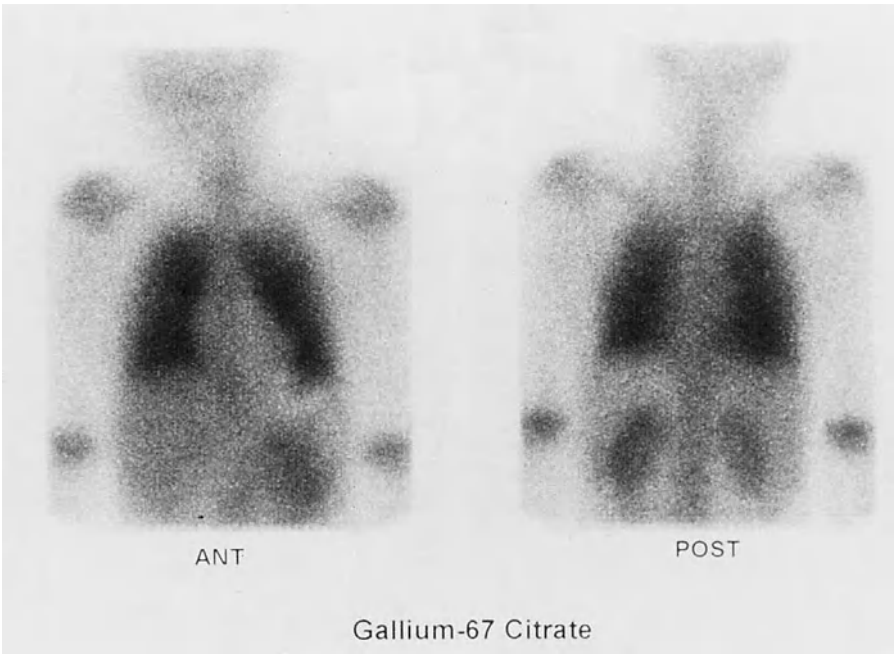

Figure 33-8 *Pneumocystis carinii* pneumonia with diffuse parenchymal lung uptake. Anterior and posterior gallium scans of the chest and abdomen reveal intense uptake of radiogallium, indicating a diffuse inflammatory process in both lungs.

Noninfectious Inflammatory Lung Disease

Gallium-67 citrate lung imaging has been used to quantify the degree of alveolitis in various interstitial lung diseases, particularly sarcoidosis and idiopathic pulmonary fibrosis. In patients with idiopathic pulmonary fibrosis, the intensity of radiogallium uptake has been shown to correlate with the degree of alveolitis assessed by open lung biopsy and the percentage of neutrophils present in bronchoalveolar lavage fluid. However, pulmonary uptake of gallium-67 citrate may be normal in patients with low-grade alveolitis. Unfortunately, pulmonary accumulation of radiogallium in idopathic pulmonary fibrosis is not reliable in predicting the response to treatment with corticosteroids or prognosis. Patients who have normal thoracic gallium scans may eventually develop pulmonary fibrosis, while patients showing a marked increased uptake may remain stable or improve. Therefore, the routine use of gallium-67 scintigraphy in patients with idiopathic pulmonary fibrosis is not recommended.

Scintigraphy with gallium-67 citrate has been advocated for assessment of disease activity in pulmonary sarcoidosis. In patients with sarcoidosis, radiogallium activity in the lung correlates well with the presence of alveolitis detected by lung biopsy and the percentage of T lymphocytes detected by bronchoalveolar lavage. Although it is not specific for sarcoidosis, this disorder is characterized by bilateral, perihilar, or peritracheal uptake of gallium-67 citrate (Fig. 33-9). This appearance, combined with increased uptake in the parotid glands, is virtually pathognomonic for sarcoidosis. Parenchymal activity can also be seen, with or without hilar activity. Parenchymal uptake is usually in the midlung, with relative sparing of the upper and lower lung zones. Gallium-67 citrate imaging in sarcoidosis is useful in selecting the site for lung biopsy and distinguishing fibrotic changes from active inflammatory disease. Several studies have also shown a correlation between the degree of uptake of radiogallium and response to therapy with corticosteroids. Gallium-67 citrate scintigraphy is also useful in assessing extrapulmonary manifestations of sarcoidosis.

SCINTIGRAPHIC ASSESSMENT OF ALVEOLAR-CAPILLARY MEMBRANE PERMEABILITY

Assessment of alveolar-capillary membrane permeability requires the inhalation of ^{99m}Tc-labeled radioaerosols. The rate of aerosol clearance from the lung is measured using a counting probe or gamma camera. Several factors influence the rate at which inhaled aerosols "wash out" from the lungs. The most important determinant is the site of aerosol deposition. Aerosols of relatively small aerodynamic diameter (e.g., ^{99m}Tc DTPA) are deposited largely within the small airways and alveoli, whereas larger particles (e.g., ^{99m}Tc MAA or ^{99m}Tc sulfur colloid) are deposited within the proximal airways. The normal half-time of ^{99m}Tc DTPA washout from the lungs is 86 $\pm$ 26 min. In the presence of epithelial alveolar damage, the clearance of ^{99m}Tc DTPA is accelerated.

A variety of acute or chronic pulmonary conditions may cause increased clearance of ^{99m}Tc DTPA from the lungs,

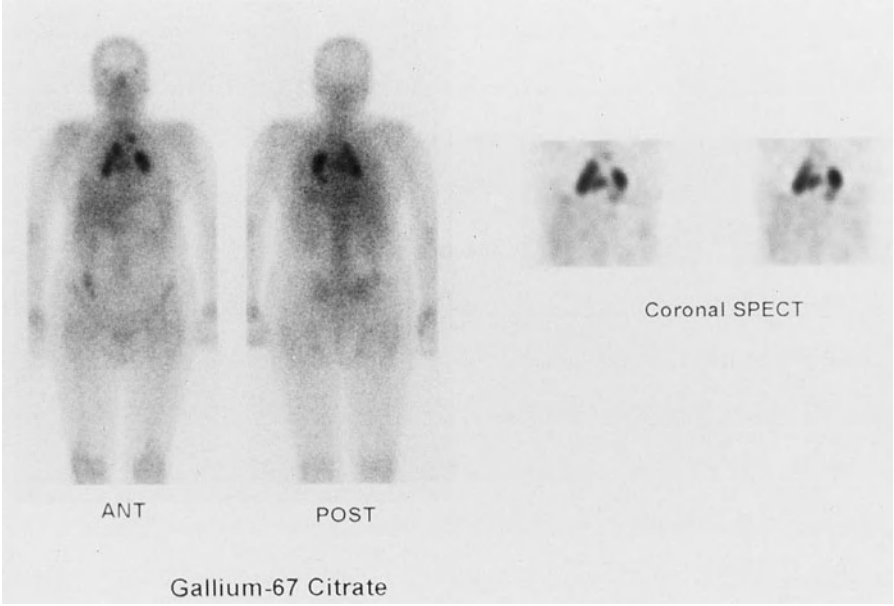

Figure 33-9 Bilateral hilar lymphadenopathy in sarcoidosis. Anterior and posterior whole-body images demonstrate intense uptake of radiogallium in both hilar regions. These areas are clearly defined on tomographic (SPECT) images in coronal planes. Similar patterns are seen in patients with lymphoma.

including pneumoconiosis, idiopathic pulmonary fibrosis, collagen vascular diseases, sarcoidosis, acute respiratory distress syndrome, and pneumocystis pneumonia. Cigarette smoking or physiological factors, such as posture and exercise, also influence epithelial lung clearance. Since increased alveolar-capillary membrane permeability is relatively nonspecific, ^{99m}Tc DTPA clearance studies have been utilized only to assess the effects of therapy in patients with known pulmonary diseases. Comparison of serial studies is of value only if a consistent pattern of distribution of radiopharmaceutical activity is demonstrated on repeated studies. Otherwise, results from such studies are of little help in determining the course of the disease.

EVALUATION OF MUCOCILIARY CLEARANCE

Determination of mucociliary clearance may be obtained after the inhalation of relatively large aerosolized particles, followed by measurement of the rate of clearance with a gamma camera. The rate of mucociliary clearance depends on several factors, including ciliary activity and mucus production. Inhaled particles, such as ^{99m}Tc MAA or ^{99m}Tc sulfur colloid, tend to be deposited within the proximal airways. The normal mucociliary clearance half-time is approximately 24 h. Delayed mucociliary clearance is seen in patients with airway inflammation (e.g., due to COPD, asthma, or viral respiratory tract infections), following bronchial surgery, or after irradiation. Physiological factors, such as aging and sleep, can also delay mucociliary clearance.

POSITRON EMISSION TOMOGRAPHY AND ASSESSMENT OF SOLITARY PULMONARY NODULES AND LUNG CANCER

PET is a nuclear medicine technique that provides images of metabolic or physiologic processes. Application of PET in respiratory medicine has primarily focused on the evaluation of solitary pulmonary nodules and lung cancer. The most commonly used radiopharmaceutical in clinical PET is F-18-fluorodeoxy-D-glucose (FDG). Metabolic differences between benign and malignant tissue can be accurately characterized using FDG-PET.

The mechanism of cellular uptake and initial phosphorylation of FDG is similar to that of glucose. However, once FDG is phosphorylated (to FDG-6-phosphate), it is trapped within the cell and can be imaged using PET (Fig. 33-10). The amount of intracellular FDG is proportional to glucose uptake and, therefore, to the metabolic activity of the tissue. Cells that have undergone malignant transformation have increased glucose transport and metabolism due to accelerated cell proliferation and increased hexokinase activity.

Current indications for PET-FDG imaging in patients with proven or suspected lung cancer include distinction of benign from malignant pulmonary nodules, mediastinal staging of non–small-cell lung cancer, detection of distant metastasis, and diagnosis of recurrent disease.

A solitary pulmonary nodule (SPN), defined as an opacity in the lung parenchyma that measures up to 3 cm and that has no associated mediastinal adenopathy or atelectasis, is commonly indentified on chest radiographs and CT scans and often poses a diagnostic challenge. Thirty to 50 percent of SPN's are malignant and may represent a potentially

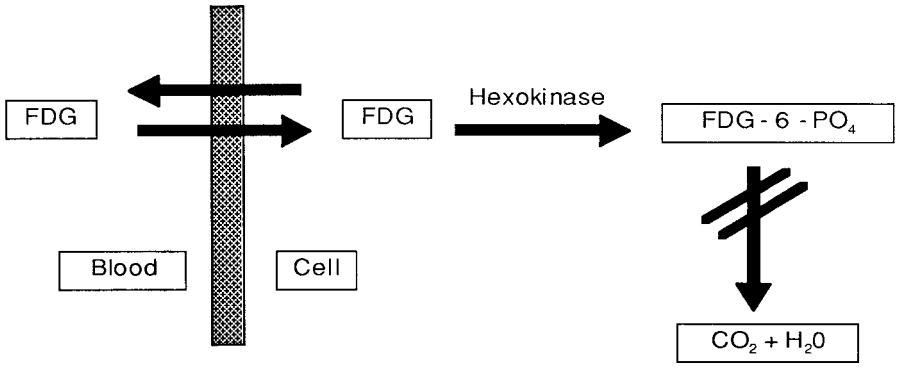

Figure 33-10 Schematic representation of FDG metabolism in metabolically active cell. FDG is preferentially transported through the cell membrane. Following phosphorylation to FDG-6-phosphate by the hexokinase system, FDG remains trapped in the cell for a while, facilitating imaging of the abnormal tissue with PET.

curable stage of bronchogenic carcinoma; however, many represent benign processes. While a number of benign etiologies for SPN's have a characteristic appearance on CT, many can not be characterized accurately using CT and often require further invasive assessment. Increased patient age, a history of smoking, large nodule size, and absence of nodule calcification are features associated with an increased probability of malignancy. FDG-PET provides an accurate, noninvasive diagnostic assessment of SPNs, without the morbidity and costs associated with invasive tissue sampling (Fig. 33-11).

Sensitivity and specificity of FDG-PET in detecting benign and malignant pulmonary nodules range from 92 to 98 percent and 79 to 100 percent, respectively (Table 33-4).

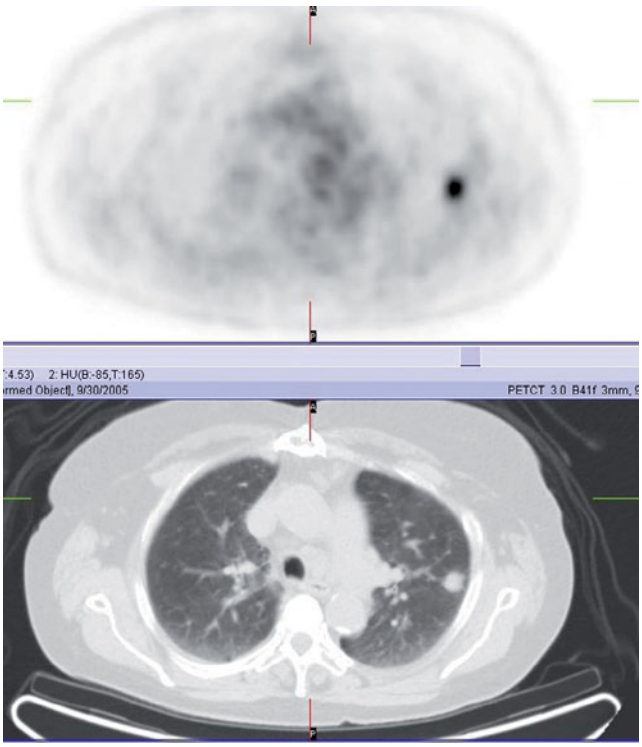

Figure 33-11 Transaxial FDG-PET and CT. Non–small-cell lung cancer in left upper lobe demonstrating increased activity (hypermetabolic) on coregistered FDG-PET/CT images.

In one meta-analysis of 40 studies that included over 1400 focal pulmonary lesions studied with FDG-PET, the technique had an average sensitivity of 97 percent and specificity of 78 percent. No differences were noted between results using a semiquantiative analysis of FDG uptake and those based on qualitative visual assessment. False-positive studies are seen with active inflammation due to aspergillosis, tuberculosis, or sarcoidosis. False-negative results are seen with malignancies which have a low metabolic activity (e.g., bronchoaveolar carcinoma or carcinoid tumors) or are less than 8 mm in diameter.

Nodules having a "ground-glass" or "mixed" appearance on CT scanning are associated with a higher incidence of malignancy than are solid-appearing nodules. Further investigation is necessary to evaluate the role of FDG-PET in evaluating ground-glass lesions. The low accuracy of PET in assessing these abnormalities is likely related to their small size and the cell types that predominate, including pure bronchioalveolar cell cancer or adenocarcinomas with bronchioalveolar features.

As noted, the sensitivity of FDG-PET is a function of lesion size. In one study addressing this issue, the technique's sensitivity in detecting malignancy was 69 percent for nodules ranging from 5 to 10 mm in diameter and 95 percent for nodules greater than 10 mm in diameter. The lower limit of spatial resolution of PET, which is about 5 to 6 mm, is lower than that of CT or MRI. One method aimed at compensating for this limitation is based on using lesion size measured on CT imaging to correct the so-called "standardized uptake value" (SUV), a semiquantitative expression of the intensity of lesion FDG accumulation determined on the PET scan. The SUV of an area in the image is calculated as the amount of tracer in the tissue (microcuries per gram) divided by the amount of radiotracer injected (millicuries) divided by the patient's weight (kilograms).

Lung cancers have a wide range of FDG uptake. Furthermore, while most infectious or inflammatory pulmonary disorders generally have a lower FDG uptake than malignancies, overlap exists. An SUV threshold of 2.5, measured at a single point in time, has been proposed to separate malignant (higher SUV) from benign (lower SUV) disorders.

Table 33-4

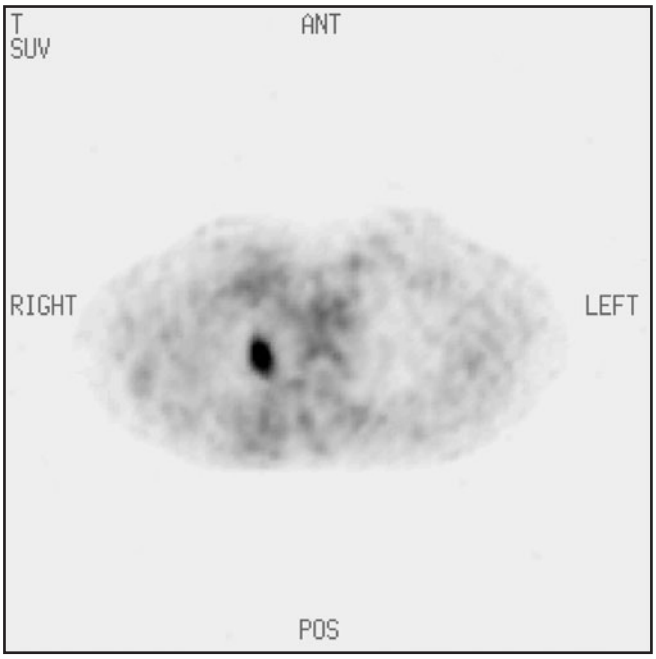
FDG-PET in Evaluation of Solitary Pulmonary Nodules

		Sensitivity		Specificity		
Nodule Size (cm)	**Type of Analysis**	**%**	**95% Confidence Interval**	**%**	**95% Confidence Interval**	**Accuracy (%)**
≤1.5	SUV	80	60–100	95	85–100	88
	Visual	100	100–100	74	55–93	
>1.5	SUV	96	90–100	80	55–100	93
	Visual	98	94–100	60	45–74	91
≤3	SUV	90	82–98	92	85–99	91
	Visual	98	94–100	69	56–82	88
All sizes	SUV	92	82–100	90	79–100	91
	Visual	98	82–100	69	57–81	89

Based on the observation in animal and human studies that FDG uptake by malignant tumors increases over time, while that of inflammatory tissue decreases (Fig. 33-12), dual-time point FDG-PET scanning has emerged as a potentially useful way of enhancing discrimination between benign and malignant diseases. Using this approach, images are obtained 1 and 2 h after administration of FDG. In one study in which an SUV cut-off value of 2.5 and a 10 percent increase in SUV was used to indicate malignancy, the sensitivity and specificity of FDG-PET were 80 and 94 percent, respectively, for the single-time point method, and 100 and 89 percent, respectively, for the dual-time point technique.

Use of Positron Emission Tomography in Lung Cancer Staging

An additional advantage of FDG-PET in evaluating solitary pulmonary nodules is that the technique can be used in staging mediastinal lymph nodes in patients with non–small-cell



A

lung cancer. The role of FDG-PET in staging of small-cell lung carcinoma remains controversial.

Patients with stage I or II non–small-cell lung cancer are typically referred for surgery, while those with stage IIIb (contralateral mediastinal disease) or stage IV (distant metastases) disease generally are not surgical candidates. Mediastinal staging using CT scanning is based primarily on assessment of lymph node size; nodes less than 1 cm in their short axis are considered benign, while those greater than 1 cm are considered potentially malignant. Using this anatomic approach, mediastinal staging based on CT scanning has a sensitivity of 57 percent and specificity of 82 percent.

In comparison with CT scanning, FDG-PET has a higher sensitivity and specificity for determining node status in patients with non–small-cell lung cancer. The average sensitivity and specificity for FDG-PET are 84 and 89 percent, respectively (Table 33-5). However, a comparison of PET and mediastinoscopy in a study of over 200 patients revealed a PPV for PET of only 45 percent. Therefore, mediastinoscopy is still necessary in the staging of PET-positive mediastinal lymph nodes. PET can also be useful in identifying the optimal site

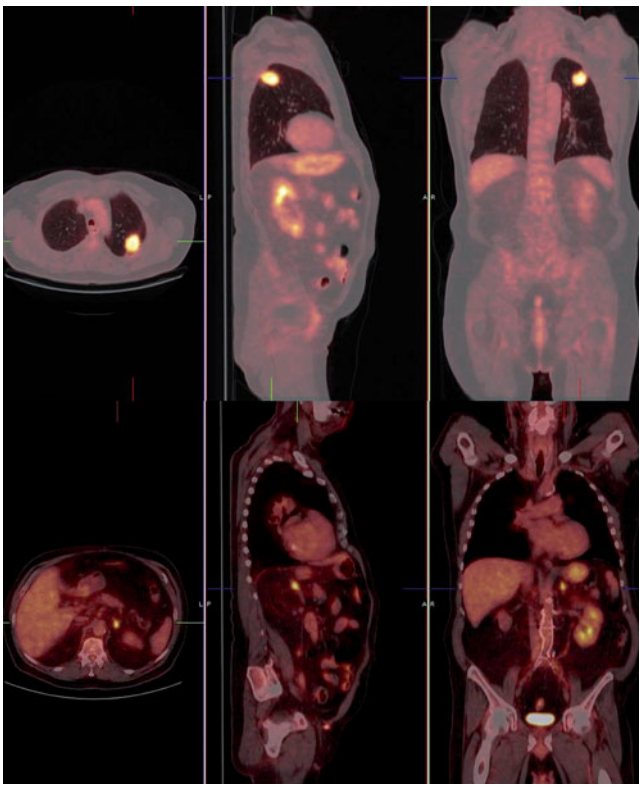

Figure 33-13 Transaxial, sagittal, and coronal composite FDG-PET/CT images (top row) of a patient being considered for pulmonary resection. A hypermetabolic nodule is seen within the left upper lobe, corresponding to the patient's known lung cancer. Composite FDG-PET/CT images (bottom row) demonstrate a small, previously unknown, hypermetabolic focus in the left adrenal gland, which was confirmed as an adrenal metastasis.

for mediastinal lymph node biopsy and aiding selection of additional invasive methods for sampling lymph nodes inaccessible by mediastinoscopy.

In addition to mediastinal evaluation, whole-body FDG-PET imaging may aid in detecting unsuspected distant metastases (Fig. 33-13). In one mutlicenter trial, adddition of PET to the conventional workup prevented unnecessary surgery in one out of five patients with suspected non–small-cell lung cancer. Two common examples of extrapulmonary sites (stage IV disease) of lung metastases are worth considering in this regard: the adrenal glands and bone marrow.

Although benign adrenal adenomas may be abnormal on PET, FDG-PET has a sensitivity of 100 percent and specificity of 80 to 94 percent in detecting adrenal metastases. In detecting bone metastases, compared with bone scintigraphy, FDG-PET has a similar sensitivity but a higher specificity. FDG-PET can detect bone marrow metastases before reactive bone formation takes place or prior to development of gross anatomic abnormalities (Fig. 33-14).

In patients with residual parenchymal abnormalities following radiotherapy for lung cancer, PET-FDG scanning can be used to distinguish between persistent or recurrent cancer and radiation fibrosis. In a study of 35 patients who had recurrent or persistent parenchymal abnormalities following radiotherapy, the sensitivity and specificity of FDG-PET in detecting recurrent tumor were 97 and 100 percent, respectively. Only one patient, who had a very thin pleural tumor rind, had a false-negative study.

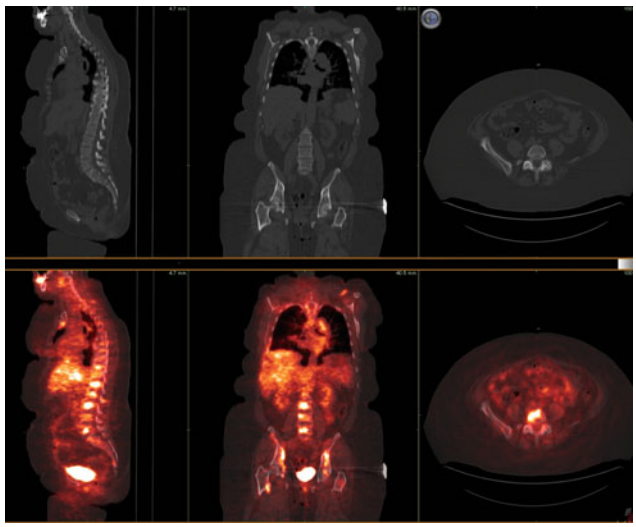

Figure 33-14 PET/CT images (lower row) demonstrate abnormal FDG uptake in the body of multiple lower thoracic and lumbar vertebral bodies, consistent with bone marrow metastases. No clear abnormalities in the CT bone windows (upper row) are evident to suggest bone destruction. Osseous abnormalities are secondary to bone marrow involvement and can be visualized in the later stages of the disease.

In patients treated for lung cancer, FDG-PET offers prognostic value that correlates strongly with survival rate. Patients with positive FDG-PET results have a significantly worse prognosis than those with negative results.

Mesothelioma

Benign fibrous mesothelioma is a rare, nonmalignant, localized tumor of the pleura that is unrelated to asbestos exposure. The tumor can be cured by excisional surgery. In contradistinction, the median survival for patients with malignant mesothelioma is 12 to 18 months. Thus, it is important to differentiate between benign lesions and malignant mesothelioma. Distinction based on histopathological criteria is difficult even for pathologists who specialize in this area.

The radiologic appearances of benign and malignant pleural diseases are very similar. More than 50 percent of patients have a pleural effusion at the time of diagnosis; however, pleural fluid cytology is positive in only approximately 25 percent. Currently, definitive diagnosis is based on thoracoscopic biopsy, which, for malignant mesothelioma, carries the risk of tumor seeding along the operative tract. CT scanning and MRI can not always differentiate between benign and malignant pleural processes.

Findings from CT and MRI studies can be used in tandem with those from FDG-PET in managing these difficult patients. Several studies have shown that FDG-PET can

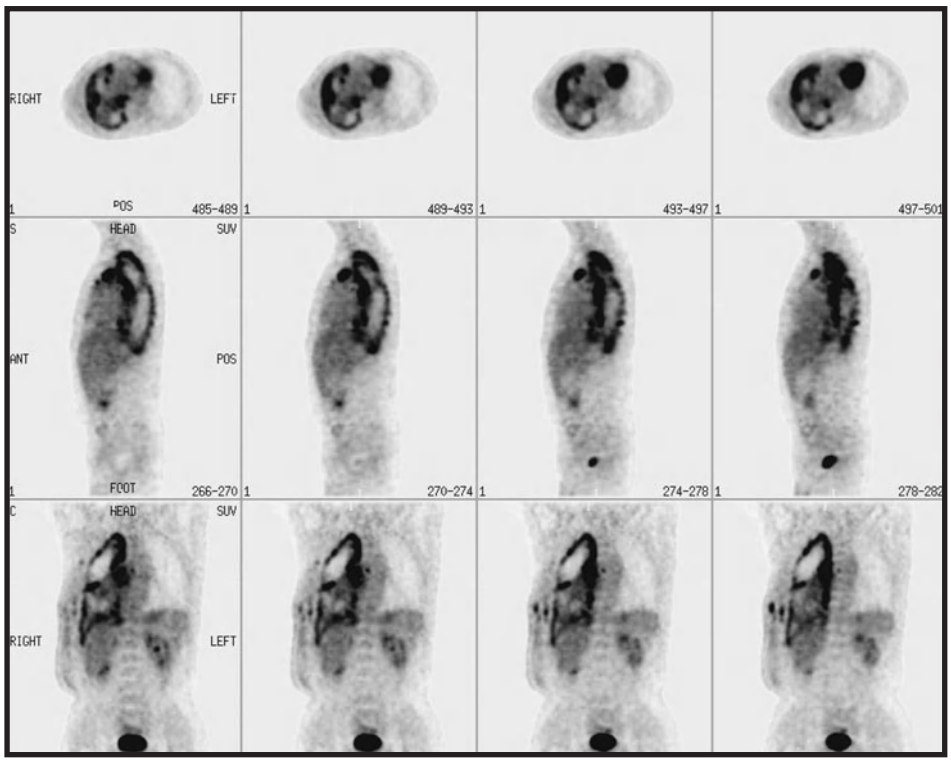

Figure 33-15 Transaxial, sagittal, and coronal views of FDG-PET scan demonstrating diffusely increased FDG activity throughout the diaphragmatic, mediastinal, and lateral right pleura, consistent with malignant mesothelioma.

accurately assess malignant transformation of reactive pleural disease, and in this regard, FDG-PET is clearly superior to CT scanning. Using an SUV cutoff of 2 to differentiate between benign and malignant mesothelioma, FDG-PET has a sensitivity of 91 percent and specificity of 100 percent and provides excellent correlation with thoracoscopic findings.

FDG-PET is also useful in identifying the extent of disease locally and in the mediastinum, evaluating abnormal findings in the contralateral lung, and detecting occult extrathoracic metastases (Fig. 33-15). High levels of FDG uptake correlate with a poor prognosis and shorter survival. FDG-PET also provides a semiquantitative index of disease activity that may be used to monitor the response to conventional or experimental therapies.

Integrated Positron Emission Tomography and Computed Tomography

In recent years, dual-modality integrated PET/CT scanners have been introduced. They hold the promise of improving the overall yield of diagnostic imaging by combining morphological and functional modalities.

In a prospective study of 50 patients with non–small-cell lung cancer, integrated PET/CT provided additional diagnostic information in 41 percent and was significantly more accurate in disease staging than either PET or CT alone. Integrated PET/CT provides important clinical information by virtue of accurate localization of known disease and identification of lesions that do not consistently accumulate FDG, such as carcinoid tumors and bronchioloalveolar carcinoma.

One of the advantages of the combined modality over PET alone in tumor staging is that PET is limited for T (tumor) staging, since the technique does not anatomically define tumor limits. In addition, PET/CT is particularly helpful in planning radiation therapy for patients with lung cancer associated with atelectasis. Currently, radiation therapy planning is based on CT imaging because of the close proximity of important structures to the radiation portals. A number of studies have demonstrated the added benefit of PET in defining and refining radiation treatment volumes, thereby reducing the radiation portal and allowing an increase in dose delivery to target tissues.

PET/CT without CT enhancement is unable to distinguish confined, centrally located tumors from those producing direct invasion of mediastinal structures. Therefore, clinicians still must rely on contrast-enhanced CT scans to help define mediastinal vascular invasion. Furthermore, in patients with extensive mediastinal disease or multiple areas of nodal involvement, N (nodal) staging can be readily accomplished. Exact localization of a solitary metastatic lymph node in the hilum (and, hence, classification as N1 or N2 disease) is somewhat difficult with PET alone; anatomic information provided by CT scanning as part of combined imaging is important for this purpose.

CT information is also essential for precise localization of lymph node metastases in patients with mediastinal shift due to atelectasis or anatomic variants. PET/CT offers the

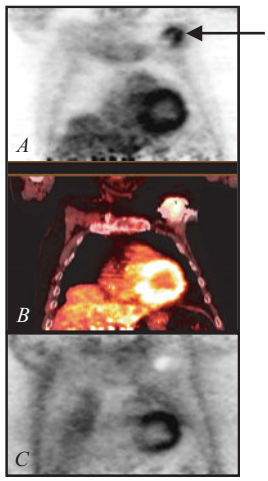

Figure 33-16 An attenuation artifact is seen in the left upper thorax as an area of increased activity on the coronal attenuation-corrected PET images (*A:* arrow). This is caused by an implantable cardioverter defibrillator (*B:* arrow), and corresponds in reality to a photopenic defect on the nonattenuation-corrected images (*C:* arrow).

advantage of determining the exact location of a focal abnormality noted on PET. PET/CT also enables exact localization of FDG in sites altered by radiation.

Assessment of multiple pulmonary nodules using FDG-PET is limited because of false-positive findings in instances of active granulomatous disease, such as tuberculosis, fungal disease, or sarcoidosis, or rheumatoid lesions. In this setting, pattern recognition on CT, in combination with FDG-PET, may improve characterization of the lesions. PET/CT increases the accuracy of malignant pleural mesothelioma staging and is important in determining appropriate therapy in patients being considered for extrapleural pneumonectomy.

Finally, PET/CT also has some limitations related to attenuation artifacts arising from use of high-density contrast agents or indwelling metallic structures, leading to false-positive results on corrected images (Fig. 33-16). Motion and misregistration between PET and CT images can also result in major artifacts in regions adjacent to the heart and diaphragm.

OTHER APPLICATIONS

Radionuclide-based techniques have been applied to investigation of other pulmonary entities, albeit on a much less frequent basis than those described previously.

Pneumonconioses

Pneumoconioses may be progressive, even after dust exposure has ceased. The inhaled particles activate pulmonary macrophages that secrete cytokines that mediate an inflammatory reaction, inducing fibroblast proliferation and collagen deposition. The intensity of pulmonary FDG uptake in pneumoconioses depends on whether active inflammation (increased uptake) or end-stage fibrosis (reduced uptake) predominates at the time of the scan. FDG is taken up by both fibroblasts and alveolar inflammatory cells. In addition, progressive massive fibrosis has been shown to be associated with increased FDG accumulation. The findings from FDG-PET have direct clinical implications; therefore, they are ineffective as therapeutic interventions in end-stage fibrosis. PET imaging using 18F-fluoroproline, which accumulates in lung scar tissue, holds promise for providing early assessment of this category of lung diseases.

Sarcoidosis

Hilar and mediastinal lymph nodes harboring active granulomas due to sarcoidosis accumulate FDG. Although FDG-PET

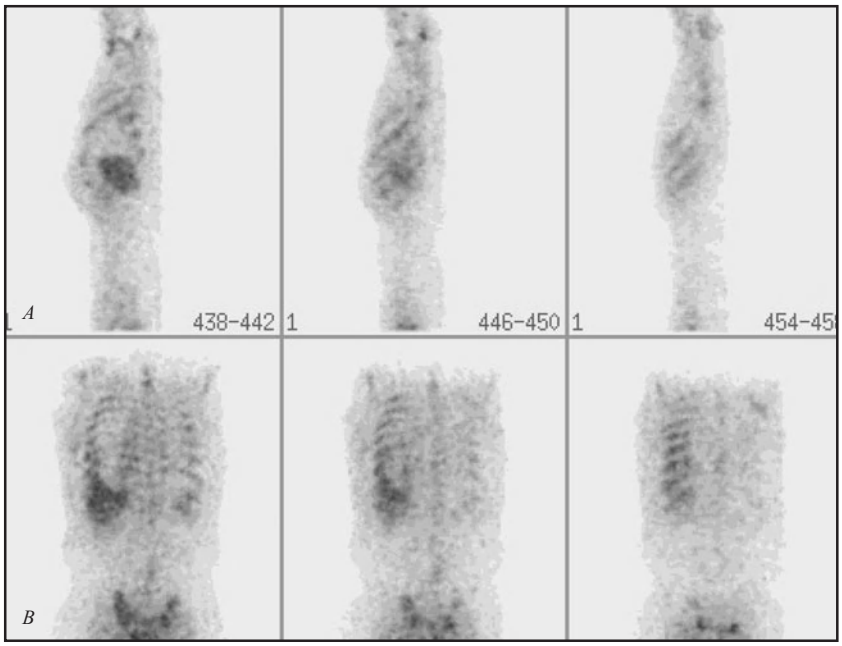

Figure 33-17 Sagittal *(A)* and coronal *(B)* FDG-PET images showing increased FDG uptake by intercostal muscles in a patient with severe COPD.

can not distinguish sarcoidosis from other diseases, such as Hodgkin's or non-Hodgkin's lymphomas, the technique is quite effective in assessing the extent of disease after an initial diagnosis is made. FDG-PET can also provide a means of assessing response to treatment.

Chronic Obstructive Pulmonary Disease and Accessory Muscles of Respiration

Physiologic FDG uptake is noted in strenuously contracting respiratory muscles in patients with COPD. In particular, uptake in intercostal, cervical, and abdominal muscles can be readily identified (Fig. 33-17). Muscular uptake may also be evident in the trapezi, scalenes, sternocleidomastoids, and paraspinal muscles.

Pulmonary Function Testing

Michael A. Grippi • Gregory Tino

The assessment of human pulmonary function dates back to the seventeenth century, when the earliest measurements of tidal volume were noted. In 1700, Humphrey Davy employed a hydrogen dilution technique to measure his own residual volume. Subsequently, John Hutchinson, in his treatise, *On the Capacity of the Lungs and on Respiratory Functions*, defined the functional subdivisions of lung volume and reported the results of vital-capacity measurements performed in more than 1800 subjects. He related these measurements to the subjects' height, age, and weight, thereby establishing a basis for determining normal values.

Progress in development of techniques for pulmonary function testing progressed slowly over the next century. However, in the 1950s, pulmonary physiologists made use of the tools provided by the evolving fields of electronics and computer science. Currently, many techniques exist for assessing both the integrated performance of the cardiovascular and respiratory systems and their individual components. This chapter focuses on commonly used tests of pulmonary function. Detailed assessment of integrated pulmonary and cardiovascular function is described in Chapter 35.

LUNG VOLUMES AND SUBDIVISIONS

Important quantitative aspects of respiratory function are the changes in lung volume with inspiration and expiration and the absolute volume of air that the lungs hold at various times during the respiratory cycle. These volumes and changes in volume are described below.

Definitions and Assessment

For purposes of quantification and comparison, the total volume of gas in the lungs is conventionally subdivided into compartments (volumes) and combinations of two or more volumes (capacities). For many of these subdivisions, the end-expiratory volume—the volume of gas remaining in the lungs at the end of normal expiration—is the point of reference. Lung volumes and capacities are defined in Table 34-1 and are depicted schematically in the tracing shown in Fig. 34-1, which was obtained using a device called a spirometer. The relationships between the volumes recorded directly by the spirometer and the other lung volumes and capacities—including total lung capacity (TLC), functional residual

Term	Symbol	Definition
Volumes		
Residual volume	RV	Volume of air remaining in the lungs after maximal expiration
Expiratory reserve volume	ERV	Maximal volume of air expired from the resting end-expiratory level
Tidal volume	TV*	Volume of air inspired or expired with each breath during quiet breathing
Inspiratory reserve volume	IRV	Maximal volume of air inspired from the resting end-inspiratory level
Capacities		
Inspiratory capacity	IC	Maximal volume of air inspired from the end-expiratory level (the sum of IRV and TV)
Vital capacity	VC	Maximal volume of air expired form the maximal inspiratory level
Inspiratory vital capacity	IVC	Maximal volume of air inspired form the maximal expiratory level
Functional residual capacity	FRC	Volume of air remaining in the lungs at the end-expiratory level (the sum of RV and ERV)
Total lung capacity	TLC	Volume of air in the lungs after maximal inspiration (the sum of all volume compartments)

** The symbol TV is traditionally used for tidal volume to indicate a subdivision of static lung volumes. However, the symbol V_T is used for tidal volume in formulas for gas exchange.*

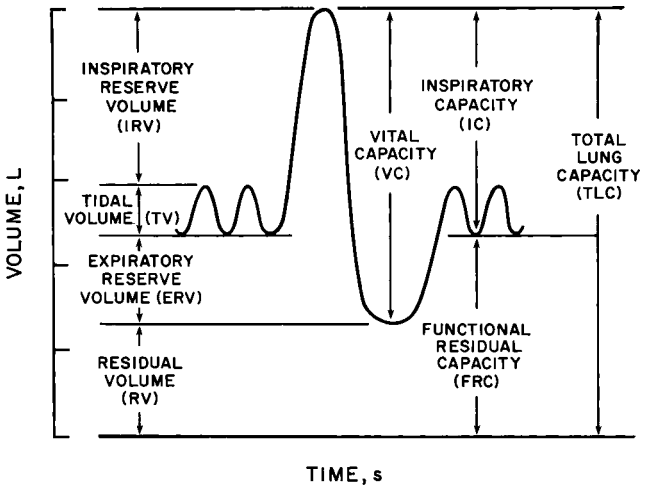

Figure 34-1 The subdivisions of lung volume as recorded by a spirometer. The record is generated on paper calibrated for volume in the vertical direction and time in the horizontal. The term *capacity* is applied to a subdivision composed of two or more *volumes*. The definitions of these subdivisions are found in Table 34-1.

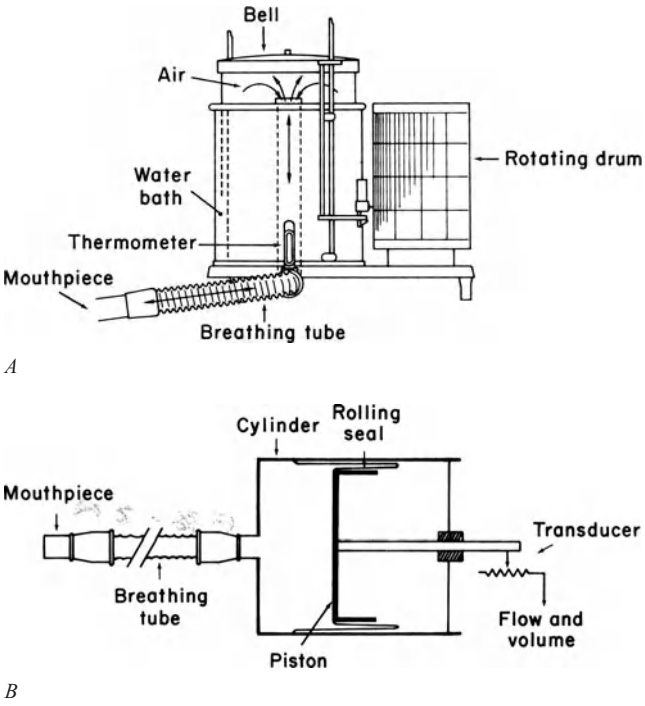

Figure 34-2 Two types of spirometers: water-sealed (*A*) and dry rolling-seal (*B*). Movement of air through the breathing tube results in movement of the bell (*A*) or piston (*B*). The output signal is either mechanical (pen on rotating drum) or electrical (flow and volume as voltage changes). The primary design criteria for these instruments are that inertia and resistance to airflow must be held to negligible levels, and the calibration must be accurate and stable.

capacity (FRC), residual volume (RV), and inspiratory capacity (IC)—are highlighted in the figure.

Spirometers that measure volume or change in volume vs. time have been used extensively in pulmonary function laboratories. Through manual calculations or use of computers, the relationship among volume, flow, and time could be generated to provide a measure of the respiratory system's ability to move air. Two examples of these volume-type spirometers are shown in Fig. 34-2.

In the water-sealed spirometer (Fig. 34-2*A*), a mouthpiece is attached to the tube through which air passes into a lightweight bell that is inverted over a water bath. Air movement through the mouthpiece into the bell during expiration causes the bell to rise; conversely, as air is withdrawn from the system during inspiration, the bell falls. The change in volume with time can be recorded on a calibrated rotating drum or digitally noted by a computer and displayed on a screen in both graphic and numeric formats.

In the dry, rolling-seal spirometer (Fig. 34-2*B*), a cylinder with a rolling plastic seal is substituted for the spirometer bell and its water seal. Movement of air through the mouthpiece effects a change in the position of the piston, which is attached to a variable resistor. The resistor, in turn, generates voltage signals proportional to volume changes reflected in displacement of the piston. These signals are processed by a computer to generate graphic and numeric outputs similar to those of the water-sealed spirometer.

Currently, most pulmonary function laboratories utilize flow-type spirometers using pneumotachographs or rotating turbines to determine airflow. Two types of pneumotachographs are in general use: hot-wire and flow-resistive. In the hot-wire type, air flowing past a heated wire cools the wire, thereby altering its resistance in proportion to changes in airflow. Flow-resistive pneumotachographs contain a resistive element composed of parallel tubes (Fig. 34-3), a wire mesh, or a fibrous, paperlike element. Airflow through the resistive element results in a pressure gradient across the

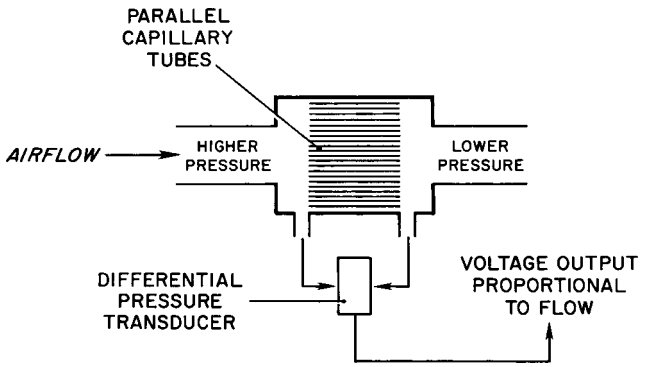

Figure 34-3 Principle of pneumotachography. During unidirectional airflow, a pressure drop is created across a resistive element made up of an array of parallel capillary tubes. The magnitude of the pressure drop is related to airflow, as described by Poiseuille's law for a laminar flow system. The pressure drop is transduced to a proportional voltage output, which can be recorded. A heating element (not shown) maintains the temperature of the expired gas near body temperature.

device, which can be measured by a very sensitive differential pressure gauge. In the model depicted in Fig. 34-3, the array of parallel small-bore tubes maintains a laminar gas flow pattern through the pneumotachograph. As a result, the pressure-flow characteristics of the system can be described by Poiseuille's law:

$$\Delta P = \dot{V}\frac{8\eta l}{\pi r^4}$$

where

ΔP = pressure drop across the resistive element, dyn/cm^2
$\dot{V}$ = gas flow, cm^3/s
η = viscosity of gas, dyn · s/cm^2
l = length of resistive element, cm
r = radius of resistive element, cm

Hence, under laminar flow conditions, the flow of gas in each tube is proportional to the pressure drop across the tube. The calculation for the overall pressure drop across the entire resistive element is based on the parallel arrangement of the array of tubes. The pressure drop across the resistive element is sensed by a pressure transducer and converted to a voltage output that is proportional to flow. The flow signal can be integrated electronically to yield volume. The output signals for flow and volume are displayed on a monitor and recorded.

Minimal standards have been established by the American Thoracic Society and the European Respiratory Society (Table 34-2) for spirometers used either for diagnostic purposes or patient monitoring.

In a diagnostic setting, spirometers are used to: (1) evaluate symptoms, signs, or abnormal laboratory tests; (2) measure the effect of disease on pulmonary function;

Table 34-2

Minimal Recommendations for Diagnostic Spirometry

Test	Range/Accuracy (BTPS)	Flow Range (L/s)	Time(s)	Resistance and Back Pressure	Test Signal
VC	0.5–8 L ± 3% of reading or ± 0.050 L, whichever is greater	0–14	30		3-L cal syringe
FVC	0.5–8 L ± 3% of reading or ± 0.050 L, whichever is greater	0–14	15	<1.5 cm H_2O/L/s	24 standard waveforms 3-L cal syringe
FEV_1	0.5–8 L ± 3% of reading or ± 0.050 L, whichever is greater	0–14	1	<1.5 cm H_2O/L/s	24 standard waveforms
Time zero	The time point from which all FEV_t measurements are taken			Back extrapolation	
PEF	Accuracy: ± 10% of reading or ± 0.30 L/s, whichever is greater Precision: ± 5% of reading or ± 0.15 L/s, whichever is greater	0–14		Mean resistance at 200, 400, 600 L/s must be <2.5 cm H_2O/L/s	26 flow standard waveforms
$FEF_{25-75\%}$	7.0 L/s ± 5% of reading or ± 0.200 L/s, whichever is even greater	±14	15	Same as FEV_1	24 standard waveforms
Instantaneous flows	±5% of reading or 0.200 L/s, whichever is greater	0–14		<1.5 cm H_2O/L/s	Proof from manufacturer
MVV	250 L/min at TV of 2 L within ± 10% of reading or ± 15 L/min, whichever is greater	±14 ± 3%	12–15	<1.5 cm H_2O/L/s	Sine wave pump

Note: BTPS = bady temperature and pressure, saturated with water vapor; VC = vital capacity; FVC = forced expiratory vital capacity; FEV_1 = forced expiratory volume in 1 s; PEF = peak expiratory flow; $FEF_{25-75\%}$ = forced expiratory flow, 25–75%; MVV = maximal voluntary ventilation; TV = tidal volume.

(3) screen persons at risk of having pulmonary disease; (4) assess preoperative risk; (5) assess prognosis; and (6) assess health status before enrollment in strenuous physical activity programs.

On the other hand, spirometers used for patient monitoring are used to: (1) assess therapeutic interventions, including bronchodilator therapy, management of congestive heart failure, etc.; (2) characterize the course of diseases affecting lung function (e.g., obstructive or interstitial lung diseases, congestive heart failure, or neuromuscular diseases); (3) track pulmonary function in persons working in occupations or receiving medications known to affect the lung; (4) evaluate large numbers of people in disability assessments; and (5) provide data as part of epidemiologic surveys.

In general, the diagnostic spirometer is used to assess a patient's lung function for purposes of comparison with values expected in a normal population. The monitoring spirometer, which is less expensive and more portable, is used to study a patient's performance over time and to study large numbers of people for epidemiologic or other purposes.

The Vital Capacity and Its Subdivisions

Two methods of performing a vital-capacity maneuver can be used: closed-circuit and open-circuit methods. In the closed-circuit method, the seated patient, with nose clip in place, breathes quietly into the apparatus. After several breaths to establish the resting end-expiratory level, which serves as a point of reference for all subsequent measurements, the patient is urged to inspire fully and then, after reaching a plateau at maximal inspiration, to expire maximally. This expiration must be performed slowly and evenly; attempts by the patient with obstructive pulmonary disease to maximize flow often reduce expiratory volumes because of dynamic compression of the airways caused by high positive pleural pressures (see Chapter 9). Figure 34-1 illustrates schematically this relaxed, or as previously known, slow vital capacity maneuver. From this record, tidal volume, inspiratory reserve volume, expiratory reserve volume, vital capacity, and inspiratory capacity are calculated. A similar maneuver in which the subject breathes out as rapidly and forcefully as possible after a maximal inspiration provides a measure of the forced vital capacity. Other timed measurements of expiratory airflow (e.g., the forced expiratory volume in 1 second, or FEV_1) are also determined from this type of record (see "Dynamic Mechanical Properties of the Respiratory System," below).

In the open-circuit method of determining vital capacity, the patient inspires maximally, inserts the mouthpiece, and then exhales with a slow, constant effort to the point of maximal expiration. With this technique, the resting end-expiratory position is not recorded. Thus, only the vital capacity, not its component volumes, can be measured. The open-circuit technique offers some advantages. Since the patient inspires from room air before expiring into the apparatus, concern over acquisition of infection from contaminated inspired air is minimized. In addition, the open-circuit method is generally completed in a shorter time, providing a major advantage when epidemiologic studies are being performed on large numbers of subjects.

Functional Residual Capacity and Residual Volume

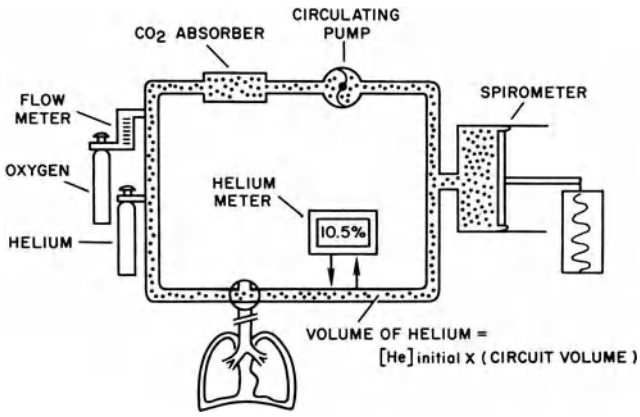
One compartment of the TLC that cannot be measured by spirometry is residual volume (RV), the volume of air remaining in the lungs at the end of a maximal expiration. RV is determined indirectly in three steps: (1) Functional residual capacity (FRC) is typically measured using one of three techniques: closed-circuit helium, open-circuit nitrogen, or total-body plethysmograph. (2) Expiratory reserve volume (ERV) is determined spirometrically. (3) RV is calculated as the difference between FRC and ERV. In principle, it is possible to determine the RV using a dilution technique or body plethysmography after maximal expiration. In practice, however, the resting end-expiratory level is a more reproducible starting point for determining FRC than is the maximal end-expiratory level for determining RV.

Closed-Circuit Helium Method

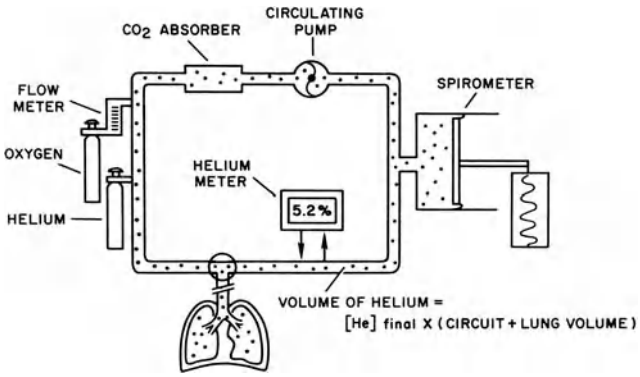
The closed-circuit helium dilution method for determining FRC is a variation of the hydrogen dilution method first used in the early nineteenth century. Both methods take advantage of the virtual insolubility of the test gas in body tissues and the law of conservation of mass. The development and simplification of this test were accomplished over a 20-year span in the mid-twentieth century. Schematic depictions of the principle upon which the technique is based and the apparatus used are shown in Fig. 34-4.

When a fully manual device is used for measuring FRC, the system is prepared by the addition of about 2 L of air and sufficient helium to achieve an initial helium concentration of approximately 10 percent in the apparatus. The patient, with nose clip in place, then breathes room air through the mouthpiece (Fig. 34-4*A*). After a preliminary period of quiet breathing to familiarize the patient with the mouthpiece, apparatus, and environment, and after the baseline resting end-expiratory level is established, the test begins.

At the end of a normal expiration, the valve at the mouthpiece is turned to connect the patient to the spirometer system (Fig. 34-4*B*). As the patient rebreathes from the closed circuit, the blower circulates the gas mixture. The CO_2 is absorbed by soda lime (CO_2 absorber), while O_2 is added through a valve and flowmeter at a rate corresponding to the subject's O_2 consumption. As the helium, which was at first contained entirely within the apparatus, mixes with air contained in the lungs, its concentration, as monitored by the helium analyzer, falls. Stabilization of the helium concentration, indicated by a rate of change in concentration of less than 0.02 percent over a 30-s interval, signals the point at which the helium concentration has equilibrated throughout the lung-breathing circuit system; equilibration, the end point of the test, occurs within 7 min in normal persons. However, in patients in whom the distribution of ventilation is abnormal (e.g., those with chronic obstructive pulmonary



A



B

Figure 34-4 Closed-circuit helium dilution method for measurement of functional residual capacity (FRC). *A.* Spirometer and tubing system with helium before subject begins breathing through the circuit. At the end of an expiration the mouthpiece valve is turned and the patient rebreathes through the circuit. Expired CO_2 is "scrubbed" out of the system, and O_2 is added to compensate for continued O_2 uptake in the lungs. *B.* During equilibration, the measured helium concentration falls, reflecting a dilutional effect of the additional volume (FRC) on the spirometer circuit.

disease) equilibration may take much longer. Upon equilibration, the following equation, based on the law of conservation of mass, is applied:

$$F_{0_{He}} \times V_0 = F_{F_{He}} \times V_F$$

where

$F_{0_{He}}$ = initial concentration of helium
V_0 = initial volume of system, L
$F_{F_{He}}$ = final concentration of helium
V_F = final volume of system, L

The initial volume of the system is the volume of the spirometer and circuit tubing, whereas the final volume consists of the initial volume plus FRC. The latter value is the only unknown in the preceding equation. Corrections are usually made for the small amount of helium dissolved in body tissues during the test and for slight volume changes caused by a respiratory exchange ratio that is not equal to 1.0. Although the method described here is based on a manually operated device, the same principles hold when all the mechanical and computational steps are accomplished with a computer-controlled system.

Nitrogen Washout Method

Conceptually, the nitrogen washout method is similar to the helium dilution method described previously; however, it relies on an open circuit rather than the closed circuit used in the helium dilution method. The open-circuit nitrogen washout method for determining FRC requires that the subject breathe 100 percent O_2 for 7 min; during this period, the concentration of N_2 in expired gas is monitored. When the expired N_2 concentration falls to zero, all the N_2 present in the lungs at the start of O_2 breathing has been "washed out." The total volume of gas expired and the concentration of N_2 in the expired gas are measured.

The calculation of FRC is based on the reasonable assumption that the volume of N_2 in the lungs at the start of the test (i.e., the product of lung volume and the concentration of N_2 in the lungs) is the same as the total volume of N_2 expired and collected during the period of the test (i.e., the product of the total volume of gas expired and the concentration of N_2 in the expired gas):

$$F_{0_{N_2}} \times V_0 = F_{E_{N_2}} \times V_E$$

where

F_{0N_2} = concentration of N_2 in the lungs
V_0 = volume of gas in the lungs, L
$F_{E_{N_2}}$ = concentration of N_2 in the expired gas
V_E = volume of expired gas, L

Since the test is started at the end of a quiet expiration, the volume of gas in the lungs is FRC. This volume is calculated by substituting into the above equation the initial concentration of N_2 in the lungs, estimated at 0.81 in fasting and 0.79 to 0.80 in nonfasting subjects, and the measured values for volume and N_2 concentration of expired gas.

Body Plethysmography

The word *plethysmography* is derived form the Greek *plethysmos*, meaning "enlargement." Although the concept of measuring FRC by recording changes in the volume of the body during "enlargement" of the chest was described in the late nineteenth century, it was not until 1956 that DuBois and coworkers introduced a practical plethysmographic technique, based on Boyle's law, for determining thoracic gas volume.

Any of three types of body plethysmographs can be used: (1) the *pressure plethysmograph*, in which pressure during breathing varies while volume remains constant; (2) the *volume plethysmograph*, in which volume varies during breathing while pressure remains constant; and (3) the *pressure-corrected flow plethysmograph*, which couples the pressure plethysmograph's fidelity of response to high-speed

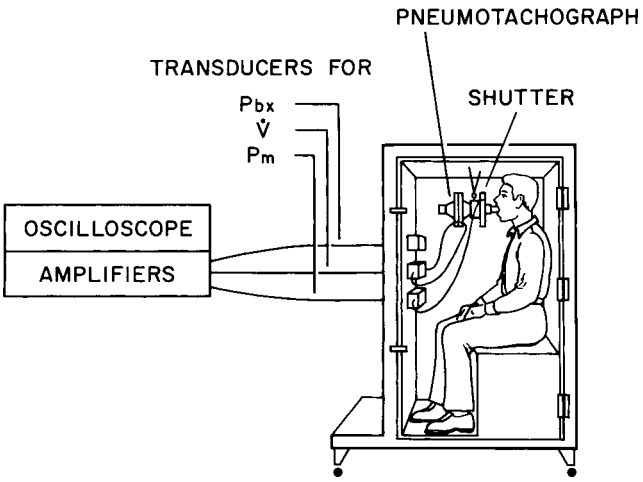


Figure 34-5 Constant-volume, variable-pressure plethysmograph used for measuring functional residual capacity and airway resistance. The device has a fixed volume. Thoracic gas volume changes associated with changes in alveolar pressure are reflected as changes in pressure within the plethysmograph.

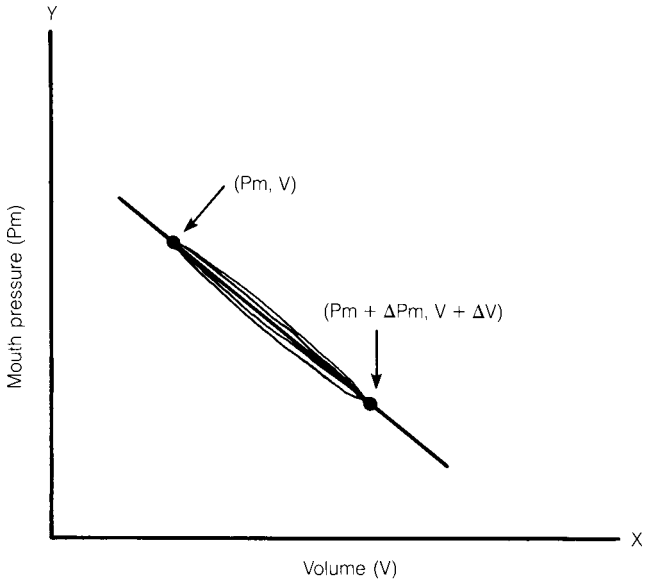

Figure 34-6 Pressure-volume loop obtained from a person seated in a body plethysmograph. Pressure at the mouth represents alveolar pressure; pressure in the box represents thoracic gas volume. After the shutter has closed at end-expiration (Pm, V), the subject attempts to inspire. Pm falls, and the pressure in the box increases. This increase in box pressure is calibrated in terms of an equivalent volume change. The new position of the trace at the end of the inspiratory effort is (Pm + Δ Pm, V + ΔV). The slope of the loop depends on the volume of gas in the lungs when the shutter is closed (FRC).

events with the volume plethysmograph's ability to follow large changes in volume. Since the conceptual basis for all three devices is about the same, only the most popular one—the pressure plethysmograph—will be described.

The pressure plethysmograph (Fig. 34-5) contains a pneumotachograph and transducer for measuring flow and volume and two strain-gauge transducers, one for sensing pressure at the mouth (Pm) and the other for sensing pressure in the box (Pbx). A solenoid-operated shutter mechanism is situated between the mouthpiece and the pneumotachograph. The three transducers are connected to an amplifying and monitoring system so that box pressure (or lung volume) and mouth pressure are displayed simultaneously on the X and Y axes, respectively, of an oscilloscope (Fig. 34-6).

In order to determine FRC, the patient, seated comfortably within the box with nose clip in place, is asked to breathe quietly through the mouthpiece. At the end of a quiet expiration, the shutter is closed and the patient is instructed to pant gently against it. The panting movements cause both mouth pressure and box pressure to change. With each inspiratory effort, as mouth pressure falls and gas in the lungs is rarefied, lung volume increases. Because the plethysmograph is a closed box, the increase in lung volume produces a corresponding increase in box pressure. With each expiratory effort, as lung volume decreases, box pressure falls. Because the shutter is closed while the measurements are made, mouth pressure equals alveolar pressure (P_A). These oscillations in mouth pressure and box pressure or lung volume appear on the oscilloscope as a closed loop (Fig. 34-6). Measurement of the slope of this loop is used to determine the volume of gas in the lungs at the time of shutter closure—i.e., thoracic gas volume (TGV or V_{TG}). When the occlusion occurs at resting end-expiratory lung volume, the measurement yields FRC (see below).

Applying Boyle's law to the plethysmographic determination of lung volume,

$$PV = (P + \Delta P)(V + \Delta V)$$

where

P = pressure in the lungs at end expiration (atmospheric pressure), cm H_2O
ΔP = change in pulmonary pressure produced by respiratory efforts, cm H_2O
V = volume of gas in the lungs at end expiration (FRC), L
ΔV = change in gas volume in the lungs produced by compression (during expiration) and rarefaction (during inspiration) secondary to respiratory efforts, L

In the pressure plethysmograph, ΔV is sensed as a change in pressure within the box, and ΔP is determined from the change in mouth pressure during breathing efforts against the closed shutter.

Rearranging the above equation and solving for V yield:

$$V = \frac{\Delta V}{\Delta P}(P + \Delta P)$$

However, since ΔP is small compared to P (atmospheric pressure), it may be disregarded. The equation then becomes:

$$V = P \times \frac{\Delta V}{\Delta P}$$

where

V = functional residual capacity, L
P = atmospheric pressure, cm H_2O
$\Delta V/\Delta P$ = inverse of slope of the loop on the oscilloscope

Therefore, the only unknown in this equation is V, which can be calculated by incorporating values for barometric pressure and the inverse of the slope of the plot of mouth pressure vs. box pressure ($\Delta P/\Delta V$).

Comparison of Methods

Compared to the dilution and washout techniques, body plethysmography is, by far, the fastest method available for determining FRC. Indeed, it enables several determinations to be made per minute. Although the equipment required for body plethysmography is more expensive than that required for the other methods, in a busy laboratory this technique generally proves to be more economical because of the time saved and the additional uses to which the equipment can be put (e.g., measurement of airway resistance; see "Airway Resistance," below). Technically, the test is only slightly more difficult than the inert gas dilution method.

Sources of error inherent in the use of body plethysmography and discrepancies between results obtained by body plethysmography and the inert gas techniques should be noted. In patients with chronic obstructive pulmonary disease (COPD) and asthma, values for FRC obtained by body plethysmography may be artifactually high because of pressure differences between the mouth and alveoli generated during panting across narrowed airways. Consequently, pressures recorded at the mouth during shutter occlusion of the airway underestimate changes in alveolar pressure.

The inert gas dilution and washout methods are similar both in principle and in results. The values for FRC with these techniques match those from the body plethysmograph except in persons in whom considerable areas of the lungs are poorly ventilated, usually due to obstructive airway disease. In these individuals, complete mixing or washout of the indicator gas is very slow, at times requiring 45 min or longer. Because of the slow equilibration of gas concentrations in the poorly ventilated areas, the usual time allotted for the test is inadequate, resulting in a lower value for FRC by the washout methods than by body plethysmography. One strategy commonly used to deal with this problem is to prolong the washout time. The primary advantage of these techniques over body plethysmography is that they can be used in persons for whom the plethysmograph is impractical (e.g., those with marked obesity, skeletal abnormalities, or claustrophobia).

Temperature Correction Factors

By convention, all lung volumes described above and airflows (see below) are expressed in terms of body temperature and pressure, saturated with water vapor (BTPS). This practice enables direct comparison of pulmonary function data from laboratories operating at different ambient temperatures and altitudes. To convert the volume of gas collected in a volume-type spirometer under ambient conditions (i.e., ambient temperature and pressure, saturated with water vapor, or ATPS) to BTPS, a conversion factor is applied (Table 34-3). Previously, it was presupposed that ambient air entering a spirometer was cooled *immediately* to ambient temperature and remained saturated with water vapor (ATPS). Under this assumption, only ambient temperature was considered in determining the appropriate correction factor. However, studies have addressed the assumption that expired gas is immediately cooled, as well as the practical consequences of temperature correction errors. The American Thoracic Society recommends temperature correction of results from volume-type spirometers based on *measured* gas temperature at the time of testing.

Table 34-3

Factors for Converting Volumes from ATPS to BTPS at Barometric Pressure of 760 mmHg*

Ambient Temperature, °C	Multiplier to Convert Volumes to BTPS†
20	1.101
21	1.096
22	1.091
23	1.085
24	1.080
25	1.074
26	1.069
27	1.062

* *Based on Boyle's, Charles's, and Dalton's laws.*
† *Volume at ATPS × multiplier = volume at BTPS.*
Note: ATPS = ambient temperature and pressure, saturated with water vapor; BTPS = body temperature and pressure, saturated with water vapor.

Radiographic Assessment of Lung Volume

Although initial reports describing use of radiographic techniques to measure lung volumes date back over 40 years, these methods have not found widespread use in adult populations. More sophisticated computed tomography (CT) applications have demonstrated good correlation with plethysmographic and gas dilution techniques in normal individuals, but

significant differences can arise in patients with a wide variety of lung diseases.

STATIC MECHANICAL PROPERTIES OF THE RESPIRATORY SYSTEM

Exploration of the elastic properties of the respiratory system and their effect on lung volumes and work of breathing began in earnest during the earlier part of the twentieth century. Although the groundwork had been laid centuries before (by Robert Hooke's *The Theory of Springs* in 1678), between 1923 and 1956 investigators provided a wealth of information about the elastic properties of the respiratory system and its components and the work done in overcoming these elastic forces during breathing.

Static Compliance of the Lungs

The elastic properties of the lungs are determined by relating the change in the volume of air contained in the lungs to the corresponding change in the recoil force of the lungs. Change in lung volume is most easily measured by determining the volume of gas inspired or expired at the mouth. Although expedient, this approach to determining the elastic properties of the lungs can underestimate the change in lung volume when incorporated into techniques (see below) that require the subject to expire gently against a closed shutter, a maneuver that compresses thoracic gas. However, the problem can be circumvented by placing the subject in a volume plethysmograph that uses a spirometer attached to the plethysmograph to record changes in thoracic gas volume due to gas compression.

The recoil force of the lungs, measured as the transpulmonary pressure (Fig. 34-7), is the difference between the alveolar and pleural pressures (P_A and Ppl, respectively). Alveolar pressure is determined as the pressure at the airway opening (Pao)—i.e., the mouth—when airflow is arrested and the glottis is open. The pleural pressure is determined indirectly by measuring the pressure in the esophagus using an esophageal balloon catheter. This technique, first introduced in 1949, has been improved over the years and provides accurate reflections of changes in pleural pressure at all lung volumes except those below FRC.

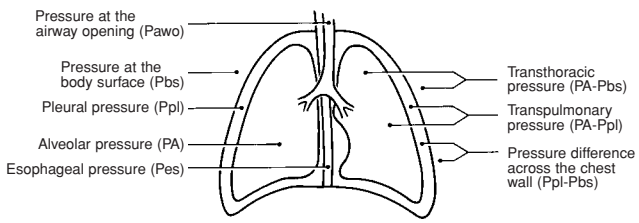

Figure 34-7 Schematic representation of the chest depicting pressure terms and gradients used in analysis of the mechanics of breathing. The expressions for individual pressure measurements on the left are relative to atmospheric pressure. Pleural pressure (Ppl) is not routinely measured directly but is approximated by esophageal pressure (Pes) measured with a balloon catheter.

A thin rubber balloon, about 10-cm long, is placed over a small-diameter polyethylene catheter. Several holes in the terminal portion of the catheter allow pressure to be transmitted from the balloon, through the catheter, to a transducer. The balloon is positioned in the lower third of the esophagus, where esophageal pressure and, therefore, balloon pressure accurately reflect the pressure acting on the lung surface (pleural pressure). Use of an elongated balloon of low volume helps to minimize changes in pressure due to esophageal contractions. By conveying mouth pressure and esophageal pressure to opposite sides of a differential pressure transducer, an output signal is generated that is proportional to the difference between these two pressures—i.e., the transpulmonary pressure P_A – Ppl.

To determine the elastic properties of the lungs, the patient, with esophageal balloon in place, is seated in a closed body plethysmograph. The patient then breathes ambient air through a tube to the outside until the volume trace, inscribed by the plethysmograph spirometer, indicates that the end-expiratory level is stable. At this juncture, the patient is instructed to first inspire slowly to TLC and then to expire slowly to the resting end-expiratory level (FRC). This maneuver is then repeated; during the second expiration, the shutter is activated to occlude the airway intermittently. Since each closure of the shutter interrupts the expiration briefly, the recorded trace of expiratory volume vs. time displays a staircase pattern (Fig. 34-8*A*). The plateau resulting from each closure of the shutter marks a finite period of zero change in lung volume as the lungs empty during expiration. Associated with each plateau is a corresponding plateau in transpulmonary pressure.

The relationship between the change in volume and the change in pressure is a measure of the *recoil force* of the lungs at each of the lung volumes that are registered (Fig. 34-8*B*). The resulting curve provides several useful indices of the elastic behavior of the lungs. The slope of the curve over the range corresponding to the tidal volume is the *static lung compliance.* The transpulmonary pressure attained at TLC is the *maximal static recoil pressure.* The ratio of the maximal static recoil pressure to the corresponding maximal lung volume is the *coefficient of retraction.* However, since these values are derived from only small segments of the curve, inspection of the total static pressure-volume curve remains the most comprehensive means of assessing the elastic properties of the lungs.

Static Compliance of the Chest Wall

Functionally, the chest wall includes the bony thorax, intercostal muscles, overlying soft tissue, pleura, and diaphragm. The chest wall is distensible and has its own distinctive elastic properties. In the normal, end-expiratory, resting position of the respiratory system (FRC), the inward recoil of the lung is balanced by the outward recoil of the chest wall (Fig. 34-9*B*). As the volume of the thoracic cavity enlarges

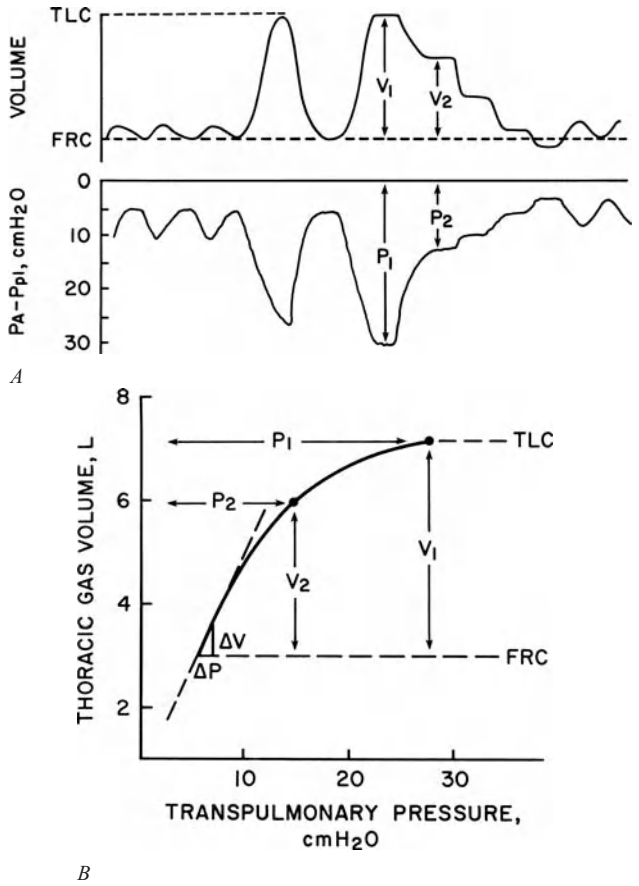

Figure 34-8 Measurement of the elastic properties of the lungs. *A.* Recordings of changes in lung volume and transpulmonary pressure (P_A-Ppl) using the esophageal balloon technique described in the text. Simultaneous measurements of volume and pressure are obtained during periods of arrested airflow at lung volumes ranging from total lung capacity (TLC) to just below functional residual capacity (FRC). *B.* Thoracic gas volume is plotted on the ordinate and transpulmonary pressure on the abscissa. The curve formed by the plot using values from *A* describes the elastic properties of the lungs. The slope of the line, $\Delta V/\Delta P$, over the range of the tidal volume is the static compliance of the lungs.

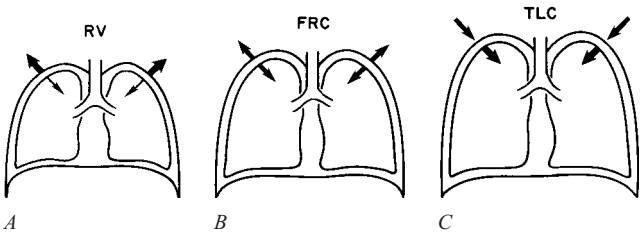

Figure 34-9 Schematic depiction of elastic recoil vectors across the lung and chest wall as determined by the level of inflation. *A.* At residual volume (RV), the outwardly directed recoil pressure of the chest wall is large and the inwardly directed recoil pressure of the lung is small. *B.* At functional residual capacity (FRC), the recoil pressures of the lung and chest wall are equal and in opposite directions. *C.* At total lung capacity (TLC), both recoil pressures are directed inward, and each contributes substantially to the overall recoil pressure of the respiratory system.

progressively during inspiration from FRC to TLC, the outward recoil pressure of the chest wall lessens, becoming zero at approximately 70 percent of TLC; beyond this point, the chest wall begins to recoil inwardly (Fig. 34-9*C*). Conversely, as the chest wall is compressed below FRC by the action of the expiratory muscles, the natural outward recoil tendency is increased (Fig. 34-9*A*).

In practice, assessment of the elastic properties of the chest wall is accomplished by first determining the compliance curve of the respiratory system as a whole and then subtracting the contribution of the lungs. For a given lung volume, the pressure across the chest wall, Ppl – Pbs (Fig. 34-7), is simply the difference between the transthoracic (P_A – Pbs) and transpulmonary (P_A – Ppl) pressures. As indicated above, Ppl is determined using an esophageal balloon catheter.

Elastic Properties of the Respiratory System as a Whole

The elasticity of the respiratory system as a whole is determined by measuring the change in volume resulting from a change in pressure applied to the system—i.e., the transthoracic pressure (P_A – Pbs)—*while the respiratory muscles are completely relaxed.*

The first method used for this evaluation employed the relaxation technique described by Rahn and colleagues. The subject breathes quietly into an apparatus consisting of a spirometer, a shutter, and a pressure transducer connected to the subject's side of the shutter (Fig. 34-10). After a period

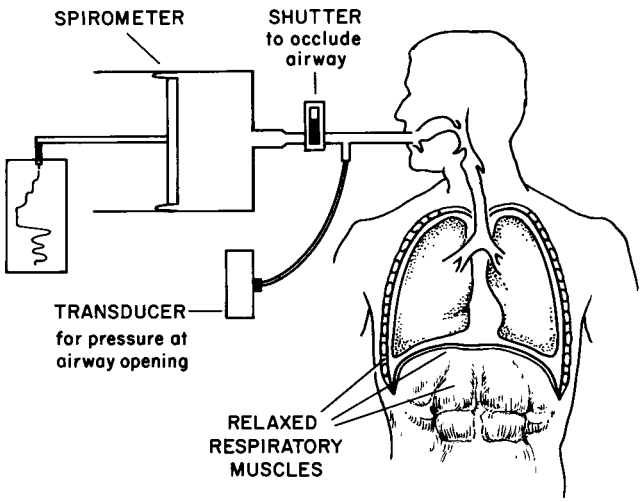

Figure 34-10 Relaxation technique for measurement of elastic recoil pressure of the respiratory system. After a period of normal tidal volume breathing, the subject inspires to total lung capacity (TLC). A shutter in the airway is closed, and the subject relaxes his or her respiratory muscles. The shutter is periodically opened, permitting exhalation of a small volume of air measured by the spirometer. Airway pressures are recorded at times of shutter closure (i.e., during no airflow, when mouth pressure equals alveolar pressure). A pressure-volume curve is then constructed from the simultaneously recorded values for pressure and volume.

of quiet breathing, the subject is instructed to inspire maximally; the shutter is closed at peak inspiration, and the subject is then asked to relax the respiratory muscles completely while keeping the glottis open. Periodically, the shutter is opened, allowing a small volume of air to move from the subject into the spirometer; the shutter is then closed again. This maneuver is repeated until FRC is reached. During the periods of arrested airflow, pressure at the mouth (Pao) is equal to the pressure in the alveoli (P_A). Provided the pressure at the body surface is atmospheric and the respiratory muscles are completely at rest, this value represents transthoracic pressure. In practice, however, full relaxation of the respiratory muscles is difficult, and a contribution by them to the pressure at the airway opening is frequently unavoidable.

A more practical technique entails the application of continuous positive pressure to the airways during spontaneous breathing. The subject breathes quietly into a water-sealed spirometer until a constant end-tidal level is achieved. A weight is then placed on the spirometer bell to increase the pressure in the respiratory system and, thereby, to raise the resting end-expiratory lung volume. This procedure is repeated using several different weights so that a pressure-volume curve of the total respiratory system can be constructed.

The individual pressure-volume curves for the lungs and chest wall and the composite curve for the intact respiratory system are shown in Fig. 34-11. As illustrated, the elastic recoil of the chest wall alone is determined by subtracting the recoil pressure of the lung from that of the total respiratory system. Chest wall elasticity is an important determinant of the subdivisions of lung volume and the overall compliance of the respiratory system; the latter is, in turn, an important determinant of the work of breathing.

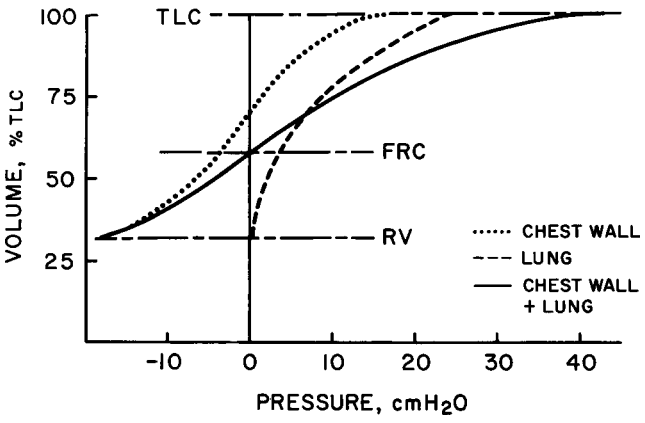

Figure 34-11 The pressure-volume curves of the respiratory system and its components. The elastic recoil pressures of the total respiratory system (solid line) over the vital capacity range are the sum of the recoil pressures of the lung (dashed line) and chest wall (dotted line). At functional residual capacity (FRC), the chest wall recoil pressure is counterbalanced by the lung recoil pressure. The net result is a total system recoil pressure of 0. The total system recoil pressure is obtained by relaxation pressure or continuous positive-pressure breathing techniques. The chest wall recoil pressure is calculated as the difference between the recoil pressure of the entire respiratory system and the recoil pressure of the lungs.

Several features of the pressure-volume relationships shown in Fig. 34-11 are worth emphasizing. As lung volume approaches RV, the elastic recoil pressure of the respiratory system is largely due to the outwardly directed recoil pressure of the chest wall. At RV, the contribution of the lung to the recoil pressure of the respiratory system is minimal. At the other extreme of lung volume, TLC, elastic recoil pressure is high and directed inwardly, due to the combined elastic recoils of the lung and chest wall. At FRC, the outwardly directed recoil of the chest wall balances the inwardly directed recoil of the lung, and the transthoracic pressure is zero (i.e., $P_A - Pbs = 0$). Indeed, the system "comes to rest" at FRC because of the counterbalancing of these forces at that volume. Since alveolar pressure at FRC is zero, no pressure gradient exists for airflow. Therefore, the system remains stationary until acted upon by the muscles of inspiration or expiration.

Elastic Properties of the Respiratory System in Health and Disease

The elastic properties of the respiratory system are altered by a wide variety of diseases that can affect the lung parenchyma or chest wall, either selectively or in concert. Most instances of clinically significant reductions in static compliance are due to abnormalities in the lung. The two standard clinical measures of the elastic properties of the lung are static lung compliance and maximal static recoil pressure.

Static lung compliance (Cst,L) is determined over the linear portion of the pressure-volume curve, between FRC and a lung volume corresponding to FRC plus 0.5 L. Normal values vary among laboratories, ranging from 0.147 to 0.375 L/cm H_2O, with a mean of 0.262 L/cm H_2O. Some variability is related to age and sex; Cst,L decreases with age and is higher in males than in females.

Maximal static recoil pressure is the recoil pressure at TLC. Once again, normal values vary. Data from one series of 51 normal subjects are shown in Table 34-4.

In disease states characterized by an increased elastic recoil pressure, such as diffuse interstitial fibrosis, the pressure-volume curve is shifted to the right and the static lung compliance decreases (Fig. 34-12*A* and *B*). The increased elastic recoil pressure contributes to a decrease in FRC and TLC. By expressing the volume axis of the pressure-volume curve in terms of *percent predicted TLC* (Fig. 34-12*B*), instead of *absolute TLC* (Fig. 34-12*A*), the reduction in maximal lung volume is clearly evident (i.e., maximal recoil pressure is increased, despite the reduced TLC).

In contrast to the effects of fibrosis, emphysema, which destroys alveolar walls and enlarges alveolar spaces, reduces lung elastic recoil pressure (Pel). This change increases both TLC and FRC. The shift of the pressure-volume curve upward and to the left (Fig. 34-12*A* and *B*) indicates that lung compliance increases and that the maximal recoil pressure decreases. If the volume axis is expressed as percent predicted

TLC (Fig. 34-12*B*), the increase in lung volume is more clearly demonstrated.

As noted previously, disorders affecting primarily the chest wall can also significantly alter the elastic properties of the respiratory system. Among these are obesity, kyphoscoliosis, and fibrothorax. These disorders limit chest wall excursion and lung expansion and reduce FRC. In addition, they produce decreases in static compliance of the lung and chest wall and maximal recoil pressure.

Respiratory Muscle Strength

Ventilatory performance depends not only on the mechanical properties of the lungs and chest wall, but also on the strength of the respiratory muscles. Evaluation of respiratory muscle strength was undertaken as early as the mid-nineteenth century. Subsequently, using simplified methods of measurement, Black and Hyatt established normal values (Table 34-5).

The maximal pressure generated by an isometric contraction varies directly with the resting length of the muscle. Consequently, values for maximal inspiratory and expiratory pressures depend on the lung volume at which the tests are performed (Fig. 34-13). When TLC is less than 70 percent of the predicted value, the maximal expiratory pressure will be low. Similarly, when RV exceeds 40 percent of the predicted TLC, the maximal inspiratory pressure will be low.

The only equipment required for measurement of maximal inspiratory or expiratory pressure is an aneroid vacuum and pressure gauge. To determine maximal expiratory pressure, the patient is urged to inspire fully to TLC and then to expire as forcefully as possible into the gauge. The highest pressure attained and held for at least 1 s is the *maximal expiratory pressure* ($P_{E_{max}}$). The *maximal inspiratory pressure* ($P_{I_{max}}$) is determined by having the patient inspire maximally from the gauge after having expired completely to RV. The value recorded is the lowest pressure attained and held for at least 1 s.

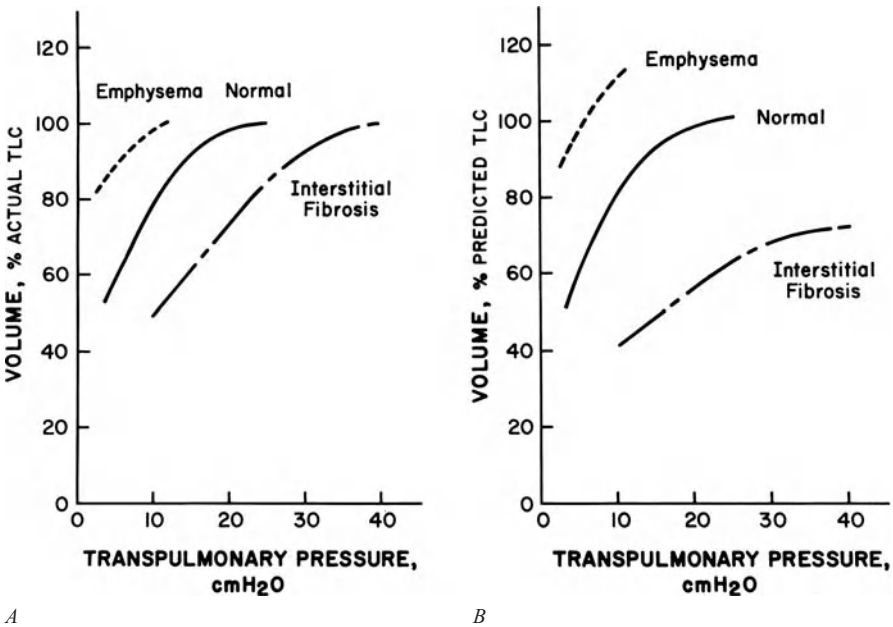

Figure 34-12 Pressure-volume curves of the lungs in health and disease. *A.* Volume expressed as percent of actual total lung capacity (TLC). Differences in transpulmonary pressures in normal and diseases states are evident. Changes in lung volume that occur with disease are demonstrated on the plots. *B.* Volume expressed as percent of predicted TLC. In addition to the differences in transpulmonary pressures, alterations in lung volumes in the disease states are evident.

Measurement of maximal static respiratory pressures is particularly important in evaluating respiratory muscle weakness in patients with neuromuscular disease, as described in Chapter 93. In such patients, spirometric tests are often normal, despite respiratory muscle weakness, because maximal pressures are not required to achieve maximal expiratory flow rates.

Another useful function of these measurements is in examining patients whose coordination in performing spirometry or whose degree of motivation is suspect. In such patients, determination of maximal pressures is often helpful in determining whether optimal efforts are being expended during pulmonary function testing (see "Approach to Interpreting Commonly Performed Pulmonary Function Tests," below).

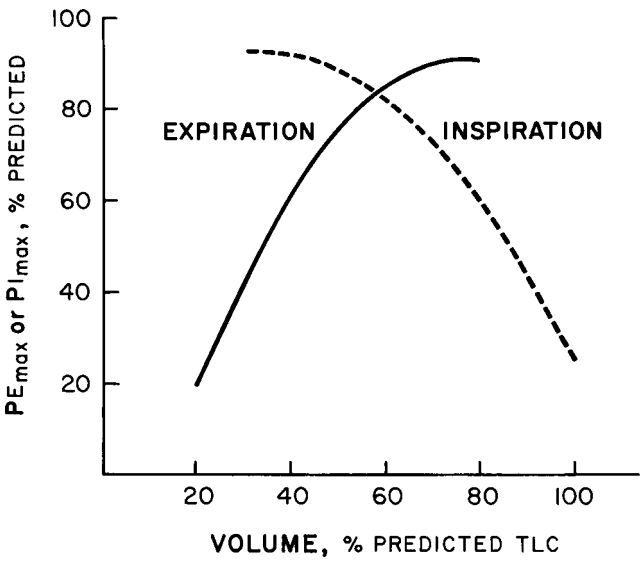

Figure 34-13 Effect of lung volume on maximal inspiratory (dashed line) and maximal expiratory (solid line) pressures. See text for discussion.

DYNAMIC MECHANICAL PROPERTIES OF THE RESPIRATORY SYSTEM

The static tests of pulmonary function described in the previous section are based on measurements of volume and pressure made while airflow is arrested. These static tests are particularly useful in defining the elastic properties of the respiratory system. Considerable additional information can be gained from tests done during airflow (i.e., under "dynamic" conditions).

Although measurements of static lung volumes began about 300 years ago, the assessment of pulmonary function during airflow began in 1933, when the test now known as the *maximal voluntary ventilation* was first proposed. This test did not become popular until a few years later, when Cournand and Richards developed regression equations to determine normal values. Subsequently, investigators proposed that the volume of air expired during specific time intervals be determined. In 1955, determination of the average airflow during the middle half of a forced expiratory vital capacity was described. Determination of these indices of dynamic lung function is now generally part of the battery of tests, both static and dynamic, included under the designation *spirometry.*

The more practical tests of dynamic function can, for convenience, be divided into four categories: forced vital capacity, flow-volume curves, maximal voluntary ventilation, and airway resistance. Other dynamic tests, including assessment of airway reactivity and the function of small airways, will be considered separately.

Forced Vital Capacity

Both expiratory and inspiratory measurements of the forced vital capacity are routinely made in pulmonary function laboratories. Unless otherwise specified, FVC refers to the forced *expiratory* maneuver.

Forced Expiratory Vital Capacity

The forced expiratory vital capacity is measured during expiration. The maneuver entails two steps: a full inspiration to TLC, followed by a rapid, forceful, maximal expiration (to RV) into a spirometer. The forced expiratory vital capacity (FVC) is normally equal to the relaxed or slow vital capacity (VC). However, a discrepancy between FVC and VC appears in obstructive disease of the airways: the FVC is less than the VC. The relationship between expired volume and time during an FVC maneuver is used to determine airflow during expiration and the volume of air expired within designated intervals; these values provide an indirect measure of the flow-resistive properties of the lung. The FVC is displayed in one of two ways: expired volume plotted against time (Fig. 34-14) or airflow plotted against lung volume—i.e., an expiratory "flow-volume curve" (see below).

The normal volume-time display of the FVC consists of a smooth curve with a gradually and progressively decreasing slope. Irregularities in the curve suggest either a failure of coordination or a suboptimal effort. At times, the onset of the forced expiration is unclear (Fig. 34-15) because of hesitation on the part of the patient. When this occurs, the start of expiration ("zero time") is determined with the "back extrapolation" method (Fig. 34-15): a tangent taken through the part of the curve with the steepest slope is extrapolated back to the maximal inspiratory volume; the point of intersection is considered to be the time of onset of expiration. Several values are commonly determined from the volume-time plot of the forced vital capacity (Table 34-6, Fig. 34-14): (1) the *volume expired in the first second*, expressed either as an absolute volume (FEV_1) or as a percentage of the forced vital capacity (FEV_1/FVC%); (2) *the volume expired in the first 3 seconds*, expressed either as an absolute volume (FEV_3) or as a percentage of the forced vital capacity (FEV_3/FVC%); and (3) *the forced mid-expiratory flow rate* ($FEF_{25-75\%}$). The $FEF_{25-75\%}$ is determined by locating the points on the volume-time curve corresponding to 25 and 75 percent of the FVC and then calculating the slope of a straight line passing through those two points. The slope of this line represents the average airflow over the mid-portion of the FVC.

Although the *relaxed* or *slow vital capacity* (VC) may be normal or only modestly reduced in patients with obstructive disease of the airways, the volume-time relationship of the FVC maneuver is usually distinctly abnormal in such

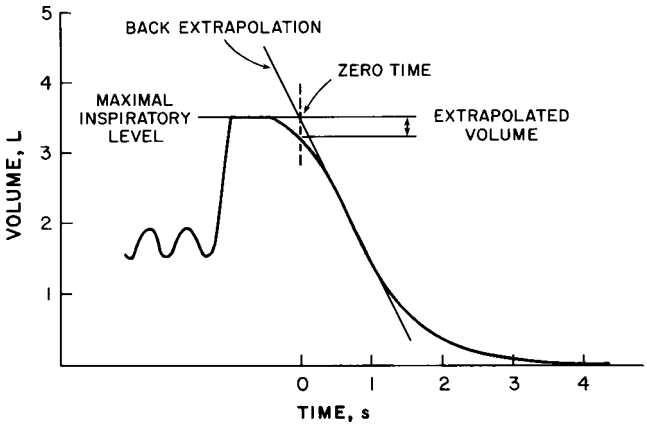

Figure 34-15 Technique of back extrapolation for determining the zero time in calculation of FEV_1. Zero time is determined as the point of intersection of a tangent drawn through the steepest portion of the spirogram and a line drawn horizontally through the maximal inspiratory level.

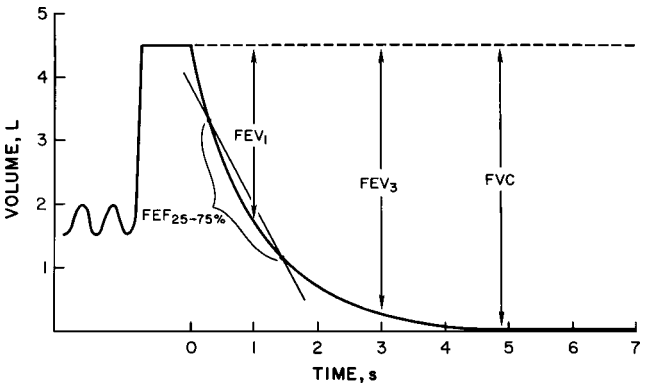

Figure 34-14 Forced expiratory vital capacity maneuver. After an initial period of tidal volume breathing, the patient inspires maximally to total lung capacity (TLC) and then exhales as rapidly and as forcefully as possible into a spirometer. Shown on the left of the tracing are a series of tidal volume breaths and the maximal inspiration to TLC. The forced expiration begins at time 0. Nearly all the volume is exhaled in the first 3 s of the maneuver. The values for FVC, FEV_1, and FEV_3 are measured from the maximal inspiratory level. The $FEF_{25-75\%}$ is the slope of the line connecting the points on the volume-time trace that correspond to 25 percent and 75 percent of the FVC.

Table 34-6

Values Obtained from Forced Expiratory Volume-Time Curves

FVC (BTPS), L	Forced vital capacity; the total volume expired
FEV_1 (BTPS), L	Volume of air expired in the first second
FEV_1/FVC%	Volume of air expired in the first second, expressed as percent of the FVC
FEV_3/FVC%	Volume of air expired in the first 3 s, expressed as percent of the FVC
$FEF_{25-75\%}$ (BTPS), L/s	Forced mid-expiratory airflow

Note: BTPS = body temperature and pressure, saturated with water vapor.

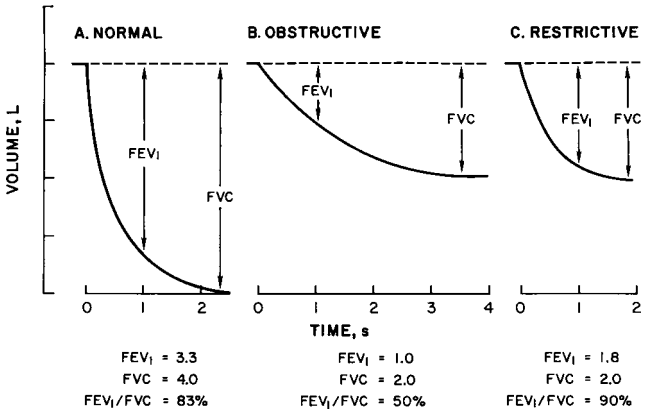

Figure 34-16 Representative spirograms from a normal subject (*A*), a patient with obstructive lung disease (*B*), and a patient with restrictive lung disease (*C*), obtained during a forced expiratory vital capacity maneuver. In the normal subject, expiration is completed within 3 s, and 83 percent of the volume is expired in the first second ($FEV_1/FVC\% = 83$). In the patient with obstructive disease, expiration is prolonged, and only half the volume is expired in the first second ($FEV_1/FVC\% = 50$). In the patient with restrictive disease, although the magnitude of the reduction in exhaled volume is the same as in the obstructed patient, most of the volume is exhaled within the first second ($FEV_1/FVC\% = 90$).

patients (Fig. 34-16*A* and *B*). Most obvious is a flattening of the slope of the curve at any given lung volume, reflecting the reduced airflow. In addition, the duration of the forced expiratory maneuver is prolonged. Normally, expiration is complete within 6 s; in obstructive airway disease, expiratory airflow may continue for 10 to 12 s. These changes in the expiratory airflow reduce the FEV_1 and FEV_3, the $FEV_1/FVC\%$, the $FEV_3/FVC\%$, and the $FEF_{25-75\%}$.

Restrictive lung disorders reduce the slow VC. However, the *configuration* of the volume-time relationship may not be abnormal (Fig. 34-16*C*). Although the FEV_1 and FEV_3 are reduced because of the reduced vital capacity, the $FEV_1/FVC\%$ and $FEV_3/FVC\%$ remain normal or even exceed normal values. Often, because of the reduced VC, the $FEF_{25-75\%}$ is also less than predicted.

Forced Inspiratory Vital Capacity

Measurement of the forced inspiratory vital capacity (FIVC) consists of two steps: (1) full expiration to RV, followed by (2) a rapid maximal inspiratory effort (Fig. 34-17). The rate of airflow over the middle half of the forced inspiratory vital capacity ($FIF_{25-75\%}$) is determined using a procedure similar to that described previously for the $FEF_{25-75\%}$.

In normal subjects, the $FIF_{25-75\%}$ is greater than the $FEF_{25-75\%}$. Since inspiratory flow is more dependent on effort than is expiratory flow, a fall in the $FIF_{25-75\%}$ is usually a more sensitive indicator of respiratory muscle dysfunction or a suboptimal effort than is the $FEF_{25-75\%}$. When airway resistance is high, a disproportionate fall in $FIF_{25-75\%}$ relative to $FEF_{25-75\%}$ suggests an extrathoracic site of airway obstruction (see "Approach to Interpreting Commonly Performed Pulmonary Function Tests," below).

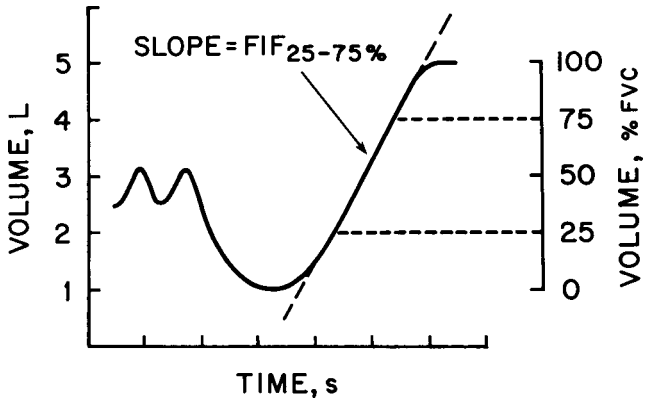

Figure 34-17 Forced inspiratory volume-time curve. The $FIF_{25-75\%}$ is the slope of a line between the points on the trace corresponding to 25 percent and 75 percent of the inspired volume.

Flow-Volume Relationships

In addition to analysis of the relationship between volume and time depicted on a spirogram, examination of the relationship between flow and volume provides useful information about lung function. A flow-volume curve, which shows the relationship between lung volume and maximal airflow as lung volume changes during a forced expiration, is shown in Fig. 34-18. The test comprises four phases of breathing into a

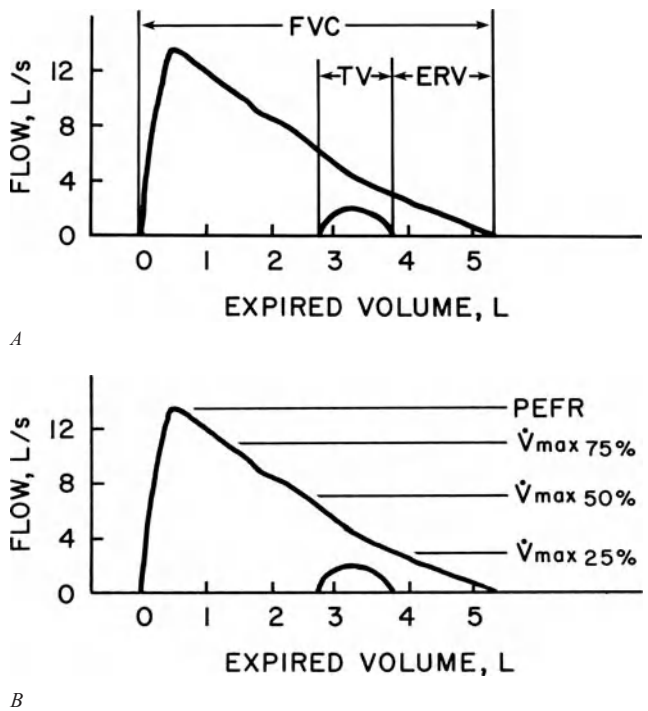

Figure 34-18 Flow-volume plots during forced expiration (outer trace) and quiet expiration (inner trace). *A.* The subdivisions of lung volume. *B.* The common flow measurements. PEFR = peak expiratory flow rate; $\dot{V}_{max\,75\%}$, $\dot{V}_{max\,50\%}$, and $\dot{V}_{max\,25\%}$ = flows at 75, 50, and 25 percent of the vital capacity, respectively.

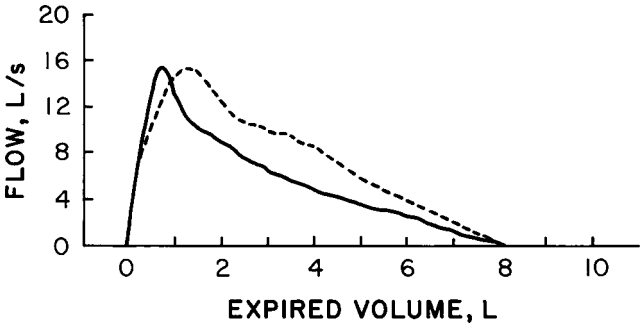

Figure 34-19 Comparison of the flow-expired volume curve (solid line) with a simultaneously recorded flow-thoracic gas volume curve (dashed line). The difference between the two curves results from the compression of gas in the lungs during a forced expiration.

spirometer: (1) tidal breathing for several breaths, (2) a maximal inspiratory effort to TLC, followed by (3) a maximal expiration to RV done as forcefully and quickly as possible, and (4) another maximal inspiratory effort to TLC. Volume is displayed on the horizontal axis and airflow on the vertical axis. Airflow is measured at the mouth using a pneumotachograph; volume is measured either by integrating the pneumotachographic record during expiration or as a change in thoracic gas volume, determined by a pressure-corrected flow plethysmograph. The records obtained by the two techniques for determining volume differ because the body plethysmograph senses compression of intrathoracic gas during a forced expiration, whereas measurements of volume made at the mouth do not (Fig. 34-19). Differences between curves obtained with the two techniques for measuring volume are most marked in patients with airway obstruction in whom considerable gas compression occurs during a forced expiration.

For the sake of comparison, tracings of flow vs. volume and volume vs. time, recorded during the same forced vital capacity maneuver and aligned by using a common volume axis as the abscissa, are shown in Fig. 34-20. Selected measurements are more evident in one tracing or the other (e.g., maximal expiratory flow in the flow-volume curve and FEV_1 in the volume-time curve).

Comparison of serial curves from a single person or curves from different subjects requires that the curves be aligned on the volume (horizontal) axis so that points of maximal inspiration or maximal expiration coincide. As may be seen in Fig. 34-21*A*, which illustrates typical curves from a normal subject and two patients, one with pulmonary fibrosis and the other with obstructive airway disease, the information provided by this form of representation is limited (i.e., the vital capacities and airflows from the patients are abnormally low). The limitation stems from the fact that the change in volume during expiration is shown relative to the *maximal inspiratory level* rather than to an *absolute volume* of gas in the lungs (i.e., RV or TLC). When RV or TLC is known so that absolute volumes can be plotted on the horizontal axis (Fig. 34-21*B*), additional insight is gained into the flow-volume relationship depicted in Fig. 34-21*A*. The patient

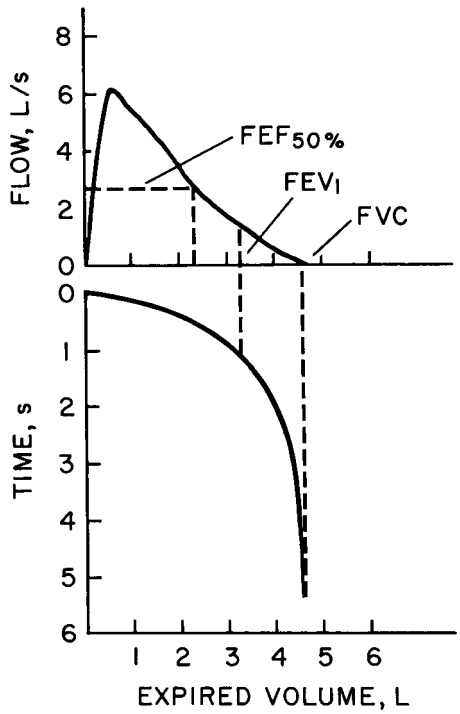

Figure 34-20 Flow-volume and volume-time curves depicting the same forced expiration aligned along a common volume axis (abscissa). Points corresponding to the FEV_1, FVC, and $FEF_{50\%}$ obtained from the volume-time plot are shown on the flow-volume curve.

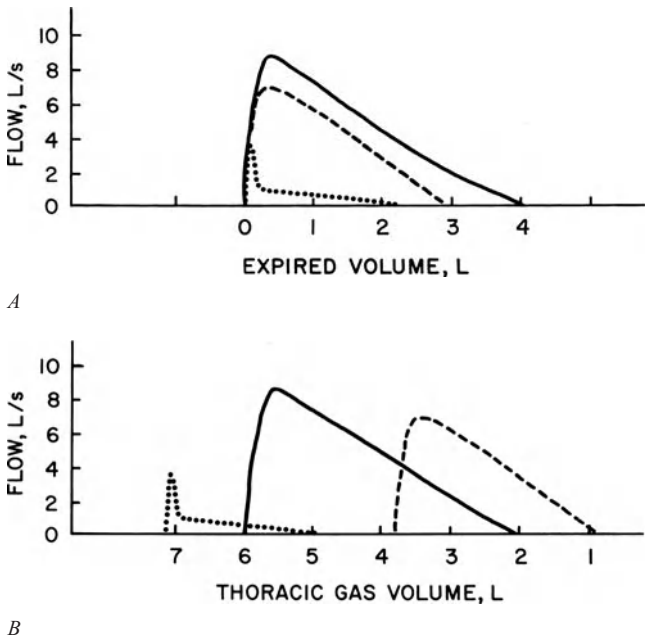

Figure 34-21 Airflow at different lung volumes. *A.* Flow-volume curves aligned at total lung capacity (TLC). *B.* Flow-volume curves displayed relative to thoracic gas volume. Although the curves aligned at TLC (*A*) show striking differences in the pattern of airflow, they provide no insight into the relationship between lung volumes and airflow. See text for discussion.

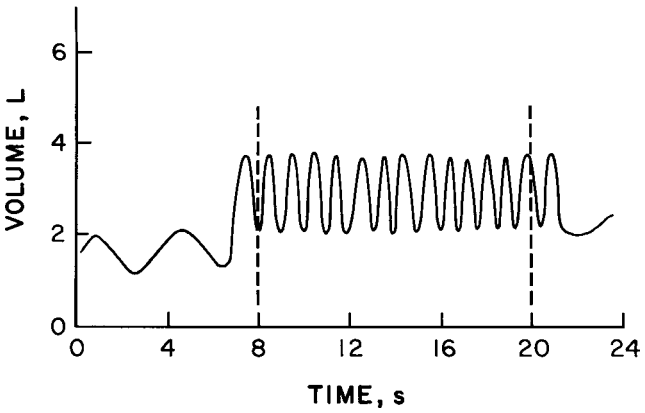

Figure 34-22 Maximal voluntary ventilation (MVV). After a period of relaxed breathing, the subject breathes rapidly and as forcefully as possible. The total volume of air inspired over 12 s and expressed in L/min is the MVV.

with obstructive disease of the airways manifests a reduction in expiratory airflow at elevated lung volumes, which should enhance airflow. In contrast, the reduced rate of airflow in the patient with pulmonary fibrosis is normal, or even supranormal, when the lung volume at which the airflow occurs is taken into account (i.e., the reduced airflow is primarily a function of the reduced lung volume, rather than of airway obstruction).

Maximal Voluntary Ventilation

The previous considerations of dynamic lung function focus on a single timed maximal expiratory or inspiratory maneuver. In contrast, the maximal voluntary ventilation (MVV) depends on the movement of air into and out of the lungs during continued maximal effort throughout a preset interval (Fig. 34-22). The MVV is a simple, informative test that provides an overall assessment of effort, coordination, and the elastic and flow-resistive properties of the respiratory system.

In performing the test, the patient is urged to breathe as hard and as fast as possible. As a rule, the patient automatically adjusts frequency and tidal volume for optimal performance. However, extremes of frequency or tidal volume are to be avoided, since neither panting nor slow deep breathing leads to the highest possible values. The total volume that is expired during a 12-s interval, expressed in liters per minute (BTPS), is the maximal voluntary ventilation. In some patients the test cannot be done because of an inability to continue the necessary effort for 12 s.

A normal value for MVV indicates that the overall integrated performance of the respiratory system is intact, thereby excluding moderate to severe restrictive or obstructive disease. In addition, a normal value suggests that the elastic and flow-resistive properties of the respiratory system, respiratory muscle strength, coordination of respiratory performance, and motivation of the patient are all normal. Although this test is very useful in detecting overall disturbances in integrated performance and diffuse tracheobronchial and pulmonary parenchymal diseases, other tests are required to pinpoint specific disorders.

The difference between the MVV and the resting minute ventilation is the *breathing reserve*. At one time, a low breathing reserve was correlated with the breathlessness in lung diseases. However, this determination is now primarily of historical interest.

Respiratory Resistance

Total respiratory resistance (Rrs) is the resistance to airflow and chest expansion offered by the airways (Raw), chest wall (Rw), and lung tissue (Rti):

$$\text{Rrs} = \text{Raw} + \text{Rw} + \text{Rti}$$

Although the overall resistance of the respiratory system can be determined with a technique employing forced oscillation, this approach has, to date, exhibited limited practical usefulness. In addition, further methodologic refinements permitting determination of *pulmonary resistance*—the sum of airway and tissue resistances (Raw + Rti)—have not proved to be worthwhile clinically, particularly since measurement of transpulmonary pressure with an esophageal balloon is necessary. Other variations of the determination of resistance measurements have also been explored. However, the only clinically useful measurement of resistance is airway resistance, which is now routinely determined in pulmonary function laboratories.

Airway Resistance

Airway resistance (Raw) is defined as the ratio of the driving pressure (P) for flow to the actual rate of airflow ($\dot{V}$) along the airways (i.e., the mouth, nasopharynx, larynx, and central and peripheral airways):

$$\text{Raw} = \frac{\Delta P}{\dot{V}}$$

where ΔP, the drop in pressure over the entire length of the airways, is determined as the difference between alveolar pressure (P_A) and pressure at the mouth (Pm) or airway opening (Pao).

Although airflow and pressure at the airway opening are easily measured, the difficulty in measuring alveolar pressure prevented the routine determination of airway resistance until DuBois and colleagues introduced the plethysmographic technique in 1956.

With this technique, the patient, seated in the body plethysmograph, pants at a rate of about two breaths per second while airflow is measured using a pneumotachograph. During inspiration and expiration, gas in the alveoli is alternately rarefied and compressed, causing changes in pressure within the sealed plethysmograph. The relationship between plethysmograph pressure and airflow during the panting maneuver is displayed on the X and Y axes of an oscilloscope (Fig. 34-23).

While the panting continues, a shutter at the airway opening is closed so that airflow is transiently interrupted.

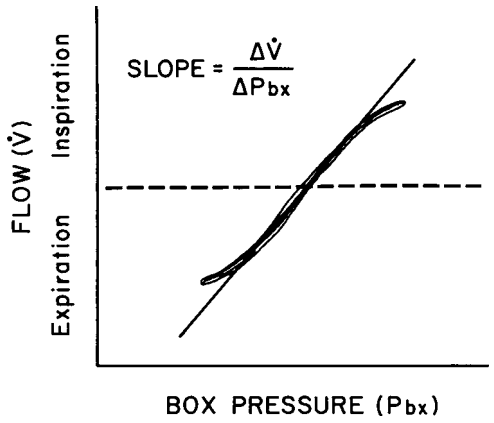

Figure 34-23 Plot of airflow (V̇) vs. body plethysmograph pressure (Pbx). The slope of this curve, in the range of 0 to 0.5 L/s of inspiratory flow, divided into the slope of the loop obtained when the shutter is closed (see Fig. 34-7) provides a measure of airway resistance (Raw).

Using the technique employed in the determination of FRC, changes in pressure in the plethysmograph (equivalent to changes in lung volume) and at the mouth are displayed on the X and Y axes, respectively, of the oscilloscope (Fig. 34-6). However, since airflow is zero while the shutter is closed, the pressure at the mouth equals alveolar pressure (Pao = P_A).

Panting while the shutter is open allows the determination of the relationship between airflow (V̇) and plethysmograph pressure (Pbx)—i.e., V̇/Pbx. Similarly, panting against a closed shutter enables the determination of the relationship between alveolar pressure (P_A) and plethysmograph pressure—i.e., P_A/Pbx. Airway resistance is calculated by dividing the slope of the loop obtained by plotting P_A vs. Pbx while the shutter is closed by the slope obtained by plotting V̇ vs. Pbx while the shutter is open:

$$\text{Raw} = \frac{P_A/\text{Pbx}}{\dot{V}/\text{Pbx}} = \frac{P_A}{\dot{V}}$$

where

Raw = airway resistance, cm H_2O/L/s
P_A = alveolar pressure, cm H_2O
V̇ = airflow, L/s

Raw is measured during a panting maneuver for several reasons: (1) The rapid respiratory frequency in panting circumvents the poor low-frequency response characteristics of many plethysmographs. (2) The small inspired and expired volumes, which minimize temperature fluctuations in the plethysmograph that would otherwise occur as tidal breaths of air at body temperature, are exchanged with breaths of air at room temperature. (3) During panting, the glottis remains open, thereby minimizing its contribution to overall airway resistance. Use of plethysmographs linked to microprocessors that automatically correct for temperature-related volume differences has made possible the determination of airway resistance during quiet breathing instead of during panting.

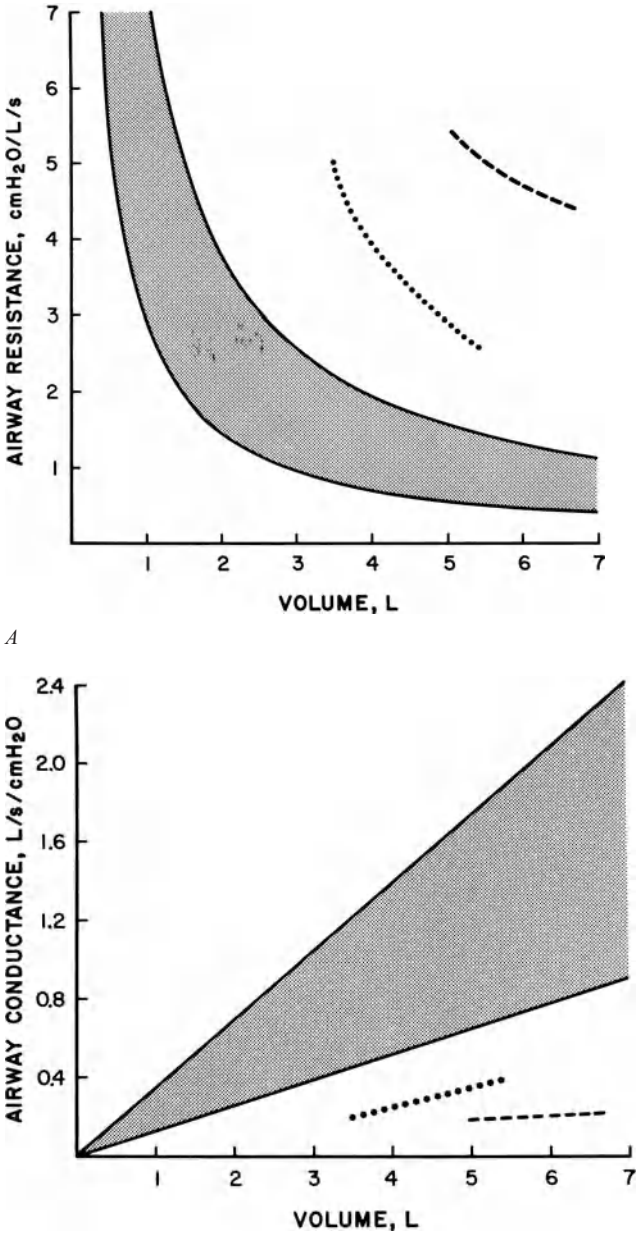

Figure 34-24 The relationship between airway resistance (*A*) and airway conductance (*B*). The shaded area represents the predicted normal range. Values are shown for an asthmatic patient before (dashed line) and after (dotted line) bronchodilator therapy. Airway resistance increases as lung volume decreases. Conversely, airway conductance, the inverse of resistance, decreases as lung volume decreases.

Airway resistance varies inversely with lung volume: it is low at large lung volumes and increases curvilinearly as lung volume and, consequently, airway diameters are reduced (Fig. 34-24*A*). In contrast, the inverse of airway resistance, airway *conductance*, is linearly related to lung volume (Fig. 34-24*B*). Interpretation of a given value for airway resistance or airway conductance requires that the lung volume at which the measurement is made be taken into account. *Specific conductance* (SGaw) is calculated by dividing airway conductance by the lung volume.

Table 34-7

Categorization of Increased Airway Resistance (Raw)

Category	Raw (cm H_2O/L/s)
Mild	2.8–4.5
Moderate	4.54–8.0
Severe	>8.0

Source: Modified from Ries A and Clausen JT, in Wilson AF (ed), Pulmonary Function Testing: Indications and Interpretations, *Orlando, FL, Grune and Stratton, 1985.*

Defining the range of normal for Raw is difficult because of the lack of data obtained from populations sorted into smoking and nonsmoking groups and because of the inter- and intraindividual variations of Raw with lung volume. One classification scheme proposed for defining normal and abnormal Raw in adults in whom FRC exceeds 2 L is given in Table 34-7.

At times, an apparent discrepancy occurs between forced expiratory flow rates and values for airway resistance. For example, although the FEV_1 and $FEF_{25-75\%}$ may be abnormally low (suggesting some degree of airway obstruction), Raw may be within normal limits (arguing against appreciable airway obstruction). This apparent contradiction arises because Raw is determined during *inspiration*, when airways are enlarged because of surrounding negative pleural pressure, whereas FEV_1 and $FEF_{25-75\%}$ are determined during a forceful *expiration*, when airways are compressed by high positive pleural pressures. Therefore, the discrepancy is simply a manifestation of dynamic airway obstruction in which the narrowing is confined to expiration.

Measurement of Exhaled Nitric Oxide

Over the last two decades, the important role of nitric oxide (NO) in a variety of biologic processes has been described. The concept that NO is a marker of airway inflammation, and, hence, has a potential role as a measure of airway function in the setting of inflammatory airway diseases, has been investigated. Studies have demonstrated that, at least in asthma, levels of exhaled NO are elevated during exacerbations (when other measures of airway inflammation show activity), even in the absence of symptoms or changes in spirometry. Levels of NO decrease with inhaled corticosteroid use and rise with corticosteroid tapering. Some advocate measurement of exhaled NO as part of routine chronic asthma management.

Standards have been developed for measuring exhaled NO levels. While exhaled NO measurement has not yet assumed the status of a "standard" pulmonary function test, pulmonary function laboratories will likely soon add the test to their repertoires.

AIRWAY REACTIVITY

The dynamic tests of airway function described previously are designed to determine intrinsic properties of the airways in a subject breathing room air at rest. In many clinical situations, such as evaluation of chronic cough, assessment of airway hyperresponsiveness is desirable. This section reviews *bronchoprovocation testing* (BPT), which assesses reactivity of the airways to selected pharmacologic or environmental agents.

Background

One test of bronchial reactivity that has been incorporated into routine pulmonary function testing is determination of the effect on airflow of administration of a nebulized bronchodilator agent. However, BPTs are designed to quantify the degree of bronchoconstriction following the application of a particular stimulus. A number of tests of bronchial reactivity are currently in clinical use (Table 34-8). Among the agents

used for inhalation challenges are methacholine, histamine, carbocholine, and specific antigens chosen in accord with the patient's history. In addition to the inhalation challenge tests in which pharmacologic agents are used, tests of bronchial reactivity may be based on inhalation of cold or dry air, isocapnic hyperventilation, or exercise.

Indications for Bronchoprovocation Testing

The principal indication for BPT is a history suggestive of bronchospasm induced by an environmental or occupational agent, generally in the setting of normal pulmonary function tests (including determination of airflow before and after administration of an inhaled bronchodilator). For example, comparison of FEV_1 before and after administration of a pharmacologic agent such as methacholine or histamine can be useful in establishing the diagnosis of asthma. Also, inhalation of a suspected specific antigen may be useful in uncovering asthma when skin tests are equivocal, or in proving that asthma is occupation-related. In some instances, exercise testing may disclose airway hyperreactivity in persons who are free of bronchoconstriction while at rest. Airway hyperresponsiveness to methacholine may presage an accelerated decline in pulmonary function. However, the impact of therapy with agents like inhaled bronchodilators or corticosteroids in preventing progression is unclear.

Table 34-9

Concentrations and Cumulative Doses of Methacholine Employed in the Methacholine Challenge Test

Methacholine Concentration (mg/ml)	Cumulative Dose (Inhalation Units)*
0.1	0.5
0.5	3
1.0	8
2.0	18
5.0	43
10.0	93
25.0	218

** After five inhalations of a nebulized solution containing methacholine in a concentration of 1 mg/ml.*

Methods of Bronchoprovocation Testing

Several methods of BPT are in general clinical use. These include methacholine challenge, exercise challenge, and antigen challenge, each of which is described briefly below.

Inhalation Challenge: Methacholine

Inhalation challenge using methacholine has become popular because of standardization of the technique, ease and safety of performing the test, and high sensitivity of the test in detecting asthma. Methacholine is a synthetic cholinergic agent that evokes airway smooth-muscle constriction. Because baseline pulmonary function and breathing pattern influence the site of deposition of the inhaled methacholine particles and, thereby, the response, a standard method for aerosolizing the agent is used to ensure reproducible results.

One method in common use is that of intermittent aerosol generation. Standardization entails the delivery of a 0.6-s pulse of airflow at 20 lb/in^2 to a nebulizer, which, in turn, discharges particles that range from 0.3 to 4 μm in diameter into the airways. Methacholine for delivery by aerosol is prepared in concentrations ranging from 0.1 to 25 mg/ml using bicarbonate-buffered isotonic saline (containing 0.4 percent phenol) as the diluent. The cumulative dose delivered is expressed in inhalation units. One inhalation unit is equivalent to the single inhalation of a solution containing 1 mg of methacholine per milliliter (Table 34-9).

At the outset, the patient is challenged with five inhalations containing only aerosolized diluent. The necessity of the diluent step has been recently questioned. In addition to adding time and expense, it may force a greater absolute drop in FEV_1 needed to prove bronchial hyperreactivity. A fall in FEV_1 below 90 percent of the baseline value (i.e., the prechallenge control FEV_1) establishes that the airways are hyperreactive, and therefore, the test is terminated. However, if the FEV_1 does not fall below 90 percent of the control value, increasing concentrations of methacholine are given in stepwise increments of five-breath inhalations. The breaths are taken slowly from FRC to TLC. Then, 1 to 1.5 min after each dose, an FVC maneuver is performed. The interval between each increase in concentration is kept to a minimum because the response is judged in terms of the *cumulative* dose. However, the deep inspiration that immediately precedes the expiratory portion of the FVC maneuver may decrease bronchomotor tone in airways narrowed by methacholine. This effect lasts up to 6 min, thus limiting the shortest acceptable interval between dosage steps. If the postchallenge FEV_1 falls below 80 percent of the control FEV_1, or if the patient experiences cough or chest tightness at any step, the test is stopped. The magnitude of the bronchoconstrictor response to inhalational challenge is related to the control FEV_1. A lower baseline FEV_1 (even in the normal range) correlates with increased bronchial reactivity. Additional measurements of dynamic airway function (e.g., specific conductance) may provide supplemental data but also prolong the study. Another dosing option in use is the 2-min tidal breathing protocol. This protocol typically yields results similar to the one previously described.

The results are plotted on four-cycle semilog graph paper: the number of cumulative inhalation units, expressed logarithmically, against the FEV_1, as percent of control

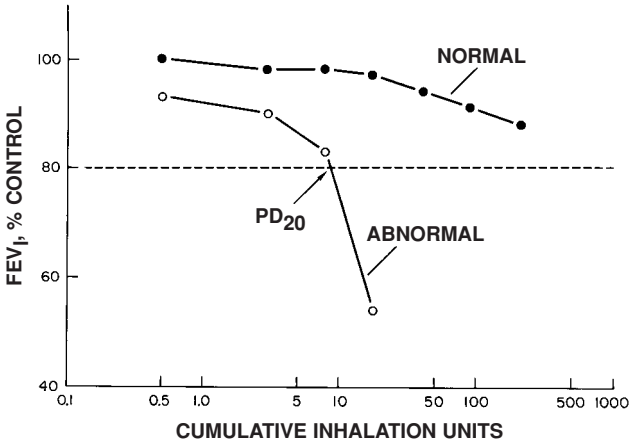

Figure 34-25 Plot of FEV_1, percent control vs. cumulative dose of methacholine administered by inhalation (logarithmic scale), to a normal subject and a subject with hyperreactive airways. The PD_{20} is the cumulative dose, which results in a 20 percent drop in the FEV_1 from the baseline measurement (after inhalation of diluent alone). In the subject with normal airway reactivity, the maximal cumulative dose of methacholine administered fails to elicit a 20 percent drop in FEV_1.

(Fig. 34-25). A curve is constructed through the points; the dose corresponding to the point at which the FEV_1 is 80 percent of the control FEV_1 is designated as the *provocation dose*, or PD_{20} FEV_1.

Exercise Challenge

Persons without a history of asthma who develop cough, wheezing, or dyspnea after exercise may have exercise-induced bronchospasm (EIB). In these individuals, an exercise test may prove useful in establishing the diagnosis. Such exercise testing in asthmatics can be useful to assess the degree of impairment during exercise, or the impact of therapies.

Several factors that may influence the outcome of the test should be kept in mind. The temperature and humidity of the laboratory should be tightly controlled. Some centers use dry air inhalation during exercise. In addition, the duration of the test needs to be monitored. The goal of testing for EIB is to produce at least 4 min of exercise at the target heart rate and ventilation. Exercise should not continue for more than 6 to 8 min, in order to avoid "run-through" of the bronchospasm (i.e., reversal at the end of the test).

The type of exercise also influences the outcome. As a rule, the more intense the exercise, the more likely is bronchoconstriction to occur. Free-range running provides the most potent stimulus for bronchoconstriction, followed by treadmill running, bicycle ergometry, swimming, and walking. An asthmatic may swim comfortably at a level of exercise that is incapacitating on the treadmill. The motor-driven treadmill or electromagnetically braked cycle ergometer are the preferred modes of exercise for formal testing.

The FEV_1 is the most useful measurement made during testing for EIB. Measurements are made just before and immediately after the exercise and at 5-min intervals for the following 30 min. A decrease in FEV_1 of 10 percent or more below the pre-exercise value constitutes a positive test. Some have suggested that a decrement of 15 percent is of greater diagnostic value. False- positive responses can occur in patients with vocal cord dysfunction or abnormal posterior arytenoid motion.

Inhalation Challenge: Antigen

Compared with the relatively safe methacholine challenge test, BPT using a specific antigen is unpredictable and potentially hazardous. Since establishing the minimum dose required to induce bronchoconstriction is difficult, too much of the antigen may be given. A late response, far more severe than the initial one, often develops about 6 h after the challenge. Despite these reservations about antigen challenge, testing is warranted under certain circumstances: (1) to uncover a particular agent in the environment that causes bronchoconstriction; (2) to establish the diagnosis of occupational asthma; (3) to prove that bronchoconstriction is caused by a particular antigen after routine skin tests have failed to support the clinical suspicion; and (4) to convince a skeptical patient about the cause of his or her asthma. Recommendations for preparing concentrations of antigens and the technique of antigen challenge testing are specific to the antigen in question and may be found in the literature. These tests should only be performed in laboratories that have considerable experience with BPT.

Precautions and Contraindications in Bronchoprovocation Testing

Although the overall risk of serious complications is low, BPT may be unnecessary, invalid, or even dangerous in some circumstances (Table 34-10). For example, the patient who manifests appreciable airway obstruction by conventional testing may develop life-threatening airway narrowing during BPT. In such a patient, a simple bronchodilator study would be more appropriate and informative. If bronchodilators fail to reverse the increase in airway resistance, and if it is important

Table 34-10

Bronchoprovocation Testing: Precautions and Contraindications

- Baseline FEV_1/FVC% <70
- Recent upper respiratory tract infection
- Recent influenza vaccination
- Recent administration of bronchodilator
- Ingestion of caffeine within 6 h before testing
- Cold-air breathing, hyperventilation, exercise within 6 h before testing
- Recent acute myocardial infarction or cerebrovascular accident, uncontrolled hypertension, or known aortic aneurysm

to prove that bronchial hyperreactivity does exist, BPT is sometimes done, with extreme caution, on another day, as antigen dosages are titrated carefully and details of the procedure monitored closely.

Absolute contraindications include severe airways obstruction (FEV_1 less than 50 percent predicted), myocardial infarction or stroke in the preceding 3 months, uncontrolled hypertension, or known aortic aneurysm. Moderate airflow limitation, pregnancy, lactation, and concurrent use of cholinesterase inhibitor medication represent relative contraindications.

A recent viral upper respiratory tract infection can cause airway hyperreactivity for up to 6 weeks in normal subjects. Similarly, influenza vaccination increases responsiveness to inhalation challenges in asthmatics for a few days to a week. In these conditions, BPT should not be undertaken until the sensitization effects of the infection or vaccination have worn off. Also, bronchodilators, including caffeine, should be withheld for at least 6 h before BPT, if possible, in order to prevent blunting of the bronchoconstrictor response. Finally, cold air, hyperventilation, and exercise should be avoided for at least 6 h before testing in order to prevent the induction of a refractory period or late response that would overlap the test results.

SMALL-AIRWAY FUNCTION

Up to this point, discussion of tests of dynamic lung function has addressed the tracheobronchial tree as a unit. Sometimes, however, particularly in cigarette smokers, obstructive disease is confined to the peripheral airways (i.e., those 2 mm or smaller in diameter). Because of their small contribution to airway resistance, estimated to be about 10 to 38 percent (at a lung volume equivalent to 50 percent of vital capacity), the small airways can undergo considerable damage before the usual tests of either static or dynamic lung function become abnormal. Consequently, efforts have been made to develop tests aimed at early detection of small-airway disease in the hope of early intervention to limit progression of the disease. The nature of small-airways obstruction and its impact on progression of COPD are currently being investigated.

In obstructive disease of the peripheral airways, the small airways' contribution to overall resistance increases, and abnormalities in their function may be detected from the expiratory vital capacity maneuver. In particular, abnormal values for $FEF_{25-75\%}$, in conjunction with normal values for FVC and FEV_1, are often useful in identifying small-airway disease. The basis for this approach is that $FEF_{25-75\%}$ measures airflow during the effort-independent part of the FVC, when the small airways contribute substantially to the limitation of airflow.

In addition to limiting airflow during expiration, obstruction of small airways results in abnormal distribution of ventilation to peripheral lung units. This abnormality forms the basis for two tests that, although not commonly performed, merit additional comment because of the relevant underlying physiology: frequency dependence of dynamic compliance and closing volume.

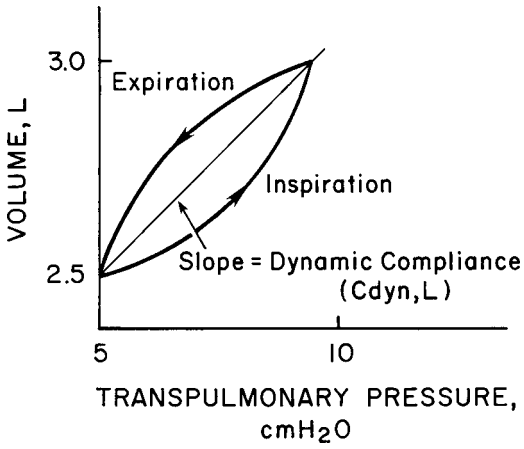

Figure 34-26 Measurement of dynamic lung compliance (Cdyn,L). During the inspiratory and expiratory phases of the respiratory cycle, a loop relating volume to transpulmonary pressure is generated. The slope of a line drawn through the points of zero airflow (at end-inspiration and end-expiration) is the dynamic compliance. Determination of Cdyn, L can be done at a variety of respiratory frequencies to assess the frequency dependence of compliance (Fig. 34-27).

Dynamic Compliance

Dynamic compliance, defined as the change in lung volume during airflow produced by a given change in transpulmonary pressure, is normally independent of breathing frequency. However, under conditions of nonuniformity of ventilation throughout the lung, increases in breathing frequency are associated with a fall in dynamic compliance. This frequency dependence of compliance was first noted in a patient with emphysema.

During the test, the patient, with an esophageal balloon in place, first inspires maximally to TLC and then expires to the resting end-expiratory position (FRC); the patient then breathes at a normal tidal volume and respiratory rate (15 breaths/min). In order to enable the patient to monitor these parameters, tidal volume and the resting end-expiratory level are displayed on an oscilloscope within sight of the patient. At the same time, changes in tidal volume and transpulmonary pressure are displayed on another oscilloscope (Fig. 34-26). The slope of the line connecting the end-inspiratory and end-expiratory points on the pressure-volume loop (i.e., the points of zero airflow) is the dynamic compliance. This procedure is repeated with breathing frequencies of 30 and 60 breaths per minute. Values for dynamic compliance (Cdyn,L) at the various frequencies are expressed as a ratio of the dynamic compliance to the static inspiratory compliance (Cst,L) or as a percentage of Cst,L (Fig. 34-27) for the same range of tidal volumes.

In normal subjects, Cdyn,L/Cst,L remains above 0.8, even at frequencies greater than 60 breaths/min. However,

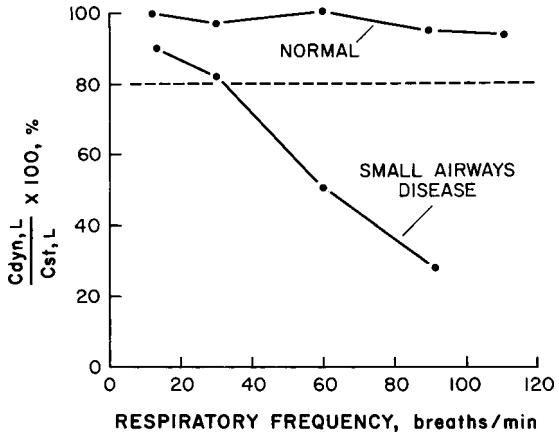

Figure 34-27 Determination of frequency dependence of dynamic compliance. Dynamic compliance is determined as shown in Fig. 34-26 and is expressed as a percentage of static lung compliance (Cdyn, L/Cst, L × 100, %) at a variety of respiratory frequencies. Normally, Cdyn, L is ≥80 percent of Cst, L and is independent of respiratory frequency. In patients with obstructive airway disease, including those with disease limited to the small airways, Cdyn, L falls relative to Cst, L as respiratory frequency increases.

in the presence of obstructive disease of the small airways, Cdyn,L/Cst,L falls progressively to values below 0.8 as breathing frequency increases. It is worth emphasizing that interpretation of frequency dependence of compliance with regard to small-airway disease is valid only if the static compliance and overall airway resistance are normal. Abnormalities in these other measurements indicate disease that is not likely to be confined to the small airways and for which frequency dependence of dynamic compliance is another manifestation. The physiological basis for the fall in Cdyn,L/Cst,L as respiratory frequency increases is the presence of unequal time constants throughout the lung (see Chapter 9).

Closing Volume

In 1949, Fowler described the single-breath nitrogen washout test for assessing the uniformity of ventilation throughout the lungs. In performing this test, the patient first expires maximally to RV before filling his or her lungs by taking a maximal breath of 100 percent O_2. During the subsequent expiration, the concentration of nitrogen at the mouth is continuously recorded and plotted against the volume of expired gas. Originally, interest focused on the initial part of the tracing that depicts the changing concentration in expired nitrogen as the first 750 to 1200 ml of gas is exhaled. Over this range, the change in nitrogen concentration in persons with normal lungs is less than 2.5 percent. In contrast, when abnormal lungs or disease of the tracheobronchial tree result in abnormal intrapulmonary distribution of inspired gas, the change in nitrogen concentration exceeds 2.5 percent.

Almost 20 years later, Fowler's test was modified to include a bolus of xenon at the beginning of inspiration and to record the concentration of xenon during the following expiration. Abrupt changes in the concentration of expired xenon as RV was approached suggested that important information about the small airways could be obtained from the terminal portion of the curve.

These observations with xenon rekindled interest in Fowler's original technique and also directed attention to the terminal portion of expiration. The procedure is depicted in Fig. 34-28. To perform the maneuver for this measurement, the seated patient takes two deep breaths of air and then expires to RV. At the end of this maximal expiration, a valve is opened so that the patient can take a full breath of 100 percent

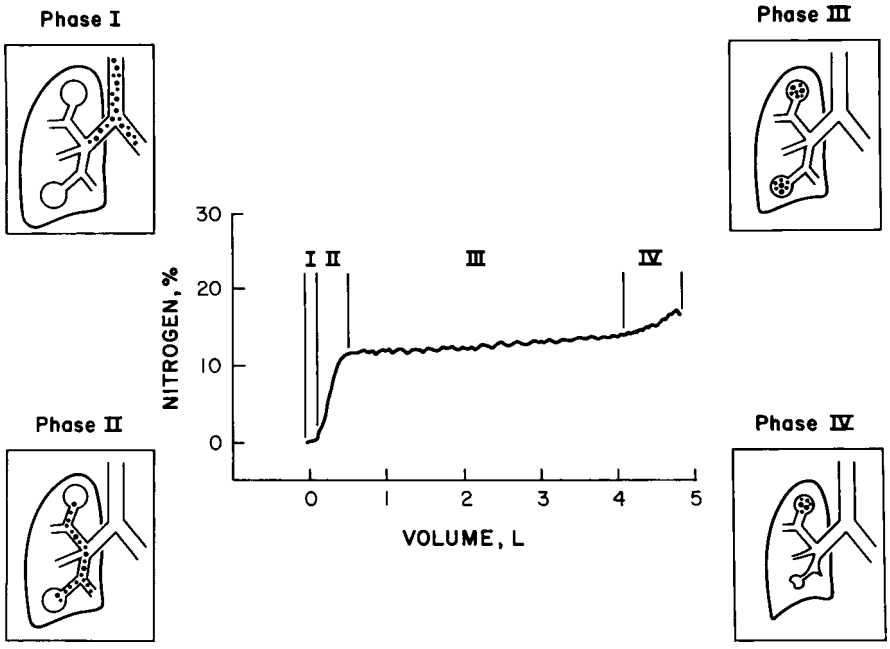

Figure 34-28 Contributions of different lung regions to the nitrogen concentration-volume curve obtained during the single-breath nitrogen washout test. See text for discussion.

O_2 to TLC. The patient then expires slowly to RV while N_2 concentration and expired volume are continuously recorded.

Four distinct phases can be identified in the continuous record relating N_2 concentration to expired volume. Phase 1, the initial expirate, contains virtually no N_2, since it derives from the O_2-containing dead space. Phase 2 represents a mixture of gases from the dead space and the alveoli. Phase 3 is due to a mixture of gases from alveoli located at the apices, midlung fields, and bases. Phase 4, characterized by an upward shift in N_2 concentration, is caused by closure of alveoli in the dependent parts of the lungs at low lung volumes. This final expirate derives from alveoli in the middle and upper regions of the lungs, where N_2 concentrations are higher than at the bases.

The explanation for these phases resides in the intrapulmonary distribution of gases during the respiratory maneuvers used in performing the test. In the normal upright person, a gradient of pleural pressures exists from apex to base, so that pleural pressure is more negative at the apices than at the bases. Because the alveoli at the bases operate on a lower portion of their pressure-volume curve (Fig. 34-11), they expand more than do apical alveoli per unit change in pleural pressure. However, the less negative pleural pressures and decrease in elastic recoil pressure at the bases also cause small airways to close during expiration as lung volume approaches RV. Thus, the pleural pressure gradient from top to bottom of the chest causes nonuniform distribution of gas within the normal upright lungs.

In the single-breath nitrogen washout test, a breath of 100 percent O_2 is taken, starting from RV. At RV, small basal airways are closed. Therefore, at the start of the O_2 breath, the N_2-containing air remaining in the dead space is preferentially drawn into the middle and apical lung zones as 100 percent O_2 gradually replaces air in the dead space. As the inspiration continues, the small airways at the bases open. Since their compliances are greater than those in the middle or at the top of the upright lungs, the inspired O_2 is then preferentially distributed to the bases.

During the expiration from TLC, the four phases then represent, as indicated above, the sequential emptying of dead-space gas and a mixture of dead-space and alveolar gas, followed by mixtures of alveolar gases from different parts of the lungs, as determined by the preceding intrapulmonary distribution of inspired O_2.

The volume from the onset of phase 4 to the completion of the full expiratory maneuver is termed the *closing volume* (CV). In healthy young adults, the normal closing volume averages about 10 percent of the vital capacity. Narrowing or obstruction of small peripheral airways causes closing volume to enlarge. The closing volume also increases progressively as people grow older, so that by the age of 50, the closing volume sometimes reaches 25 percent of the vital capacity. Cigarette smokers consistently experience an increase in closing volume. In both aging normal persons and cigarette smokers at any age, a decrease in pulmonary elasticity seems to be responsible for the increase in closing volume.

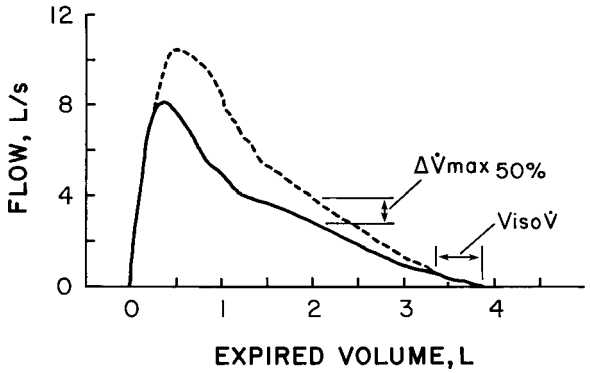

Figure 34-29 Maximal expiratory flow-volume curves generated in breathing room air (solid line) and breathing a helium-oxygen mixture (dashed line). The airflows achieved with the less dense helium mixture are higher than those with air at all but the lowest lung volumes. The point of first intersection of these two curves demarcates the volume of isoflow (Viso $\dot{v}$). The difference between the flows achieved when 50 percent of the vital capacity has been expired is the $\Delta V_{max,\%}$. The use of these measurements as indicators of small-airway disease is described in the text.

Helium-Oxygen Flow-Volume Curves

In 1963, the effects of changes in gas density and viscosity on maximal expiratory flow throughout the vital capacity range were described. Almost 10 years later, gas density and viscosity related concepts were applied to determine the site of airway obstruction in asthma. These principles were then applied for the specific purpose of detecting obstruction of small airways when other tests of pulmonary function were within normal limits.

The use of a helium-oxygen mixture to detect small-airway disease requires comparison of two maximal expiratory flow-volume curves, one that is generated while the patient breathes air and the other while the patient breathes helium and oxygen (Fig. 34-29). At least three maximal expiratory flow curves are obtained with room air and three with helium-oxygen.

In normal subjects, at lung volumes greater than 10 percent of the vital capacity (VC), the primary site of resistance to airflow is in the larger airways, where flow is turbulent and, therefore, density-dependent. At these lung volumes, the flow attained with the helium-oxygen mixture will be higher than that attained with air. At lung volumes less than 10 percent of the VC, the primary site of resistance is in the smaller airways, where flow is laminar and, therefore, not density-dependent. In this circumstance, the less-dense helium mixture has no effect on flow (Fig. 34-29). In disease of the small airways, the primary site of resistance shifts at large volumes from the larger to the smaller airways. As a result, the flow-enhancing effect of the less-dense gas disappears at volumes well above 10 percent of the VC.

In practice, two sets of maximal expiratory flow-volume curves are obtained, one while the subject is breathing air and the other after three VC breaths of the helium-oxygen mixture to replace at least 95 percent of the alveolar N_2. Comparisons

are then made of the superimposed curves (Fig. 34-29). One comparison is made at 50 percent of the VC in order to compare maximal expiratory flows (i.e., the $\Delta\dot{V}_{max,50\%}$); the other is at the volume at which the flows become identical—i.e., the *volume of isoflow* (V_{iso} $\dot{V}$). The curves are superimposed at RV or TLC, as long as the vital capacities of each curve are within 2.5 to 5.0 percent of the largest VC recorded.

The percentage change in expiratory flow while breathing helium-oxygen compared to air at 50 percent of the VC, $\Delta\dot{V}E_{max,50\%}$, is calculated as:

$$\Delta\dot{V}E_{max,50\%} = \frac{\dot{V}E_{max,50\%}(\text{helium-oxygen}) - \dot{V}E_{max,50\%}(\text{air})}{\dot{V}E_{max,50\%}(\text{air})} \times 100$$

where $\dot{V}E_{max,50\%}$ (helium-oxygen) and $\dot{V}E_{max,50\%}$ (air) are the expiratory flows at 50 percent of the VC during helium-oxygen and air breathing, respectively. As noted previously, the volume of isoflow is normally less than 10 percent of the VC; when it is increased, it indicates small-airway obstruction. The $\Delta\dot{V}E_{max,50\%}$ is also specific for small-airway disease, and unlike the closing volume, it is considered to be unaffected by changes in the elastic properties of the lung. Questions remain, however, about the validity and sensitivity of tests of density dependence of flow in assessing small-airway disease. Although they are conceptually attractive, the practical value of helium-oxygen flow-volume curves in detecting small-airway disease is debatable.

GAS EXCHANGE FUNCTIONS

Traditional measurements of the gas exchange functions of the lung include oxygen uptake ($\dot{V}O_2$), carbon dioxide elimination ($\dot{V}CO_2$), respiratory dead space (V_D), alveolar gas composition (P_{AO_2} and P_{ACO_2}), diffusing capacity for carbon monoxide ($D_{L_{CO}}$), and arterial blood gas tensions (Pa_{O_2} and Pa_{CO_2}). These determinations require a steady state of the ventilation and circulation and constant body stores of O_2 and CO_2. A steady state with respect to O_2 implies that O_2 uptake measured at the mouth equals the rate of O_2 transport across the alveolar membrane, and that, in turn, both rates are equal to O_2 consumption by the tissues. The same type of definition applies to CO_2 exchange in the tissues, in the alveolar capillaries, and at the mouth.

Ventilation, Oxygen Uptake, and Carbon Dioxide Elimination

The total volume of air breathed per minute ($\dot{V}E$) is the *minute ventilation*. It is equal to the product of the tidal volume (V_T) and the breathing frequency (f). As a rule, minute ventilation is determined by measuring the volume of expired gas relative to time. When the measurement is performed manually, the necessary equipment includes gas-collecting bags, low-resistance directional valves, a stopwatch, and a device for measuring gas volume. In practice, the patient, with nose clip in place, breathes through a mouthpiece for at least 3 to 5 min while expired gas is vented to the atmosphere. This preliminary period is intended to put the patient at ease and to achieve a steady state of respiration and circulation. When steady heart rate and breathing pattern are achieved, a valve is turned without the patient's knowledge, and expired gas is collected for 3 min.

The minute ventilation is determined by dividing the total volume of expired gas collected in the spirometer by the time of collection (3 min). The average tidal volume is obtained by dividing $\dot{V}E$ by the number of breaths per minute. Values for minute ventilation and tidal volume are expressed in terms of body conditions (BTPS). In the resting adult, the minute ventilation is typically 6 to 8 L/min; the corresponding tidal volume is 0.4 to 0.6 L.

The quantity of CO_2 in inspired air is negligible. Consequently, the amount of CO_2 produced per minute ($\dot{V}CO_2$) can be calculated as the product of the expired volume of ventilation ($\dot{V}E$) and the concentration of CO_2 in the expired air (F_{ECO_2}):

$$\dot{V}CO_2 = V_E \times F_{ECO_2}$$

Oxygen uptake ($\dot{V}O_2$) is calculated as the difference between the amounts of O_2 in inspired and expired air:

$$\dot{V}O_2 = (\dot{V}I \times F_{IO_2}) - (\dot{V}E \times F_{EO_2})$$

where

$\dot{V}I$ = inspired volume of ventilation, L/min
F_{IO_2} = concentration of O_2 in the inspired air
F_{EO_2} = concentration of O_2 in the expired air

In the steady state, O_2 uptake by alveolar capillary blood exceeds CO_2 output from alveolar capillary blood. As a result, the expired volume of gas is less than the corresponding inspired volume. Since N_2 does not undergo exchange in the lungs, the difference between CO_2 output and O_2 uptake results in a higher concentration of N_2 in expired air than in inspired air. Based on the change in nitrogen concentration, the inspired volume of ventilation can be calculated from the expired volume of ventilation:

$$\dot{V}_I = \dot{V}_E \frac{F_{E_{N_2}}}{F_{I_{N_2}}}$$

where

$F_{E_{N_2}}$ = concentration of N_2 in expired air
$F_{I_{N_2}}$ = concentration of N_2 in inspired air

In the normal, resting subject who is tested after several hours of fasting, the ratio of CO_2 output to O_2 uptake, the *respiratory exchange ratio* (R), is about 0.8. The respiratory exchange ratio at any instant is calculated by simultaneously determining the P_{O_2} and P_{CO_2} in an alveolar gas sample. As indicated above, in the steady state, the R determined by sampling alveolar gas equals the R of alveolar capillary blood, which, in turn, equals the R of the tissues. The steady-state R, when

alveolar gas, blood, and tissue are all in dynamic equilibrium, is the *respiratory quotient* (RQ). Hence, in the steady state, when the O_2 and CO_2 stores of the body are not changing, the RQ, reflecting cellular metabolism, can be determined by analyzing alveolar gas for O_2 and CO_2.

Unlike tidal volume and ventilation, which are expressed in terms of BTPS, $\dot{V}O_2$ and $\dot{V}CO_2$ are given in terms of standard temperature and pressure, dry (STPD).

Dead Space

Not all of the air breathed participates in gas exchange. Part of each breath remains in the mouth, nose, pharynx, larynx, trachea, bronchi, and bronchioles. This volume, the *anatomic dead space*, is about equal, in milliliters, to the subject's ideal body weight, in pounds (e.g., about 150 ml in a typical adult male). Inspired air reaching alveoli that are not exposed to pulmonary capillary blood also does not participate in gas exchange. This volume plus the anatomic dead space equals the *physiological dead space*. In a normal person, the anatomic and physiological dead spaces are virtually identical and constitute about one-third of the tidal volume.

Determination of the physiological dead space has proved to be of practical importance in a variety of clinical conditions. It is calculated by considering each breath (V_T) to consist of dead space (V_D) and an alveolar volume that participates in gas exchange (V_A):

$$V_T = V_D + V_A$$

Physiological dead space can be calculated using a modification of the *Bohr equation*, which recognizes that all of the test gas expired derives from two sources: the physiological dead space and the alveolar gas-exchanging volume. If we use CO_2 as the marker gas, the total amount of CO_2 eliminated per minute equals the sum of the CO_2 coming from the dead space per minute and from the alveolar compartment per minute:

$$\dot{V}_E \times F_{ECO_2} = (\dot{V}_D \times F_{ICO_2}) + (\dot{V}_A \times F_{ACO_2})$$

where

$\dot{V}_E$ = minute ventilation, L/min
F_{ECO_2} = fractional concentration of CO_2 in expired gas
$\dot{V}_D$ = minute dead space ventilation, L/min
F_{ICO_2} = fractional concentration of CO_2 in inspired gas
$\dot{V}_A$ = alveolar ventilation, L/min
F_{ACO_2} = fractional concentration of CO_2 in alveolar gas

Since, in a subject breathing room air, F_{ICO_2} is practically zero, the last equation is generally simplified as follows.

$$V_E \times F_{ECO_2} = V_A \times F_{ACO_2}$$

where V_E and V_A represent volumes of ventilation, rather than rates.

Recalling that $V_A = V_T - V_D$ and substituting partial pressures for the fractional concentration terms, the relationship becomes:

$$V_E \times P_{ECO_2} = (V_T - V_D)P_{ACO_2}$$

where P_{ECO_2} and P_{ACO_2} are the partial pressures of CO_2 in mixed expired gas and alveolar gas, respectively.

Assuming that arterial blood and alveolar gas are in equilibrium with respect to CO_2, when Pa_{CO_2} is substituted for P_{ACO_2} and the equation rearranged, it becomes:

$$V_D = V_T \frac{Pa_{CO_2} - P_{E_{CO_2}}}{Pa_{CO_2}}$$

Thus, if arterial blood is sampled during collection of expired gas, and if the partial pressures of CO_2 in expired gas and arterial blood are determined, the physiological dead space can be calculated. In order for the physiological dead space to be separated from the total dead space determined by the above equation, the dead space of the apparatus is subtracted from the value for total dead space.

Alveolar Gas Composition

In normal subjects, values for P_{O_2} and P_{CO_2} in an end-tidal sample approximate mean alveolar values. However, when imbalances exist in alveolar ventilation and blood flow because of lung disease, inhomogeneity in alveolar gas composition often invalidates the use of end-tidal gas tensions as a measure of mean alveolar gas composition.

In practice, mean alveolar P_{O_2} ($\bar{P}_{AO_2}$) and mean alveolar P_{CO_2} ($\bar{P}_{ACO_2}$) are often determined indirectly. Arterial P_{CO_2} is assumed to equal mean alveolar P_{CO_2} on the grounds of the narrow arteriovenous difference for P_{CO_2} across the lungs, the high solubility of CO_2, and the presumed role of pulmonary capillary blood as a tonometer. Mean alveolar P_{O_2} is calculated using the alveolar gas equation:

$$\bar{P}_{ACO_2} = P_{IO_2} - \bar{P}_{ACO_2}\left(F_{IO_2} + \frac{1 + F_{IO_2}}{R}\right)$$

The alveolar gas equation takes advantage of the fact that the total pressure of gases in the alveoli is equal to the sum of the partial pressures of the individual gases. This equation simply states that the mean alveolar P_{O_2} is the difference between inspired P_{O_2} and mean alveolar P_{CO_2}, allowing for a correction factor when the respiratory exchange ratio differs from 1.0.

Diffusing Capacity

The diffusing capacity of the lung for carbon monoxide (D_{LCO}) can be determined by steady-state, rebreathing, and single-breath methods. The most frequently used method is a modification of the single-breath method first described in 1915 and subsequently modified in 1957. Although the single-breath test has been shown to exhibit a large interlaboratory variation, it has proved to be a valuable measure of lung function in a wide variety of disease states. In fact, with continuing refinement of the standards, the variability, which

may be as much as 12 percent or greater, is likely to decrease; however, the variability will probably not be reduced to the range for vital capacity measurements (about 4 percent).

The diffusing capacity is intended to provide an estimate of the rate at which test molecules—usually carbon monoxide (CO)—move by diffusion from alveolar gas to pulmonary capillary blood. Factors that influence the measurement are the physicochemical properties of the test gas, the extent and thickness of the alveolar-capillary barrier, the resistance to diffusion offered by the red blood cell membrane, and the reaction rates of the test gas and hemoglobin, and pulmonary capillary blood volume. As a rule, the diffusing capacity is interpreted as an index of the surface area engaged in alveolar-capillary diffusion. Clinical entities that can reduce the diffusing capacity include parenchymal lung diseases, particularly interstitial lung disease, emphysema, pulmonary hypertension, and anemia. Polycythemia and alveolar hemorrhage syndromes, on the other hand, may increase the diffusing capacity.

Carbon monoxide has emerged as the most practical test gas because of its affinity for hemoglobin. The diffusing capacity for CO is defined as the amount of CO transferred per minute per mmHg of driving pressure:

$$D_{L_{CO}} = \frac{\dot{V}_{CO}}{\bar{P}_{A_{CO}} - \bar{P}_{c_{CO}}}$$

where

$D_{L_{CO}}$ = the diffusing capacity of the lung for CO, ml/min/mmHg (STPD)
$\dot{V}_{CO}$ = the amount of CO transferred, ml/min
$\bar{P}_{A_{CO}}$ = the mean alveolar PCO, mmHg
$\bar{P}_{c_{CO}}$ = the mean capillary PCO, mmHg

Since the blood P_{CO} in nonsmokers is essentially zero, the term $\bar{P}_{c_{CO}}$ is customarily neglected. In practice, $D_{L_{CO}}$ is determined by calculating $\dot{V}_{CO}$ as the difference between inspired and expired samples and estimating the mean alveolar Pco. Generally, one of two techniques is used to determine $D_{L_{CO}}$: the single-breath or the steady-state technique.

The Single-Breath Method

The breathing maneuvers required for the single-breath method consist of tidal breathing for a few breaths, unforced expiration to RV, and then a single full, rapid inspiration of a gas mixture containing approximately 0.3 percent CO and an inert gas—traditionally, 10 percent helium. (Some newer systems use methane.) The breath is held for 10 + 2 s and then rapidly expired. An inspiratory time of less than 4 seconds, and a sample collection of no more than 3 s are required. Longer expiratory times and sample collection time greater than 3 s should be noted in the test report. The initial portion of the expirate containing dead-space gas is discarded; the remainder is collected, and the concentrations of CO and helium are measured. A variety of automated systems are commercially available for performing the single-breath diffusing capacity. However, the essential components in all systems are a source of the special inspired gas mixture, a device for measuring the volume of gas inspired and expired, rapid response analyzers to measure the concentration of gases (see below), a timer, and appropriate valving and collection devices to trap the desired portion of the expirate.

The diffusing capacity of the lung for CO is calculated according to the following equation.

$$D_{L_{CO}} = \frac{V_A \times 60}{(\text{barometric pressure} - 47)} \times \text{time} \times \ln \frac{F_{A_{CO}}, \text{initial}}{F_{A_{CO}}, \text{final}}$$

where

V_A = alveolar volume
$F_{A_{CO}}$, initial = alveolar concentration of CO at start of breath hold
$F_{A_{CO}}$, final = alveolar concentration of CO at end of breath hold

The concentration of CO in the alveoli at the start of the period of breath holding ($F_{A_{CO}}$, initial) is calculated from the inspired concentration of CO and, for helium-based systems, the inspired concentration of helium and the expired concentration of helium, according to the equation

$$F_{A_{CO}},\ \text{initial} = \frac{F_{E_{He}}}{F_{I_{He}}} \times F_{I_{CO}}$$

where

$F_{E_{He}}$ = expired concentration of helium
$F_{I_{He}}$ = inspired concentration of helium
$F_{I_{CO}}$ = inspired concentration of CO

The concentration of CO in the alveoli at the end of the breath-holding period ($F_{A_{CO}}$, final) is equal to the concentration of CO in the expired gas. The alveolar volume (V_A) is determined in one of two ways. Originally, V_A was calculated as the sum of the RV, determined by the closed-circuit helium or body plethysmograph techniques described previously, and the volume of inspired gas, as recorded on the spirometer. Later, V_A came to be calculated from the single-breath dilution of helium that occurs during the determination of $D_{L_{CO}}$. Finally, the time of breath holding is measured (in seconds) from the spirometer recording of the maneuver.

Although the single-breath method is relatively simple and has the advantage of requiring no blood samples, breath holding is clearly artificial, and the maneuver is difficult for dyspneic patients. Therefore, a steady-state method is sometimes used.

The Steady-State Method

In the steady-state method, a gas mixture containing 0.1 percent CO is breathed until the rate of CO uptake from the lung is constant. CO uptake ($\dot{V}_{CO}$) is determined from the difference between the amount of CO in the inspired and expired gas using an equation similar to that presented previously for calculation of O_2 consumption.

Comparison of Single-Breath and Steady-State Methods

Certain differences between the single-breath and steady-state techniques merit special mention. The single-breath method is more popular because it is relatively easy to perform; it is well standardized, and it is less affected by nonuniformity of ventilation in comparison to the steady-state method. However, one drawback is that the patient is required to perform an inspiratory vital capacity maneuver of at least 88 percent of the VC and to hold his or her breath for 10 s. Another is that the test is extremely difficult to perform during exercise. The steady-state method is more attractive intrinsically than the single-breath method, since it requires no respiratory maneuvers and can be done during exercise. However, it does require an arterial blood sample (for determination of P_{CO_2}), and it is technically more difficult to perform.

The steady-state method for determining diffusing capacity tends to give lower values for the resting subject than does the single-breath method. The discrepancy is generally attributed to the fact that the surface area for diffusion is smaller during the quiet tidal breathing employed in the steady-state method than during the full inspiration to TLC, as required in the single-breath method. Also, during quiet breathing, some areas of the lung receive considerably less ventilation than during a breath hold at TLC.

Factors Other than Diffusion That Influence Test Results

A low D_{LCO} need not indicate a diffusion defect. A number of additional respiratory and nonrespiratory factors may reduce or increase the D_{LCO}. A reduction in the lung volume alone can reduce the D_{LCO}. Therefore, some laboratories "normalize" the diffusing capacity for lung volume by dividing D_{LCO} by alveolar volume—a manipulation that assumes a linear relationship between D_{LCO} and V_A, which is not the case.

Anemia artificially decreases the D_{LCO} as determined by either method, but the effect of low hemoglobin concentration can be adjusted by application of a correction factor. Conversely, polycythemia and intrapulmonary hemorrhage tend to increase the value for D_{LCO}. In fact, an unexpectedly high value for D_{LCO} may be a helpful clinical clue in detecting radiographically occult pulmonary hemorrhage.

Although the equation for D_{LCO} assumes that the CO back pressure in blood is negligible, the blood of a heavy smoker sometimes contains as much as 10 percent CO Hb. Such levels of CO Hb will be accompanied by appreciable concentrations of dissolved CO in the plasma. The resulting back pressure of CO will reduce the D_{LCO}. A correction equation may be applied to adjust the D_{LCO} for this effect.

Altitude also affects the D_{LCO}. P_{AO_2} falls with increasing altitude above sea level. The reduction in P_{AO_2} allows CO to diffuse more rapidly into the blood. A specific adjustment should be made for inspired oxygen partial pressure.

Measurement of diffusing capacity is quite useful in the evaluation of patients with a number of pulmonary conditions. Decrement in D_{LCO} has been shown to predict exertional hypoxemia. In addition, D_{LCO} levels have been correlated with disease severity and prognosis in primary pulmonary hypertension, idiopathic pulmonary fibrosis, and alveolitis associated with systemic sclerosis.

Arterial Blood Gas Composition

The determination of arterial P_{O_2} and P_{CO_2} provides useful information about the overall efficiency of external gas exchange. Heavy reliance is placed upon them for this purpose in managing acute respiratory failure, particularly in intensive care units. Less dramatic, but important, is their use in a variety of other settings (e.g., exercise testing) and for assorted calculations (e.g., the alveolar-arterial O_2 gradient and respiratory dead space).

Technique for Sampling Arterial Blood

Arterial blood is sampled either through an indwelling arterial catheter or by percutaneous arterial puncture. Sampling through an indwelling catheter avoids the acute changes in ventilation that can result from apprehension and pain associated with percutaneous puncture.

Three anatomic sites are generally used for obtaining arterial blood samples: the radial, brachial, and femoral arteries. For several reasons, the radial artery is the preferred sampling site. Because of its superficial location at the wrist, the radial artery is easy to palpate and easy to compress by direct pressure, facilitating hemostasis when sampling is complete. In addition, no large veins lie in its immediate vicinity. Furthermore, the ulnar artery usually provides an adequate collateral circulation to the hand in the rare instance of postsampling thrombosis of the radial artery.

Arterial blood samples are drawn anaerobically into plastic or glass syringes coated with heparin. Because room air at sea level has a P_{O_2} of approximately 150 mmHg and a P_{CO_2} of approximately zero mmHg, air bubbles in the syringe will artificially increase the arterial P_{O_2} and reduce the arterial P_{CO_2}. The sample either is immediately analyzed or is placed on ice in order to minimize the metabolism of blood cells, particularly the white cells. If the icing precaution is neglected and the analysis is delayed, the P_{aCO_2} of the sample will increase and the P_{aO_2} and pH will decrease; the rate of change depends on the temperature of the sample and the elapsed time before analysis (Table 34-11).

Interpretations

Analysis of arterial blood gases as part of pulmonary function testing is based primarily on determination of P_{aO_2}, P_{aCO_2}, and pH. As a rule, these parameters are measured directly. Other values, including O_2 saturation, bicarbonate concentration, and base excess (or deficit), are usually calculated. This section deals with the interpretation of P_{aO_2}, P_{aCO_2}, and pH. Additional consideration of arterial blood gases, with particular reference to acid-base balance, is found in Chapter 14.

Arterial P_{O_2} (P_{aO_2})

The physiological determinants of normal P_{aO_2} have been described elsewhere. For example, normal values for arterial P_{O_2}

Table 34-11

In vitro Changes in Arterial Blood Gas Values at 37°C

Measurement	Change over 10 Min
pH (units)	−0.01
P_{CO_2} (mmHg)	+1.000
O_2 content (vol %)	−0.001

depend on altitude (Table 34-12). Therefore, normal values for arterial P_{O_2} in Denver (altitude of approximately 1500 m) are less than those at sea level by about 20 mmHg.

Arterial P_{O_2} also decreases with age. A regression equation can be used to predict the decrease:

$$Pa_{O_2} = 109 - 0.43 \text{ (age in years)}$$

Table 34-12

Effect of Altitude on Mean Alveolar and Arterial O_2 Pressures

Altitude (Feet)	Barometric Pressure (mmHg)	Ambient P_{O_2} (mmHg)	Alveolar P_{O_2} (mmHg)

The standard deviation of this relationship is ±4.10 mmHg. A third physiological influence is body position. Assumption of the supine position causes abdominal contents to displace the diaphragm cephalad, thereby closing small airways at the lung bases and creating ventilation-perfusion inhomogeneities that decrease Pa_{O_2}.

Many more pathological conditions than physiological states can lower Pa_{O_2}. In each instance, however, arterial hypoxemia may be attributed to one or more of the following generic mechanisms: alveolar hypoventilation, ventilation-perfusion mismatch, diffusion impairment, and venous admixture ("shunt"). Considerations of the individual disorders within these categories and the mechanisms leading to hypoxemia are found throughout this book.

Arterial Pco_2 ($Paco_2$) and pH

In a steady state, the level of Pa_{CO_2} reflects the level of alveolar ventilation. In the absence of a disorder in metabolic acid-base balance, an increase or decrease in Pa_{CO_2} beyond normal limits indicates a primary disorder in alveolar ventilation. A summary of these disorders and useful criteria for distinguishing among them, based on arterial blood gas composition, are given in Table 34-13.

Acute *respiratory alkalosis*, produced by alveolar hyperventilation, is characterized by hypocapnia (Pa_{CO_2} less than

Table 34-13

Classification of Primary Respiratory Disorders of Acid-Base Balance

Disorder	Definition
Acute respiratory alkalosis (acute alveolar hyperventilation)	Pa_{CO_2} below lower limit of normal (<36 mmHg), with accompanying alkalemia (pH > 7.44)
Chronic respiratory alkalosis (chronic alveolar hyperventilation)	Pa_{CO_2} below lower limit of normal, with pH normal (or near normal) due to renal compensation and lowered serum bicarbonate concentration (<19 mEq/L)
Acute respiratory acidosis (acute alveolar hypoventilation	Pa_{CO_2} above upper limit of normal (>44 mmHg), with accompanying acidemia (pH < 7.36)
Chronic respiratory acidosis (chronic alveolar hypoventilation)	Pa_{CO_2} above upper limit of normal, with pH normal (or near normal) due to renal compensation and elevated serum bicarbonate concentration (>30 mEq/L)

36 mmHg) and an appropriately elevated pH (greater than 7.44). In time (e.g., 24 h or more), renal compensation occurs, and the concentration of bicarbonate in serum decreases. If alveolar hyperventilation continues, a chronic respiratory alkalosis, partly or completely "compensated," ensues.

A low $Paco_2$ is not necessarily indicative of a primary disturbance in alveolar ventilation. Instead, it may be a consequence of respiratory compensation (partial or complete) for metabolic acidosis; this possibility is signaled by the coexistence of hypocapnia and a low pH (under 7.36). Since the kidney and respiratory system do not overcompensate for acid-base derangements, the coexistence of hypocapnia and acidemia suggest the presence of two primary disturbances.

Acute respiratory acidosis, caused by alveolar hypoventilation, is characterized by an abnormally high $Paco_2$ (over 44 mmHg) and a subnormal pH (under 7.36). Again, in time (24 h or more), renal compensation for the primary respiratory disorder restores the serum bicarbonate concentration and blood pH toward normal. A high value for $Paco_2$ may also reflect respiratory compensation for a primary metabolic alkalosis ($[HCO_3^-]$ greater than 30 mEq/L). In this circumstance, however, blood pH will be abnormally high (pH over 7.44), rather than low. In general, the elevation in $Paco_2$ in compensation for metabolic alkalosis does not exceed about 55 mmHg. A $Paco_2$ exceeding this value in the setting of a metabolic alkalosis suggests the likely coexistence of a primary respiratory acidosis.

This discussion has been limited primarily to alterations in arterial blood gas values in primary respiratory acidosis or alkalosis. Metabolic derangements often complicate the picture. These disorders are considered elsewhere (see Chapter 14).

Testing for Air Travel-Related Hypoxemia

Travel in commercial jet airliners typically results in exposure of passengers and crew to conditions equivalent to about 6000 to 8000 feet above sea level. For individuals with normal pulmonary gas exchange, the resulting Pao_2 falls within a clinically acceptable range. However, for many patients with lung disease, the resulting Pao_2 may well be problematic, even in those patients who do not require supplemental oxygen at sea level. Consequently, assessment of patients with chronic lung diseases, particularly COPD and interstitial lung diseases, has become part of the repertoire of tests offered by many pulmonary function laboratories.

One approach to estimating the resultant Pao_2 during air travel is based upon use of regression equations (Fig. 34-30). Using the patient's resting Pao_2 at sea level and his or her FEV_1 percent of predicted, the expected in-flight Pao_2 can be estimated. Some experts advocate use of the nomogram for determining which patients ought to undergo hypoxia inhalation testing (HIT), while others advocate performance of HIT for all traveling patients at risk for in-flight hypoxemia.

HIT is based on the observation that exposure to hypoxic gas mixtures can reproducibly mimic the Pao_2 arising

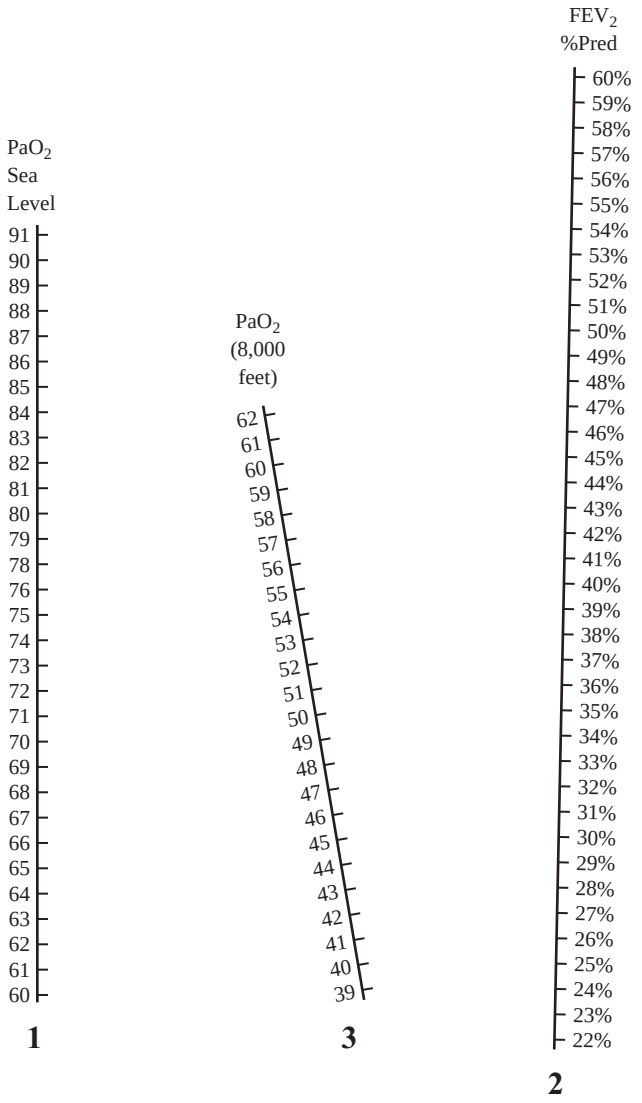

Figure 34-30 Nomogram for predicting in-flight oxygen tension. Using a straight edge, the patient's resting Pao_2 at sea level (Column 1) is aligned with his or her FEV_1% of predicted (Column 2). The expected in-flight Pao_2 (Column 3) is estimated as the value where the line crosses the center scale. *(From Dillard TA, Ewald FW: The use of pulmonary function testing in piloting, air travel, mountain climbing, and diving. Clin Chest Med 22:803, 2001.)*

under true hypobaric conditions. Exposure to 15.1 percent oxygen for 20 min reliably duplicates the resultant Pao_2 at 8000 feet. During performance of the test, the patient, with nose clips in place, breathes from a reservoir though a mouthpiece. The electrocardiogram is monitored, and arterial blood gases are obtained at the conclusion of the test. Supplemental oxygen can then be titrated and prescribed according to the findings.

CONTROL OF BREATHING

The rate, depth, and pattern of breathing reflect a complex interplay of neurohumoral and chemical regulatory

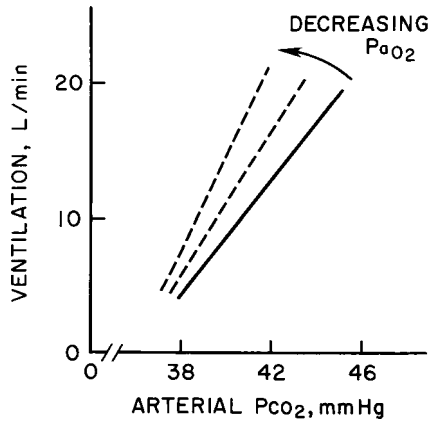

Figure 34-31 Linear relationship between minute ventilation ($\dot{V}_E$) and arterial P_{CO_2}. The dashed lines show the increased slope of the relationship of $\dot{V}_E$ vs. P_{CO_2} as P_{aO_2} decreases.

mechanisms that drive the respiratory apparatus. Tests used to evaluate the control of breathing, based on assessment of the ventilatory response to controlled hypercapnia or hypoxia, are uncommonly performed in the clinical setting. However, since these tests highlight important physiological mechanisms that affect the level and pattern of ventilation, they are summarized below.

Ventilatory Response to CO_2

The ventilatory response to changes in P_{aCO_2} is linear over a broad range (Fig. 34-31). Determination of the ventilatory response to controlled hypercapnia generally is based on one of two methods: the steady-state method or the rebreathing method.

Steady-State Method

After a control period in which CO_2-free air is breathed to establish a baseline, the patient is subjected to two or more periods of breathing CO_2-enriched air. Care is taken to achieve a steady state of ventilation and circulation during each exposure. Especially at the higher concentrations of inspired CO_2, at least 10 to 20 min is required for a steady state to be reached in alveoli, arterial blood, cerebrospinal fluid, and the chemosensitive areas of the brain. The ventilatory response to CO_2 is then determined from a plot of $\dot{V}_E$ vs. P_{aCO_2}. In patients without underlying lung disease, end-tidal CO_2 concentration is often substituted for P_{aCO_2}. In addition, in order to eliminate the influence of variations in arterial PO_2 on the ventilatory response to CO_2, the inspired gas is enriched with O_2 during the control and test periods.

Rebreathing Method

This method entails rebreathing a CO_2-enriched gas mixture from a bag for approximately 4 min. The validity of the approach requires rapid equilibration of CO_2 among alveolar gas, arterial and mixed venous blood, and the chemosensitive areas of the brain. The bag is filled at the outset with a mixture of 7 percent CO_2 in O_2; O_2 is substituted for air in this mixture to avoid the ambiguity of a hypoxic stimulus to ventilatory drive.

The result of the CO_2 rebreathing test is described by use of two terms: (1) the *slope* of the line relating change in ventilation response to change in end-tidal P_{CO_2} ($\Delta\dot{V}_E/P_{CO_2}$), determined by using the method of least squares linear regression analysis, and (2) the *x-intercept* of the relationship between $\dot{V}_E$ and end-tidal P_{CO_2}.

Normal Response to CO_2 and Modifying Influences

As indicated above, the normal increase in ventilatory response to increasing concentrations of inspired CO_2 is linear. Normal responses are categorized as low (under 1.5 L/min/mmHg), intermediate (1.5 to 5.0 L/min/mmHg), or high (more than 5.0 L/min/mmHg). Most normal persons (about 80 percent) have an intermediate ventilatory response. A variety of factors, both genetic and environmental, seem to influence the ventilatory response to CO_2 (Table 34-14).

Ventilatory Response to Hypoxia

The response to acute hypoxia in normal persons is largely determined by the peripheral arterial chemoreceptors, as long as the level of hypoxia is mild to moderate. Even at sea level, the level of arterial P_{O_2} in normal persons provides an appreciable chemoreceptor drive, accounting for about 10 percent of the minute ventilation. Unlike the linear response of $\dot{V}_E$ to progressive hypercapnia, the response to hypoxemia is curvilinear (Fig. 34-32). The magnitude of the ventilatory response to a decrease in arterial P_{O_2} depends on the P_{aCO_2}, increasing as the concentration of CO_2 in arterial blood is increased.

As may be seen from the hyperbolic curves in Fig. 34-32, the rate of change in ventilation is greater over the lower range of oxygenation (when P_{aO_2} falls below 60 mmHg). Not shown in Fig. 34-32 is the depression of ventilation brought about by severe hypoxemia, presumably because of the central depressing effect of severe hypoxia on respiratory neurons.

Although tests for assessing the ventilatory response to hypoxia are less well standardized than those for measuring the hypercapnic response, they, too, may be conveniently categorized into steady-state and non–steady-state methods. In one steady-state method, successive ventilatory responses are determined to a series of increasingly severe hypoxic gas mixtures, each administered for at least 10 min; P_{aCO_2} is kept constant by the addition of CO_2 to the inspired gas mixture as hypoxia-induced hyperventilation develops. In another, the effect of hypoxia on the slope of the plot of $\dot{V}_E$ vs. P_{CO_2}, as P_{O_2} is lowered from hyperoxic (at least 200 mmHg) to hypoxic (40 mmHg) levels, is determined. The normal response to diminished inspired oxygen concentrations is characterized by an increase in sensitivity (slope) without a change in the CO_2 threshold.

Three non–steady-state techniques are currently in use. In the hypoxic rebreathing test, the subject rebreathes a hypoxic gas mixture containing 7 percent CO_2. As arterial hypoxemia intensifies, causing an increase in ventilation and

in CO_2 elimination into the closed circuit, the P_{CO_2} in the system is held constant at a predetermined level by the diversion of a fraction of the expired gas through a CO_2 absorber. The ventilatory response is determined at two or more levels of P_{CO_2}, since the hypoxic response is influenced by P_{CO_2}. An alternative rebreathing test induces progressive hypoxemia by adding N_2 to the inspired gas mixture over a 20-min period. Finally, in a relatively simple test, the patient induces a transient drop in arterial P_{O_2} by inhaling pure N_2 for a few breaths. The relationship between $\dot{V}_E$ and P_{aO_2} is plotted; the slope of the relationship is the sensitivity to hypoxia. Because the duration of the hypoxia is brief, presumably only the peripheral chemoreceptors are stimulated. No adjustment is made for the drop in P_{CO_2} that occurs during the hypoxia-stimulated increase in ventilation.

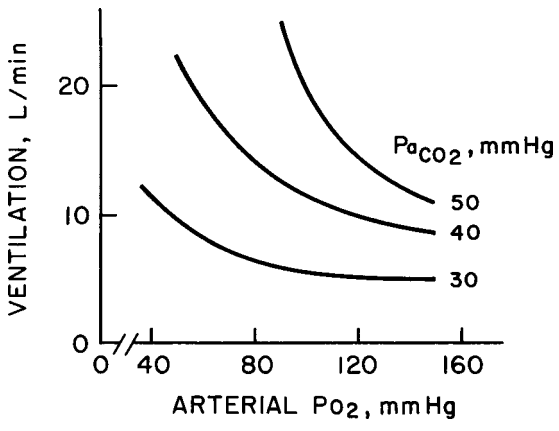

Figure 34-32 The curvilinear relationship between ventilation and arterial P_{O_2} at various levels of arterial P_{CO_2}. The rate of change of ventilation as P_{O_2} falls (slope) increases precipitously at a P_{O_2} of approximately 60 mmHg when P_{CO_2} is 40 mmHg. The abrupt increase in ventilation occurs at a higher P_{O_2} when the level of P_{CO_2} is elevated, and at a lower P_{O_2} when the prevailing P_{CO_2} is lower.

Normal Responses to Hypoxia and Modifying Influences

The normal ventilatory response to acute hypoxia varies among individuals. Several factors may influence the relationship (Table 34-15). A high ventilatory response to CO_2 may be associated with a high sensitivity to hypoxia; in addition, higher levels of arterial P_{CO_2} are associated with a higher ventilatory response to hypoxia. Interestingly, in long durations of hypoxia before the test period, as is the case in native residents at high altitude or persons with cyanotic congenital heart disease, a blunted response to acute hypoxia is observed. Finally, a variety of other clinical disorders, including myxedema and hypothyroidism, autonomic nervous system dysfunction, chronic narcotic addiction, and the chronic use of methadone, are characterized by a reduced hypoxic response.

Nonventilatory Measures of Ventilatory Drive

Measurement of ventilation in response to acute hypoxia or hypercapnia provides a useful index of respiratory output when the ventilatory apparatus (thorax, diaphragm, abdominal muscles, lung, and airways) is normal. This situation obviously does not apply in certain neuromuscular disorders in which the thorax and diaphragm behave abnormally. In addition, it does not apply in some instances of pulmonary disease, notably obstructive airway disease, in which the respiratory apparatus may not be capable of responding normally, even though it is intact and chemosensitivity is normal. In this instance, a decrease in ventilatory response may be attributable to the excessive mechanical load placed on the muscles of respiration.

When ventilation fails to provide a reliable measure of the ventilatory drive (efferent discharge from the respiratory neurons), the diaphragmatic electromyograph (EMG) or the pressure generated by the inspiratory muscles during the first 0.1 s of an occluded inspiration (the $P_{0.1}$) has been used for the clinical assessment of the control of breathing.

The electrical activity of the diaphragm is directly related to neural activity of the phrenic nerve. Therefore, it provides a measure of efferent neural traffic to the diaphragm. The diaphragmatic EMG may be recorded in patients by placing the tip of an esophageal catheter, containing bipolar electrodes, at the level of the diaphragm.

The second approach to obtaining a nonventilatory measure of ventilatory drive is the determination of $P_{0.1}$, which is the negative pressure generated by the inspiratory muscles during the first 100 ms of an inspiratory effort made against an occluded airway. During this brief period, contraction of the respiratory muscles is virtually isometric, and the force generated correlates with activity recorded by the diaphragmatic EMG.

In performing the test, airflow in the inspiratory line of the breathing circuit is randomly interrupted during the preceding expiration. The 100-ms period has proved to be so brief as to be imperceptible, thereby obviating any corrective action by the subject during the breath against the occlusion. However, the $P_{0.1}$ is far from foolproof. A major concern is that $P_{0.1}$ is affected by resting lung volume: $P_{0.1}$ is reduced when FRC is abnormally high, a common occurrence in obstructive disease of the airways.

ASSESSMENT OF INTEGRATED FUNCTIONS: 6-MINUTE WALK TEST

A complete evaluation of a patient with respiratory symptoms often requires assessment of exercise capacity, in addition to traditional pulmonary function tests and radiographic studies. A number of exercise studies can be employed, including cardiopulmonary exercise tests (Chapter 135), cardiac stress tests, and EIB protocols. One of the most widely used, practical modalities is the 6-minute walk test (6MWT). Despite its simplicity, the 6MWT has become a powerful tool in the evaluation of functional status and prognosis of patients with a variety of functional impairments.

Technical Aspects

The 6MWT is performed indoors. There is an initial period of rest in a chair for at least 10 min, during which baseline vital signs are taken. The patient then stands and is asked to rate baseline dyspnea and overall fatigue using the Borg scale (from 1 to 10). The patient, walking at a comfortable pace, completes 60-m laps on a walking course that is 30 m in length. Cones are used to mark the turnaround points. For patients using supplemental oxygen, the oxygen is delivered at standard rate, or as prescribed by a physician, or as determined by protocol. The patient should not carry or push the oxygen source during testing. The number of laps and a post-walk Borg scale assessment are recorded, as is the total distance walked over 6 min (6MWD).

Although pulse oximetry during the 6MWT is considered optional, it has become standard at many institutions. In some cases, pulse oximetry can be used to titrate levels of oxygen supplementation. Obtaining a high-quality oximeter signal is imperative.

A number of sources of variability are inherent in the 6MWT. A modest training effect has been reported when two studies are performed within one week. Concomitant medication use can also impact the 6MWT. Improved test performance, for example, occurs after bronchodilator use in patients with COPD. Shorter height, female sex, and higher body weight are associated with reduced performance. Despite these factors, the 6MWT has been found to have excellent reproducibility, especially when performed in evaluation of specific clinical entities, such as idiopathic pulmonary fibrosis.

Several modifications of the 6MWT are in clinical use. During a *shuttle-walking test*, the patient walks on a 10-m course while the walking speed is increased every minute until the patient cannot reach the turnaround point within the set time. The *timed walk test (TWT)*, which has been designed for patients with idiopathic pulmonary fibrosis, has three stopping criteria based on changes in oxyhemoglobin saturation.

Absolute contraindications to performing the 6MWT include unstable angina or myocardial infarction within 1 month of the study. Resting tachycardia of greater than 120 beats per minute, systolic blood pressure greater than 180 mmHg, or diastolic blood pressure greater than 100 mmHg are relative contraindications. The study should be terminated if the patient develops chest pain, severe dyspnea, leg cramps, diaphoresis, or profound oxyhemoglobin desaturation.

Interpretation

Although the 6MWT is limited in its inability to provide objective measures of functional capacity, such as oxygen uptake, the test provides very useful clinical information. In addition, it realistically represents the patient's functional capacity during physical effort that more closely reflects his or her daily activity. Reliable reference equations establishing standard performance during a 6MWT in healthy patients are not currently available.

The 6MWT has several indications, most notably, measurement of the response to a number of medical and surgical interventions. Pulmonary rehabilitation clearly improves 6MWT performance in patients with COPD, while pharmacologic interventions for pulmonary arterial hypertension and heart failure, among other disorders, have also been shown to favorably affect test results. Lung transplantation (unilateral and bilateral) and lung volume reduction surgery for emphysema have been shown to significantly improve results of the 6MWT.

The 6MWT also has been used to assess functional status in patients with COPD, cystic fibrosis, heart failure, and peripheral vascular disease, and in determining eligibility for, and timing of, lung transplantation. In the absence of well-established reference standards, the clinical value of performing a single test in these patient groups is limited. Serial studies are likely to be more useful than a single 6MWT.

Recently, a number of publications have established the value of the 6MWT in predicting morbidity and mortality from heart and lung disease. Results from the test have been shown to have an inverse relationship with mortality in severe COPD. Walk distance and velocity, as well as magnitude of oxyhemoglobin desaturation, are correlated with survival in idiopathic pulmonary fibrosis. Similar correlations have been made in heart failure and primary pulmonary hypertension.

Finally, at some institutions, results of the 6MWT are used to not only establish the presence of exertional hypoxemia, but also to titrate supplemental oxygen with activity.

QUALITY CONTROL IN THE PULMONARY FUNCTION LABORATORY

Meaningful interpretation of pulmonary function tests requires confidence in the accuracy and reproducibility of results provided by the pulmonary function laboratory. Previously, it was tacitly assumed that all data from all laboratories, especially when reported as "percent predicted," were equally reliable. In recent years, the fallacy of this assumption has been explicitly recognized, and steps have been taken to standardize equipment and procedures and to ensure accuracy, reproducibility, and uniformity in testing and reporting. To accomplish this goal, both analytical and nonanalytical factors must be taken into account.

Nonanalytical Factors in Quality Control

A familiar example of a confounding influence that may distort test results is the anxious patient who pauses outside the laboratory door to "calm the nerves" by smoking one or more cigarettes before undergoing pulmonary function testing. Cigarette smoking before the diffusing capacity of the lungs is determined can generate enough carboxyhemoglobin to reduce a normal value to subnormal levels.

Another example of a nonanalytical factor is the failure to achieve patient understanding and comfort for tests that usually require patient cooperation. Unfortunately, a preliminary explanation before the patient arrives at the laboratory or prior exposure of the patient to the laboratory and its personnel is usually impractical. Use of explanatory sheets or descriptive brochures may prove helpful. If such materials are not available, laboratory personnel are obligated to make the patient comfortable and even perform "practice runs" before undertaking final testing.

When the patient arrives at the pulmonary function laboratory, an assessment should be made of his or her prior experiences. Did the patient undergo other tests or procedures that could alter the outcome of the pulmonary function tests in question? Is the patient fatigued or in pain? Should a period of rest precede the tests in order to ensure optimal performance? If delay is impractical, the test report should include the fact that the patient was fatigued or in pain.

Medication use before pulmonary function testing can seriously affect the results. For example, self-administration of bronchodilators before testing can artificially enhance tests of airflow. If medications have been taken before the patient arrives at the laboratory, the time of administration should be part of the record. Also, a request for pulmonary function test results for patients who regularly take bronchodilators should indicate whether the tests are to be done without interruption of the regular schedule of medications, whether bronchodilators are to be discontinued before the test is done, or whether regular bronchodilators are to be discontinued so that the effects of bronchodilation can be tested. Appropriate comments about bronchodilators are part of the report.

A major nonanalytical cause of misinterpreting results is the inappropriate application of predicted normal values to the patient population by the laboratory (see "Approach to Interpreting Commonly Performed Pulmonary Function Tests," below). For example, normal values based on data obtained using physically fit hospital personnel do not necessarily apply to those who have a sedentary existence. Noncomparable race, as well as lifestyle, may complicate comparisons. Anthropological differences among control and test populations are not easily reconciled. Extraordinary height, weight, or age cannot be easily extrapolated if corresponding subjects are not represented in the control group. Using patient-reported height, rather than making measurement of patient height, may introduce an error in the selection of appropriate normal values. Comparison of control and test results at different altitudes can be invalid if due regard is not paid to the influence of hypoxia on certain measurements (e.g., diffusing capacity).

Analytical Factors in Quality Control

Performance of pulmonary function tests is replete with opportunities for error. The equipment, techniques, use of control values, and calculations are potential sources of error. In an attempt to minimize errors, standardization of techniques has been advocated. For example, with respect to performing the forced vital capacity maneuver, guidelines have been established for the number of attempts required, acceptable variability between efforts, and methods for selecting test data in order to arrive at acceptable results. To avoid misuse of spirometers, criteria have been set for minimal performance with respect to capacity, accuracy, and frequency response of various spirometers; in addition, standards have been developed for determining the single-breath diffusing capacity. Potential sources of discrepancies—such as breath-holding time, concentration of hemoglobin, dead space of the equipment and the patient, F_{IO_2}, volume of the alveolar sample, number of tests, and acceptable variability in results—are taken into account.

Quality Control of Test Results

Guidelines for standardization play a major role in reducing discrepancies between laboratories. However, measures are also required to ensure accuracy and reproducibility within any given laboratory. Among the elements of control that merit consideration are calibration, validation of calibration, and performance of a control measurement. *Calibration* is the adjustment of an instrument's output so that it validly reflects a known input. *Verification of calibration* entails introduction of the same known input and demonstration that the correct output is reproduced. *Performance of a control measurement* refers to the testing of a substrate that has known properties, similar to those usually tested, to prove the accuracy of the instrumentation. One example of the application of these principles is blood gas analysis. Use of control measurements derived from tonometered blood or commercially prepared buffer solutions is now widespread.

Unfortunately, similar controls do not exist for pulmonary function tests. Therefore, laboratory technologists have the responsibility for continuing to be alert, not only with respect to faithful observance of guidelines for standardization but also to detect in-house sources of error (e.g., a leak in the system, malfunction of gas analyzers, faulty analog-to-digital converters, and faulty electronics that reduce frequency response).

Responsibility and Cost in Quality Control

All who work in the laboratory must be concerned with quality control, despite the frequent temptation to cut corners. Indeed, one common rationalization for not doing so is the misguided impression that quality control, as described above, is too expensive. Time has to be set aside for the technologist to care for and calibrate equipment, to establish proper control values for the laboratory, to search for inconsistencies in the data and interpretation, and to keep up with changing standards. Also, equipment and supplies, including calibrating syringes and calibrating gases, are expensive. However, when put into the balance, the cost and waste of producing erroneous results exceed, by far, the expense of practicing quality control.

Infection Control

Given the relatively close contact between patients and technical staff during performance of pulmonary function tests, the issue of infection control is one that must be carefully considered. To date, the role of pulmonary function equipment in transmission of disease appears to be minimal. Although the presence of potential pathogens on laboratory mouthpieces, valves, and tubing has been well documented, implication of these organisms in the transmission of disease has not been established. Nevertheless, the potential hazards should be recognized and appropriate care exercised.

Infection control begins with practice of the basic principles of hygiene. Staff should always wash their hands between patients and use protective gloves when handling potentially contaminated equipment. Care must be taken in working with mouthpieces, nose clips, and any other implements that come in contact with mucosal surfaces. These

devices, if reused, should be disinfected or sterilized after each use. Other equipment—manifolds, tubing, etc.—should be sterilized on a regular basis. In fact, guidelines from the American Thoracic Society call for the disinfection or sterilization before reuse of any equipment surface with visible condensation from expired air.

Because of recent growing concern over cross-contamination among patients and laboratory personnel, manufacturers now produce a variety of in-line filters and disposable pneumotachographs. Care should be taken, however, to assure that response characteristics of the test equipment are not driven to unacceptable levels by use of these devices. Current literature on this topic should be consulted regularly.

APPROACH TO INTERPRETING COMMONLY PERFORMED PULMONARY FUNCTION TESTS

A standard battery of pulmonary function tests is commonly used to identify and quantify abnormalities in the performance of the respiratory system. An organized approach to interpreting these studies is critical. Once a patient's baseline values are established, the tests are valuable in tracking the course of the disorder and its response to treatment.

Results of pulmonary function tests are interpreted by comparing individual patient data with reference or predicted values for normal subjects. Ideally, predicted values should be generated from large groups of well-defined, normal or healthy subjects with proper distribution of anthropometric characteristics such as sex, age and height, and ethnic background. Despite dedicated attempts to improve prediction formulas, however, many still fail to take into account important sources of discrepancy, such as the racial and ethnic backgrounds of the patients and the control population, the effects of altitude and exposure to air pollution, and effects of inordinate body size or old age. As a result, not all sets of predicted normals are applicable in pulmonary function laboratories outside the immediate vicinity of the patient populations from whom the data were collected. Extrapolation beyond the characteristics of the reference population should be avoided.

Recently published guidelines from a joint Task Force of the American Thoracic Society (ATS) and European Respiratory Society (ERS) recommended that in the United States, ethnically appropriate reference equations from the National Health and Nutrition Examination Survey (NHANES) III be used for individuals between the ages of 8 and 80 years. The ATS/ERS Task Force did not recommend any specific set of reference equations for laboratories in Europe, but it suggested the need for an investigation conducted throughout Europe to derive contemporary equations for prediction of normal lung function.

The same ATS/ERS Task Force recommended that each pulmonary function test result falling below the fifth percentile of the frequency distribution of values measured in the reference population be considered abnormal. If normal test results fall in a normal distribution, values below the fifth percentile can be estimated using Gaussian statistics. If the distribution of normal values is non-Gaussian, the lower limit of normal is estimated using a nonparametric technique (e.g., the 95th percentile method). Traditionally, but without a sound statistical basis, most laboratories have used an arbitrary cutoff of 80 percent predicted to define normal. While this method may be reasonable in children, errors may arise if it is applied to adult test results.

Interpretation Scheme and Classification of Abnormal Patterns

A variety of schemes have been proposed for sorting out abnormalities in pulmonary function test results. Many are based on initial categorization of findings reflective of one of four basic patterns described below.

An *obstructive* pattern stems from narrowing of any portion of the airways—from upper airway to bronchioles less than 2 mm in diameter—that results in a reduction of maximal airflow in relation to maximal volume.

A r*estrictive* pattern is elicited by diseases of the lung, chest wall, pleural space, or neuromuscular respiratory apparatus that reduce lung volumes, particularly TLC, and vital capacity.

A *combined obstructive-restrictive* pattern results from pathological processes that reduce lung volumes, vital capacity, and airflow, and that also include an element of airway narrowing.

Finally, *abnormal gas transfer* may be noted as part of one of the aforementioned patterns or in isolation and reflects an abnormality in the alveolar-capillary membrane, impairing oxygen uptake from alveolar gas to pulmonary capillary blood.

Overlap among categories is not uncommon. For example, widespread interstitial disease, as in idiopathic pulmonary fibrosis, often shows a pattern that indicates important components of both restrictive disease and abnormal gas transfer.

One useful sequence recommended by the ATS/ERS Task Force for analyzing a conventional battery of pulmonary function test results is illustrated in Fig. 34-33.

Analysis begins with evaluation of the ratio of FEV_1 to VC. While, historically, the ratio of FEV_1 to FVC (FEV_1/FVC%) served as the basis for distinguishing obstructive disorders from normality or restrictive disease, the ATS/ERS Task Force currently recommends using as the denominator the FVC, *or* the VC ("slow" VC or SVC), *or* the FIVC, whichever is greatest. If the ratio is less than the lower limit of normal (i.e., below the fifth percentile) and the VC (defining VC as any of the three previously noted vital capacity measurements) is at or above the lower limit of normal, the pattern is obstructive. If TLC is not at or above the lower limit of normal, a mixed obstructive-restrictive pattern is

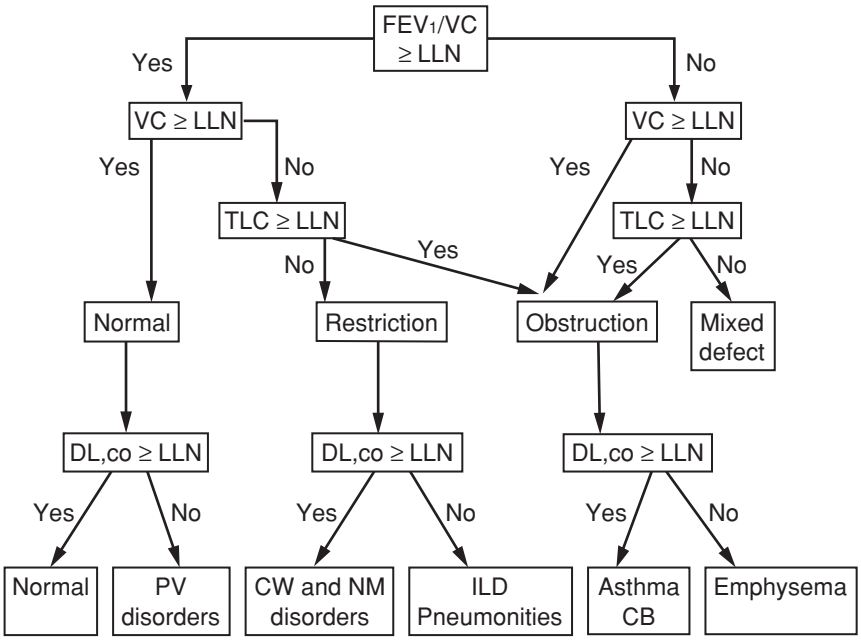

Figure 34-33 Proposed sequence of test review in the interpretation of pulmonary function tests (see text for discussion). LLN, lower limit of normal; PV, pulmonary vascular; CW, chest wall; NM, neuromuscular; ILD, interstitial lung disease; CB, chronic bronchitis. *(From Pellegrino R, Viegi G, Brusasco V, et al: Interpretive strategies for lung function tests. Eur Respir J 26:948, 2005.)*

suggested. Distinction between asthma and chronic bronchitis on the one hand, and emphysema on the other, is based upon whether the D_{LCO} is normal (asthma or chronic bronchitis) or reduced (emphysema). The previous practice of using a value for FEV_1/FVC% of less than 70 percent to define obstruction results in misdiagnosis of airway obstruction in men over 40 years and women over 50 years, as well as overdiagnosis of COPD in elderly, asymptomatic nonsmokers.

If FEV_1/VC and VC are each equal to or greater than the respective lower limits of normal, spirometry is considered normal; measurement of the D_{LCO} can then help distinguish between normal pulmonary function and pulmonary vascular disorders. If VC is below the lower limit of normal, a reduced TLC supports a diagnosis of restriction, while a normal TLC indicates an obstructive pattern. Once again, in the setting of a restrictive pattern, measurement of D_{LCO} can be used to distinguish between pulmonary parenchymal disorders and disorders of the chest wall or respiratory muscles. Note that according to these guidelines, an obstructive pattern may be diagnosed in the setting of a *normal* FEV_1/VC, if VC is reduced and TLC is normal or elevated.

Once the predominant abnormality is defined with initial pulmonary function testing, the whole battery may not be necessary in following the course of the disease or in assessing its response to treatment. For example, particular determinations, such as spirometry, may suffice in patients with airway diseases. Notably, according to the ATS/ERS guidelines, the severity of the abnormality in each of the obstructive, restrictive, or mixed patterns is expressed on the basis of the FEV_1 (Table 34-16). Standards have been established for defining significant changes in results over time: a 15 percent or greater change in FVC or in FEV_1, or a greater than 10 percent change in D_{LCO} is considered significant.

Assessing Respiratory Muscle Strength and Effort

One additional measurement that is frequently useful in assessing results of routine spirometry is assessment of respiratory muscle strength. Respiratory muscle strength is expressed in terms of peak inspiratory ($P_{I_{max}}$) and peak expiratory ($P_{E_{max}}$) pressures, determined under static conditions. The technique was outlined in a previous section. Any of a number of factors may be responsible for low peak inspiratory or expiratory pressures (Table 34-17): suboptimal effort, fatigue, weakness of the respiratory muscles, deformity of the chest wall, or intrinsic diseases of the lungs or chest wall. Although

Table 34-16

Grading of Severity of Abnormal Spirometry Based on FEV_1

Severity	FEV_1 Percent Predicted
Mild	>70
Moderate	60–69
Moderately severe	50–59
Severe	35–49
Very severe	<35

Table 34-17

Conditions Associated with Reduced Peak Inspiratory ($P_{I_{max}}$) and Expiratory ($P_{E_{max}}$) Pressures

Condition	$P_{I_{max}}$	$P_{E_{max}}$
Poor effort	↓	↓
Fatigue	↓	↓
Neuromuscular disease	↓	↓
Increased lung volume	↓	N
Decreased lung volume	N	↓

Note: ↓ = decreased; N = normal.

the first three factors characteristically reduce both peak inspiratory and expiratory pressures, disease of the lungs or chest wall often reduces, selectively, one or the other peak pressure. Thus, diseases that reduce lung volumes (e.g., widespread interstitial fibrosis) and shorten the length of the expiratory muscles at the end-inspiratory position generally reduce maximal expiratory pressure. Conversely, diseases that increase lung volume, such as obstructive airway disease, by decreasing the inspiratory muscle length at end-expiration generally reduce maximal inspiratory pressure.

If airflow during spirometry is reduced, determination of the peak inspiratory and expiratory pressures may be helpful in suggesting the mechanism. Many pulmonary function tests depend on the cooperation of the patient. Poorly reproducible peak flows that are consistently subnormal raise the question of poor effort. Conversely, consistently low values that occur despite maximal effort may signal neuromuscular disease.

Additional Details of Pulmonary Function Test Results in an Obstructive Pattern

Included in the obstructive pulmonary disorders (Table 34-18) are chronic obstructive diseases of the airways (chronic bronchitis and emphysema), bronchiectasis, asthma, small-airway disease, and upper-airway obstruction.

Except for diseases confined to the small airways, as noted previously, the hallmark of the obstructive pattern is a reduction in the FEV_1/VC%. Notably, some healthy subjects have a reduced FEV_1/FVC% and an FEV_1 in the normal range. The clinical significance of these findings is unclear. Results of additional tests (e.g., lung volumes, $D_{L_{CO}}$, assessment of bronchodilator responsiveness) may help distinguish those with airway obstruction from true normals. Measurement of airway resistance (Raw) or specific airway conductance (SGaw) may be useful in assessing airway obstruction in subjects unable to perform a maximal forced expiratory maneuver.

Changes in lung volume commonly accompany the abnormal findings on spirometry but, as indicated in Fig. 34-33, lung volume measurement is not mandatory in establishing

Table 34-18

Causes of an Obstructive Pattern

Disease Process	Anatomic Location of Lesion	Cause of Reduced Airflow
Chronic obstructive pulmonary disease (COPD)		
Chronic bronchitis	Large and small (<2-mm diameter) airways	Narrowing of airways by fibrosis, secretions, edema
Emphysema	Lung parenchyma	Loss of lung elastic recoil
Cystic fibrosis	Large and small airways	Narrowing of airway by fibrosis, retained secretions, edema Loss of elastic recoil
Asthma	Large and small airways	Narrowing of airways by smooth-muscle contraction, edema, retained secretions
Small-airway disease	Small airways	Narrowing, stenosis of small airways
Upper-airway obstruction	Major, central airways (trachea, main bronchi)	Anatomic or functional narrowing of upper airway

the presence of obstruction. Frequently, but not invariably, lung volumes are abnormally high. Typically, all three lung volumes—RV, FRC, and TLC—are increased.

In addition to uncovering the pattern of chronic obstructive airway disease described previously, certain additional tests provide insight into the sites and mechanisms of obstructive airway disease.

Reversible vs. Irreversible Obstructive Airway Disease

The response to inhaled bronchodilators traditionally has been used to help distinguish between chronic obstructive airway disease (chronic bronchitis and emphysema), in which airway resistance is virtually fixed, and asthma, in which bronchoconstriction is a prominent feature. This is an oversimplification, since a sizable minority of patients with COPD manifest a bronchodilator response. Furthermore, the absence of a bronchodilator response in a laboratory setting does not necessarily predict lack of a clinical response.

A universally agreed upon definition of reversibility is lacking. Expressing change in FEV_1 or FVC as a percent of predicted values may be more advantageous than expression of changes in the values relative to baseline. In general, an increase in FEV_1 or FVC of at least 12 percent above baseline *and* an absolute increment of at least 200 ml is considered evidence of significant bronchodilation. If the increase in spirometric values is not significant, a decrease in lung volumes toward normal may be an indication of bronchodilator responsiveness.

Chronic Bronchitis vs. Emphysema

Although chronic bronchitis and emphysema usually coexist, occasionally one or the other exists in virtually pure form. Two pulmonary function tests have proved valuable in distinguishing between the two—diffusing capacity (D_{LCO}), which is routinely measured, and static lung compliance (Cst,L), which is uncommonly measured clinically. Emphysema, characterized by a loss of alveolar units and a decrease in alveolar surface area, is associated with a low D_{LCO}, whereas the D_{LCO} in chronic bronchitis is usually normal or near normal.

The loss of alveolar units in emphysema also causes a decrease in the elastic recoil pressure of the lungs. As a result, Cst,L is increased in emphysema, whereas it is usually not appreciably altered in chronic bronchitis.

Small-Airway Disease

In obstructive disease of the small airways (i.e., those less than 2 mm in diameter), expiratory flow is usually normal, except at low lung volumes (i.e., the FEV_3 and $FEF_{25-75\%}$ are abnormally low). Other, uncommonly performed tests for isolated, small-airway disease, including the helium-oxygen flow-volume loop, nitrogen washout test, and frequency dependence of dynamic compliance, would also be anticipated to be abnormal. Lung volumes and D_{LCO} are normal. Bronchodilators are virtually without effect.

The practical value of tests of small-airway function is problematic. At one time, high hopes were held that early detection of small-airway disease might reinforce measures, such as cessation of smoking, that would prevent or arrest progression to irreversible obstructive disease of the airways. However, enthusiasm for testing for small-airway disease has waned, since it is still unclear if small-airway disease is a reversible phase in the evolution of clinically significant obstructive airway disease that affects larger bronchi.

Upper-Airway Obstruction

The designation *upper-airway obstruction* is an umbrella for anatomic or functional narrowing of the large upper airways—the larynx, extra- and intrathoracic trachea, and lobar bronchi. Although upper-airway obstruction of any cause may reduce expiratory or inspiratory airflow, an alteration in the contour of the flow-volume loop has proved to be the most reliable abnormality in conventional pulmonary function testing. The observation from routine spirometry that the ratio of FEV_1 to PEFR (peak expiratory flow rate) exceeds 8 ml/L/min should prompt careful performance and review of the flow-volume loop, as described below.

Upper-airway obstruction can be divided into three major types: (1) fixed obstruction, (2) variable extrathoracic obstruction, and (3) variable intrathoracic obstruction.

A *fixed obstruction*, such as tracheal narrowing by scar tissue at the site of a previous tracheotomy, is one in which the geometry and cross-sectional area of the lesion do not change during the respiratory cycle. Characteristically, both inspiratory and expiratory flows are affected about equally (Fig. 34-34*A*).

A *variable obstruction* is one in which the configuration of the obstructive lesion changes with the phases of respiration. Depending on its location in the tracheobronchial tree (extra- or intrathoracic), this type of lesion usually affects predominantly either inspiration or expiration.

The inspiratory arm of the flow-volume loop is primarily affected by a *variable extrathoracic* obstruction, leaving the expiratory limb relatively unaffected (Fig. 34-34*B*). The abnormal configuration of the flow-volume loop is attributable to the following sequence: during forced expiration, tracheal pressure exceeds atmospheric, so that the degree of obstruction decreases; conversely, during forced inspiration, intratracheal pressure becomes less than atmospheric and the trachea tends to collapse.

The expiratory arm of the flow-volume loop is primarily affected by a *variable intrathoracic* obstruction (Fig. 34-34*C*). The following sequence is responsible for producing this abnormality in the flow-volume loop: during forced expiration, as pleural pressure reaches and then exceeds intratracheal pressure downstream from the lesion (i.e., toward the mouth), the obstruction tends to increase; conversely, during a forced inspiration, as intratracheal pressure exceeds pleural pressure, the intrathoracic obstruction decreases.

Variable intrathoracic lesions often coexist with obstructive airway disease. In considering a variable intrathoracic lesion, the respective roles played by obstructive disease of the airways (i.e., chronic bronchitis, emphysema, and

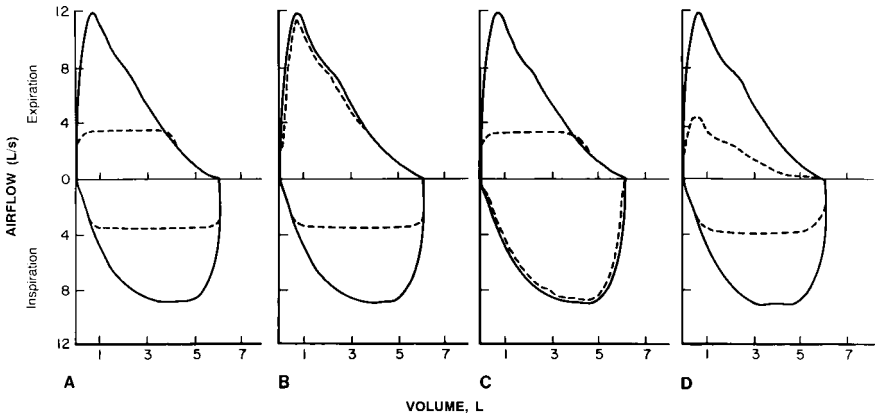

Figure 34-34 Schematic flow-volume loops in four pathological conditions. *A.* In a fixed upper-airway obstruction, both inspiratory and expiratory limbs are truncated. *B.* In a variable extrathoracic obstruction, the inspiratory limb is flattened while the expiratory limb is not altered. *C.* In a variable intrathoracic obstruction, the expiratory limb is flattened while the inspiratory portion is unchanged. *D.* In chronic obstructive airway disease, although expiratory airflow is reduced, the tapering in airflow during expiration is generally maintained so that the configuration of the loop is different from that in variable intrathoracic obstruction.

asthma) and an obstructive upper-airway lesion (anatomic or functional) in deforming the flow-volume loop must be determined. Fortunately, this distinction is often possible. Although both upper-airway obstruction and obstructive airway disease (reversible and irreversible) do decrease maximal expiratory flow, the shapes of the flow-volume curves are frequently quite distinctive (Fig. 34-34*C* and *D*). Thus, in obstructive airway disease, despite a decrease in airflow, the expiratory limb of the loop generally retains its normal configuration (Fig. 34-34*D*)—i.e., an early peak in flow, followed by gradual tapering. In contrast, in upper-airway obstruction (fixed and variable intrathoracic), the expiratory limb is flat and flow is decreased throughout most of expiration (Fig. 34-34*C*).

In addition to changes in the shape of the flow-volume loop, clues from routine pulmonary function tests often alert the clinician to the possibility of upper-airway obstruction. As noted previously, when FEV_1/PEFR is greater than 8, the possibility of upper-airway obstruction should be considered. Finally, the presence of any of the following may also provide clues: $FEF_{50\%}/FIF_{50\%}$ of at least 1, where $FEF_{50\%}$ and $FIF_{50\%}$ are the forced expiratory flow at 50 percent of FVC and the forced inspiratory flow at 50 percent of FIVC, respectively; $FIF_{50\%}$ less than 100 L/min; and $FEV_1/FEV_{0.5}$ at least 1.5.

Distinguishing test features of disorders producing an obstructive pattern are summarized in Table 34-19.

Additional Details of Pulmonary Function Test Results in a Restrictive Pattern

The restrictive pattern (Table 34-20) characteristically occurs in several groups of disorders including: (1) a primary disorder of the lung parenchyma in which functional tissue is lost through disease (e.g., an alveolar filling process, such as pneumonia, tumor, atelectasis, or fibrosis); (2) surgical removal of lung tissue (e.g., lobectomy); (3) constrictive disease of the

Table 34-19

Distinguishing Features of Disorders Producing an Obstructive Pattern

Disorder	FEV_1	FVC	$FEV_1/VC\%$	Response of FEV_1 to Administration of Bronchodilator	Tests of Small-Airway Function	Lung Volumes	D_{LCO}	Flow-Volume Loop
COPD								
Chronic bronchitis	↓	↓	↓	NC	ABN	↑	NL	ABN
Emphysema	↓	↓	↓	NC	ABN	↑	↓	ABN
Asthma	↓	↓	↓	↑	ABN	↑	NL	ABN
Small-airway disease	NL	NL	NL	NC	ABN	NL	NL	NL
Upper-airway obstruction	↓	↓	↓	NC	NL or ABN	NL or ↑	NL	ABN*

** Configuration frequently characteristic for upper-airway obstruction.*

Note: ↓ = decrease; ↑ = increase, NC = no significant change; NL = normal; ABN = abnormal.

Table 34-20

Causes of a Restrictive Pattern

Disease Process	Anatomic Location of Lesion	Cause of Pulmonary Function Test Abnormality
Primary parenchymal disease	Lung parenchyma	Loss of lung tissue → reduced volumes and flows
Surgical removal of lung tissue	Lung parenchyma	Loss of lung tissue → reduced volumes and flows
Diseases of pleura and chest wall	Pleura, chest wall	Limited expansion of thoracic cavity → reduced volumes and flows
Reduced generation of expiratory force	Central nervous system, peripheral nerves, neuromuscular junction, muscles of respiration	Reduced muscle tension → reduced expiratory flow, atelectasis

pleura and chest wall (e.g., extensive pleural fibrosis, large pleural effusion or pleural mass, kyphoscoliosis, obesity); and (4) neuromuscular diseases, notably those in which the generation of respiratory force is reduced (e.g., disorders of the spinal cord, peripheral nerves, neuromuscular junction, and muscle).

The diagnosis of restriction is based upon the finding of a normal FEV_1/VC and reduced VC in the setting of a decreased TLC. While TLC generally is reduced in most disorders producing a restrictive pattern, FRC is usually preserved in disorders characterized by decreased respiratory force (e.g., the neuromuscular disorders) and is reduced in the others. In neuromuscular disorders, ERV is decreased because of loss of expiratory force, so that RV is often increased. In the other types of restrictive disorders, RV is usually reduced.

Whether or not the $D_{L_{CO}}$ is reduced in the restrictive disorders depends on the underlying disease process. Primary parenchymal disorders and removal of lung tissue decrease the diffusing surface area and reduce $D_{L_{CO}}$. Diseases of the pleura and chest wall that limit thoracic excursion during the inspiratory VC maneuver, which is part of the technique for determining $D_{L_{CO}}$, also reduce this measurement.

Additional Details of Pulmonary Function Test Results in a Mixed Obstructive-Restrictive Pattern

Occasionally, a battery of pulmonary function tests demonstrates features of both obstructive and restrictive patterns. Most often, the mixed pattern is characterized by a low $FEV_1/VC\%$ (indicating obstructive airway disease) and VC and reduced TLC (indicating coexisting restrictive disease).

A number of disorders can produce the mixed obstructive/restrictive pattern. Sarcoidosis and interstitial fibrosis, when severe, generally result in this pattern because the parenchymal disease causes restriction and narrowing of the airways by adjacent fibrosis, evoking signs of airway obstruction. The mixed pattern also occurs in complicated situations when there is more than one cause (e.g., a lobar pneumonia or large pleural effusion occurring in a patient with underlying chronic bronchitis or emphysema).

Isolated Decrease in the Efficiency of Gas Transfer

An isolated reduction in the D_{LCO} suggests one of two possible abnormalities: (1) interstitial lung disease that is so mild as not to affect measurements of airflow or lung volume, or (2) widespread occlusive disease of the pulmonary microcirculation (e.g., due to an inflammatory process or multiple small emboli). In occlusive vascular disorders, tests of airflow and lung volume are usually normal. Although other disorders can also decrease D_{LCO}, almost invariably they also reduce airflow, lung volumes, or both. Quantification of the degree to which the D_{LCO} is reduced by any of these processes is indicated in Table 34-21. Notably, interlaboratory differences are substantial for measurements of D_{LCO}.

Table 34-21

Categorization of Reduction in Efficiency of Gas Transfer: Measurement of D_{LCO}

Severity	D_{LCO}, Percent Predicted
Mild	>60, but less than lower limit of normal
Moderate	40–60
Severe	<40

Characteristic Alterations in Pulmonary Function Tests According to the Major Patterns of Abnormality

Pattern	Airflow ($FEV_1/VC\%$)	Airflow Response to Bronchodilators	Volumes	Lung D_{LCO}
Obstructive				
Irreversible	↓	↔	↑	↔ or ↓
Reversible	↓	↑	↑	↔
Small-airway disease	↓	↔	↔	↔
Upper-airway obstruction	↓	↔	↔ or ↑	↔
Restrictive				
Parenchymal disease	↔ or ↑	↔	↓	↓
Surgical resection	↔	↔	↓	↓
Pleural, chest wall disease	↔	↔	↓	↔
Reduced expiratory force generation	↔	↔	↓	↔
Mixed obstructive-restrictive	↓	↔ or ↑	↓	↓
Isolated reduction in efficiency of gas transfer	↔	↔	↔	↓

Note: ↓ = decreased; ↑ = increased; ↔= no change or normal.

Summary of Approach to Interpretation

Pulmonary function tests are designed to detect common disorders. Test interpretation relies heavily on recognition of major patterns of abnormality (Table 34-22). These patterns often suggest pathogenetic mechanisms and are helpful to the clinician in arriving at a diagnosis. The degree of abnormality provides a quantitative measure of the extent of involvement at a particular time. Moreover, repeated testing makes it possible to pace and quantify the course of the illness and to assess the effects of therapeutic interventions.

Principles and Applications of Cardiopulmonary Exercise Testing

Karl T. Weber • Ahmad Munir

Cardiopulmonary exercise testing draws on the recognition that the thorax is a structure for the transport of the respiratory gases involved in metabolism and that the function of its components—diaphragm, heart, lungs, rib cage, and corresponding skeletal muscles—is to transport O_2 to and CO_2 from metabolizing tissues. The transport of O_2 and CO_2 must adjust to physiological and pathophysiological stresses that augment the body's consumption of oxygen ($\dot{V}_{O_2}$) and carbon dioxide production ($\dot{V}_{CO_2}$). During strenuous levels of muscular work, for example, $\dot{V}_{O_2}$ may rise eightfold, accompanied by increased $\dot{V}_{CO_2}$. Cardiovascular or ventilatory disease can disrupt the unit's functional integrity. Severe disease may elicit abnormality in respiratory gas transport that may be evident at rest, when the O_2 requirements of the body are modest. Lesser disease may allow resting pulmonary function to be preserved but abnormal respiratory gas transport becomes apparent when the unit is stressed by an increase in the oxygen requirement.

Cardiopulmonary exercise testing includes the monitoring of respiratory gas exchange ($\dot{V}_{O_2}$ and $\dot{V}_{CO_2}$), minute ventilation ($\dot{V}_E$) and its components, tidal volume and respiratory rate, together with blood pressure, heart rate, and the electrocardiogram. Cardiopulmonary exercise testing represents a useful approach in the clinical evaluation of a wide variety of disorders and circumstances. This chapter addresses physiological principles and the clinical application of cardiopulmonary exercise testing in the evaluation of major disorders that impair cardiac or pulmonary function.

PRINCIPLES, DEFINITIONS, AND CLINICAL APPLICATION OF CARDIOPULMONARY EXERCISE TESTING

The metabolic gas transport unit, also referred to as the "cardiopulmonary unit," links metabolizing tissues to the atmospheric supply of O_2. O_2 transport to the tissues must be precise and based upon prevailing need. CO_2 produced by tissues must be eliminated into the atmosphere in an equally efficient manner.

Resting Oxygen Uptake and Transport

Concepts and calculations pertaining to $\dot{V}_{O_2}$ and O_2 content, transport, and extraction are reviewed in Table 35-1. The heart and lungs accommodate to the metabolic requirements of tissues on a moment-to-moment basis, according to physiological priorities. Tissue requirements for O_2 dictate a certain$\dot{V}_E$ and cardiac output. In an average-sized person, the resting $\dot{V}_{O_2}$ averages 250 ml/min or 3.5 ml/min/kg body weight (one metabolic equivalent) and is associated with a $\dot{V}_E$ of 8 to 10 L/min and cardiac output of 4 to 6 L/min. O_2 transport, also termed O_2 delivery, ranges between 730 and 1040 ml/min and is more than adequate to satisfy the resting $\dot{V}_{O_2}$. On average, 25 percent of the arterial O_2 content is extracted by tissues. O_2 delivery and extraction increase during physiological stress in proportion to the increase in O_2 demand. Factors that normally determine O_2 availability at rest and during exercise include cardiac output, hemoglobin concentration and the percent of its O_2 saturation, and O_2 extraction.

Exercise Oxygen Uptake and Transport

$\dot{V}_E$ and O_2 delivery increase during exercise. Strenuous work can increase $\dot{V}_E$ eight to ten times its resting level. Ventilation normally poses no limitation on the ability of tissues to conduct aerobic work. In contrast, the extent to which cardiac output rises during progressive work is less dramatic. In untrained subjects, cardiac output increases four to five times its resting value. Cardiac output rises 600 ml/min for every 100 ml/min increment in $\dot{V}_{O_2}$. This is considered to be the normal "gain" setting between the heart and its cardiac output and $\dot{V}_{O_2}$. O_2 availability during physical activity is further ensured by enhanced O_2 extraction and circulatory autoregulation. Reflex and humoral influences produce vasoconstriction in tissues that are less metabolically active, permitting a greater apportionment of blood flow to exercising muscle.

Physiological limits to the increase in cardiac output and O_2 extraction (approximately 75 to 80 percent of arterial O_2 content) determine the aerobic capacity of untrained subjects to incremental exercise. Beyond these physiological limits, any additional increment in work is not accompanied by an increase in O_2 uptake; a plateau in $\dot{V}_{O_2}$ is reached. This plateau is termed the *maximal oxygen uptake* ($\dot{V}_{O_2max}$). The results of cardiopulmonary exercise testing, including the $\dot{V}_{O_2max}$, are shown in Fig. 35-1 for a 40-year-old man

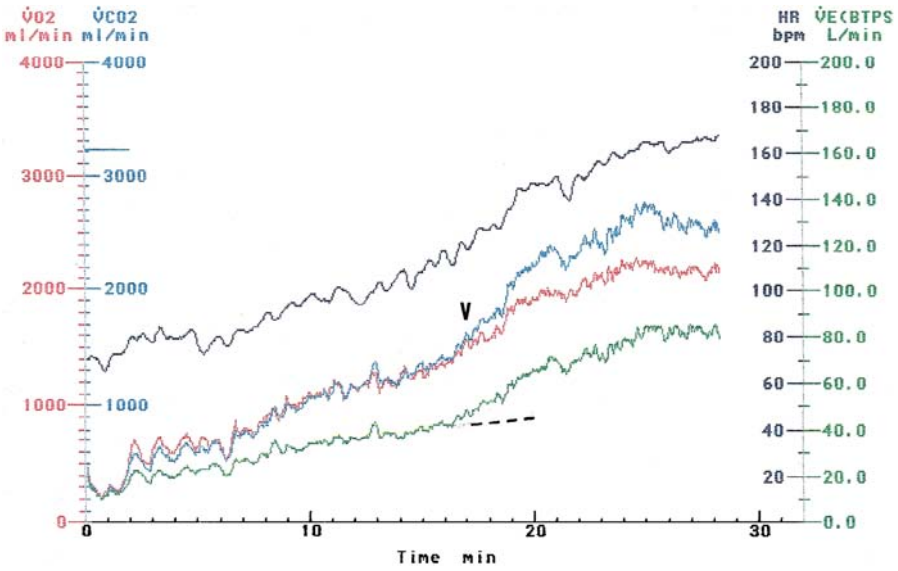

Figure 35-1 Cardiopulmonary exercise response in a 40-year-old man without heart or lung disease. Shown are 2 min of standing rest, followed by incremental treadmill exercise. Individual responses (color coded) include oxygen uptake ($\dot{V}_{O_2}$), carbon dioxide production ($\dot{V}_{CO_2}$), minute ventilation ($\dot{V}_E$), and heart rate (HR). Maximal O_2 uptake, a plateau in $\dot{V}_{O_2}$ was attained after the crossover of $\dot{V}_{CO_2}$ and $\dot{V}_{O_2}$ (arrowhead), representing the anaerobic threshold (AT) and accompanied by a disproportionate (broken line) rise in $\dot{V}_E$.

without heart or lung disease. The individual responses in $\dot{V}_{O_2}$, $\dot{V}_{CO_2}$, $\dot{V}_E$, and heart rate are illuminated during progressive increments in treadmill work. A $\dot{V}_{O_2max}$ of 2198 ml/min (27.2 ml/min/kg) was attained. This is a true plateau in $\dot{V}_{O_2}$, with $\dot{V}_{O_2}$ remaining invariant for 2.5 stages (5 min) of exercise.

$\dot{V}_{O_2max}$ should not be equated to, or used as synonym for, peak $\dot{V}_{O_2}$ achieved during symptom-limited exercise. $\dot{V}_{O_2max}$ reflects the individual's aerobic capacity—a physiological capacity of the cardiovascular system. In an average-sized, untrained individual whose maximum cardiac output and arteriovenous oxygen difference are 20 L/min and 12 ml/dl, respectively, a $\dot{V}_{O_2max}$ of 2400 ml/min is expected. In athletes, a greater cardiac reserve and enhanced capacity for oxidative metabolism by trained skeletal muscle provide a greater aerobic capacity. In patients with heart disease, in whom the ability to increase cardiac output during exercise is impaired, $\dot{V}_{O_2max}$ is proportionally reduced.

Carbon Dioxide Production

The right heart "accepts" metabolically produced CO_2, and the alveolar exchange surface expels the CO_2 into the atmosphere. CO_2 is a major respiratory stimulant that maintains eucapnia. Between 75 and 80 percent of O_2 is converted to CO_2. Accordingly, resting $\dot{V}_{CO_2}$ averages 190 ml/min and represents a *metabolic source* of CO_2. The resting $\dot{V}_{CO_2}/\dot{V}_{O_2}$ ratio, or respiratory gas exchange ratio (R), typically ranges between 0.75 and 0.85. The absolute value of R depends on the proportion of carbohydrates and fats provided by the diet. $\dot{V}_{O_2}$ and $\dot{V}_{CO_2}$ increase proportionally during physical activity as long as an adequate amount of O_2 is available to sustain oxidative metabolism.

During strenuous muscular work, $\dot{V}_{O_2}$ increases to a level at which the heart is unable to provide O_2 at the required rate. Consequently, tissue O_2 availability becomes inadequate. Working skeletal muscle calls upon less efficient anaerobic metabolism to derive energy. This leads to lactate production from working muscle which exceeds that normally produced. This *nonmetabolic source* of CO_2 is derived from rapid buffering of the lactate by bicarbonate; the CO_2 that is generated serves as a respiratory stimulant. The accompanying increase in $\dot{V}_E$ maintains eucapnia and increases the respiratory gas exchange ratio which is greater than that associated with aerobic metabolism. Anaerobic metabolism during a progressive exercise test is heralded by the disproportionate rise in $\dot{V}_E$ and $\dot{V}_{CO_2}$ relative to $\dot{V}_{O_2}$. The corresponding level of $\dot{V}_{O_2}$ at which anaerobic metabolism occurs is termed the *anaerobic threshold* (AT). The point during exercise at which $\dot{V}_{O_2}$ exceeds $\dot{V}_{O_2}$ and $\dot{V}_E$ rises disproportionately is shown in Fig. 35-1. Anaerobiosis normally occurs when 60 percent or more of a person's aerobic capacity has been reached. For the 40-year-old man whose exercise response is shown in Fig. 35-1, the AT occurred at a $\dot{V}_{O_2}$ of 18.8 ml/min/kg, or 69 percent of his $\dot{V}_{O_2}$max.

Clinical Application of Cardiopulmonary Exercise Testing

In patients with mild to moderate cardiovascular or respiratory disease, symptoms of fatigue or breathlessness frequently limit physical activity. Because their quality of life is compromised, they seek, or are referred for, medical evaluation.

Re-creating muscular work in a monitored setting permits an evaluation of the nature and severity of such symptoms and the relative importance of abnormal heart or lung function. This strategy provides information that surpasses that available from measures of heart and lung function determined at rest, such as ejection fraction, lung volumes, or airflows. The continuous monitoring of $\dot{V}_{O_2}$, $\dot{V}_{CO_2}$, $\dot{V}_E$, respiratory rate, and tidal volume during incremental exercise can be performed simply and on a breath-by-breath basis. Data shown in Fig. 35-1 are displayed throughout the test. The choice of a particular cardiopulmonary exercise test depends on the nature and expression of the clinical disorder and the particular problem to be addressed. For most clinical evaluations, isotonic forms of exercise afford an acceptable and reproducible form of exercise for patients with heart or lung disease. However, even though noninvasive cardiopulmonary exercise testing in patients with lung disease may help to identify the impairment in aerobic capacity, the abnormalities in ventilation and the severity of the abnormalities, these parameters are not necessarily diagnostic. For example, $\dot{V}_{O_2max}$, AT, or exercise $\dot{V}_E$ does not identify the underlying structural defect responsible for a patient's abnormal response. This diagnosis may require invasive monitoring during cardiopulmonary exercise testing to identify specific hemodynamic abnormalities. Echocardiography and specialized pulmonary function studies may be required.

Noninvasive Treadmill Exercise

Walking represents a common daily exercise rather than a specialized skill. A patient who walks into the physician's office or down a hospital corridor can walk on a treadmill at 1.0 or 1.5 mph, zero grade. Treadmills are programmable. The Bruce protocol, which employs specific increments in treadmill speed and slope over short periods to evaluate myocardial ischemia, may not be useful for patients with limited exercise tolerance. A modified Naughton protocol of gradually progressive exercise (Table 35-2) is useful for patients with heart or lung disease who have a wide range of exercise tolerance. In this protocol, the first two stages of exercise constitute very low workloads and serve as a warmup for patients with heart or lung disease of minor severity; in contrast, these stages represent near-maximal exercise for patients with more advanced disease.

$\dot{V}_{O_2max}$ is defined as $\dot{V}_{O_2}$ that remains invariant (less than 1 ml/min/kg for 30 s or more) despite increment in workload. An invariant $\dot{V}_{O_2}$ for at least two stages of exercise is preferred (Fig. 35-1). $\dot{V}_{O_2max}$ follows the AT, and this definition of $\dot{V}o_2max$ presumes that the AT has already been achieved. The AT generally occurs at 60 percent of a patient's aerobic capacity. $\dot{V}_{O_2max}$ associated with incremental treadmill exercise provides a greater aerobic capacity than does cycle ergometry because it works a larger group of muscles. A patient's aerobic capacity to incremental treadmill exercise is used to grade the functional impairment (Table 35-3). $\dot{V}_{O_2max}$ is an objective measure of functional status—in contradistinction to the New York Heart Association classification, which is

Table 35-2

Modified Naughton Treadmill Exercise Protocol

Stage	Speed	Grade	Physical Activities
1	1.0	0	Driving a car Sitting and writing or eating
2	1.5	0	Dressing; knitting Walking to bathroom Light auto repair

Table 35-3

Classification of Cardiac and Circulatory Failure

Class	Severity	$\dot{V}_{O_2max}$ (ml/kg/min)	Anerobic Threshold (ml/kg/min)	Predicted Cardiac Index (L/m²/min)
A	Mild to none	>20	>14	>8
B	Mild to moderate	16 to 20	11 to 14	6 to 8
C	Moderate to severe	10 to 16	8 to 11	4 to 6
D	Severe	6 to 10	5 to 8	<4

Source: Adapted from Weber KT, Janicki JS, McElroy PA: Cardiopulmonary exercise (CPX) testing, in Weber KT, Janicki JS (eds), Cardiopulmonary Exercise Testing: Physiologic Principles and Clinical Applications. Philadelphia, Saunders, 1986, pp 151–167.

based on perceptions and biases of the patient and physician. The determination of O_{2max} by treadmill is reproducible in patients with a wide variety of cardiovascular disorders. A $\dot{V}_{O_2max}$ of under 20 ml/min/kg has been designated as the cutoff for grading impairment of aerobic capacity; adult men and women, including the elderly (over 65 years of age), have an expected $\dot{V}_{O_2max}$ greater than 20 ml/min/kg.

The duration of symptom-free treadmill exercise should not be equated with the $\dot{V}_{O_2max}$. Treadmill time suffers from not having an objective, quantitative end point. Differences in gait and body weight create different levels of work for equivalent stages of treadmill exercise. Symptom-limited exercise time is subject to patient motivation and physician bias. Peak heart rate attained during exercise is also a less precise measure of $\dot{V}_{O_2max}$. This is particularly true in patients with atrial fibrillation.

Determination of the AT can be defined according to one or more criteria. These include: (1) a disproportionate rise in $\dot{V}_{CO_2}$, $\dot{V}_E$, or R relative to $\dot{V}_{O_2}$ and (2) a disproportionate rise in end-tidal O_2 relative to end-tidal CO_2. These criteria can best be applied to data on breath-by-breath respiratory gas exchange. In our laboratory, a simple strategy is used. The AT is identified as the level of $\dot{V}_{O_2}$ attained during treadmill work after the plots of $\dot{V}_{O_2}$ and CO_2 cross, when R exceeds 1.0. Figure 35-1 depicts the crossover in $\dot{V}_{CO_2}$ and $\dot{V}_{O_2}$ from breath-by-breath gas exchange data monitored throughout incremental treadmill exercise. It also demonstrates the point at which $\dot{V}_E$ rises disproportionately. Measured days or weeks apart, this noninvasive determination of the AT is reproducible in a wide range of patients with cardiac or circulatory failure and correlates with the lactate threshold.

The normal ventilatory response to incremental treadmill exercise consists of an increase in $\dot{V}_E$ created by an increase in respiratory rate and tidal volume. Ventilatory reserves, represented by maximal voluntary ventilation (MVV) and vital capacity determined during routine pulmonary function testing, are only partly utilized during light, moderate, and maximal exercise by normal persons. The ratio of maximal exercise $\dot{V}_E$ to MVV reflects use of this ventilatory reserve. Exercise $\dot{V}_E$ in normal subjects and patients with predominant cardiovascular disease rarely exceeds 50 percent of MVV. The same is true of the ratio between maximal exercise tidal volume and vital capacity. These limitations in ventilatory responses are consistent with a ventilatory effort that can be voluntarily sustained at rest without the appearance of fatigue or breathlessness.

An oximeter, worn on either an earlobe or a finger, affords noninvasive monitoring of arterial O_2 saturation during exercise. This is a useful screening procedure in patients in whom O_2 desaturation might be anticipated (e.g., those with congenital heart disease with right-to-left shunt, restrictive or obstructive lung disease, or pulmonary vascular disease). Normal subjects and patients with chronic cardiac or circulatory failure do not develop arterial hypoxemia (arterial O_2 saturation under 90 percent) during exercise. In patients in whom oximetry indicates O_2 desaturation, confirmatory evidence from direct measurement of arterial blood gases during repeat exercise may be advisable.

Thus, incremental treadmill exercise can be used to determine the following: the AT with a submaximal test, the AT and $\dot{V}_{O_2max}$ with a maximal test, the ventilatory response to submaximal or maximal exercise, and arterial O_2 desaturation during submaximal or maximal exercise.

Invasive Treadmill Exercise

Invasive hemodynamic monitoring may be necessary for better definition of the nature and severity of an underlying cardiopulmonary disorder. A triple-lumen flotation catheter can be safely used for hemodynamic monitoring during upright exercise. The hemodynamic response to incremental treadmill exercise in normal subjects is characterized by a progressive increase in cardiac output, accompanied by minimal increments in left and right ventricular filling pressures. The increase in cardiac output occurs because of an increment in stroke volume, which is most apparent at low and moderate

workloads, and because of an increase in heart rate, which accompanies the exercise response. Systemic O_2 extraction increases progressively during incremental exercise to exceed 70 percent at maximal workloads. An increase in the concentration of lactate in mixed venous blood, demonstrated by sampling pulmonary arterial blood, occurs when O_2 extraction exceeds 60 percent and when the subject is working at greater than 60 percent of $\dot{V}_{O_2max}$.

Systolic and mean arterial pressures increase during upright exercise. Because of skeletal muscle vasodilation, arterial diastolic pressure remains essentially unchanged during exercise. Systemic vascular resistance falls by 50 percent to approximately 600 dynes · s · cm^{-5} during incremental, isotonic treadmill exercise. In normal persons, pulmonary artery systolic, mean, and diastolic pressures increase only minimally during exercise and only at higher workloads. Pulmonary vascular resistance, like systemic vascular resistance, falls 50 percent to about 60 dynes · s · cm^{-5} during incremental isotonic exercise.

CHRONIC CARDIAC FAILURE

In physiological terms, *cardiac failure* is defined as an impairment in cardiac output secondary to a disease process affecting the myocardium. Ischemic heart disease and dilated cardiomyopathies are examples of disease entities that can result in chronic cardiac failure. $\dot{V}_{O_2max}$ and the AT each predict cardiac reserve and, thereby, the severity of cardiac failure. These parameters further serve to demonstrate objectively a patient's functional capacity, which is not predictable by the cardiac ejection fraction. Patients with an ejection fraction of under 20 percent may still be able to swim.

Systolic Dysfunction

In patients with chronic cardiac failure, $\dot{V}_{O_2max}$ attained during incremental treadmill exercise is primarily a function of maximal cardiac output. This conclusion has been confirmed by numerous studies. An impairment in aerobic capacity is gauged according to the exercise AT and $\dot{V}_{O_2max}$ and assigned a functional class, as reviewed in Table 35-3. These parameters are, in turn, used to predict maximal exercise cardiac index (or cardiac reserve). Examples of $\dot{V}_{O_2max}$ and the AT attained by two patients with chronic cardiac failure (one class B, the other class C) are given in Fig. 35-2. To measure $\dot{V}_{O_2max}$ in such patients, they must be exercised to exhaustion. The AT is achieved at submaximal workloads short of exhaustion; it, too, stratifies the degree of cardiac dysfunction.

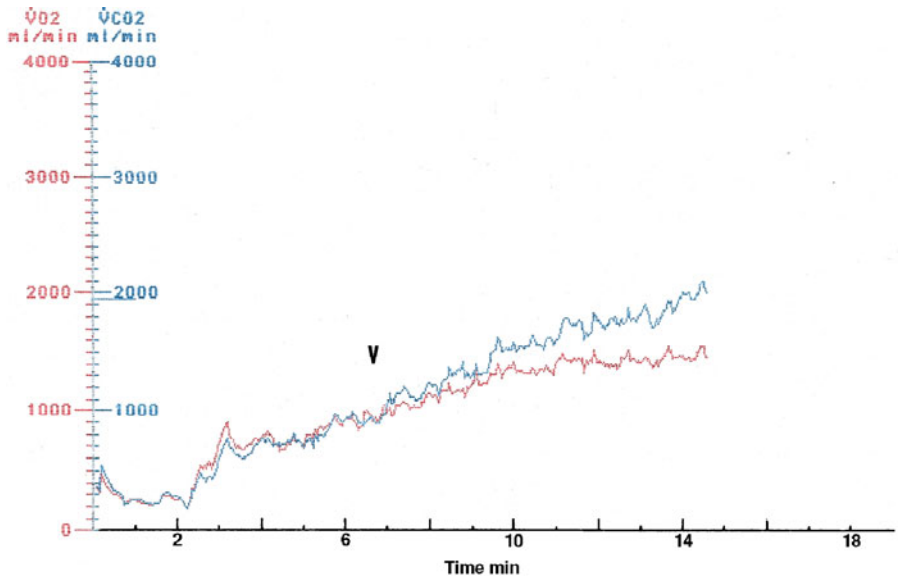
Validation of these concepts was obtained during treadmill exercise using invasive measures of cardiac output and mixed venous lactate concentration. Patients had chronic cardiac failure of varying severity (classes A to D) due to either ischemic or myopathic heart disease. In each exercise class, the arteriovenous O_2 difference rose to 12 ml/dl or more at maximum exercise, corresponding to a systemic O_2 extraction in excess of 70 percent, suggesting that O_2 extraction had reached maximal physiological levels. The reduction in aerobic capacity of a patient with chronic cardiac failure is, therefore, due primarily to impaired cardiac reserve. The cardiac output–O_2 relation to progressive treadmill exercise for these patients is given in Fig. 35-3. For each exercise class, cardiac output is presented as a percentage of $\dot{V}_{O_2max}$ (set equal to 100 percent) that existed at rest and throughout each stage of exercise. Cardiac output increased by 600 ml/min/m^2 for each dl/min/m^2 increase in $\dot{V}_{O_2}$ in each class. This indicates that the heart responds to tissue O_2 requirements irrespective of the severity of heart failure, but it is limited by the maximal cardiac output that it can attain. Differences in cardiac output achieved at peak exercise are seen between classes. Progressive reductions in cardiac reserve are responsible for different aerobic capacities observed in these patients. $\dot{V}_{O_2max}$, therefore, serves as a noninvasive measure of peak exercise cardiac output and is given for each functional class in Table 35-3.

The cardiac output response to exercise is a function of the increases in stroke volume and heart rate. Responses in stroke volume for patients in chronic cardiac failure are shown in Fig. 35-4 for each exercise class. In class A and B patients, stroke volume rises 50 percent during lighter workloads that represent less than 60 percent of $\dot{V}_{O_2max}$; at larger workloads, further increments in stroke volume are less apparent. A 25 percent rise in stroke volume occurs at submaximal exercise in class C patients, whereas in class D patients, exercise stroke volume is no different from its resting value. Exercise stroke volume is a result of several factors, including systolic wall stress, mitral or tricuspid regurgitation that may appear during exercise, and depressed myocardial contractility.

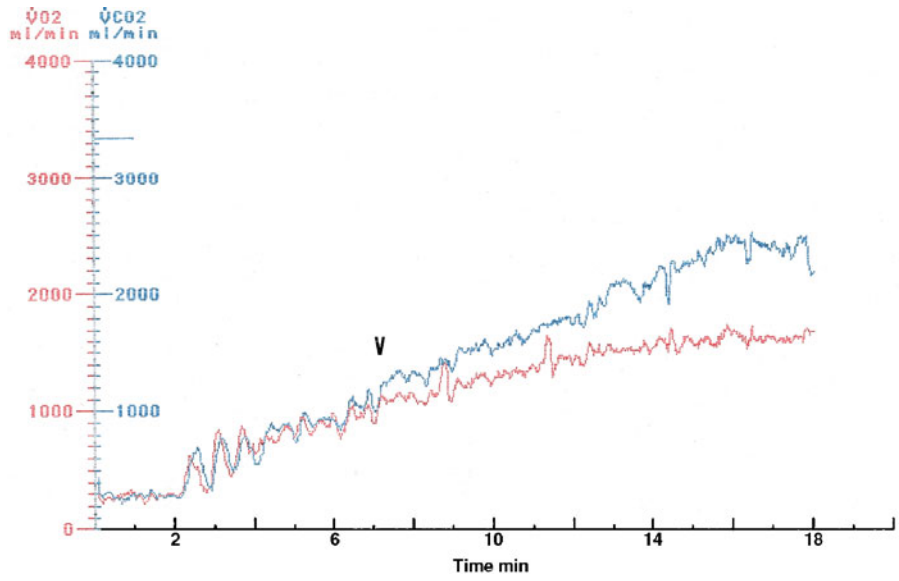
For each functional class of chronic cardiac failure, the heart rate–$\dot{V}O_2$ response to upright incremental exercise is represented by a common slope. The average slope is 3.6 beats per minute for every 1-ml/min/kg increment in $\dot{V}_{O_2}$. Peak heart rate achieved is a function of maximal workload performed. Maximal exercise heart rate is, therefore, different for each class. In class D patients, the increase in heart rate is the sole mechanism by which cardiac output increases during exercise.

Some patients with chronic cardiac failure deviate from this heart rate–$\dot{V}_{O_2}$ relation by having an inappropriate sinus tachycardia, either at rest and throughout exercise, or simply during exercise. In the presence of a reduced ejection fraction and ventricular dilation, this inappropriately rapid heart rate further compromises exercise cardiac output and reduces aerobic capacity. Under these circumstances, β-adrenergic receptor blockade is useful in attenuating the resting or exercise heart rate. Such chronotropic dysfunction (see below) to exercise may also apply to patients with chronic atrial fibrillation. An example of an inappropriate rapid heart rate during incremental treadmill exercise (Naughton protocol) is given in Fig. 35-5 for a patient with atrial fibrillation and dilated cardiomyopathy of uncertain origin.

As in normal persons, lactate production appears in patients with chronic cardiac failure when systemic O_2 extraction exceeds 60 percent. Mixed venous lactate concentration



A



B

Figure 35-2 Cardiopulmonary exercise test results for a 45-year-old woman (*A*) and a 40-year-old man (*B*), each with ischemic heart disease and chronic cardiac failure. Only $\dot{V}_{O_2}$ and $\dot{V}_{CO_2}$ are shown, to better demonstrate the anaerobic threshold (AT) and $\dot{V}_{O_2max}$ attained by each patient. In panel *A*, the AT was seen with a $\dot{V}_{O_2}$ of 11.6 ml/min/kg and a $\dot{V}_{O_2max}$ of 16.5 ml/min/kg. This represents a functional class B response. The AT and $\dot{V}_{O_2max}$ are 8.5 and 13.7 ml/min/kg, respectively (panel *B*). This corresponds to functional class C.

during exercise increases above resting values when 60 percent or more of $\dot{V}_{O_2max}$ is attained. Given differences in aerobic capacity between exercise classes, different workloads are associated with this lactate threshold (Fig. 35-6). In class D patients, in whom the cardiac output response is limited, the lactate threshold occurs at very light workloads ($\dot{V}_{O_2}$ of 5 to 8 ml/min/kg). Corresponding values for class C, B, and A patients are 8 to 11 ml/min/kg, 11 to 14 ml/min/kg, and more than 14 ml/min/kg, respectively. Thus, the lactate threshold and the $\dot{V}_{O_2max}$ reflect the severity of chronic cardiac failure, as given in Table 35-3. A noninvasively determined AT based on measurements of respiratory gas exchange, as discussed previously, corresponds to the invasively measured lactate threshold.

In chronic cardiac failure, the left ventricular filling pressure during exercise, as gauged from recordings of the occlusive wedge pressure, increases to a different degree in each exercise class (Fig. 35-7). In class A patients, the rise in wedge pressure during isotonic exercise rarely exceeds 18 mmHg. This resembles a normal response. In class B patients, more dramatic elevations in exercise wedge pressure—to 25 mmHg or higher—frequently occur. Resting filling pressure

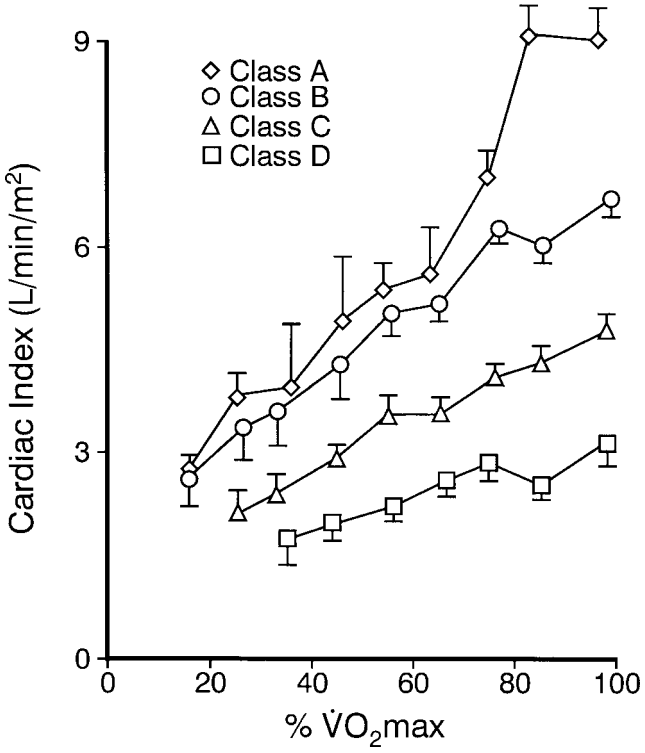


Figure 35-3 Relationship between treadmill exercise cardiac index and normalized aerobic capacity for patients with chronic cardiac failure of diverse origin and severity, subdivided according to each functional class. *(From Weber KT, Janicki JS: Cardiopulmonary exercise testing for evaluation of chronic cardiac failure. Am J Cardiol 55:22A–31A, 1985.)*

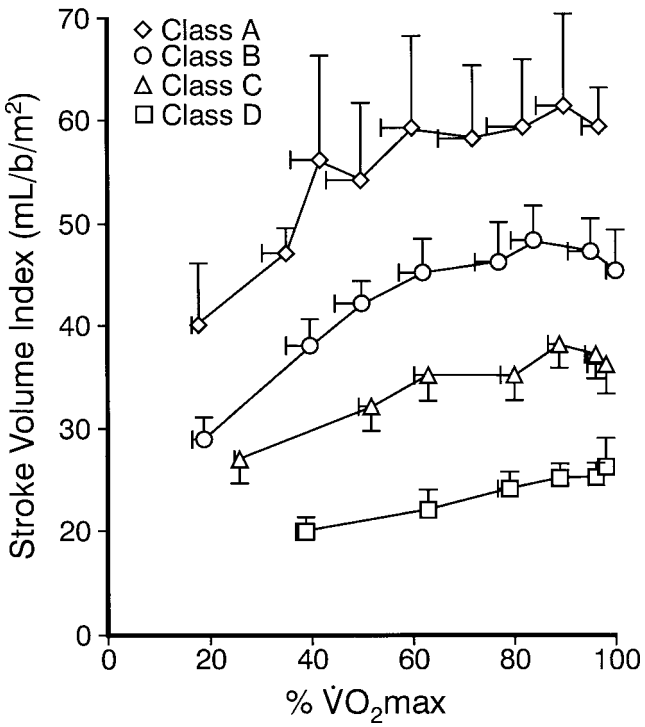

Figure 35-4 Relationship between treadmill exercise stroke volume index and normalized aerobic capacity for patients with chronic cardiac failure of varying severity, as expressed by each functional class. *(From Weber KT, Janicki JS: Cardiopulmonary exercise testing for evaluation of chronic cardiac failure. Am J Cardiol 55:22A–31A, 1985.)*

is increased in class C and D patients; a further increase may occur during upright exercise, often to levels in excess of 30 mmHg. Despite these marked levels of pulmonary venous pressure, patients do not develop evidence of pulmonary congestion after exercise. Moreover, elevations in wedge pressure neither predict exercise cardiac reserve and aerobic capacity nor are responsible for exertional dyspnea in these patients. Dyspnea corresponds with the lactate threshold and a disproportionate rise in $\dot{V}_E$ relative to $\dot{V}_{O_2}$. Despite dyspnea, patients can be encouraged to exercise to exhaustion, attaining $\dot{V}_{O_2max}$. In patients with acute cardiac failure, pulmonary congestion

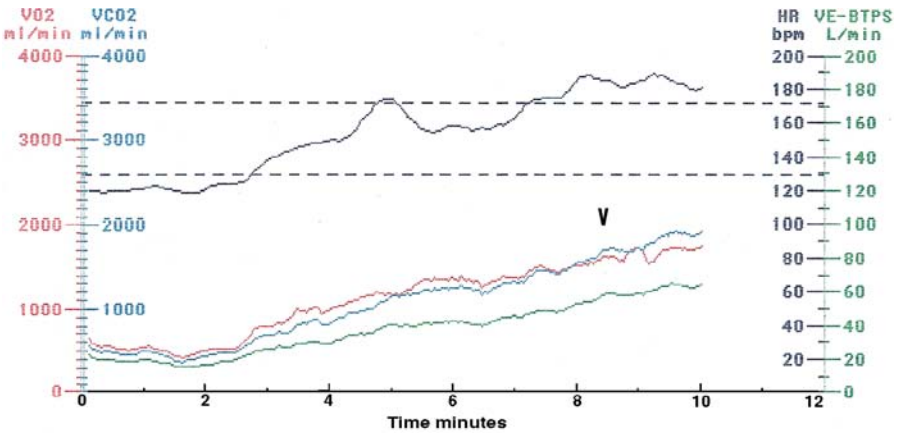

Figure 35-5 Cardiopulmonary exercise test results in a 48-year-old man with atrial fibrillation and dilated (idiopathic) cardiomyopathy. Note the rapid heart rate at rest and throughout incremental treadmill exercise. Predicted maximum heart rate range in this patient is shown by the broken lines. He achieved this rate during the first stage of exercise and exceeded it during the last stage of exercise. This is an inappropriate heart rate response. The anaerobic threshold (AT) is 13 ml/min/kg (arrow), in keeping with functional class B. He did not achieve $\dot{V}_{O_2max}$ and, therefore, had a peak $\dot{V}_{O_2}$ of 15 ml/min/kg.

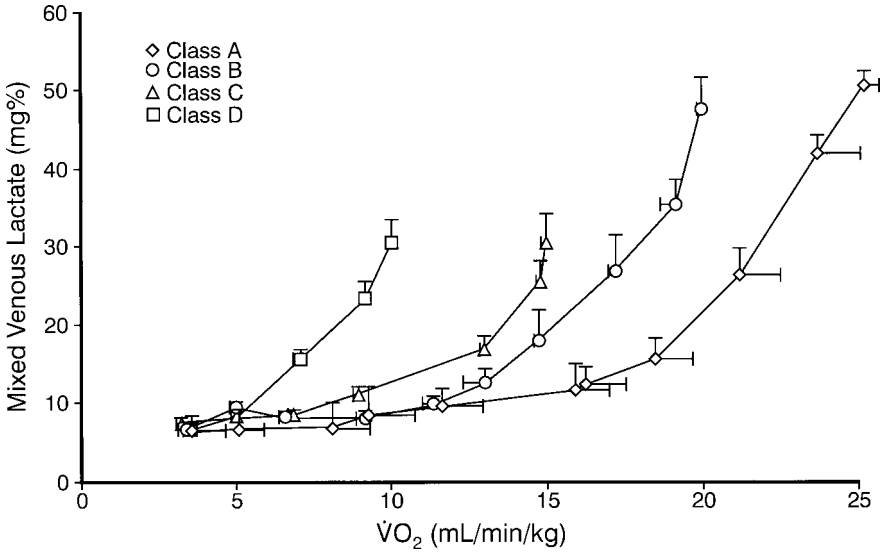

Figure 35-6 Relationship between mixed venous lactate concentration and $\dot{V}_{O_2}$ to incremental treadmill exercise for patients with chronic cardiac failure of varying severity, as expressed by each functional class. *(From Weber KT, Janicki JS: Cardiopulmonary exercise testing for evaluation of chronic cardiac failure. Am J Cardiol 55:22A–31A, 1985.)*

and dyspnea correlate with the increase in wedge pressure; pulmonary edema occurs when hydrostatic pressure exceeds the colloidal osmotic pressure of 25 mmHg.

$\dot{V}_E$ rises appropriately during incremental exercise in patients with chronic cardiac failure. The response in $\dot{V}_E$ corresponds most closely to $\dot{V}_{CO_2}$ throughout exercise (aerobic and anaerobic work) and is sufficient to sustain alveolar ventilation, thereby preventing hypoxemia and hypercapnia.

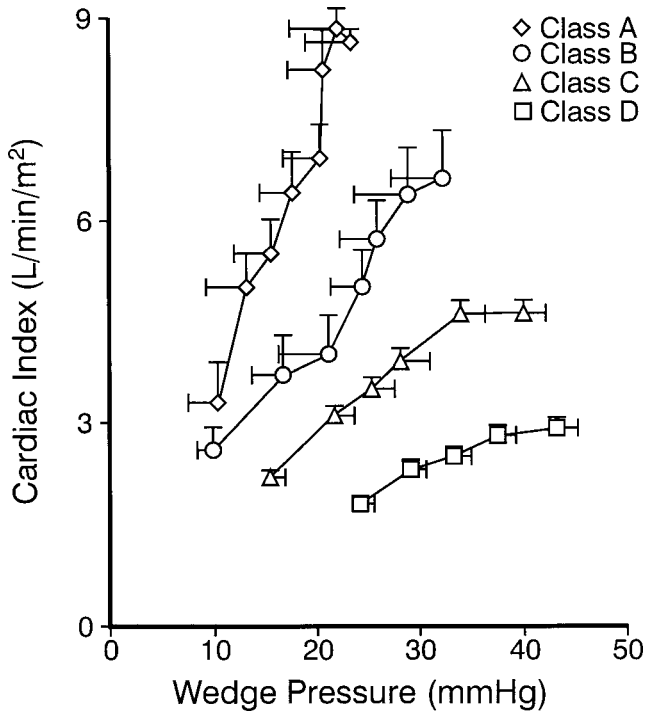

Figure 35-7 Relationship between treadmill exercise cardiac index and occlusion wedge pressure in patients with chronic cardiac failure, subdivided according to functional class. *(From Weber KT, Janicki JS: Cardiopulmonary exercise testing for evaluation of chronic cardiac failure. Am J Cardiol 55:22A–31A, 1985.)*

Maximum $\dot{V}_E$ attained during exercise is less than 50 percent of MVV. Thus, these patients do not exhaust their ventilatory reserve in responding to exercise, even when their pulmonary compliance may be adversely affected by the chronic pulmonary congestion and increments in pulmonary venous pressure that appear during exercise. In order to minimize the work of breathing during exercise, class C and D patients use a pattern of rapid, shallow breathing to increase $\dot{V}_E$. Thus, the rise in tidal volume during exercise above its resting value is modest and compatible with a substantial portion of each breath being wasted in ventilation of the anatomic dead space. The response of class A and B patients more closely approximates that of healthy persons, in whom respiratory rate rises progressively during incremental exercise and the increase in tidal volume occurs early during the transition from rest to low-level exercise.

Diastolic Dysfunction

In 30 percent or more of patients with symptomatic heart failure, primary diastolic dysfunction is responsible. The ejection fraction is normal or only minimally impaired in these patients. Diastolic dysfunction relates to an inability of the left ventricle to accommodate left atrial and pulmonary venous blood flow during diastole without a marked increase in filling pressure. Abnormal diastolic relaxation and filling typically appear in patients with chronic ischemic heart disease (with previous myocardial infarction), in those with hypertensive heart disease, and in the elderly. Responsible mechanisms are thought to include abnormal tissue structure, as occurs with the accumulation of fibrous tissue or infiltration with amyloid and abnormal handling of calcium by the sarcoplasmic reticulum. Factors extrinsic to the myocardium may also contribute. Examples include the interaction between the pressure- or volume-overloaded right ventricle with the left ventricle and the interplay between the heart and pericardium.

Invasive cardiopulmonary exercise testing, together with incremental bicycle exercise, has been used to address the hemodynamic response of patients with primary diastolic dysfunction. Most patients studied had systemic hypertension, and many were elderly; all had a clinical history of pulmonary congestion. Peak exercise $\dot{V}_{O_2}$ was reduced, owing to a reduction in the responses of the cardiac output and stroke volume; arteriovenous O_2 difference increased above 10 ml/dl. The level of $\dot{V}_{O_2}$ achieved with exercise correlated with the peak response of the cardiac output. In comparison to age-matched controls, expected exercise-associated increments in left ventricular end-diastolic volume were not seen and were accompanied by increased left ventricular filling pressure. Thus, abnormalities in diastolic filling abrogated the Frank-Starling mechanism, thereby restricting the rise in cardiac output during exercise; this finding may explain symptoms of fatigue and breathlessness that these patients experience on exertion.

Primary diastolic dysfunction has been observed in patients following cardiac transplantation in which there is an abnormal blunting of the stroke volume and heart rate responses to exercise. Despite the slower exercise heart rate in the transplanted, denervated heart, in which diastolic filling periods would accordingly be longer, diastolic dysfunction is present, limiting the response of the cardiac output to exercise. Abnormal diastolic function has also been observed in the elderly and contributes to impaired exercise cardiac output response.

Chronotropic Dysfunction

Cardiac reserve during exercise depends not only on systolic and diastolic function but also on heart rate and rhythm, including a coordinated contraction of the atria and ventricles. Cardiopulmonary exercise testing has been used to address the contribution of abnormal heart rate and rhythm on the AT and $\dot{V}_{O_2 max}$, broadly categorized here as chronotropic dysfunction. This includes abnormal sinus tachycardia, bradyarrhythmias, atrioventricular dissociation, and atrial fibrillation. Cardiopulmonary exercise testing has proved useful in the evaluation of pacemaker function and technique. Improvements in the AT at submaximal levels of work have been demonstrated for single-chamber, activity-triggered pacing compared with fixed-rate atrial or ventricular pacing. It, too, can help determine the optimum upper rate limit in heart failure patients with pacemakers. This can be determined by the highest pacing rate that still produces an increase in oxygen consumption. With recent advancements in pacemaker technology, cardiac resynchronization therapy (CRT) is being increasingly offered to patients with heart failure. In a study involving patients with CRT undergoing cardiopulmonary exercise testing, significant increments in peak $\dot{V}_{O_2}$, $\dot{V}_{O_2}$ at AT and in all ventilation and metabolic parameters occurred. Patients with baseline $\dot{V}_{O_2}$ of less than 14 ml/min/kg had the most benefit. Similarly, patients with severe heart failure and atrial fibrillation had better hemodynamic performance with chronic biventricular pacing than with left ventricular pacing alone.

Survival and Prognosis

Various gas exchange parameters have been used to assess prognosis in patients with heart failure, including AT, peak $\dot{V}_{O_2}$, and $\dot{V}_E/\dot{V}_{CO_2}$ slope (a marker of ventilatory efficiency). $\dot{V}_{O_2}$ at AT and $\dot{V}_{CO_2}$ slope are less subject to patient motivation or premature cessation of exercise and, hence, are more useful parameters. Class D patients with little or no exercise cardiac reserve (Table 35-3) with AT less than 8 ml/min/kg have a marked reduction in 1- and 2-year survival as contrasted to class A and B patients with respective exercise cardiac index responses of greater than 8 and 6 to 8 L/min/m^2. $\dot{V}_{O_2}$ at AT, combined with $\dot{V}_E/\dot{V}_{CO_2}$, is a better prognostic indicator than peak $\dot{V}_{O_2}$ alone. A low peak $Paco_2$ with exercise is responsible for the prognostic power of $\dot{V}_E/\dot{V}_{CO_2}$ slope and by itself is also an independent prognosticator. Resting end-tidal CO_2 has been shown to be a predictor of cardiac-related events. Another $\dot{V}_{O_2}$ kinetics parameter that is a strong predictor of survival and is less dependent on motivation is the mean response time ($\dot{V}_{O_2}$ deficit/$\Delta\dot{V}_{O_2}$). In the recovery period, slow normalization of $\dot{V}_{O_2}$ is associated with a poor prognosis.

The fluctuations in breathing patterns and its association with prognosis have also been studied in patients with heart failure. Cyclic fluctuations in minute ventilation at rest that persist during effort (external oscillatory ventilation) are associated with poor prognosis whereas oscillations at rest alone are not.

Efficacy of Medications

The response to various heart failure medications on gas exchange and hemodynamics has been evaluated. Patients with heart failure who are taking spironolactone have a significant increase in peak oxygen consumption, D_{LCO}, and membrane diffusing capacity. In addition, in one study, use of an angiotensin-receptor blocker (losartan), along with an angiotensin-converting enzyme (ACE) inhibitor, resulted in a significant increase in peak $\dot{V}_{O_2}$ and exercise capacity. However, in another study, addition of candesartan to an ACE inhibitor had no such effect. Finally, in patients with chronic heart failure who were taking carvedilol, determination of peak $\dot{V}_{O_2}$, which has been used as a prognostic marker in this group of patients, was not found to be useful.

Exercise Training

Exercise training improves exercise tolerance and peak $\dot{V}_{O_2}$ in patients with heart failure and left ventricular dysfunction. Exercise training in moderate stable heart failure results in favorable qualitative, rather than quantitative, changes in skeletal muscle. Correction of maximum oxygen uptake for skeletal muscle mass is a more sensitive measure of changes associated with exercise training than is total body mass. Only a

progressive, increasing workload seems to markedly improve oxygen uptake.

Ischemic Heart Disease

Ischemia can be diagnosed during cardiopulmonary exercise testing with the help of ST segment changes during incremental exercise on a treadmill or an ergometer. The sensitivity and specificity of ST changes for ischemia is not high. Parameters of gas exchange on cardiopulmonary exercise testing can be used to improve the diagnostic ability of the exercise-induced ST changes. In one study, which examined the duration of "O_2 pulse flattening" and changes in $\dot{V}_{O_2}$ relative to the work rate slope along with electrocardiographic ST changes, sensitivity increased from 46 to 87 percent and specificity from 66 to 74 percent. In another study, exercise cardiac output, estimated from $\dot{V}_{O_2}$ at AT, correlated with multivessel coronary artery disease, adverse cardiac events, and clinically driven revascularization. In patients who experienced myocardial infarction and who subsequently underwent 3 weeks of exercise training, a significant improvement in peak $\dot{V}_{O_2}$ was found.

CHRONIC CIRCULATORY FAILURE

Circulatory failure, in physiological terms, refers to an inability of the heart to increase its cardiac output in a manner commensurate with prevailing $\dot{V}_{O_2}$. Responsible factors may be extrinsic to the myocardium and include such entities as valvular heart disease, intrinsic pulmonary vascular disease, pericardial disease, and anemia.

Valvular Heart Disease

Mitral or aortic valve disease may alter the functional integrity of the cardiopulmonary unit by impairing the heart's ability to increase cardiac output in accord with increments in $\dot{V}_{O_2}$. Pathophysiological alterations that result from chronic valvular disease and that determine the clinical course and outcome following valve replacement include right heart overload and structural remodeling of the pulmonary vasculature and lung interstitium. The more marked the preoperative impairment in cardiac reserve, the poorer the long-term prognosis. Similarly, the greater the elevation in pulmonary vascular resistance, the more delayed is its return to normal levels and the slower the postoperative abatement of symptoms. The decision for surgical intervention requires an assessment of cardiopulmonary status—one that can be assessed noninvasively and monitored over time to detect a decline in cardiac reserve. Noninvasive cardiopulmonary exercise testing serves this purpose. Because of the heightened risk of syncope and the myocardial ischemia and arrhythmias that can occur during exercise in patients with aortic valvular stenosis, these patients should exercise with extreme caution, if at all.

Incompetence of the mitral and aortic valves is an example of a disorder that can result in chronic circulatory failure.

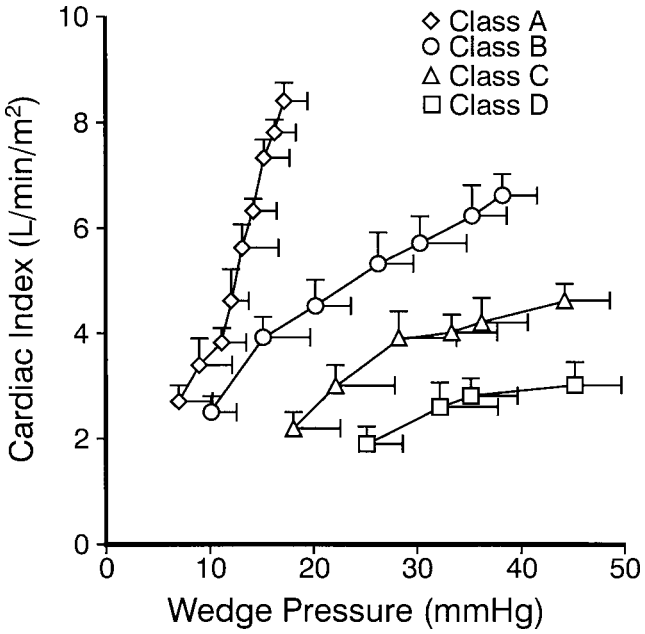

Figure 35-8 Relationship between treadmill exercise cardiac index and wedge pressure in patients with chronic mitral or aortic regurgitation, divided according to functional class. *(From Weber KT, Janicki JS (eds): Cardiopulmonary Exercise Testing: Physiologic Principles and Clinical Applications. Philadelphia, WB Saunders, 1986.)*

Each creates a volume overload on the left ventricle. The onset of ventricular dysfunction is generally unpredictable and may initially appear only during vigorous levels of physical activity. As dysfunction progresses, symptoms appear at lower levels of activity and, finally, at rest.

Resting cardiac output is often not distinguishable among class A, B, C, or D patients with mitral or aortic regurgitation. Cardiac reserve is reduced, however, and, accordingly, so is aerobic capacity. No impairment in systemic O_2 extraction has been reported. Thus, as in chronic cardiac failure, any observed decrease in aerobic capacity must be due to a decline in maximal cardiac output. To the extent that cardiac output can increase, the exercise cardiac output–$\dot{V}_{O_2}$ relation is preserved among these classes, averaging 600 ml/min/m^2 for every dl/min/m^2 rise in $\dot{V}_{O_2}$. Responses in cardiac output and wedge pressure for each exercise class are given in Fig. 35-8. As in chronic cardiac failure, marked increases in wedge pressure are seen in class C and D patients; this is also true for class B patients with mitral or aortic regurgitation. However, these patients do not develop clinical evidence of pulmonary congestion following exercise, and dyspnea correlates with the lactate threshold. In these patients, exercise wedge pressure does not presage aerobic capacity or functional class.

AT can be used as an alternative measure in patients with valvular incompetence who are unable to attain $\dot{V}_{O_2max}$. The lactate threshold occurs at 60 to 70 percent of the patient's aerobic capacity and corresponds to a level of systemic O_2 extraction of 60 percent or more. Figure 35-9 depicts the response of mixed venous lactate concentration as a function

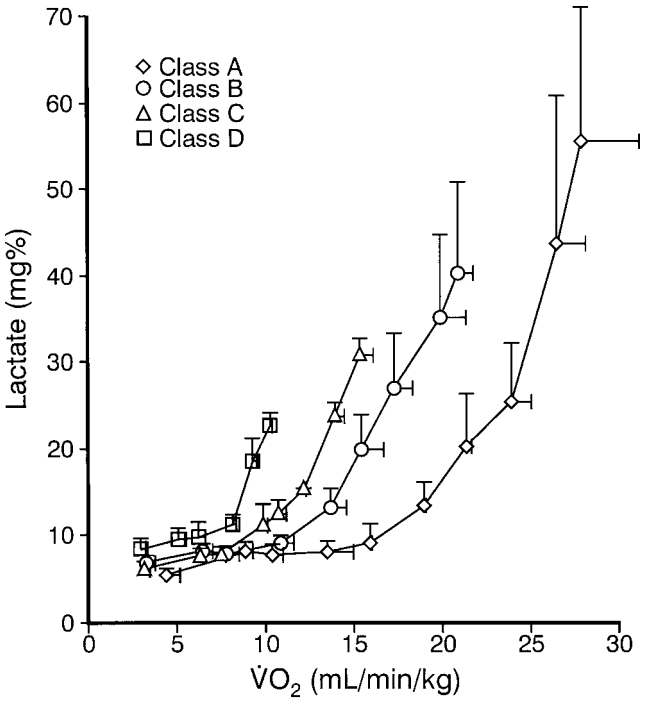

Figure 35-9 Relationship between mixed venous lactate concentration and $\dot{V}_{O_2}$ observed during incremental treadmill exercise in patients with chronic mitral or aortic regurgitation. As in chronic cardiac failure, the lactate threshold (lactate >12 mg/dl) occurs at different levels of $\dot{V}_{O_2}$, depending on functional class. *(From Weber KT, Janicki JS (eds): Cardiopulmonary Exercise Testing: Physiologic Principles and Clinical Applications. Philadelphia, WB Saunders, 1986.)*

of O_2 for each exercise class with mitral or aortic regurgitation. As in patients with chronic cardiac failure, the lactate threshold occurs at progressively lower levels of work as the severity of valvular disease increases. The invasively measured lactate threshold correlates well with the value obtained using noninvasive respiratory gas exchange measurements (see above).

The reduced mitral valve orifice that accompanies rheumatic mitral valvular stenosis leads to left atrial chamber enlargement, pulmonary venous hypertension, and pressure overload of the right heart. Pulmonary vascular resistance in most patients ranges between 200 and 600 dynes · s · cm^{-5}. Mitral stenosis is responsible for reduced left ventricular filling at rest and during exercise. An exercise-associated increase in heart rate reduces the diastolic filling period, thereby further curtailing left ventricular filling.

Cardiac output fails to rise appropriately during exercise in patients with chronic circulatory failure due to mitral stenosis. For most symptomatic patients, cardiac output fails to increase appropriately during symptom-limited exercise because of a limited stroke volume response. Systemic O_2 extraction increases markedly during exercise, as do pulmonary capillary wedge and mean pulmonary artery pressures. Preoperative assessment of mitral stenosis should include not only calculation of mitral valve area but also exercise test-determined cardiac reserve and functional status. A decision regarding surgery should be based on these objective measures and clinical judgment, not simply on a laboratory-based calculation of reduced valve area.

A preoperative assessment of patients undergoing valvular surgery using cardiopulmonary exercise testing can help predict the degree of postoperative recovery. Preoperative peak $\dot{V}_{O_2}$ of 19 ml/min/kg and greater in patients undergoing surgery for mitral and aortic regurgitation correlates with higher percentage of patients attaining New York Heart Association (NYHA) functional class I at 1 year after surgery. $\dot{V}_{O_2max}$, along with AT, has been used to follow the course of postoperative rehabilitation and training in patients who have had valve surgery. Exercise parameters can be helpful in assessing patients with valvular disease when there is a discrepancy between symptoms and echocardiographic data. A $\dot{V}_{O_2max}$ less than 75 percent of predicted in patients with moderate-to-severe mitral stenosis correlates with higher transvalvular gradients and higher pulmonary artery pressures at the end of exercise than in patients who have $\dot{V}_{O_2max}$ greater than 75 percent of max predicted.

Obstructive Sleep Apnea

Cardiopulmonary exercise testing can be performed safely in patients with sleep apnea to evaluate abnormalities in gas exchange and the response to continuous positive airway pressure therapy. Patients with moderate to severe obstructive sleep apnea have impaired exercise capacity, low peak $\dot{V}_{O_2}$, and low AT. The abnormal parameters on cardiopulmonary exercise testing can be improved by continuous positive airway pressure therapy. In one study involving patients with severe sleep apnea, 2 months of treatment using nasal continuous positive airway pressure resulted in higher right ventricular ejection fraction, peak $\dot{V}_{O_2}$, peak $\dot{V}_{O_2}$/kg, AT, and oxygen pulse.

In patients with heart failure who have central sleep apnea (CSA) mortality rate is higher than in patients without CSA. Patients with heart failure often lack the classic symptoms of CSA; hence, its presence may be underestimated. Treating CSA in patients with heart failure benefits cardiac function. Patients with heart failure and CSA have a highly augmented ventilatory response to exercise. This is manifested by a significantly increased slope of $\dot{V}_E/\dot{V}_{CO_2}$, which correlates with the severity of sleep apnea. Thus, patients with heart failure who have an increased $\dot{V}_E/\dot{V}_{CO_2}$ slope should be considered for a full sleep study to confirm the presence of sleep apnea.

Congenital Heart Disease

Patients with cyanotic congenital heart disease have limitations in exercise tolerance. Cardiopulmonary exercise testing can be used to objectively assess these patients' exercise limitation and ventilatory efficiency.

In a study of 25 adults with uncorrected cyanotic congenital heart disease, peak oxygen uptake and Pao_2 were

significantly reduced compared to normal; $Paco_2$ was only slightly reduced. Ventilatory efficiency, expressed as $\dot{V}_E/\dot{V}_{CO_2}$, was markedly impaired at rest and during exercise. $\dot{V}_E/\dot{V}_{CO_2}$ correlated more strongly with patients' symptoms than did hypoxemia and peak oxygen uptake. For corresponding NYHA classes, patients with adult congenital heart disease and those with heart failure demonstrate no significant differences in peak $\dot{V}_{O_2}$.

In adults, cardiopulmonary exercise testing has also been used for assessing the response to transcatheter-based closure of atrial septal defects. Increased peak oxygen uptake, peak oxygen pulse, and vital capacity have been reported, as have improvements in the prolonged $\dot{V}_{O_2}$ and $\dot{V}_{CO_2}$ slopes, reflecting improvement in recovery from maximal exercise.

Pulmonary Hypertension

Pulmonary hypertension is expressed as an abnormal elevation in resting or exercise pulmonary artery pressure. Chronic left heart failure and the accompanying increase in left atrial pressure remain the most common cause of pulmonary *venous* hypertension. Pulmonary *arterial* hypertension (PAH) accompanies intrinsic pulmonary vascular disease or arteriolar vasoconstriction associated with hypoxemia due to intrinsic lung disease. PAH creates right ventricular pressure overload and an impediment to left ventricular filling. Accordingly, exercise cardiac output is compromised and aerobic capacity declines.

Patients with PAH have been studied during elective right heart catheterization using a triple-lumen flotation catheter and subsequent exercise testing. Resting and peak treadmill exercise hemodynamic responses are given in Table 35-4. At rest, right heart and pulmonary arterial pressures exceeded the normal range. Right ventricular systolic pressure at rest was in excess of 50 mmHg, and in one-fourth of patients it approximated or exceeded left ventricular (and systemic arterial) systolic pressure. Resting wedge pressure was normal in these patients. Calculated pulmonary vascular resistance exceeded the upper range of normal (170 dynes $\cdot$ s $\cdot$ cm^{-5}) in all patients; in more than one-third, it was above 1000 dynes $\cdot$ s $\cdot$ cm^{-5}, approximating systemic vascular resistance.

Peak cardiac output attained with maximal exercise for each functional class (Table 35-3) is similar to that observed for chronic cardiac failure and valvular heart disease. The impairment in exercise cardiac output is related to the extent to which pulmonary vascular resistance is increased. Patients with a markedly increased resting pulmonary vascular resistance (above 1000 dynes $\cdot$ s $\cdot$ cm^{-5}) proved to be functional class D. In this group of patients with intrinsic pulmonary vascular disease, arterial O_2 desaturation during exercise was not observed, emphasizing the importance of compromised cardiac reserve—a function of the inability of the right ventricle to generate sufficient pulmonary blood flow to sustain left ventricular filling and, thereby, systemic blood flow. Patients with PAH stopped exercising because of breathlessness or fatigue or both; none experienced retrosternal chest pain, light-headedness, or syncope; none developed arrhythmias. In most, it was possible to determine the $\dot{V}_{O_2max}$; in all, the AT could be attained (see above). Cardiopulmonary exercise test results for a 42-year-old woman with PAH are shown in Fig. 35-10.

Table 35-4

Resting and Peak Exercise Hemodynamics for Patients with Nonhypoxic Pulmonary Vascular Disease and Pulmonary Hypertension

		Resting	Exercise
PA	(mmHg)	29 ± 9	47 ± 20
RVSP	(mmHg)	52 ± 30	86 ± 37
RVDP	(mmHg)	7 ± 4	16 ± 10
PCW	(mmHg)	10 ± 3	22 ± 14
PVR	(dynes $\cdot$ s $\cdot$ cm^{-5})	412 ± 319	302 ± 331
CO	($L/m^2/min$)	2.8 ± 1.6	5.3 ± 2.2
AP	(mmHg)	106 ± 6	130 ± 8
Art O_2 sat	(%)	97 ± 2	96 ± 2

Note: PA = mean pulmonary artery pressure: RVSP and RVDP = right ventricular systolic and diastolic pressures, respectively; PCW = wedge pressure; PVR = pulmonary vascular resistance; CO = cardiac output; AP = mean arterial pressure.

Source: Reproduced from Weber KT, Janicki JS: Pulmonary hypertension, in Weber KT, Janicki JS (eds), Cardiopulmonary Exercise Testing: Physiologic Principles and Clinical Applications. Philadelphia. Saunders. 1986. pp 220–234.

In patients with hypoxic pulmonary vasoconstriction, upright isotonic exercise also results in an increase in mean pulmonary artery and right ventricular systolic and diastolic pressures. In many of these patients, pulmonary vascular resistance increases during exercise because of marked hypoxemia, with arterial O_2 saturation ranging between 70 and 80 percent. This response can be attenuated with use of supplemental O_2.

Patients with PAH have significant ventilation-perfusion mismatch; during exercise, ventilation is increased. This abnormality in ventilatory inefficiency is reflected in the reduction in end-tidal CO_2 concentration ($pETco_2$). The reduction in end-tidal CO_2 concentration is proportional to the decrease in percent predicted $\dot{V}_{O_2}$ and increase in mean pulmonary artery pressure. In normal subjects, $pETco_2$ increases from rest to attainment of AT, whereas in patients with PAH, $pETco_2$ decreases from rest to AT. During cardiopulmonary

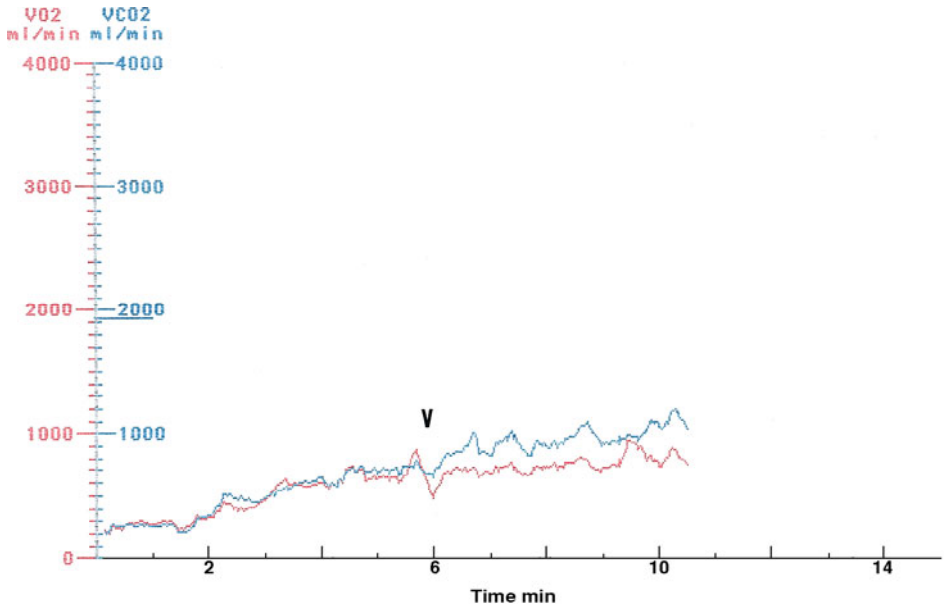

Figure 35-10 Cardiopulmonary exercise test results for a 42-year-old woman with pulmonary arterial hypertension of uncertain origin. The first 2 minutes represent standing rest. The patient attained the anaerobic threshold (AT) (7 ml/min/kg) during stage 2 of exercise (1.5 mph, 0 grade) and a $\dot{V}_{O_2max}$ of 10 ml/min/kg, corresponding to functional class D.

exercise testing, the slope of regression between CO_2 production and minute ventilation can also be used to assess the ventilation-perfusion mismatch. At the same peak $\dot{V}_{O_2}$, the $\dot{V}_E/\dot{V}_{CO_2}$ slope is greater in patients with PAH than those with cardiac dysfunction. Conversely, for the same slope of $\dot{V}_E/\dot{V}_{CO_2}$, patients with left ventricular dysfunction have a lower peak $\dot{V}_{O_2}$.

The measurement of cardiopulmonary exercise testing-based parameters in patients with PAH is reliable and reproducible, even in patients with limited exercise tolerance. The parameters correlate well with decreases in D_{LCO} and NYHA class. Even in children with pulmonary hypertension, peak $\dot{V}_{O_2}$ strongly correlates with pulmonary vascular index. Cardiopulmonary exercise testing can be used for the objective assessment of safety and efficacy of treatment strategies in patients with PAH. Peak $\dot{V}_{O_2}$ is an independent, strong predictor of survival in these patients.

CHRONIC LUNG DISEASES

In a normal subject performing maximal exercise, $\dot{V}_E$ rarely exceeds 50 percent of MVV; similarly, tidal volume uncommonly exceeds 50 percent of vital capacity. Given this large ventilatory reserve, exercise is not normally limited by ventilation. This is not the case in patients with lung disease, in whom ventilatory reserves are reduced. Other factors that may limit exercise in patients with lung disease are altered lung mechanics, impaired gas exchange with arterial hypoxemia and the appearance of pulmonary hypertension, and respiratory muscle fatigue.

Obstructive Lung Disease

Exercise intolerance commonly accompanies chronic obstructive pulmonary disease (COPD), with dyspnea limiting physical activity to modest levels of work. Patients with COPD have a higher $\dot{V}_E$ for any given workload; this is largely due to increased dead space ventilation. Given their reduction in MVV and greater exercise $\dot{V}_E$, these patients often exercise with a ratio of $\dot{V}_E$ to MVV that exceeds 75 percent. Use of such a large portion of this ventilatory reserve cannot be sustained, accounting for breathlessness and termination of exercise. This generally occurs in patients with moderate to severe COPD before they have reached their AT, implying a ventilatory, rather than cardiac, limitation to exercise. The workload at which patients terminate exercise represents a peak $\dot{V}_{O_2}$; it is not their $\dot{V}_{O_2max}$, as can be attained in patients with chronic cardiac or circulatory failure in whom ventilatory responses pose no limitation to exercise.

In severe emphysema, D_{LCO} is reduced in keeping with alveolar capillary destruction. In such patients, a significant fall in arterial O_2 saturation often occurs during exercise. This is in contrast to patients with chronic bronchitis, in whom arterial O_2 saturation may actually increase. The improvement in oxygenation in these patients is a result of improved ventilation in areas with low ventilation-perfusion ratios. D_{LCO} portends exercise-induced arterial O_2 desaturation: patients who have a D_{LCO} less than 55 percent predicted are most likely to experience hypoxemia during exercise. Several factors account for limited exercise tolerance in the setting of arterial hypoxemia: (1) reduced O_2 delivery to exercising muscles, including those associated with respiration; (2) increased chemical drive to respiration and corresponding inappropriate $\dot{V}_E$

for a given level of work; and (3) secondary pulmonary vasoconstriction.

By measuring $\dot{V}_{O_2}$ peak in patients with COPD undergoing cardiopulmonary exercise testing, an objective assessment of exercise capacity can be made. Peak $\dot{V}_{O_2}$ in severe COPD correlates with resting forced expiratory volume in 1 second (FEV_1) (percent predicted), total treadmill time, and total metabolic equivalent values. Cardiopulmonary exercise testing can better define respiratory limitations than pulmonary function testing alone in patients filing for disability due to COPD-related shortness of breath (see Chapter 39).

The increase in breathing capacity during exercise in patients with COPD, as measured by the ratio of $\dot{V}_E$/MVV, correlates with peak $\dot{V}_{O_2}$; it can be predicted by the FEV_1/percent of forced vital capacity (FVC,%) assessed during routine pulmonary function testing. In chronic COPD, peak $\dot{V}_{O_2}$ can be estimated using equations that take into account patient walking distance and pulmonary function tests. However, the correlation between measured and estimated peak $\dot{V}_{O_2}$ is not strong enough to predict exercise capacity. If peak $\dot{V}_{O_2}$ is to be used for clinical decision making, it should be measured, rather than estimated. Furthermore, patients with COPD have skeletal muscle abnormalities that may contribute to reduced exercise capacity. Peak $\dot{V}_{O_2}$ in COPD correlates well with fat-free mass, a bioimpedance index of muscle mass.

In COPD, physiological parameters measured by cardiopulmonary exercise testing also have prognostic implications. Based on multivariate analysis, the slope of the relationship between Pao_2 and $\dot{V}_{O_2}$ is most closely associated with survival. Similarly, Pao_2max, along with measured FEV_1, have been found to be independent predictors of mortality. Overall, in COPD, a linear relationship exists between peak $\dot{V}_{O_2}$ and pulmonary function test parameters.

Restrictive Lung Disease

Patients with known interstitial lung disease, a diverse group of disease entities, experience limiting dyspnea on exertion. This may be secondary to reduced ventilatory reserve or development of arterial O_2 desaturation. Dyspnea may appear on exertion in a patient with an abnormal chest radiograph before pulmonary function studies are abnormal.

Exercise testing may be indicated in patients with interstitial lung disease to detect abnormal ventilatory reserve and its response over time. Patients with interstitial lung disease tend to breathe at a higher respiratory rate and lower tidal volume than do normal subjects for any given $\dot{V}_{O_2}$. Because they have a reduced MVV, their ability to exercise is limited by nearly full utilization of their reduced ventilatory reserve.

As in patients with airway disease, D_{LCO} is a good predictor of arterial O_2 desaturation during exercise in patients with interstitial lung disease. Most patients with a D_{LCO} below 60 percent develop arterial O_2 desaturation. If a patient has a normal D_{LCO}, he or she is unlikely to develop exercise-induced arterial O_2 desaturation. Measurement of D_{LCO} can be used to screen patients for exercise studies. Finally, the degree of arterial O_2 desaturation during exercise correlates with the reduction in D_{LCO}.

Cardiopulmonary exercise testing is a sensitive test for detecting abnormalities in gas exchange. In one study that dealt with biopsy-proven sarcoidosis, cardiopulmonary exercise testing predicted pulmonary dysfunction earlier than did physical examination, chest radiography, or spirometry. In survivors of severe acute respiratory distress syndrome (ARDS), aerobic capacity assessed by cardiopulmonary exercise testing was found to be abnormal in 41 percent of patients in whom mild pulmonary function abnormalities were not enough to explain the low-exercise capacity. Cardiopulmonary exercise testing has also been used prognostically in patients with interstitial lung disease.

EVALUATION OF EXERTIONAL DYSPNEA

Normally, a person is unaware of the act of breathing and the fact that 500 to 750 ml of air enters and leaves the lungs 10 to 15 times each minute. Minute ventilation ($\dot{V}_E$) increases secondary to normal or abnormal chemical stimuli (e.g., hypercapnia, hypoxemia, acidemia) or anxiety. When breathing is perceived to be inappropriate relative to the level of physical activity, it is considered to be an abnormal awareness of breathing that is termed breathlessness, shortness of breath, or dyspnea. Dyspnea on exertion is common in patients with heart disease, pulmonary parenchymal or airway disease, and pulmonary vascular disease. Deformities of the chest wall and diseases associated with weakness of the respiratory muscles are also accompanied by breathlessness on exertion. Dyspnea may seriously hinder a patient's ability to carry out muscular work, thereby compromising quality of life. The evaluation of dyspnea includes historical information that characterizes the symptom onset, severity, and relationship to exercise, and the patient's underlying physical condition and customary daily activity. Other associated symptoms—such as palpitations, anginal chest pain, and light-headedness—must be taken into consideration.

An objective and reliable estimate of dyspnea on exertion and its severity can be gauged from exercise testing. Dyspnea occurs when $\dot{V}_E$ is excessive relative to $\dot{V}_{O_2}$, and when $\dot{V}_E$ is driven by chemical stimuli or altered lung mechanics. Dyspnea during exercise can appear when $\dot{V}_E$ represents an excessive proportion of MVV. An estimation of MVV can be derived by multiplying the patient's FEV_1 by 35. As a corollary, maximal encroachment on the vital capacity by exercise tidal volume cannot be sustained for long. Such ventilatory effort poses a substantial workload on respiratory muscles. An MVV maneuver during pulmonary function testing cannot be sustained for more than a few seconds, while more than 70 percent of the MVV cannot be sustained by normal subjects for more than several minutes. Hence, the ventilatory response to exercise that is associated with dyspnea in

patients with heart or lung disease follows a similar pattern of short-lived, near-maximal ventilation.

The patient with pulmonary vascular disease or advanced interstitial lung disease may be unable to sustain adequate arterial O_2 saturation during exercise. Consequently, hypoxemia may compound the patient's exercise response and may be responsible for a heightened chemical drive to respiration. In the case of COPD, the need to move air through a partly obstructed tracheobronchial tree creates an added workload on respiratory muscles. Airflows in these patients are already compromised at rest and must increase with exercise; they may approach peak expiratory flows observed with maximal effort during pulmonary function testing.

Patients with mild, moderate, or severe cardiac or circulatory failure rarely use more than 50 percent of their ventilatory reserve at maximal exercise, and they do not experience arterial O_2 desaturation during exercise. If one estimates MVV from the FEV_1 (as noted above), for an FEV_1 of 1, 2, or 3 L, MVV is expected to equal 35, 70, or 105 L, respectively. In patients with chronic cardiac or circulatory failure, maximum exercise $\dot{V}_E$ has been found to range between 62 and 29 L per min for class A through D patients. Hence, unless there is a major reduction in MVV (or in FEV_1 to less than 3 L), these patients will not have a ventilatory limitation to exercise.

Finally, patients are able to cross their AT and, if encouraged, may reach their point of exhaustion attaining $\dot{V}_{O_2max}$. By monitoring the breath-by-breath response in $\dot{V}_{O_2}$ and $\dot{V}_{CO_2}$ during exercise, the physician can immediately determine when the patient has achieved the AT and $\dot{V}_{O_2max}$. These end points are not attained in the patients with lung disease or those with coexistent heart and lung disease in whom the respiratory system is the primary limitation to exercise. Table 35-5 summarizes the salient points used to differentiate primary ventilatory from cardiac or circulatory failure as the cause of exertional dyspnea, as detected by exercise testing.

Table 35-5

Ventilatory vs. Cardiac/Circulatory Failure as the Predominant Cause of Exertional Dyspnea

Ventilatory Failure
1. Exercise maximum $\dot{V}_E$ utilizes > 70% of MVV
2. Exercise-associated arterial hypoxemia
3. Failure to cross AT and to achieve $\dot{V}_{O_2max}$
Cardiac/Circulatory Failure
1. Cross AT and can achieve $\dot{V}_{O_2max}$
2. Maximum exercise $\dot{V}_E$ does not exceed 50% of MVV
3. Does not develop arterial hypoxemia with exercise

Note: AT = anaerobic threshold; MVV = maximal voluntary ventilation.

OTHER APPLICATIONS OF CARDIOPULMONARY EXERCISE TESTING

Cardiopulmonary exercise testing, with its ability to foretell cardiac and ventilatory reserves, has proved useful in clinical decision making in a variety of circumstances, including assessment of a patient's candidacy for cardiac transplantation and preoperative assessment of preoperative risk.

Cardiac Transplantation

The severity of chronic cardiac and circulatory failure is gauged according to $\dot{V}_{O_2max}$ and the AT (Table 35-3) and is used to predict exercise cardiac reserve. This approach has been applied to patients with systolic dysfunction secondary to chronic ischemic heart disease or dilated (idiopathic) cardiomyopathy, who are considered to be potential candidates for cardiac transplantation. Neither the ejection fraction nor resting hemodynamic parameters (e.g., resting cardiac index or wedge pressure) help to predict the severity of cardiac failure or functional capacity and are no longer a mainstay in decision making. The same is true for subjective evaluation of functional status using the NYHA criteria. Incremental exercise testing, with identification of AT and peak $\dot{V}_{O_2}$ achieved thereafter, has emerged as a valuable tool to address cardiac reserve and functional capacity objectively and to predict survival. In fact, consensus has been reached on recommending transplantation using clinical criteria in combination with functional stratification based on the results of exercise tests.

Class D patients, having little or no cardiac reserve, have a marked reduction in 1- and 2-year survival and, therefore, are candidates for urgent transplantation. Class C patients, who have a modest increment in cardiac output with exercise, are probable candidates. On the other hand, class A and B patients in whom cardiac reserve remains intact, or class B patients in whom cardiac reserve is only minimally impaired, do not have an adequate indication for transplantation. Decision is deferred, and serial exercise studies are used to assess recovery or deterioration in the setting of optimal medical therapy.

Incremental exercise testing may also provide useful information after cardiac transplantation, including recovery of cardiac and ventilatory reserves. The importance of diastolic dysfunction in limiting exercise tolerance following cardiac transplantation was reviewed earlier. A blunted heart rate response to exercise is expected in these patients due to cardiac denervation. Such chronotropic incompetence is demonstrated in Fig. 35-11, along with the results of exercise testing.

Surgical Risk Assessment

Preoperative incremental exercise testing has proved useful in assessing postoperative morbidity and mortality in the elderly and in patients with underlying heart or lung disease who are scheduled for major intrathoracic or intra-abdominal

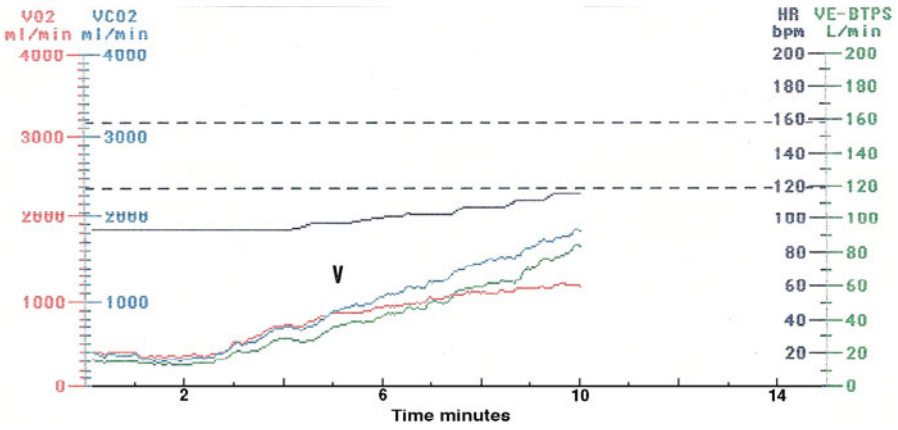

Figure 35-11 Cardiopulmonary exercise test results for a 62-year-old male cardiac transplant recipient. During this incremental treadmill test this patient attained an anaerobic threshold (AT) and $\dot{V}_{O_2max}$ of 8 and 11 ml/min/kg, respectively. Note the blunted heart rate response (predicted peak heart rate range shown as broken lines).

surgery. The premise underlying this approach is based on a recognition that during and after surgery, there may be a need to call on cardiac and ventilatory reserves—namely, the ability to increase cardiac output and maintain O_2 delivery, and to increase $\dot{V}_E$ and prevent hypoxemia. Several studies have demonstrated the utility of measuring the AT and peak $\dot{V}_{O_2}$ using exercise testing to estimate these reserves, and to identify patients prone to postoperative complications. Pulmonary function testing proved insensitive in forecasting postoperative course. Class C and D patients, with little or no cardiac reserve, had a greater number of morbid and mortal events following surgical interventions than did class A or B patients. Class A patients had few, if any, postoperative complications and no mortality. Therefore, the risk of complications could best be gauged by a patient's preoperative aerobic capacity. Direct assessment of the AT or $\dot{V}_{O_2max}$ and prediction of cardiac reserve, and, by inference, ventilatory reserve, supersede the value of an age-determined impairment in aerobic capacity.

AT is a particularly important parameter in assessing preoperative risk. It provides an objective assessment that is independent of patient motivation and does not require inordinate amounts of exercise. In a large study of elderly patients undergoing major intra-abdominal surgery, an AT of less than 11 ml/min/kg, along with preoperative ischemia, was associated with high mortality. Patients evaluated by cardiopulmonary exercise testing who have an unfavorable AT can be admitted electively to intensive care units for optimization of hemodynamics prior to major surgery.

Patients undergoing other major surgeries, such as radical esophagectomy with three-field lymphadenectomy, have also been risk-stratified using cardiopulmonary exercise testing. Extensive fluid shifts are expected in the postoperative period with surgical interventions on the lymphatic system. Cardiopulmonary exercise testing can provide a thorough assessment of the cardiopulmonary reserve in such patients. For example, in one study, a peak $\dot{V}_{O_2}$ of 800 ml/min/m^2 was associated with low risk of complications. Similarly, in another study of patients undergoing repair of an abdominal aortic aneurysm, those with a peak $\dot{V}_{O_2}$ less than 20 ml/min/kg had a higher incidence of adverse complications. Finally, a study of patients undergoing liver transplantation demonstrated that patients dying within 100 days of transplantation were more likely to have had a preoperative peak $\dot{V}_{O_2}$ less than 60 percent of predicted and an AT less than 50 percent of predicted peak $\dot{V}_{O_2}$ than those who survived.

Patients with lung cancer have a high likelihood of concomitant COPD and coronary artery disease due to the common risk factor of smoking. Surgery might offer the only chance of cure in these patients and often implies resection of a variable portion of the lung tissue surrounding the cancer to ensure eradication. Removal of functional lung tissue in an already compromised cardiopulmonary system resection can be risky. It is imperative that a preoperative assessment of cardiopulmonary reserve be made before such a surgery. Cardiopulmonary exercise testing in such patients provides an objective assessment of cardiopulmonary reserve. In addition, peak $\dot{V}_{O_2}$, along with FEV_1 and D_{LCO}, has been used to risk-stratify these patients. Correcting peak $\dot{V}_{O_2}$ for weight and expressing it as a percentage of predicted improves the predictive power of peak $\dot{V}o_2$measurements. Elderly patients, females, and patients with short stature may have a peak $\dot{V}_{O_2}$ below the absolute cutoff value, but they may still be eligible for surgery when peak $\dot{V}_{O_2}$ is expressed as percent of predicted.

The predictive value of peak $\dot{V}_{O_2}$ is greater in patients with an FEV_1 less than 70 percent of predicted. Peak $\dot{V}_{O_2}$ less than 50 percent of predicted is associated with high complication rates. Patients with peak $\dot{V}_{O_2}$ greater than 50 percent of predicted can undergo surgery without excess mortality. A peak $\dot{V}_{O_2}$ less than 10 ml/min/kg is generally considered prohibitive for surgery. Risk-stratification based upon peak $\dot{V}_{O_2}$ is particularly useful in patients undergoing lung resection who have borderline pulmonary function (predicted postoperative FEV_1 or D_{LCO} less than 40 percent). In these patients, a peak $\dot{V}_{O_2}$ less than 15 ml/min/kg is associated with

an increased risk, and peak $\dot{V}_{O_2}$ less than 10 ml/min/kg carries a very high risk of postoperative complications (see Chapter 38 for additional discussion).

Bronchoscopy, Transthoracic Needle Aspiration, and Related Procedures

Anil Vachani • Luis Seijo • Michael Unger • Daniel Sterman

Gustav Killian reported his experience with the first bronchoscopy in 1898. Technological advances during the next century facilitated development of bronchoscopy as a pivotal diagnostic and therapeutic tool in pulmonary medicine. Although a number of bronchoesophagologists contributed to refinement of the technique based upon use of a rigid instrument, the advent of flexible fiberoptic bronchoscopy, pioneered by Ikeda in 1967, opened new horizons to clinicians.

More recently, transthoracic needle aspiration and biopsy have been added to the pulmonologist's diagnostic armamentarium. These techniques are particularly useful for evaluating localized or peripheral lung lesions. Transthoracic needle aspiration permits acquisition of material for cytologic and microbiologic analysis, while transthoracic needle biopsy provides tissue for histological study.

This chapter comprises an overview of bronchoscopy, transthoracic needle aspiration and biopsy, and related techniques. Following a general discussion of bronchoscopy and associated general instrumentation, indications for the technique and patient preparation are considered. Specific applications of diagnostic and therapeutic bronchoscopy are discussed. Subsequently, safety factors related to bronchoscopy and complications of the technique are reviewed. Finally, transthoracic needle aspiration and biopsy are described.

TYPES OF BRONCHOSCOPY AND GENERAL INSTRUMENTATION

In the first three-fourths of the twentieth century, pulmonary endoscopy was performed with open-tube steel bronchoscopes. The advent of fiberoptic technology and, subsequently, miniaturized electronics permitted application of flexible endoscopy, as discussed below.

Rigid Bronchoscopy

The initial bronchoscope, developed by Killian in Europe and further perfected by Chevalier Jackson in the United States, was a rigid metal tube that permitted either spontaneous or mechanical ventilation. Over the decades, rigid bronchoscopes of various lengths and sizes, which are adaptable for diverse applications in children and adults, have become available. With development of fiberoptic and advanced electronic technology, the flexible bronchoscope has, to a large extent, replaced the rigid bronchoscope for most diagnostic and some therapeutic indications.

Both rigid and flexible modern systems are equipped with optic capabilities for airway observation alone. With the rigid bronchoscope, various types of telescopic rods, equipped with circumferential illumination, permit direct and magnified visualization. Specially designed telescopes allow viewing not only directly forward but also at oblique and lateral angles. Various diagnostic and therapeutic accessories can be inserted through the rigid bronchoscope while the patient remains ventilated.

In recent years, development of small cameras based on charge coupled device (CCD) technology has facilitated transmission of bronchoscopic images to television monitors, enhancing the education of trainees and permitting improved documentation of bronchoscopic findings.

Flexible Fiberoptic and Videobronchoscopy

Although the optical resolution of early fiberoptic bronchoscopes was inferior to that of rigid devices, their flexibility, ease of manipulation, and simplicity of use, which permit rapid examination under topical anesthesia, have made flexible bronchoscopy the primary endoscopic procedure in pulmonary diseases.

Unlike the larger-bore rigid bronchoscope, the flexible bronchoscope varies from ultra-thin—allowing for neonatal endoscopy—to larger, adult-size therapeutic devices. The diameter of the working channel permits aspiration of secretions or introduction of accessories required for diagnostic or therapeutic purposes (see below). With flexible bronchoscopy, the patient's ventilation is assured by airflow around the bronchoscope, between the external wall of the device and the tracheobronchial tree. Thus, the appropriate selection of bronchoscope size is crucial.

Recent technological advances have permitted the replacement of fiberoptic systems by a miniaturized CCD camera at the tip of the scope that provides electronic transmission of images to a television monitor. Flexible bronchoscopes are more fragile and more prone to damage than are rigid metal instruments. Appropriate care and adherence to safety techniques during procedures, as well as during routine cleaning and maintenance of the instruments, help assure extended instrument life and reduce repair costs.

PATIENT PREPARATION AND MONITORING DURING BRONCHOSCOPY

Most fiberoptic bronchoscopies are performed after patient premedication with sedative agents. Most frequently, a combination of a short-acting benzodiazepine (e.g., midazolam) and a narcotic agent (e.g., fentanyl) is used. The sedatives are generally administered along with an anticholinergic medication (e.g., atropine or glycopyrrolate) in order to reduce the risk of vasovagal reactions and to minimize airway secretions. Local anesthesia of the upper airway, larynx, and tracheobronchial tree is achieved with inhaled or bronchoscopically instilled lidocaine. Although rigid bronchoscopy was performed initially with minimal anesthesia and later under general anesthesia, the recent trend has been to perform the procedure with patients either breathing spontaneously or ventilated with a jet ventilator, often under total intravenous anesthesia (TIVA) with drugs such as propofol or remifentanil. With appropriate monitoring, good oxygenation and adequate ventilation can be assured.

Success of bronchoscopy, whether diagnostic or therapeutic, depends, in large part, on proper preparation of the patient, including relief of anxiety, muscle relaxation, cough suppression, and adequate anesthesia. Time spent in achieving these goals will be well worth it in reducing the risks of complications and in increasing the ease of performance of the procedure. As with any other procedure, analysis of the risk-benefit ratio helps reduce the complication rate. During and shortly after the procedure, appropriate monitoring of hemodynamic parameters (heart rate, rhythm, and blood pressure), oxygenation, and ventilation contributes to the safety of bronchoscopy.

DIAGNOSTIC BRONCHOSCOPY ACCESSORIES

The working channel of the fiberoptic or videobronchoscope, although of relatively small diameter, allows the insertion of

various diagnostic and therapeutic accessories. Specially constructed accessories of larger caliber have been developed for use with the rigid bronchoscope.

Biopsy Forceps

Simple visualization of lesions is usually not sufficient to determine a precise diagnosis and to guide management. Pathological confirmation through biopsy is frequently required. A variety of instruments with improved distal control (i.e., control beyond the tip of the bronchoscope) have been developed that permit tissue cutting and retrieval of biopsy specimens.

The cutting cups of biopsy forceps may be round or elliptic and may have smooth or jagged edges. The use of nonserrated edges, however, seems to reduce tissue trauma and the concomitant risk of bleeding. The biopsy procedure is simple and generally associated with only minimal complications in the case of a visible lesion. Even peripheral lesions, which are not visible through the bronchoscope, may be biopsied. With diffuse parenchymal or interstitial lung disease, specimens may be obtained without fluoroscopic guidance. With smaller or focal lesions, however, the diagnostic yield of biopsies increases when fluoroscopy is used. The recent development of new electromagnetic and remote guidance systems suggests that further improvement in the diagnostic yield of bronchoscopic biopsies can be expected.

Bronchial Brushes

Lesions not accessible to direct biopsy with a forceps can be approached with a bronchial brush. This device consists of a rigid central wire surrounded by brushes of various sizes and shapes. To-and-fro movement of the brush against the adjacent tissue produces minor trauma but enables collection of ample specimens for cytologic or microbiologic analysis.

In some clinical circumstances, there is a need to obtain from the lower respiratory tract an uncontaminated specimen for microbiologic studies. A brush protected by an additional sheath and tip may be passed through the working channel of the bronchoscope (protected brush specimen, as discussed below). In these cases, special attention is needed not to use an excessive amount of local anesthetic or saline lavage, since these solutions contain bacteriostatic material that may inhibit microbial growth. The diagnostic yield depends on use of proper technique, appropriate choice of brush, and careful collection and preservation of the specimen.

Needles for Aspiration and Biopsy

The first performance of a transbronchoscopic needle aspiration (TBNA) through a rigid bronchoscope was reported by Schieppati in 1958. Wang then developed a flexible needle technique, using a fiberoptic bronchoscope in 1978. Initially, several models of needles were designed to obtain cytological material; subsequently, histological specimens from peribronchial mediastinal and hilar lymph nodes were obtained with larger-bore needles. These biopsy needles are also useful in the diagnosis of endobronchial and submucosal lesions, and can serve as a complementary technique to percutaneous needle aspiration of peripheral pulmonary nodules or masses.

The tip of the needle is protected by a metal hub during the insertion and withdrawal to avoid damage to the flexible scope. Perforation of the working channel of the scope may occur if the needle is advanced in an exposed position. The diagnostic yield depends on two factors: optimization of the bend of the tip of the bronchoscope and proper performance of bronchial wall puncture by the needle through the intercartilaginous space. Familiarity with the type of needle used increases the success rate.

TBNA is generally safe, although pneumothorax and hemomediastinum can occur. Clinically significant bleeding is extremely rare, particularly when a 22-gauge needle is used, even if a major vessel is inadvertently punctured or if the patient suffers from superior vena cava syndrome.

Dedicated Catheters and Balloons

Various investigational protocols for study of lung diseases use the technique of bronchoalveolar lavage (see below) and collection of uncontaminated specimens. In performing this procedure, selective aspiration catheters are necessary. These bronchoscopically guided, double-lumen catheters are wedged in the selected bronchus. After inflation of a balloon and isolation of the bronchus, instillation of fluid through the central lumen of the catheter is followed by aspiration of the fluid. In another application, the low-pressure balloon catheters contribute to estimation of airway diameter before the insertion of a stent (see below). Sometimes, inflation of the balloon at the tip of the bronchoscope permits enlargement of the lumen and eventual penetration of the bronchoscope beyond the area of stenosis, allowing exploration of peripheral airways.

Endobronchial Ultrasound

Endobronchial ultrasound (EBUS) enhances traditional white light bronchoscopy (WLB) by providing real-time, 360-degree images that reach beyond the bronchial lumen, providing information unattainable by airway inspection alone. In general, higher acoustic frequencies afford only shallow penetration, but result in high-resolution images; lower frequencies provide deeper tissue penetration, but impaired image resolution. The quality of the ultrasonic image depends primarily upon adequate contact of the probe with the airway wall, depth of penetration of the ultrasound wave, and spatial resolution of different structures. EBUS uses a frequency in the range of 20 MHz, which allows a tissue penetration depth up to 5 cm. However, the abundant presence of air in the lung, which distorts the ultrasound image by reflecting sound waves, is a major obstacle to obtaining adequate images. Currently, probes reduce artifact arising from air-filled bronchi by transmitting sound through a fluid- or gel-filled balloon.

While EBUS has been used in a variety of clinical scenarios, its role in clinical practice remains to be fully defined. Currently, the three main indications for EBUS are: (1) evaluation of endobronchial masses, (2) aspiration of mediastinal lymph nodes (Fig. 36-1), and (3) facilitation of the distinction between neoplastic and benign mediastinal masses.

Figure 36-1 Endobronchial ultrasound (EBUS) image of an enlarged lymph node. EBUS image from the left main carina demonstrates an enlarged subcarinal lymph node (white arrow). *(Courtesy of Felix Herth, M.D.)*

Less frequent indications include assessment of mediastinal infiltration by tumor, evaluation of anastomotic recurrences, and identification of submucosal lesions. Identifying submucosal lesions may be useful prior to planned thoracic resections in determining the likely bronchial margin of an infiltrating tumor. In some cases, patients diagnosed with "early" carcinomas are found by EBUS to harbor extensive intraluminal disease as well as regional lymph node metastases. EBUS may also be used as an adjunct to planning of interventional procedures, such as endobronchial stenting, photodynamic therapy (vs. use of brachytherapy), and laser photoablation.

APPLICATIONS OF DIAGNOSTIC BRONCHOSCOPY

Although the initial indications for bronchoscopy described by Killian and Jackson centered primarily on therapeutic applications, both recognized the central role the technique plays in visual examination of the tracheobronchial tree and in diagnosis of various pulmonary diseases. Development of the flexible bronchoscope and various accessory instruments that can be inserted via the working channel has extended bronchoscopic exploration to the lung periphery.

Assessment of Airway Anatomy and Function

Thorough bronchoscopic evaluation begins with examination of the upper airways. Special attention should be paid to the integrity of air passages and the function of the nasopharynx and larynx. The vocal cords should be examined for the presence of polyps and tumors, and for evidence of cord paralysis.

Once the upper-airway inspection is completed, a systematic evaluation of the lower respiratory tract should be performed. Critically important is the distinction among normal anatomy, anatomic variations without clinical significance, and frankly pathological conditions. These considerations have important implications regarding potential diagnostic and therapeutic approaches. For example, finding an abnormal branching of a bronchus may be of no clinical significance. On the other hand, such an abnormality could explain symptoms of frequent infections due to impaired ventilation and drainage of the affected area. Special skills and observational experience are required for bronchoscopic examination after surgery, especially following creative bronchoplastic procedures or lung transplantation.

Assessment of airway integrity, with special attention to dynamic changes in airway caliber during either relaxed breathing or forced expiration and coughing, may be crucial in determining appropriate therapeutic maneuvers. Flexible bronchoscopy is superior to rigid bronchoscopy for this assessment. Relaxation and prolapse of the membranous portion of the trachea and main bronchi secondary to destruction of elastic connective tissue may account for exacerbations of expiratory airflow obstruction. On the other hand, finding localized, posttraumatic chondromalacia has very different therapeutic implications. On the basis of these bronchoscopic determinations, the choice of performing an open surgical approach or bronchoscopic therapeutic correction may be made.

Bronchoscopic examination generally permits evaluation and localization of congenital or postsurgical pathological changes in bronchial integrity, such as tracheoesophageal or bronchopleural fistulas. Bronchoscopic observation and early diagnosis of bronchial rupture after chest trauma also greatly influence further therapy and prognosis. The same is true for evaluation of postsurgical anastomoses following reconstructive surgery or lung transplantation.

Advances in airway management of critically ill patients who require prolonged intubation or tracheotomy have resulted in reduction in the incidence of tracheal injuries. Tracheal injuries documented by bronchoscopy are not rare, however. Important complications of tracheotomy include tracheal stenosis, tracheomalacia, and tracheoinnominate fistula. Complications specific to the use of percutaneous tracheotomy, which is increasingly used in the intensive care unit, include flaps of cartilage protruding into the tracheal lumen and extraluminal placement of the tracheostomy tube. Such complications can have significant bearing on clinical outcome.

Evaluation of Tracheobronchial Mucosa

Careful examination of the mucosal surface is crucial in the formulation of differential diagnosis. Rapid development of

granulation tissue is frequently associated with reaction to a foreign body. Inflammatory mucosal reactions, although not very characteristic, should raise the possibility of mycobacterial infection, nonspecific viral and nonviral infections, and other granulomatous diseases, such as sarcoidosis.

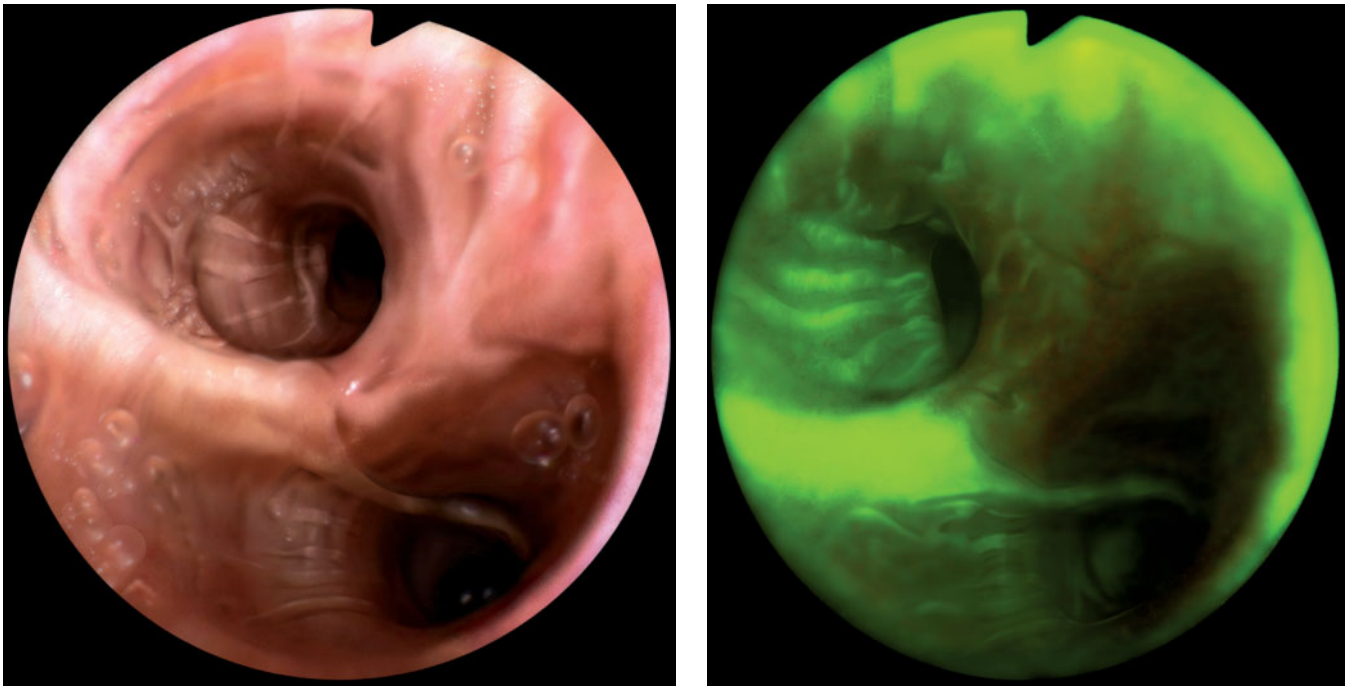
The distinction between normal, pale-pink mucosa and hypervascular areas in the tracheobronchial tree may provide important diagnostic clues. Most frequently, changes in mucosal coloration are associated with an inflammatory reaction due to bronchitis. These findings are, however, very distinctive from small hemangiomas or vascular distentions due to compression by enlarged, neoplastic lymph nodes. Similarly, a network of small mucosal lymphatics may be visible, with lymphatic interruption due to surgery, radiation therapy, fibrosis, or malignancy. This is most frequently associated with local edema, which contributes to airflow obstruction. In addition, distinct and characteristic mucosal discoloration can be observed in Kaposi's sarcoma.

Ulcerations of the mucosa are more characteristic of Wegener's granulomatosis or malignancy. Loss of the usual mucosal luster and presence of a roughened surface may alert the expert bronchoscopist to an early infiltrative or neoplastic process. Previously sustained injuries are characterized by the formation of mucosal and submucosal fibrosis, resulting in airway retraction or distortion.

Recently, various photosensitizers have been applied for the bronchoscopic evaluation of the tracheobronchial mucosa. Photosensitizers, such as hematoporphyrin derivative (HPD) and Δ-aminolevulinic acid (Δ-ALA), are retained more selectively by neoplastic tissues. When stimulated by blue light (wavelength approximately 440 nm), tissues containing these photosensitizers (i.e., tumors, but not normal tissues) emit weak fluorescence in the red spectrum (wavelength approximately 630 nm). The low-intensity fluorescence can be captured by specially designed image intensifiers. The technique may be helpful in cancer detection or in the delineation of tumor limits. Use of photosensitizers, however, is cumbersome and associated with skin photosensitivity and risk of sunburn. For these reasons, photosensitizer-mediated photodynamic techniques are not practical for diagnostic purposes.

Recent technological developments permit observation and analysis of tracheobronchial mucosal surfaces using the discriminant characteristic of tissue autofluorescence. It is well known that when stimulated with light of a specific wavelength, normal tissues emit specific fluorescence. Changes in the structural integrity of the same tissues due to pathological processes modify or suppress the autofluorescence. The fluorescent emissions are too low in intensity to be seen by the human eye. With the use of a monochromatic light source, computer-controlled image analysis, and a sophisticated camera attached to a fiberoptic bronchoscope, the airways can be examined for varying degrees of autofluorescence as an indicator of early-stage malignant changes (Fig. 36-2).

The acquisition of images is obtained in real-time and helps in the detection of minute areas of change in normal



A *B*

Figure 36-2 White light and autofluorescence images of carcinoma in situ. Standard white light bronchoscopy demonstrates normal-appearing mucosa. Fluorescence endoscopy demonstrates abnormal-appearing tissue (reddish brown area), which was confirmed as carcinoma in situ by histological evaluation. *(Courtesy of Xillix Technologies Corp.)*

tracheobronchial mucosal fluorescence. Biopsies from areas of abnormal fluorescence increase the rate of detection of small, premalignant (dysplasia) or early malignant (carcinoma in situ) lesions in the tracheobronchial tree. Confirmation is provided by biopsy of the suspect or abnormal areas under direct bronchoscopic control, followed by pathological review. Attempts are underway to develop bronchoscopic spectrophotometric techniques for study of metabolic functions in vivo and performance of "optical biopsies," which provide information on specific tissue components—e.g., changes in intracellular concentrations of nicotinamide adenine dinucleotide phosphate (NADPH) or other cellular constituents. Another promising technique, opitical coherence tomography (OCT), is analogous to ultrasound imaging except that infrared light waves, rather than acoustic waves, are used. At present, OCT can resolve structures as small as 3 μm, rendering this imaging technique superior to conventional CT or magnetic resonance imaging for detecting microscopic airway abnormalities. The ability to acquire such precise views in real-time may have important clinical implications in the near future.

Evaluation of Hemoptysis

One of the most frequent indications for bronchoscopy is hemoptysis. Bronchoscopic evaluation can be of help in determining the precise location and source of bleeding. The choice of instrument (rigid vs. flexible scope) and timing of the procedure are dictated by clinical circumstances. Studies have shown that active bleeding and its site are visualized more commonly with early bronchoscopy (within 48 hours) than with more delayed examination. In the case of a normal chest radiograph and hemoptysis, traces of bleeding are commonly seen, but not the site of origin. In these circumstances, examination using an ultrathin flexible instrument may be beneficial in identifying the source of bleeding in a peripheral airway, once the more proximal airways have been cleared of blood by the therapeutic scope. In some instances, bronchoscopy becomes useful not only as a diagnostic method, but also as a therapeutic procedure (see below).

Evaluation of Peribronchial Structures

The trachea and bronchi are surrounded by mediastinal and parenchymal structures. Developmental or pathological changes in these organs may be noted during bronchoscopic evaluation. An enlarged goiter or thymus can compress upper airways, resulting in airflow obstruction. Lymphadenopathy may produce structural changes, including widening of the carina due to subcarinal involvement and compression of other bronchi—as, for example, in the right-middle-lobe syndrome. Calcification of peribronchial lymph nodes may result in erosion of the bronchial wall and formation of a broncholith. These lesions are potential sources of obstruction, infection, or dangerous hemoptysis.

Development of the techniques of transbronchoscopic needle aspiration (TBNA) and biopsy (TBNB) has permitted sampling of peribronchial lymph nodes (Fig. 36-3). These transbronchial approaches provide us with diagnostic options that pose much less risk and a lower complication rate than mediastinoscopy; in addition, they are less costly.

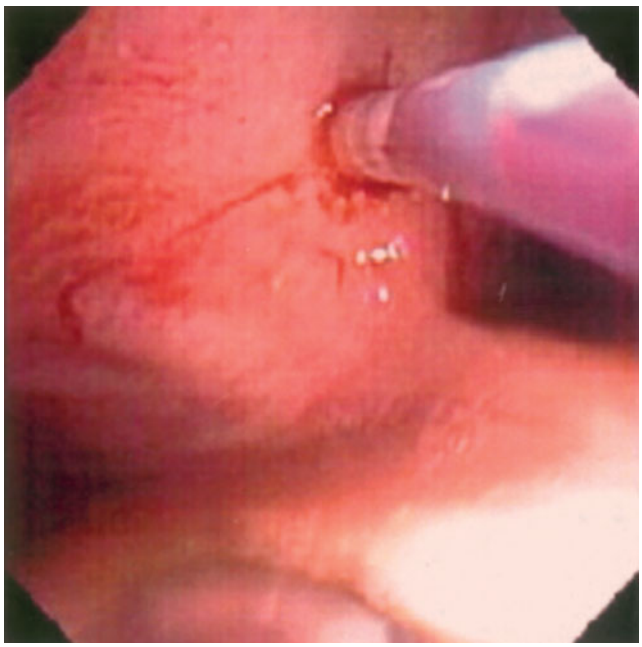


Figure 36-3 TBNA of subcarinal lymph node using a 21-gauge transbronchial needle.

Diagnosis and staging of lung carcinoma are the major indications for use of TBNA. The procedure is particularly useful for patients who are marginal or poor surgical candidates; in these patients, more invasive approaches, such as mediastinoscopy or mediastinotomy, may be obviated. TBNA has proven particularly useful with the employment of rapid on-site evaluation (ROSE), where a cytopathologist present in or near the bronchoscopy suite can evaluate obtained specimens in real-time. However, because of a high false-negative rate (approximately 25 percent), a negative result with TBNA should prompt consideration of more invasive staging methods (e.g., mediastinoscopy). A positive TBNA is more likely in the presence of significant adenopathy noted on CT scanning, the presence of endoscopically visible tumors, subcarinal lymph nodes greater than 2 cm in diameter, or an abnormal-appearing carina.

The use of image guidance with TBNA, such as CT fluoroscopy, electromagnetic guidance, or EBUS, is promising and may provide higher diagnostic yields with TBNA. The use of EBUS in combination with TBNA for the evaluation of mediastinal adenopathy has been most extensively evaluated. Endobronchial ultrasound-directed TBNA (USTBNA) appears to increase diagnostic accuracy and may be particularly useful in centers where ROSE is unavailable.

Until recently, the major limitation with USTBNA has been the need for the EBUS and TBNA components to be performed sequentially. A newly developed bronchoscope with an additional working channel that incorporates EBUS allows

for real-time needle insertion and aspiration under direct lymph node visualization. Early studies suggest an improved diagnostic yield for hilar and mediastinal adenopathy using this modality.

Recently, the use of TBNA has been extended to the diagnosis of benign processes, including infection and granulomatous disease. In HIV-positive patients with mediastinal adenopathy, TBNA can provide a definitive diagnosis in as many as one-third of the patients, sparing them more invasive procedures. The ability to obtain core biopsy specimens using a TBNA histology needle has proven particularly useful for diagnosing sarcoidosis. Traditionally, sarcoidosis is documented by the presence of noncaseating granulomata in lung parenchyma obtained by transbronchial biopsy during fiberoptic bronchoscopy. However, the sensitivity is only about 60 to 70 percent, and many patients require further invasive testing, such as surgical lung biopsy. The addition of TBNA to transbronchial biopsy can provide the diagnosis in over 85 percent of cases of sarcoidosis.

Performance of Bronchial and Parenchymal Biopsies

Improvements in bronchoscopic instrumentation since the days of Chevalier Jackson have permitted performance of endobronchial biopsies, as well as biopsy of peripheral lung lesions. Knowledge of the underlying disease process has a significant influence on the choice of study procedures and risk of complications. In the case of diffuse lung diseases, such as sarcoidosis, use of fluoroscopy has not been demonstrated to improve the diagnostic yield of transbronchial biopsies. Fluoroscopy is useful, however, in providing information regarding the proximity of the forceps to the pleura and in more rapidly establishing the diagnosis of complications (e.g., pneumothorax).

Bronchoscopically visible lesions are generally biopsied with minimal risk; if bleeding occurs, it can usually be controlled easily (Fig. 36-4). The diagnostic yield of bronchoscopy for peripheral lesions depends on a number of factors, including lesion size, its location in the lung, and on the relationship between the lesion and bronchus. The presence of a bronchus sign on chest CT predicts a much higher yield of bronchoscopy for peripheral lung lesions. In these cases, fluoroscopy is mandatory to assure proper positioning of the brush, biopsy forceps, or needle. An exciting new area is the potential application of EBUS in evaluation of peripheral pulmonary nodules. EBUS allows for acquisition of diagnostic tissue via transbronchial biopsy with fewer passes and may permit differentiation between benign and malignant nodules based entirely on nodule architecture. In the future, peripheral EBUS nodule characterization may even obviate the need for pathological diagnosis in certain patients with suspicious nodules.

The diagnosis of various infectious diseases can be established using a variety of transbronchoscopic sampling techniques. The role of bronchoscopic biopsy has been reaffirmed in immunocompromised hosts, in whom documentation of the precise pathogen is crucial for appropriate therapy. For example, while the presence of cytomegalovirus in bronchoalveolar lavage fluid may not be diagnostic, documentation of intracellular inclusion bodies on a biopsy specimen is practically pathognomonic. Simple, cost-effective transbronchoscopic tissue sampling can obviate much more complicated, expensive, and higher-risk transthoracic needle biopsy or thoracic surgical procedures.

Figure 36-4 "Hot" forceps biopsy of a vascular endobronchial lesion. Use of the electrocautery forceps allows for safe, hemostatic biopsy of friable or vascularized endobronchial lesions (such as bronchial carcinoids), while obtaining pathologically interpretable tissue biopsy specimens.

Sampling of Airway and Alveolar Constituents

Bronchoscopy provides easy and relatively safe access to material in the tracheobronchial tree and distal alveolar spaces. A variety of studies are routinely performed on specimens obtained from the airways and alveolar spaces using several techniques. For example, aspirated secretions can be sent for microscopy and culture to determine the offending organism in cases of infection or suspected infection. Cytologic analysis of bronchoscopically obtained materials can provide proof of malignancy. With the advent of lung transplantation, the success of the procedure depends, in large measure, on the early diagnosis of rejection or infection in these immunocompromised subjects. The most commonly employed bronchoscopic techniques for sampling the airways and alveolar spaces include "bronchial washing," bronchial brushing (see above), and bronchoalveolar lavage.

Bronchoalveolar Lavage

A very useful bronchoscopic technique is bronchoalveolar lavage (BAL). BAL is safe, even in critically ill patients, when

biopsy or brushings are not recommended because of the risk of bleeding. Normal saline solution, devoid of any bacteriostatic material, is instilled into distal airspaces through the "wedged" bronchoscope and then aspirated through the instrument's suction channel. The fluid collected in this manner is analyzed for gross appearance to detect possible alveolar hemorrhage. The fluid may also be subjected to a variety of tests, depending on the clinical circumstances: microbiologic testing, specific cytologic analysis and cell count, immunologic parameters, presence of various biochemical mediators related to pathological processes, tissue markers, polymerase chain reaction, electron microscopy, flow cytometry, and DNA probes.

The value of BAL is well documented in the diagnosis of diffuse parenchymal diseases, such as eosinophilic pneumonia, eosinophilic granuloma, and pulmonary alveolar proteinosis. It remains investigational in the evaluation of many other diseases—e.g., sarcoidosis, hypersensitivity pneumonitis, and idiopathic pulmonary fibrosis. Overall, the diagnostic yield of BAL is very much dependent on specific patient characteristics, underlying pathological process, and many technical factors.

Application of Quantitative Microbiologic Techniques

Two bronchoscopic methods that are useful in the diagnosis of pulmonary infections are quantitative BAL and protected-specimen brush (PSB). They are, perhaps, most useful in the setting of suspected ventilator-associated pneumonia (VAP), wherein a patient who is endotracheally intubated and receiving mechanical ventilation has signs of infection and an abnormal chest radiograph. Intubated patients experience colonization of their upper and lower airways with nosocomial organisms. Because of an abnormal mucociliary clearance mechanism, these patients are at greater risk for developing pulmonary infections. In addition, mechanically ventilated, intubated patients are often treated empirically with broad-spectrum antibiotics and, therefore, are at greater risk for infection with resistant organisms and unusual lower respiratory tract pathogens.

When quantitative cultures are used, growth above a certain threshold is required to diagnose VAP, whereas growth below the threshold is assumed to be due to colonization or contamination. The American Thoracic Society's position statement allows for the use of either a quantitative or semi-quantitative strategy (e.g., tracheal aspirates) in suspected VAP. However, evidence suggests that quantitative cultures are more reliable in documenting the presence of pneumonia.

Protected Specimen Brush

PSB uses a double-catheter system in which an outer cannula and distal, biodegradable plug protect the bronchoscopic brush within the inner cannula from contamination with secretions in the upper airway and suction channel of the bronchoscope. When the bronchoscope is positioned proximal to the segmental orifice of interest, the PSB inner cannula is advanced into a subsegment and the protective distal plug ejected. The brush is then advanced peripherally, rotated gently, and retracted into the inner cannula. The inner cannula is subsequently retracted into the outer cannula and the bronchoscope removed from the airway. The distal portion of the catheter is cleaned with 70 percent alcohol and the brush clipped into saline solution under sterile conditions. The PSB is then submitted for quantitative bacterial culture within 15 minutes of performance of the procedure. The threshold for diagnosis of VAP with PSB is 10^3 colony-forming units (CFU) per milliliter. PSB appears to have higher specificity than sensitivity for the presence of VAP—a positive result greatly increases the likelihood of pneumonia being present.

Quantitative Bronchoalveolar Lavage

Quantitative BAL entails the performance of a standardized BAL, with infusion of at least 120 ml of saline for adequate sampling of a pulmonary subsegment. Quantitative culture of the aspirated material is performed to determine the number of CFU recovered. For quantitative BAL, a threshold of 10^4 or 10^5 CFU per milliliter is used for the diagnosis of pneumonia. The detection of pneumonia by quantitative BAL culture has a sensitivity of 42 to 93 percent and a specificity of 45 to 100 percent.

Quantitative BAL may be superior to PSB in the diagnosis of VAP, since BAL samples a much larger proportion of lung parenchyma; PSB samples only a single bronchial segment. Protected BAL, which requires the use of a balloon-tipped catheter with a distal ejectable plug inserted through the suction channel of the bronchoscope, has a greater specificity than standard BAL. A quantitative BAL strategy which uses detection of intracellular organisms in recovered cells to diagnose pneumonia provides information in a rapid time frame, but it does not identify the etiologic pathogen. BAL techniques incorporating molecular testing in addition to microbiologic cultures are also being evaluated.

TECHNIQUES USED IN THERAPEUTIC BRONCHOSCOPY

Since the introduction of bronchoscopy, the technique has been used not only for observation but also for treatment of local airway disorders. As with any clinical intervention, the guiding rule for treatment always remains, "If I can do no good, I will at least do no harm."

Rigid Bronchoscopic Debulking or Balloon Dilatation

Rigid bronchoscopes have beveled tips, which are ideal for coring through large tumors in the airways and for dilating strictures. In addition, they have large internal diameters, which facilitate debridement of tumors, evacuation of

clots, and ventilation. Despite advances in other adjunctive endoscopic techniques, rigid bronchoscopic recanalization remains the treatment of choice for life-threatening tracheobronchial obstruction.

In less urgent cases of obstruction caused by malignant tumors, balloon dilatation has become an attractive alternative to dissection using a blunt rigid bronchoscope. High-pressure angioplasty catheters with various balloon lengths and diameters were commonly used in the past. Currently available balloons, designed specifically for tracheobronchial use (e.g., CRE balloon, Boston Scientific Corp., Cambridge, MA), are expandable to specific diameters by application of defined atmospheric pressure. The balloons are inserted through the working channel of the bronchoscope under fluoroscopic guidance or direct visualization. The balloon, filled with saline or radiopaque liquid, is inflated at the site of the stenosis until a smooth, uniform lumen of predictable diameter is attained. Major risks of the technique are rupture of the bronchial wall, bleeding, and postprocedure airway edema. This technique is often used in combination with bronchoscopic laser therapy and placement of a tracheobronchial stent for the treatment of airway stenosis.

Balloon bronchoplasty has also been used successfully to treat other disorders, including tuberculosis, fibrosing mediastinitis, and strictures associated with lung transplantation or prolonged intubation. The technique is less successful when used alone to treat stenosis accompanied by extrinsic airway compression, and it is contraindicated in patients with tracheobronchomalacia.

Although in the majority of cases, balloon dilatation is performed while the patient is under general anesthesia, treatment of many airway lesions (e.g., short fibrotic strictures) can be accomplished with use of a flexible bronchoscope while the patient is under conscious sedation. Complications of balloon dilatation of airway lesions include bronchospasm, chest pain, airway perforation, pneumothorax, and pneumomediastinum.

Endobronchial Laser Therapy

Perhaps, the most widely known technique in interventional pulmonology is laser bronchoscopy. Lasers produce a beam of monochromatic, coherent light that can induce tissue vaporization, coagulation, hemostasis, and necrosis. Although useful in the ablation of endoluminal malignant tumors, bronchoscopic laser therapy is also beneficial in the treatment of other tracheobronchial disorders, including inflammatory strictures, obstructive granulation tissue, amyloidosis, and benign tumors such as hamartomas.

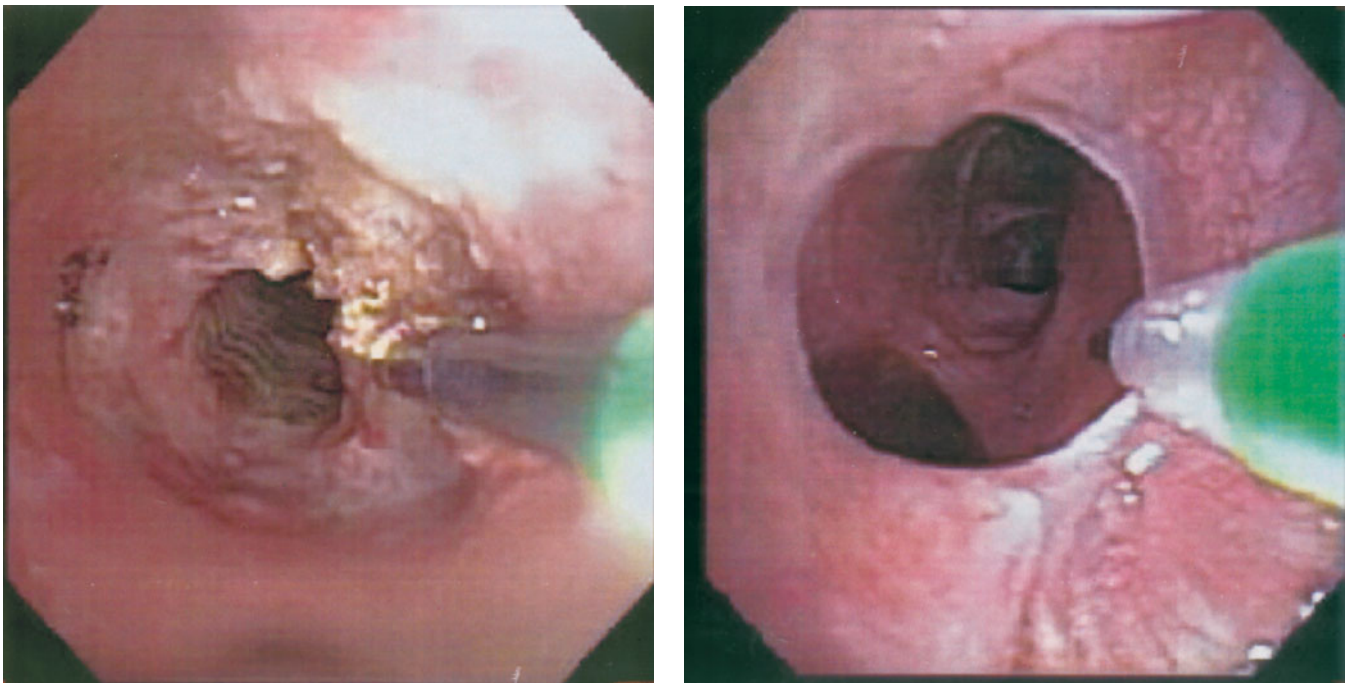
Since the initial report of endobronchial laser ablation of an obstructive neoplasm by Laforet in 1976, several types of lasers have become available for the management of tracheobronchial obstruction. The carbon dioxide (CO_2) laser, used mainly by otolaryngologists, allows shallow penetration of tissue (to a depth of 0.1 to 0.5 mm) and highly precise cutting; however, it has minimal hemostatic properties and, traditionally, was used in conjunction with rigid bronchoscopy. Recently developed technology has facilitated delivery of CO_2 laser energy via unique reflective fiberoptic probes (OmniGuide, Inc., Cambridge, MA), allowing applications with flexible laryngoscopy and flexible bronchoscopy. The CO_2 laser, with its fine control of tissue ablation, is ideal in the management of laryngeal lesions (e.g., webs, vocal cord nodules, etc).

Interventional pulmonologists primarily use the neodymium:yttrium aluminum garnet (Nd:YAG) laser, which provides deeper penetration of tissue (to a depth of 3 to 5 mm), superior photocoagulation, and improved hemostasis, but with less precision in cutting. Photocoagulation using an Nd:YAG laser can be performed through a rigid or flexible bronchoscope, but rigid bronchoscopy remains the preferred method for treatment of patients who have respiratory distress due to severe tracheobronchial obstruction or active intraluminal bleeding.

Use of a laser in the tracheobronchial tree requires careful consideration of the anatomic location and configuration of the lesion. If the lesion is in close proximity to the esophagus or pulmonary artery, endobronchial laser therapy poses a risk of fistula formation. Use of laser therapy in a patient with tracheobronchial narrowing due to extrinsic compression may result in perforation of the airway. In addition, prolonged obstruction of the airway (for more than 6 weeks) may lead to refractory atelectasis or bronchiectasis, minimizing the benefits of endobronchial recanalization. The potential for airway recanalization in the setting of long-standing endoluminal obstruction can be assessed by bronchography or perfusion scanning.

Although endobronchial laser therapy is generally safe and well tolerated, complications may arise and include cardiac arrhythmias, airway perforation, pneumothorax, hemorrhage, hypoxemia, or endobronchial fire (ignition of the bronchoscope or endotracheal tube). In rare cases, pulmonary edema or fatal pulmonary venous gas embolism has been reported. Patients with standard silicone endotracheal tubes or silicone tracheobronchial stents, and those who require high concentrations of supplemental oxygen, are at increased risk for endobronchial fire. Fortunately, the overall risk is less than 0.1 percent. The overall rate of mortality attributable to endoscopic laser therapy is quite low, not exceeding 0.3 to 0.5 percent in several large series.

Success rates and complications directly related to laser therapy are not different when the procedure is performed under general anesthesia through the rigid bronchoscope or under topical anesthesia and conscious sedation through a flexible bronchoscope. Nd:YAG laser photoradiation therapy has demonstrated a single-modality recanalization rate of greater than 90 percent for endobronchial obstruction of large central airways, but it is less successful with peripheral lesions or with associated extrinsic airway compression. Laser therapy may improve the likelihood of successful weaning from mechanical ventilation in patients with advanced lung cancer who present in respiratory failure. In addition, photocoagulation with an Nd:YAG laser is an invaluable treatment for patients with airway obstruction due to benign endoluminal tumors.



A *B*

Figure 36-5 Electrocautery. Use of electrocautery accessory devices for *(A)* treatment of a malignant endobronchial lesion with associated tissue destruction (cautery probe) or for *(B)* management of an endobronchial web related to posttransplant anastomotic stricture (cautery knife).

Endobronchial Cryotherapy and Electrocautery

Cryotherapy and electrocautery are excellent, cost-effective alternatives to laser therapy for the management of tracheobronchial obstruction. The depth of penetration and resulting injury are, however, much more difficult to control. As with the Nd:YAG laser, both electrocautery and cryotherapy can be administered through a rigid or flexible bronchoscope. The effects of electrocautery on tissue are similar to those of the Nd:YAG laser, with tissue destruction induced by intense coagulation and vaporization (Fig. 36-5). Argon plasma coagulation (APC) is similar to electrocautery, except that it uses argon gas to conduct the electrical current rather than a contact probe. APC has a depth of penetration of only a few millimeters and is, therefore, more suitable for treatment of superficial and spreading lesions. Cryotherapy probes induce tissue necrosis through hypothermic cellular crystallization and microthrombosis. Specially designed probes are inserted via the bronchoscope until they contact the target tissue. Through the channel in the probe, liquid nitrous oxide or liquid nitrogen is introduced, resulting in the rapid creation of an "ice ball" (approximate temperature, −20°C) at the end of the tip. This freezing effect is maintained for about 20 s; the area is then rewarmed, resulting in thawing. Treatment of an endobronchial lesion using a cryoprobe requires several freeze-thaw cycles.

Cryotherapy and electrocautery have been used successfully to relieve airway obstruction caused by benign tracheobronchial tumors, polyps, and granulation tissue. These techniques—cryotherapy in particular—may be superior to lasers for distal lesions because of the lower risk of airway perforation. Similarly, carcinoma in situ and mucosal dysplasia may be adequately treated using cryotherapy or electrocautery alone, although multiple treatments may be required for optimal results. Cryotherapy is a safe treatment for infiltrative lesions of the airway, and according to anecdotal reports, the technique has proved beneficial in patients with posttransplantation anastomotic stenosis and in those with foreign-body aspiration. In fact, cryotherapy may be the modality of choice for the removal of endobronchial blood clots and mucus plugs.

Endobronchial cryotherapy is generally not effective for paucicellular lesions that are relatively impervious to freezing, such as fibrotic stenoses, cartilaginous or bony lesions, or lipomas. Furthermore, endobronchial cryotherapy, unlike either laser therapy or electrocautery, cannot be used to achieve rapid relief of symptomatic airway obstruction. The most common serious complication of both electrocautery and cryotherapy is hemorrhage. The estimated incidence of clinically significant bleeding in patients treated with electrocautery is 2.5 percent.

Endobronchial Brachytherapy

Brachytherapy is the treatment of tumors with radiation delivered internally through implanted radioactive seeds or inserted wires. This technique ensures the delivery of a maximal therapeutic dose of radiation to the tumor with

a minimal effect on normal surrounding tissues. Endobronchial brachytherapy involves the bronchoscopic insertion of a thin, hollow catheter through a malignant obstruction under fluoroscopic guidance. A radioactive implant is then inserted into the catheter and left in position for a predetermined period (2 to 40 hours, depending on the dose rate).

In 1922, Yankauer reported the use of rigid bronchoscopic brachytherapy for the palliation of airway obstruction due to malignant tumors. Modern techniques, including the use of flexible bronchoscopes, polyethylene afterloading catheters, and ^{192}iridium implants, were first described in 1983. Since the development of techniques involving high dose-rate delivery in the 1980s, endobronchial brachytherapy has become a particularly attractive option for outpatient treatment.

Relief of airway obstruction is the primary goal of endobronchial brachytherapy, although curative treatment may be attempted in conjunction with external-beam radiation in selected patients. Brachytherapy is safest and most effective for central airway lesions, although in one study, small peripheral tumors proved to be more responsive than bulkier central tumors. Among patients with obstruction due to malignant tumors, rates of recanalization range from 60 to 90 percent, with decreased dyspnea, cessation of hemoptysis, and relief of cough in most cases. Brachytherapy has also been used for the prevention and treatment of airway stenosis related to recurrent growth of granulation tissue in patients with lung transplants.

Endobronchial brachytherapy may require multiple treatments to be effective. It is generally used as an adjunct to either Nd:YAG photocoagulation or conventional external-beam irradiation in an effort to achieve both rapid and sustained recanalization in patients with obstruction due to malignant tumors. Brachytherapy may also be administered in conjunction with placement of an endobronchial stent in patients with extrinsic compression of the airways due to malignant tumors. Brachytherapy works best with submucosal and peribronchial malignant disease.

Serious complications of brachytherapy include massive hemoptysis and fistula formation. Because of the risk of fatal hemorrhage, every effort should be made to rule out involvement of central vessels before treatment is administered. The incidence of serious complications varies widely, with rates as low as 0 to 10 percent in some of the largest studies, and as high as 30 to 40 percent in smaller studies.

Photodynamic Therapy

Photodynamic therapy (PDT) is currently approved by the Food and Drug Administration for the palliation of airway obstruction caused by malignant tumors and as an alternative to surgery in selected patients with minimally invasive central lung cancer. PDT works on the principle that certain compounds, such as hematoporphyrin derivatives, function as photosensitizing agents, rendering malignant cells susceptible to damage from monochromatic light. Tumor necrosis occurs as a result of cellular destruction through the generation of oxygen-free radicals or by ischemic necrosis mediated by vascular occlusion resulting from thromboxane A_2 release. The selective effect of PDT on malignant cells is thought to be due to the differential uptake and retention of photosensitizing agents in neoplastic cells rather than in normal cells. This selectivity effect appears to be most pronounced approximately 24 to 48 hours after infusion of the photosensitizing agent. For this reason, bronchoscopic treatment of target lesions is often performed 1 to 2 days after the agent has been injected. Given the delayed onset of action of PDT, it is not useful in patients with acute respiratory distress from tracheobronchial obstruction. Frequent bronchoscopies are often required to debride necrotic tissue.

Ideal candidates for PDT include patients with airway obstruction due to malignant polypoid endobronchial masses, those with minimal extrinsic airway compression, and patients with minimally invasive tumors of the central airways. Although surgical resection remains the treatment of choice for early lung cancer, some patients refuse surgery or are deemed inoperable because of high surgical risk. PDT may represent an appropriate alternative. Response rates are highest in patients with small tumors and minimal depth of penetration. In patients with bulky tumors, endobronchial PDT may substantially reduce the obstruction, with objective increases in spirometric measurements and subjective improvements in dyspnea and the quality of life. Metastatic tumors have also been treated successfully with PDT. Complications of PDT include increased skin photosensitivity and hemoptysis resulting from extensive tumor necrosis.

Tracheobronchial Stenting

The medical term "stent" was first used to denote a device that supported the healing of gingival grafts, developed by the British dentist, Charles R. Stent. The term has since been used to refer to any device designed to maintain the integrity of hollow tubular structures, such as the coronary arteries and the esophagus. Anecdotal reports of attempts to use stents in the tracheobronchial tree date back to 1915. The Montgomery T tube, designed in the 1960s, was the first reliable, dedicated airway stent. However, stent implantation in the lower trachea and bronchi did not become standard medical practice until Dumon's 1990 report on the safety and ease of placement of a dedicated airway stent made of silicone.

Two main types of endobronchial stents are in use today: tube stents made of silicone or plastic and self-expandable metallic stents (SEMS). Silicone stents, including the Dumon stent, are usually placed via rigid bronchoscopy while the patient is under general anesthesia. These stents are inexpensive and easy to remove from the airway; they provide protection from tumor ingrowth and cause minimal irritation to adjacent normal tissues. Potential complications of silicone stents include migration, formation of granulation tissue, and inspissation of secretions. Bifurcated silicone and composite stents are also available for the palliation of distal tracheal and main carinal lesions. These stents have been

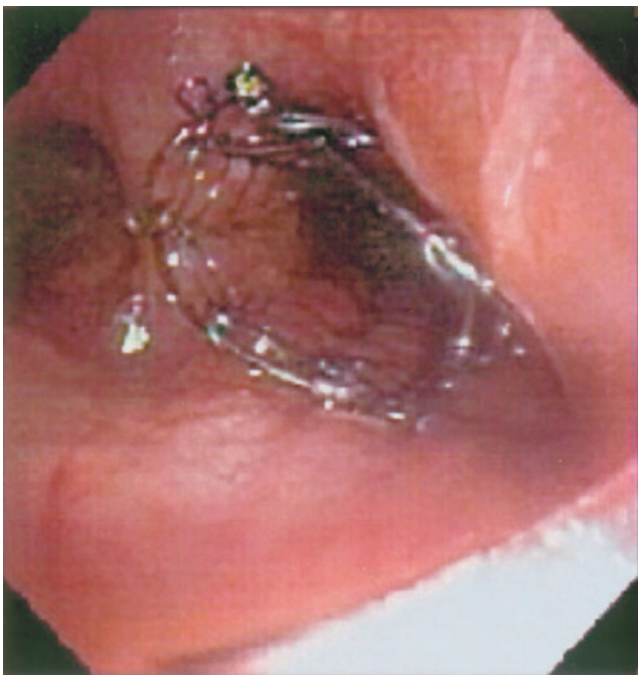


Figure 36-6 Self-expandable metallic stent (SEMS). Uncovered stent placed in right main-stem bronchus for malignant extrinsic compression (Ultraflex, Boston Scientific Corp., Cambridge, MA).

effective in the management of carinal compression associated with malignant tumors, tracheoesophageal fistulas, and tracheobronchomalacia.

Unlike silicone stents, SEMS can be placed with the use of a flexible bronchoscope, and they are less likely to migrate and are more likely to preserve normal mucociliary clearance (Fig. 36-6). Metal stents remain fairly expensive, however, and if they are misplaced in the airway, rigid bronchoscopy is often required for their removal. In addition, mucosal inflammation and the formation of granulation tissue are common at the proximal and distal ends of metal stents, and endoscopic intervention may be required to restore airway patency. Long-standing SEMS often require rigid bronchoscopic techniques for complete removal. For all these reasons, SEMS are not recommended for most patients with nonmalignant airway stenoses.

Endobronchial stents have a critical role in a multimodal endoscopic approach to both benign and malignant stenoses of the airways. Stenosis due to locally advanced bronchogenic carcinoma, for example, can be treated with a combination of endoscopic laser therapy and stent implantation in order to prevent respiratory failure. Stent placement can also be used to maintain airway patency after endobronchial brachytherapy or can be combined with laser therapy and balloon dilatation in the endoscopic management of fibrotic strictures.

Most studies of the efficacy of endobronchial stent placement have had impressive results. Dumon and colleagues reported excellent clinical outcomes and few complications with the use of silicone stents in patients with extrinsic airway compression due to malignant tumors, but a lower success rate among patients with tracheal stenosis caused by other disorders. The most common complications are stent migration, granulation tissue formation, and secretion inspissation. In limited studies, success rates, broadly defined as symptomatic relief, have ranged between 78 percent and 98 percent. In studies of patients who had been intubated because of respiratory failure due to unresectable tracheobronchial and mediastinal disease, stent placement facilitated extubation in nearly all the patients.

The benefits of stent placement appear to persist in patients who survive for a period of several months or years after implantation. Long-term follow-up data, however, are limited to benign disease, since the mean follow-up period in patients with airway compression due to malignant tumors does not usually exceed 3 to 4 months. Some authors have reported poor long-term results with use of metal stents in patients with fibro-inflammatory stenosis due to nonmalignant disorders. In addition, case reports describe massive hemorrhage associated with the use of stents in patients with extrinsic compression attributable to aneurysmal dilatation or congenital malformations of the aorta.

APPLICATIONS OF THERAPEUTIC BRONCHOSCOPY

Therapeutic bronchoscopy may be used in a wide variety of settings, the most common of which are described below.

Control of Hemoptysis

In cases of hemoptysis, bronchoscopy may be of value not only for diagnosis, but also for emergency management of endobronchial bleeding. Because of difficulties with visualization, instruments with large and maximally effective suction channels should be used. In assessment of massive bleeding, when the need to remove large clots is anticipated, rigid bronchoscopy is generally preferred.

When continuous suctioning of blood fails to clear the airways, other means can be used. An iced saline solution can be instilled along with vasoactive drugs, such as epinephrine, to induce spasm of the bleeding vessels. The bronchoscope itself can also be used to stem the bleeding by tamponade of the bleeding site or to occlude the lumen of the bronchus from which the bleeding originates. The same effect, perhaps with better local control, can be achieved using bronchoscopic balloon catheters. Specially designed catheters have been developed for introduction through the working channel of the flexible bronchoscope, some permitting subsequent removal of the scope while the tamponading balloon remains in place. Another effective method for control of visible sources of bleeding, particularly from endobronchial neoplasms, is Nd:YAG laser photocoagulation.

Endoluminal Airway Obstruction

Endoluminal obstruction of the tracheobronchial tree may result from various benign and malignant processes. The most

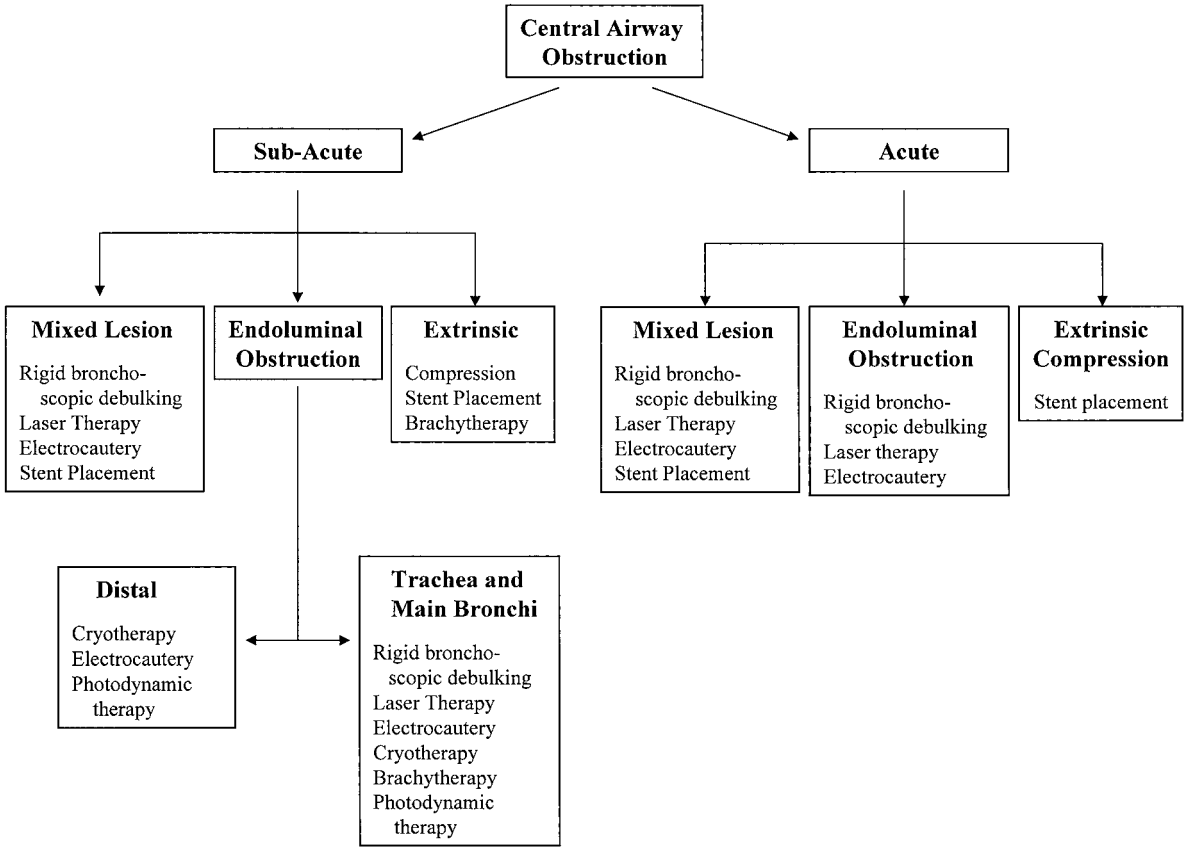

Figure 36-7 Algorithm for the management of central-airway obstruction due to malignant tumor. This treatment algorithm addresses both acute and subacute central-airway obstruction, as well as the location and type of lesion—characteristics that can be determined using CT and diagnostic bronchoscopy.

common cause of endobronchial obstruction is advanced bronchogenic carcinoma. In patients with inoperable tumors of the central airways, restoration of airway patency may provide palliation and may even prolong life, particularly in the case of impending respiratory failure.

Signs and symptoms of central airway obstruction vary, but often include wheezing, cough, stridor, hoarseness, hemoptysis, and chest pain. A careful pretreatment evaluation should be performed to distinguish symptoms attributable to focal tracheobronchial lesions from those related to underlying diffuse airflow obstruction, parenchymal lung disease, or both. Mild-to-moderate tracheal stenosis, for example, may contribute only marginally to the degree of dyspnea experienced by a patient with severe chronic obstructive lung disease. Although pulmonary function testing and thoracic imaging techniques such as computed tomography (CT) and magnetic resonance imaging may be useful in the evaluation of a patient with suspected obstruction of the central airway, bronchoscopy—either rigid or flexible—remains the diagnostic gold standard. Increasingly, however, three-dimensional reconstruction CT imaging—so-called "virtual bronchoscopy"—is being applied as a reliable, noninvasive method of assessing the nature and extent of airway obstruction.

The bronchoscopic approach to the management of endoluminal obstruction depends on the location of the lesion, presence or absence of associated extrinsic compression, and degree of clinical urgency (Fig. 36-7). Rigid-bronchoscopic debulking, with adjunctive laser therapy or electrocautery, is recommended when airway recanalization must be performed on an emergency basis. If endobronchial obstruction is accompanied by marked extrinsic compression, placement of a stent may be beneficial.

The complexity of a lesion is equally important in determining the best approach to resection. Tracheal webs, for example, are often managed by laser resection alone, whereas complex fibrotic strictures may warrant the combination of rigid-bronchoscopic or balloon dilatation, laser resection, and stent placement. For focal tracheal stenoses in low-risk patients, surgical resection and primary reanastomosis should remain the first-line therapy.

Extrinsic Airway Compression

Extrinsic airway compression usually results from malignant involvement of structures adjacent to the central airways, such as mediastinal lymph nodes or the esophagus, but it may be associated with a benign process, such as fibrosing mediastinitis,

tuberculosis, aneurysmal dilatation of the aorta, or sarcoidosis. Clinical signs and symptoms of extrinsic airway compression often mimic those of endobronchial obstruction. The diagnosis is established on the basis of bronchoscopic evidence of marked airway narrowing in the absence of an endoluminal mass. Chest CT, and increasingly, EBUS have important adjunctive roles in identifying anatomic structures external to the narrowed lumen.

Therapeutic options in the management of extrinsic airway compression are limited. Ablative endoscopic approaches, such as laser therapy, cryotherapy, PDT, and electrocautery are contraindicated because of the risk of airway perforation. Although some patients with malignant disease may benefit from endobronchial brachytherapy, tracheobronchial stent placement is the palliative treatment of choice for patients with symptomatic extrinsic airway compression.

Tracheobronchomalacia

Diffuse or focal tracheobronchomalacia is perhaps the most challenging disorder encountered by the interventional pulmonologist. Cartilaginous tracheobronchomalacia, as seen in patients with postintubation injury or relapsing polychondritis, reflects a loss of the structural integrity of the trachea or main-stem bronchi due to destruction of the airway's cartilaginous rings. Membranous, or crescentic, tracheobronchomalacia is manifested by airway collapse during exhalation as a result of laxity of the membranous portion of the trachea and main bronchi and is usually seen in patients with long-standing chronic obstructive pulmonary disease. Focal tracheobronchomalacia may be a complication of long-standing intubation or an anastomotic complication after lung transplantation. Tracheobronchomalacia is best diagnosed on the basis of flexible bronchoscopy, with the patient breathing spontaneously, although dynamic CT scanning, with images obtained on inspiration and expiration, is often helpful.

The endoscopic treatment of choice for patients with diffuse tracheobronchomalacia is the insertion of a standard or bifurcated silicone tracheobronchial stent. This intervention is more likely to be successful in patients with the cartilaginous type of tracheobronchomalacia than in those with the membranous type. For those patients with membranous tracheobronchomalacia, a trial of stenting with a silicone endoprosthesis should be performed. For those who benefit in terms of decreased respiratory symptoms and improved pulmonary function, surgical placation or buttressing of the posterior membrane can be performed with good results. For many patients with focal tracheobronchomalacia, surgery is the best therapeutic option. An alternative treatment for selected patients with diffuse tracheobronchomalacia is the pneumatic stent afforded by noninvasive ventilatory techniques, such as nasal continuous positive airway pressure.

Removal of Foreign Bodies

Foreign body aspiration is more likely to occur in children than in adults, with most occurring in children younger than 3 years. In children the obstruction most often involves a main-stem bronchus, whereas in adults the majority of foreign bodies are wedged distally, most commonly in the right lower lobe. Prior to the development of bronchoscopy, most foreign body aspirations resulted in high morbidity and mortality, commonly from postobstructive pneumonia. Until the introduction of the flexible bronchoscope, all foreign body removals were accomplished with the rigid bronchoscope. Even at present, it is well accepted that the rigid bronchoscope is the tool of choice for the removal of foreign bodies, especially in children. The advantage of the rigid instrument resides in its larger access channel, permitting use of more adaptable retrieval tools, and its ability to provide and control the patient's ventilation. In adults, a flexible bronchoscopy is the most common initial diagnostic tool and allows for successful removal of the foreign body in the majority of cases.

Various types of instruments have been developed for use with bronchoscopy for the removal of foreign bodies, including grasping forceps, balloon catheters, retrieval baskets, snares, and magnetic extractors. The choice of instrument depends on the specifics of the type of foreign body and its location in the tracheobronchial tree. Grasping forceps may be helpful in the retrieval of hard objects with an irregular surface. Smooth objects or organic material (e.g., nuts or food particles) may require use of expandable baskets or a combination of balloon catheters, suction devices, and grasping forceps. A frequently used technique employs a Fogarty balloon catheter to dislodge the foreign body and to bring it proximally into the trachea prior to attempting removal using other instruments (Fig. 36-8).

Figure 36-8 Flexible bronchoscopic-mediated foreign body removal from the distal right bronchus intermedius using balloon catheter.The Fogarty embolectomy balloon catheter is inflated beyond the foreign body and used to dislodge it to a more proximal location where it can be easily grasped and removed with a basket or snare.

Special attention should be paid to the period after removal of the foreign body—a time when complications can occur. Patients should be observed for any signs of hemoptysis or subglottic edema. Trauma inflicted during the extraction or forceful manipulation of instruments greatly accentuates the risk of postoperative complications, particularly if oversized instruments are used or if the bronchoscopy is prolonged.

Aspiration of Secretions

According to a survey of bronchoscopists conducted in the United States, removal of retained secretions is cited as a leading indication for therapeutic bronchoscopy. Bronchoscopic aspiration of secretions may be indicated in patients presenting with weakness of respiratory muscles (e.g., due to underlying neuromuscular disease or the postoperative state) or disorders leading to recurrent aspiration of food or excessive upper-airway secretions. In critically ill or mechanically ventilated patients, removal of secretions and mucous plugs usually can be rapidly achieved with the flexible bronchoscope. A flexible scope with a large-diameter suction channel should be chosen for this procedure. The nature of the retained material—its consistency and viscosity—may dictate frequent bronchoscopies to relieve segmental or lobar atelectasis due to inspissated mucous plugs. Underlying pulmonary diseases, such as bronchiectasis, may aggravate the retention of airway secretions. Bronchoscopic aspiration of secretions should not be considered "routine" in the postoperative period or in other conditions where good chest physiotherapy and maintenance of adequate pulmonary toilet can be more effective.

Two specific disorders are worth highlighting in the context of therapeutic bronchoscopy: pulmonary alveolar proteinosis (PAP) and allergic bronchopulmonary aspergillosis (ABPA). In PAP, BAL for clearance of alveolar material is a time-honored therapeutic procedure that may be facilitated by use of a bronchoscopic approach. In ABPA, lavage with saline solution may be insufficient to remove tenacious impactions (described as "plastic bronchitis"). In these circumstances, use of bronchoscopic forceps or snare may prove helpful.

Closure of Bronchial Fistulae

Flexible bronchoscopy can be a useful intervention in confirming the diagnosis of suspected bronchopleural fistula and specifying its precise location. Depending on the location and the size of the fistula, it can be approached bronchoscopically and an attempt made to seal it. Simple tamponade using the body of the flexible bronchoscope or a balloon catheter provides only temporary relief. Many different techniques have been employed, including introduction of irritating substances—e.g., silver nitrate, with the object of stimulating reactive granulation tissue formation. Several potentially useful agents have been described, including Gelfoam, autologous blood patch, cryoprecipitate, and thrombin injection to create fibrin clot. Small bronchial openings in an otherwise normal bronchus following thoracic surgery respond much better, with a higher rate of success of bronchoscopic sealing. It is much more difficult to achieve good obliteration of the fistula when the fistula is infected or is due to an underlying malignancy.

SAFETY FACTORS IN BRONCHOSCOPY

Bronchoscopy is a specialized procedure that requires extensive training. Familiarity with both the physiology and anatomy of the airways and other intrathoracic structures is essential. Any diagnostic or therapeutic manipulation should be considered in relation to the underlying condition of the patient, localization of the area of investigation, and other surrounding structures in the thorax. It is essential to develop good communication between the bronchoscopist and other members of the team. While the bronchoscopist concentrates on the field of work—which, as seen through the bronchoscope, is two-dimensional—other team members are responsible for monitoring the patient (oxygen saturation, blood pressure, heart rhythm, etc.) and checking and maintaining the adequacy of ancillary equipment (suction, oxygenation, and accessories such as forceps, balloons, catheters, and laser light guides). Risks are decreased if, for example, special attention is paid to the control of accessories during their manipulation beyond the tip of the bronchoscope. Premature deployment of the needle biopsy device or inappropriate bending of the bronchoscope while an instrument is inside the flexible portion can result in perforation of the bronchoscope. Activation of the laser with a broken light guide inside the bronchoscope or inadequate protrusion of the tip of the fiber beyond the bronchoscope may result in airway fires or severe burns to the patient. Attention to details and proper maintenance of the equipment, including accessories, enhance safety for the patient and staff. Diagnostic yield and therapeutic results are also improved. Last, but not least, proper knowledge and application of safety standards and maintenance procedures decrease the cost of bronchoscopy.

COMPLICATIONS OF BRONCHOSCOPY

Bronchoscopy is a potentially hazardous procedure. Complications are generally due to inappropriate preparation of patients before bronchoscopy, effects of local or general anesthesia, and manipulation of various instruments. Appropriate training and experience of the bronchoscopist and supporting team are crucial in reducing the rate of complications.

Anesthesia and Related Blood Gas Abnormalities

Approximately half of the life-threatening complications of diagnostic bronchoscopy are associated with premedication and use of topical anesthesia. Risk is significantly increased

in the elderly, and in those with serious concomitant illnesses. Predisposing factors include cardiovascular disease, chronic pulmonary disease, renal and hepatic dysfunction, seizures, and altered mental status. Mild sedation, anxiolysis, muscular relaxation, and anterograde amnesia increase patient cooperation and permit quicker and less traumatic procedures. Doses of benzodiazepines, opiates, anticholinergics, and topical anesthetics must be adjusted if there is underlying organ dysfunction. Conscious sedation using short-acting benzodiazepines (e.g., midazolam) offers significant anterograde amnesia; its use has reduced the incidence of potentially dangerous hypotension and respiratory depression.

Inadequate topical anesthesia potentiates coughing, gagging, and patient discomfort and increases the risk of injury during bronchoscopy. However, topical anesthetics such as lidocaine, the most frequently used agent, are absorbed systemically through the respiratory mucosa, increasing the risk of cardiac or central nervous system toxicity. These complications are more likely to occur in patients with underlying low cardiac output, hepatic dysfunction, and oropharyngeal candidiasis. Another, less frequent complication of excessive lidocaine use is methemoglobinemia and resultant tissue hypoxia.

Skillful manipulation of rigid and flexible bronchoscopes reduces the risk of injury to the upper airways, which can result in life-threatening laryngospasm during or after completion of the procedure. Particular caution must be exercised in patients with underlying bronchospastic disorders, superior vena cava syndrome, or history of angioedema.

Introduction of the bronchoscope under general anesthesia or under conscious sedation with topical anesthesia frequently results in a decrease in oxygenation and in hypoventilation, with demonstrable increases in Pa_{CO_2}. In patients with underlying chronic lung disease, severe hypoxemia may occur, triggering life-threatening cardiac arrhythmias.

All patients undergoing bronchoscopic procedures should be monitored continuously (electrocardiogram, blood pressure, O_2 saturation, and, if indicated, expiratory CO_2 concentration). Use of supplemental oxygen during the procedure should be routine. Bronchoscopy probably should not be performed in patients who are unable to maintain a Pa_{O_2} of 65 mmHg while an FI_{O_2} of 1.0 and full ventilatory support are administered.

Significant oxygen desaturation may occur during BAL. The degree of desaturation is directly related to the duration of the procedure and the volume of lavage fluid used. Return to the prebronchoscopy level of O_2 saturation may be prolonged after removal of the bronchoscope, and supplemental O_2 should be continued throughout the procedure and during the postbronchoscopy observation period.

Fever and Infection

In patients with underlying valvular cardiac disease and those predisposed to endocarditis, the American Heart Association recommends use of prophylactic antibiotics before rigid bronchoscopy, but not before flexible bronchoscopy. Antibiotic prophylaxis is mandatory, however, in patients with prosthetic valves, surgical vascular shunts, or a history of endocarditis.

Appearance of transient fever after bronchoscopy is not unusual and generally does not require any therapy. However, persistent fever in the setting of progressive radiographic infiltrates necessitates antibiotic therapy. The incidence of fever is increased in the elderly, in those with underlying chronic pulmonary disease or documented endobronchial obstruction, and in those with bronchoscopic interventions for malignancy. The incidence of fever and extension of pulmonary infiltrates increase with the volume of BAL fluid and the total number of pulmonary segments lavaged. In most cases, these complications resolve spontaneously within 24 h. The incidence of postbronchoscopic infections is higher in immunocompromised hosts and those with chronic suppurative lung disease (e.g., cystic fibrosis).

Airway Obstruction and Perforation

The advent of interventional bronchoscopy has resulted in complications not ordinarily seen with diagnostic bronchoscopy. Inappropriate use of lasers has resulted in endobronchial burns and bronchial perforations associated with catastrophic bleeding, pneumomediastinum, or pneumothorax. Endobronchial edema may also occur as a result of laser thermal effects.

As noted previously, airway stent insertion is associated with several complications. Stents may not be properly adapted to the diameter of the airway, resulting in either incomplete stent deployment or stent migration, possibly engendering life-threatening airway obstruction. The presence of this palliative endoprosthesis in the airway may predispose to difficulties with secretion clearance and accumulation of inspissated mucus. Placement of SEMS may result in severe local airway reactions, particularly at the edges of the device, producing granulation tissue, hemorrhage, or bronchial perforation.

Pneumothorax

Most of the serious complications directly due to bronchoscopic intervention have been reported in association with performance of transbronchial biopsies. Pneumothorax following transbronchial biopsy occurs in about 4 percent of cases, even when the procedure is done under fluoroscopic guidance. The impact of fluoroscopy on the incidence of pneumothorax remains controversial. Uncontrolled studies have not found a difference in the incidence of pneumothorax following transbronchial biopsy when performed with and without fluoroscopy.

The risk of pneumothorax is not related to the size of the bronchoscopic biopsy forceps. The incidence of pneumothorax is increased, however, in immunocompromised hosts. This is likely due to the increased risk of pneumothorax associated with *Pneumocystis* pneumonia (PCP). The

risk is also elevated in mechanically ventilated patients, with peripheral lung biopsies, and in the presence of bullous lung disease. For these reasons, a postbronchoscopic expiratory chest radiograph is routinely performed. In case of a significant pneumothorax, a chest tube should be inserted immediately to avoid oxygen desaturation and/or tension physiology.

Hemorrhage

One of the most frequently reported complications related to bronchoscopy is hemorrhage—a complication that can be largely avoided by proper evaluation of the patient before the procedure. An incidence of postbronchoscopy hemorrhage of 45 percent has been reported in uremic patients. For these reasons, a blood urea nitrogen (BUN) level above 30 mg/dl or a creatinine level above 3 mg/dl should be considered relative contraindications to bronchoscopy. Similarly, patients with known underlying bleeding disorders, especially those caused by platelet dysfunction or thrombocytopenia, have an increased risk of bleeding (epistaxis or hemoptysis) during bronchoscopy. Bronchoscopy should not be performed if the platelet count is below 50,000/mm^3; transbronchial biopsy or aggressive interventional procedures (laser therapy, bronchoplasty, or stent placement) are probably safe only with platelet counts above 75,000/mm^3.

Manipulation of the bronchoscope, mechanical trauma, vigorous suctioning, endobronchial brushing, and biopsy may result in bleeding in 1 to 4 percent of patients without underlying risks for hemorrhage. Hemorrhage can also occur with inadvertent perforation of pulmonary vessels during transbronchial needle aspiration or biopsy.

Overall, when bronchoscopy is performed by an experienced endoscopist, backed up by a well-trained team and appropriate facilities, mortality and morbidity are very low.

TRANSTHORACIC NEEDLE ASPIRATION AND BIOPSY

Indications and Contraindications

Transthoracic needle aspiration (TTNA) was first used for the diagnosis of pulmonary disease in 1883, when Leyden performed the procedure on three patients with pneumonia. In 1886, Ménétrier reported the use of TTNA in the diagnosis of lung carcinoma. Since that time, many published series have described the use of TTNA for the diagnosis of a variety of benign and malignant thoracic lesions, using fluoroscopic, CT, or ultrasound guidance. The related technique of transthoracic needle biopsy (TTNB) provides core biopsy material from pulmonary nodules for histological examination. The ability to analyze histology is critical in establishing a definitive diagnosis for certain disease states (e.g., histoplasmosis, sarcoidosis) in which cytologic aspiration is inadequate in documenting the characteristic noncaseating granulomas. TTNB also provides improved diagnostic accuracy in lymphoma, both Hodgkin's and non-Hodgkin's varieties, in which anatomic structure is important in delineating the type of lymphoma and in distinguishing between clonal, neoplastic processes and inflammatory conglomerations of lymphocytes. Histological specimens may improve the yield in the diagnosis of pulmonary hamartomas, characterized by the presence of cartilage and/or adipose tissue.

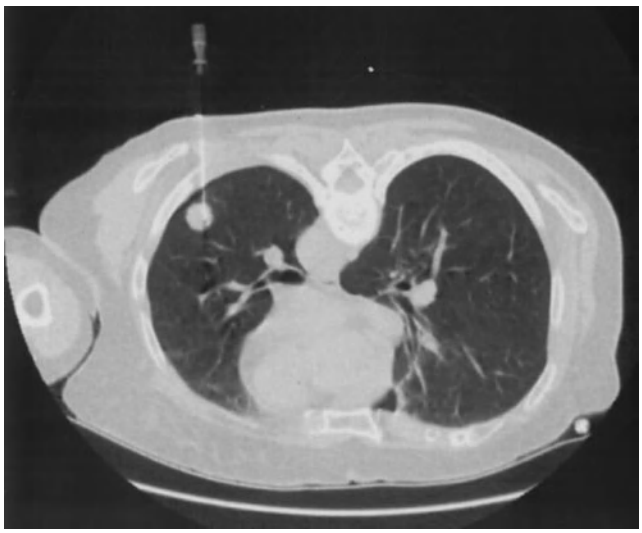

Figure 36-9 Transthoracic needle aspiration of pulmonary nodule. CT scan image of TTNA performed for a 2-cm right-lower-lobe nodule using a 22-gauge Westcott needle (Becton Dickinson & Co, Franklin Lakes, NJ). The needle can be seen entering the nodule. *(Courtesy of Ana Kolansky, M.D.)*

The major indications for TTNA or TTNB include evaluation of solitary lung nodules and masses (Fig. 36-9), mediastinal and hilar lesions, metastatic disease to the lung from a known extrathoracic malignancy, chest wall invasion by lung carcinoma, and pulmonary consolidation or infiltrates that are likely to be of infectious origin.

With the "reemergence" of thoracoscopy and recent development of video-assisted thoracic surgical techniques, patients can more easily undergo complete excision of pulmonary nodules. In the past, many pulmonologists performed TTNA as the initial diagnostic procedure for intrapulmonary lesions, especially those in the lung periphery. Physicians are now faced with the dilemma of whether to send patients directly to thoracoscopic biopsy for a definitive answer. Two commonly used strategies—the use of positron emission tomography (PET) or serial CT scanning—can be used to obtain additional evidence regarding the likelihood of malignancy. In appropriately selected patients, the presence of a PET-positive lesion or a lesion increasing in size on serial CT scans may obviate the need for TTNA.

Few absolute contraindications to TTNA exist. These include an uncooperative patient or one with an intractable cough, as patients must be able to suspend respirations for 5

to 10 s while the needle crosses the pleura. In addition, TTNA is absolutely contraindicated in patients with a suspected pulmonary hydatid cyst because of the risk of capsule rupture and systemic dissemination. Relative contraindications include bullous emphysema, pulmonary arterial hypertension, and coagulation or platelet disorders. Patients with bullous emphysema are at increased risk of developing symptomatic or tension pneumothoraces after TTNA, although most induced pneumothoraces are small and can be treated conservatively. Those with pulmonary hypertension who undergo TTNA have a higher chance of developing pulmonary hemorrhage and significant hemoptysis.

Technique

Proper technique in performing TTNA is critical in obtaining adequate material for reliable interpretation. In addition to the mechanics of needle insertion and aspiration, the choice of needle type and careful specimen processing are important aspects of the procedure.

Choice of Needle

Many needle types are available for TTNA. They vary in both length and width. In the early 1960s, TTNA was performed using large-bore cutting needles; significant hemorrhagic complications were reported. More recently, thin-needle aspiration has become standard with devices ranging in size from 18- to 22-gauge. Coaxial needle systems have been introduced for the purpose of obtaining multiple samples from a single pleural penetration. These systems are also useful for procuring specimens for histological evaluation.

Radiographic Guidance

Most transthoracic needle procedures are performed with fluoroscopic guidance, which allows for real-time imaging of pulmonary lesions during needle insertion and specimen retrieval. CT has been used to guide TTNA of pulmonary lesions, typically those that are too small to be seen fluoroscopically or are centrally located and adjacent to major vascular structures. Because CT-guided TTNA is not typically done using real-time visualization, the procedure takes longer to perform and requires several transthoracic passes to obtain diagnostic material. Not surprisingly, CT-guided TTNA is associated with an increased incidence of pneumothorax (up to 60 percent in some series). Ultrasound guidance of TTNA offers the advantage of real-time lesion imaging, easy portability, and absence of exposure to ionizing radiation for both the clinician and the patient. Ultrasound is used most commonly for peripheral lung lesions that extend to the pleural edge, or for the diagnosis of mediastinal masses. The sensitivity of ultrasound-guided TTNB of pulmonary and mediastinal lesions larger than 3 cm may be as high as 96.8 percent; the rate of pneumothorax is less than 2 percent.

Needle Insertion

The lesion is localized by fluoroscopic guidance, and the overlying skin is marked and anesthetized with 1 percent lidocaine. With the patient lying as still as possible, the aspiration needle is inserted perpendicularly through the anesthetized region into the lesion, as seen under fluoroscopy. The needle may be seen to displace the lesion, or if properly positioned, the needle will move in concert with the lesion during quiet breathing. If the needle is seen to move independently of the lesion during respiration, it is positioned unsatisfactorily.

Ideal aspiration technique necessitates having the tip of the needle as close to the center of the lesion as possible. A 20-ml lockable syringe containing approximately 3 ml of sterile saline is attached to the needle hub, and the tip is maintained in proper position using fluoroscopic guidance. Suction is then applied by pulling the syringe plunger back and locking it into position with clockwise rotation. While suction is sustained with the locked syringe, the needle tip is advanced and withdrawn about 0.5 to 1 cm within the lesion under real-time fluoroscopic guidance. The needle is then removed from the chest, suction is released, and the aspirated material is flushed into a specimen container. Several samples should be obtained to increase the diagnostic yield. With a necrotic mass, aspiration should also be performed in peripheral locations of the lesion in order to obtain viable cells and to decrease the risk of false-negative results.

Results

TTNA and TTNB have excellent success rates in the diagnosis of primary or metastatic pulmonary malignancies; for TTNA, the sensitivity is 85 to 95 percent. Major causes of false-negative results in malignant disease are inadequate sampling of the lesion and aspiration in an area of necrosis or postobstructive pneumonia. In addition, small, central malignant lesions may be difficult to diagnose accurately with TTNA. Aspiration of vascular tumors, such as angiosarcoma, carcinoid, or metastatic renal cell carcinoma, may yield a bloody aspirate with few, if any, malignant cells. TTNA rarely leads to misclassification of primary pulmonary neoplasms, with a reported rate of misdiagnosis of small-cell carcinoma of 0 to 1.1 percent. False-positive results are extremely rare (under 0.5 percent) and are typically reported in the setting of inflammatory processes, such as tuberculosis, radiation fibrosis, organizing pneumonia, and pulmonary infarction.

Specific diagnosis of a benign lesion with TTNA is more problematic, with published sensitivities ranging widely, from 11.7 to 68 percent. A TTNA that is negative for malignancy does not rule out the presence of neoplastic disease, especially if the aspirate was unsatisfactory. The degree of suspicion of malignancy in a particular clinical situation becomes extremely important in dictating the next step following a negative TTNA. For a smoker with a high risk of bronchogenic

carcinoma, the proper course may lead to videothoracoscopic biopsy of the lesion, whereas in a young, otherwise healthy nonsmoker, close observation with serial CT scans may be the preferred option.

Complications

As mentioned previously, the most common complication of both TTNA and TTNB is pneumothorax; incidence rates reported in the literature vary from 8 to 61 percent. A small percentage of the pneumothoraces are clinically significant; only about 8 percent require thoracostomy tube drainage. Preexisting lung disease—in particular, bullous emphysema—is the most significant predisposing factor to development of pneumothorax after TTNA or TTNB. Other risk factors are deep lesions, increased number of transthoracic passes, crossing more than one pleural surface with the needle, and increased patient age. The vast majority of patients who develop clinically significant pneumothoraces after the procedure have an underlying diagnosis of chronic obstructive pulmonary disease.

Uncommon complications of TTNA and TTNB include hemorrhage and hemoptysis, although these are typically minor. Cases of fatal hemorrhage from tracheobronchial obstruction from clot and subsequent asphyxia after use of large-bore (18-gauge) cutting needles have been reported.

Air embolism is a rare complication caused by creation of a communication between atmospheric air and a pulmonary vein. To minimize this risk, the needle should never be left open to air while in the chest, and the patient should be discouraged from deep breathing, straining, or coughing during the procedure. The procedure should be halted and the needle withdrawn if the patient is actively coughing. If an air embolism is suspected, 100 percent oxygen should be administered through a non-rebreather face mask and the patient placed in the left lateral decubitus position, with the head down: this position optimizes capture of air in the right heart. The patient should be transferred immediately to a hyperbaric chamber.

SUMMARY

Technological advances in diagnostic and therapeutic bronchoscopy continue to improve our ability to perform minimally invasive, accurate evaluations of the tracheobronchial tree and to perform an ever-increasing array of therapeutic and palliative interventions. The continued development of imaging technologies will certainly provide improvements in many of the modalities described above. Future improvements will include refinements in video and ultrasound imaging technology and the development of newer modalities, such as molecular imaging. With the continued refinement of interventional modalities, therapeutic bronchoscopy may soon provide alternative therapies for conditions that are traditionally treated with surgery. These opportunities will need to be accompanied by well-designed studies to delineate the appropriate use of these techniques in clinical practice.

Thoracoscopy

Larry R. Kaiser

Thoracoscopy is a type of surgery in which a motivated medical specialist can develop a level of expertise that puts certain procedures well within his or her reach. These procedures are complementary to bronchoscopy in many instances and aid greatly in the diagnostic evaluation and potentially in therapy for a number of patients, especially those with pleural disease. Within the past several years, videothoracoscopy has, in many ways, changed the way pulmonary medicine and thoracic surgery are practiced, allowing us to alter the approach to a number of clinical problems.

HISTORICAL PERSPECTIVE

In the early 1920s, Jacobaeus, a Swedish physician, used a cystoscope in the pleural space to lyse pleural adhesions as an adjunct to collapse therapy in the treatment of pulmonary tuberculosis. He subsequently used this technique of thoracoscopy to localize and diagnose benign and malignant lesions of the pleura and pulmonary parenchyma. Despite the work of Jacobaeus, the procedure was performed only on a limited basis in the United States and was never truly endorsed. In one of the early textbooks of thoracic surgery, Lilienthal mentioned thoracoscopy but warned against its routine use in patients with tuberculosis because of the risk of significant bleeding and the perceived possibility of spreading infection within the pleural space.

Thoracoscopy evolved mainly as "pleuroscopy," which was used as an adjunct to other procedures in the *diagnosis* of pleural pathology—specifically in cases of an effusion of unknown cause, in which the thoracentesis was negative and a closed pleural biopsy was nondiagnostic. In many of these cases, the presence of malignancy was proved at the time of pleuroscopic examination. A number of instruments were used for thoracoscopic examination, including rigid bronchoscopes, mediastinoscopes, and flexible bronchoscopes, as well as rigid fiberoptic thoracoscopes. A mediastinoscope offered a large working channel and excellent visualization of the pleural space; an effusion could be drained, biopsies taken, and pleurodesis effected with talc. The procedure was mainly of diagnostic utility and, other than pleurodesis, offered little in the way of therapeutic applications. It was possible to biopsy the lung, but only small pieces could be removed, and the area that was amenable to biopsy was limited.

The availability of the charged coupling device, a silicon chip that is light sensitive, led to the sufficient miniaturization of a video camera so that, when coupled to a fiberoptic telescope, it was practical for use in the operating room by providing a magnified image projected on a video monitor that allowed the operating surgeon to work with an assistant (Fig. 37-1). Previously, it was possible only for a single operator to work with the thoracoscope, but the videothoracoscope frees up the surgeon's hands and allows more complex procedures to be performed. The power of this technique has

This chapter has been slightly modified from the version that appeared in the third edition of *Fishman's Pulmonary Diseases and Disorders.*

Figure 37-1 Surgeons carrying out a videothoracoscopic procedure. Note the video monitors, which allow the surgeon and assistants to view the surgical field. The work area is kept between the surgeon and the monitor.

been amply demonstrated by the rapid rise of laparoscopic cholecystectomy, a procedure that changed the specialty of general surgery in a remarkably short time. It was not long before a number of thoracic surgeons began to adapt this new technique for work in the chest, even though thoracoscopy had never been a mainstay in the practice of most such surgeons.

CURRENT TECHNIQUES

The term video-assisted thoracic surgery (VATS) encompasses all procedures performed with the thoracoscope, including those that are purely "thoracoscopic."

The bony thorax provides its own space once the lung is collapsed, so that insufflation of gas, used in the abdomen to create a working space, is unnecessary and even slightly dangerous. The space in the chest is created simply by placing an endobronchial tube and collapsing the ipsilateral lung. This requires a general anesthetic, but certain procedures—namely, those involving the parietal pleura—may be performed with only regional anesthesia and intravenous sedation, since the lung collapses in the spontaneously breathing patient once the negative, intrathoracic pressure is lost.

The patient is placed on the operating table in the lateral decubitus position, and the chest is prepared and draped as for a thoracotomy. Incision placement depends somewhat on the procedure to be performed, but the location of the incision for insertion of the videothoracoscope remains constant in the seventh or eighth intercostal space aligned with the anterior superior iliac spine. A 1-cm incision is made, deepened to the intercostal muscles, as if one were inserting a chest tube. Indeed, it is through this incision that the chest tube is placed at the conclusion of the surgical procedure. Entry into the chest is made with the index finger, to assure safety. Occasionally, the lung is adherent to the chest wall, and these adhesions must be broken up with the index finger to allow for placement of the trocar sheath. Additional incisions are made as needed—usually arrayed in a triangular fashion, which facilitates instrument placement and allows one to work in coordination with an assistant (Fig. 37-2). It

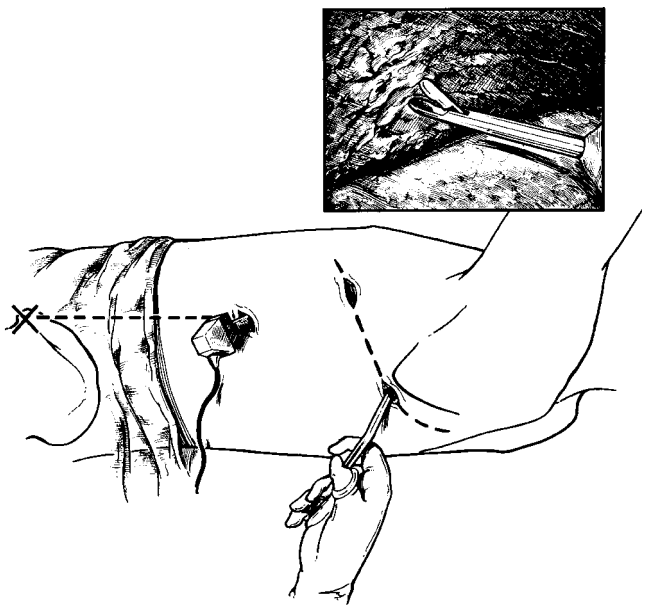

Figure 37-2 For most cases three incisions are used, as shown. The thoracoscope most commonly is placed through the inferior incision, allowing other instruments to be placed through the two opposed incisions. *Inset:* A view within the chest, as would be seen on the monitor, of a biopsy forceps in place to take a specimen of parietal pleura.

is best to work with two video monitors, which are placed at the head of the table on each side, so that both the operator and the assistant may have an unobstructed view of the surgical field. As long as one maintains the surgical field between oneself and the video monitor, the image is as it seems—that is, forward is forward, backward is backward, etc. It takes some adjustment to become accustomed to working in three dimensions while being able to see in only two.

The instrumentation available for thoracoscopy has been slowly improving. Instruments designed specifically for laparoscopy proved to be poor for this new application. Grasping the lung without teating the parenchyma proved to be especially difficult with these instruments. The most significant development in instrumentation, one that markedly expanded the utility of thoracoscopy, was the introduction of the endoscopic linear stapler. This instrument, more than any other, propelled thoracoscopy out of an almost purely diagnostic realm into the mainstream of therapeutic applications.

SPECIFIC PROCEDURES

Pleural Disease

For many physicians, closed pleural biopsy has become a dying art—and perhaps it should be—with the emergence of videothoracoscopic techniques that allow one to biopsy specific areas of the parietal pleura under direct vision. The major, but certainly not the only, indication for thoracoscopy in the management of pleural disease remains the undiagnosed pleural effusion. In the past, the patient with an empyema often was forced to undergo thoracotomy for débridement and decortication to rid the space of infection and allow the lung to reexpand. With thoracoscopic techniques, many of these patients may now avoid thoracotomy, especially if they are seen early in the course of the empyema. Thoracoscopic débridement and decortication are indicated in the febrile patient with a pleural effusion in whom tube thoracostomy provides incomplete drainage. The fibrinous nature of the exudate precludes complete drainage with a tube alone, and mechanical débridement is required. Likewise, videothoracoscopic techniques have proved useful in the management of the organized posttraumatic hemothorax, in which a chest tube is unable to effectively drain the organized clot and debris.

Benign pleural tumors, specifically solitary fibrous tumors, do occur; most commonly they arise from the visceral pleural surface and are ideal lesions for thoracoscopic resection (Fig. 37-3).

Videothoracoscopy has also increased our ability to deal successfully with malignant pleural effusions, especially those in which loculations are present. When tube thoracostomy results in incomplete drainage or one attempt at chest tube pleurodesis has failed, thoracoscopy—whereby the chest is evacuated under direct vision and talc is insufflated—is the procedure of choice. Hartman and colleagues compared the thoracoscopic insufflation of talc in patients who underwent tube thoracostomy and sclerosis with either tetracycline or bleomycin. Talc pleurodesis was performed under local anesthesia supplemented with intravenous sedation. For patients

Figure 37-3 A benign schwannoma arising from the parietal pleural surface--a lesion that is easily amenable to thoracoscopic excision.

in the talc group, there was a 97 percent rate of successful pleurodesis at 30 days and 95 percent at 90 days. This is significantly better than results seen in patients treated with the tube thoracotomy, only 33 percent of whom had achieved a successful pleurodesis at 30 days. The results were slightly better when bleomycin was used in the tube thoracostomy group. Patients sclerosed with talc seemed to have less pain following the procedure. The ability to perform thoracoscopic talc pleurodesis under local anesthesia may make the technique attractive for most patients with malignant effusions. In a randomized, prospective trial, Dresler and colleagues examined the outcomes of treating malignant pleural effusions with talc poudrage administered by thoracoscopy versus an instillation of talc slurry through a chest tube.Overall, there was no significant difference in the primary outcome of malignant effusion recurrence at day 30. However, subgroups of patients, including those with breast cancer and lung cancer, were significantly more likely to be effusion free at 30 days when treated by thoracoscopy. Morbidity and mortality were similar in both groups, although there were more respiratory complications in the thoracoscopy group.

Parenchymal Disease

Transbronchial lung biopsy is often successful in providing diagnostic material in patients with diffuse pulmonary infiltrates. In situations in which a transbronchial biopsy fails to provide diagnostic material, a VATS procedure is indicated. Before the advent of videothoracoscopy, many of these patients were treated empirically, usually with steroids. Lung biopsy, which required a thoracotomy, albeit a "mini" one, was reserved for patients who either failed empiric therapy or were desperately ill and in intensive care. The empiric approach probably is warranted and may, in fact, be preferred in the non-neutropenic cancer patient with acute pneumonitis, for whom broad-spectrum antibiotic therapy usually is the treatment of choice. In the nonimmunocompromised patient, usually with a chronic interstitial process, serious consideration must be given to obtaining a piece of lung tissue. The pulmonologist must make a judgment as to whether a transbronchial lung biopsy is indicated—a decision that must take into account the most likely diagnostic possibility and whether a transbronchial specimen will be adequate to establish that diagnosis and the small but very real risks of bleeding and pneumothorax. VATS lung biopsy consistantly provides diagnostic material. Burt and colleagues found a 94 percent diagnostic yield from open lung biopsy versus 59 percent for transbronchial biopsy in a series of 20 patients subjected to both procedures.

Before the introduction of videothoracoscopy, a thoracotomy was required solely for the purpose of obtaining a piece of lung tissue. The thoracotomy usually consisted of a small inframammary incision into the chest through the fourth or fifth intercostal space, a procedure that can be done expeditiously and allows one to obtain enough lung parenchyma to make a diagnosis. There should be minimal morbidity with this approach, and it still represents the best approach to lung biopsy in the critically ill, hemodynamically fragile patient who is ventilator dependent (requiring high peak airway pressures and high inspired oxygen concentration), for whom transport to the operating room represents a substantial risk. The "mini" anterior thoracotomy does not require single-lung ventilation and thus avoids the potential morbidity and mortality associated with exchange of the endotracheal tube for an endobronchial tube in these high-risk patients. However, the surgical exposure achieved by this approach can significantly limit the area of lung that may be accessible for biopsy. It is also difficult to obtain tissue from more than one site of the lung with this approach.

In most patients, however, VATS wedge lung biopsy, which we and others have referred to as "closed lung biopsy," represents the best alternative to the "mini" thoracotomy. It offers the advantage of excellent visualization of the entire lung so that suspect areas can be biopsied under direct vision and all areas of the lung can be reached with relative ease. The technique avoids spreading of the ribs, which seems to be one of the factors responsible for the pain that results following thoracotomy, including anterior thoracotomy. It may be that thoracoscopic biopsy causes less postoperative pain, which may be important in weaning patients from a ventilator in the immediate postoperative period, and results in a shorter hospital stay. In a nonrandomized, retrospective study using historical controls, Ferson and colleagues from two other centers compared a group of 47 patients undergoing thoracoscopic lung biopsy with a group of 28 patients who had had open wedge resection via limited thoracotomy. Adequate tissue for diagnosis was obtained for all patients in both groups. Mean surgical time was significantly longer in the thoracoscopic group (69 vs. 93 minutes), but, as would be expected, the time decreased as additional experience was gained. The authors excluded from the study patients requiring mechanical ventilation and still found that hospital stay was significantly shorter in the group undergoing thoracoscopic biopsy (4.9 vs. 12.2 days). There were significantly more complications in the open group (50 percent incidence) than in the VATS group (19 percent), a finding that no doubt explains the variation in duration of hospital stay. All surgeons engaged in the study believed that thoracoscopic biopsy provided better visualization of the entire lung than a "mini" thoracotomy.

Our own experience with 80 thoracoscopic lung biopsies in non–ventilator-dependent patients confirms the above-mentioned findings. Diagnostic tissue was obtained in all cases, and in several our ability to provide tissue from different areas of the lung greatly aided in establishing a diagnosis. The mean hospital stay in our series was 1.9 days, significantly shorter than that of Ferson and colleagues. There was no mortality and no significant morbidity, including no prolonged air leaks. When lung biopsy is indicated, thoracoscopic biopsy is our procedure of choice for nonventilated patients. For patients requiring mechanical ventilation, in most cases we prefer a limited anterior thoracotomy with minimal rib spreading—a simple procedure that can be

performed expeditiously and avoids the need for single-lung ventilation.

Thoracoscopic lung biopsies were reported before the advent of VATS techniques and before the linear stapler was available. With a cup biopsy forceps, pieces of lung parenchyma were obtained, and an insulated electrocautery provided the only means of hemostasis. Daniel and colleagues compared results obtained in the era before the advent of video technology with those obtained by current methods. In 30 patients undergoing thoracoscopic cup biopsy, there were 10 deaths and one prolonged air leak that required a thoracotomy for repair. Mean hospital stay was 16.6 days. In contrast, 11 patients underwent videothoracoscopic biopsy with one death and a mean hospital stay of 8.2 days. The significantly better hemostatic as well as aerostatic qualities of the linear stapler than those of a cup biopsy forceps and the larger amount of tissue obtained using a stapler clearly are advantageous. These authors also noted no advantage to either endoscopic approach over limited thoracotomy in patients requiring mechanical ventilation.

The availability of VATS lung biopsy should prompt earlier referral for lung biopsy of patients with interstitial disease who either would be treated empirically and not referred for biopsy or would be referred in desperation at the time of marked decompensation, usually after being intubated and ventilated. Utilizing these techniques to obtain an earlier tissue diagnosis in patients with interstitial lung disease should improve management and, it is hoped, improve the long-term outlook.

VATS techniques have also had a major impact on the management of spontaneous pneumothorax in the two major groups of patients who present with this problem: young patients with apical blebs and older patients with bullous emphysema. Primary spontaneous pneumothorax in a young person typically can be managed nonsurgically, with the likelihood of recurrence being approximately 30 percent. Surgical treatment for a first-time pneumothorax classically has been reserved for patients with persistent air leaks (longer than 1 week), those whose occupations require them to experience extremes in atmospheric pressure, and those who live in isolated areas without access to medical care. Otherwise, surgery is indicated after a first recurrence or for the patient who has experienced bilateral pneumothoraxes. Surgery for a spontaneous pneumothorax has required either a thoracotomy with stapling of apical blebs and, at times, a pleurectomy or, more recently, a transaxillary thoracotomy with excision of blebs and pleural ablation or pleurectomy to create pleural symphysis. These are both substantial procedures for what is really a trivial problem in terms of what needs to be done intraoperatively. An alternative approach to management, mentioned here only to be dismissed, involves installation of talc or other sclerosant via tube thoracostomy.

VATS management of spontaneous pneumothorax provides a simple surgical alternative that is associated with minimal morbidity. With recognition that in young patients the pneumothorax usually results from rupture of a bleb located at the lung apex or occasionally in the apical portion of the superior segment of the lower lobe, the surgical procedures include resection of the apical blebs and mechanical pleural abrasion to effect a pleural symphysis (Fig. 37-4). The blebs are easily visualized with the thoracoscope and excised with several applications of the linear stapler. The parietal pleural surface is mechanically abraded with a gauze sponge, which creates enough inflammation to cause pleurodesis. Talc or other sclerosing agents are not recommended for these young patients. Obliteration of the apical blebs alone probably would be sufficient, and the contribution of the pleurodesis is probably minimal. A very low recurrence rate is expected (less than 5 percent) following this procedure, similar to that achieved after a transaxillary procedure or formal thoracotomy; the handling of the blebs is identical no matter which approach is used.

Figure 37-4 Thoracoscopic appearance of a typical apical bleb responsible for a spontaneous pneumothorax, usually in a young person. These are most commonly found at the lung apex, but they can also occur at the apex of the superior segment of the lower lobe.

Cannon and associates performed thoracoscopic excision of apical blebs in nine patients with primary spontaneous pneumothorax and noted one recurrent small apical pneumothorax that resolved without treatment. We performed 70 thoracoscopic procedures for primary spontaneous pneumothorax over a 4-year period. We noted three recurrences, two in patients with catamenial pneumothorax, at the time of their first menstrual period following the procedure, and one in a patient with routine apical blebs. The lesion responsible for catamenial pneumothorax is unknown, and we were unable to detect any pathology at the time of the procedure. These patients experienced recurrence despite the performance of what was believed to be adequate pleurodesis, but the recurrences were early, probably before the development of pleural adhesions. Allen's team reported on 46 patients who underwent wedge excision and pleurodesis for spontaneous pneumothorax. Only one patient required conversion to an open procedure. Seven patients had persistent air leaks (more than 10 days), and two of these required thoracotomy for correction. No recurrences have been seen with

a median follow-up time of 25 months. Median hospital stay was 5 days. Our own experience, along with that of other groups, suggests that hospital stay after VATS operation for spontaneous pneumothorax is closer to 2 days; prolonged air leaks following the procedure, causing longer hospital stays, are rare.

Indications for surgery for spontaneous pneumothorax have not changed significantly despite the availability of the VATS technique, which allows most patients to leave the hospital on the first or second postoperative day. Patients with primary pneumothorax are managed with either aspiration of the pneumothorax or chest tube placement. We used to wait 7 days for an air leak to seal before proceeding with surgery. We now wait only 48 to 72 hours before recommending the thoracoscopic procedure, which allows the patient to leave the hospital sooner than if treated in the conventional fashion. The decision for earlier surgery is justified by the decreased morbidity associated with the VATS procedure when compared with an open procedure, even the transaxillary approach. In a patient treated conservatively for a first-time pneumothorax, recurrence on the same side or a pneumothorax on the opposite side is an indication for surgery. If the pneumothorax occurs on the same side as the first one, we operate only on that side. With a contralateral pneumothorax, both sides should be operated on, since the consequences of spontaneous bilateral pneumothoraxes may be devastating. Bilateral VATS procedures conducted with a single anesthetic may be performed without significant additional morbidity, especially in young patients. If necessary, thoracic epidural analgesia may be used in the early postoperative period. VATS excision of apical blebs and mechanical pleural abrasion constitute the procedure of choice when surgery is indicated in a patient with spontaneous pneumothorax.

Pneumothorax occurring secondarily to a process other than the apical blebs seen in young people can also be managed with a VATS approach. In these situations, the pathology may be somewhat more complex, and one needs to search for the air leak and repair it, usually by stapling; but fibrin glue, the neodynium-YAG laser, and the argon beam coagulator have also been used with success. Over a recent 2-year period, we performed 13 procedures for so-called secondary pneumothorax—seven in patients with emphysema who presented in respiratory distress after developing a pneumothorax, two for persistent air leaks following thoracotomy and lobectomy, one in a patient with AIDS and bilateral pneumothoraxes secondary to *Pneumocystis carinii* infection causing necrotic parenchymal cavitary lesions, and three in patients with metastatic sarcomas. We were successful in managing the air leak in 12 patients; one patient was converted to open thoracotomy. Cannon and colleagues operated on six patients with secondary pneumothorax, two of whom subsequently required a thoracotomy to deal with persistent air leaks following the thoracoscopic procedure. Although recognizing that some patients may still require thoracotomy, we prefer to attempt a VATS approach for an air leak because these patients often have significantly compromised pulmonary function and avoidance of a thoracotomy is advantageous. If a surgeon develops an interest and gains experience with VATS techniques, the frequency of conversion to an open procedure should remain low. It requires a commitment on the part of the surgeon, however, especially early in one's experience, to take the extra time that may be required to complete some of the more complex procedures rather than quickly converting to an open operation.

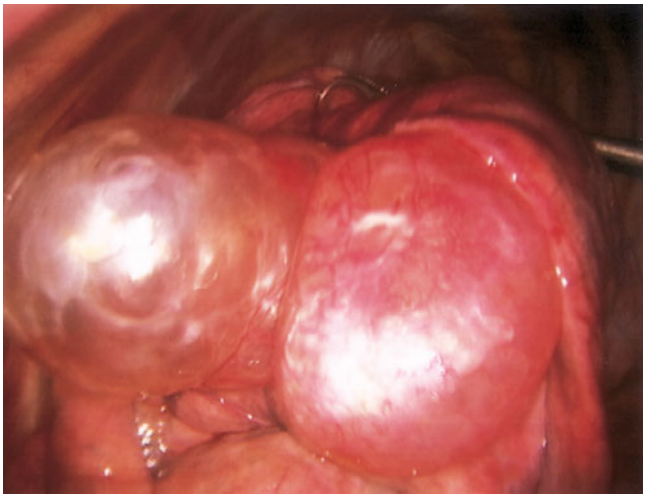

Figure 37-5 A giant bulla occurring as an isolated finding, resulting in compression of adjacent lung parenchyma. Excision usually offers significant relief of symptoms.

The management of bullous lung disease has also changed with the introduction of VATS techniques. The standard indication for surgery in patients with bullous emphysema is the presence of a giant bulla causing significant compression of adjacent, relatively normal lung parenchyma (Fig. 37-5). These giant bullae are readily recognizable on a plain chest radiograph, and a computed tomography (CT) scan helps to define the presence and extent of compressed lung tissue. The major factor that enters into a decision on whether bullectomy is likely to result in improvement in a patient's condition relates to the compressed lung parenchyma and whether there is significant compressed parenchyma to expand and fill the pleural space after bullectomy. A residual space after bullectomy promotes the development of a persistent air leak and, in a small percentage of cases, an empyema, with resultant devastating consequences and usually a prolonged hospital stay. Reviewing a series of chest radiographs performed over the preceding several years to determine the progression in the size of the bullae allows for an assessment of the amount of compressed adjacent lung tissue. Pulmonary function studies should document a decrease in function, and the patient should note a decrease in exercise tolerance. Patients who fulfill these criteria are ideal candidates for VATS bullectomy.

The procedure itself requires obliteration of the bulla with the avoidance of air leaks, if possible. We prefer to use the argon beam coagulator, which, when applied at a low power

setting, causes the wall of the bulla to shrivel although the bulla is not entered. Once the bulla has shrunk, the base may be delineated and then stapled in an attempt to minimize air leak. The walls of the bulla may be used as a buttress for the staple line. Alternatively, a piece of prosthetic material, specifically bovine pericardium (PeriGuard, Biovascular Medical, St. Paul, MN), may be used to reinforce the staple line to prevent air leaks. Performing a VATS procedure rather than open thoracotomy in these markedly compromised patients, most of whom are oxygen dependent and have FEV_1 well under 1 L, seems to be preferable. Still, in the early postoperative period these patients are most at risk of secretion retention and pneumonia—which, for many, would be a terminal event. Thus, postoperative pain management and aggressive chest physiotherapy are of major importance. We use thoracic epidural analgesia provided by a continuous infusion of narcotic for pain management in the early postoperative period so that patients may cough more effectively. Patients are extubated as soon as possible, ideally at the completion of the surgical procedure.

Unfortunately, giant bullae do occur in some patients with bullous emphysema. Wakabayashi identified 17 cases of giant bullous disease among more than 500 cases of bullous emphysema seen over a 3-year period. Of more than 2000 thoracoscopic cases reported to the Video Assisted Thoracic Surgical Study Group (VATSSG) Registry, only 33 (1.8 percent) were for excision of giant bullae.

Diffuse emphysema, with or without a bullous component, is a significantly greater clinical problem in terms of numbers of patients affected. Until recently, the therapeutic options of these patients were extremely limited, with oxygen therapy and bronchodilators being the mainstay for those with a reversible airway component. The reintroduction of a surgical procedure, volume reduction, which has been shown to be efficacious in some cases, may offer many of these desperate patients some relief from their symptoms. Although the initial procedure of volume reduction for diffuse emphysema, as described by Cooper and colleagues, entailed a median sternotomy and bilateral excision of lung parenchyma, other authors have reported on either unilateral or bilateral VATS procedures to accomplish essentially the same outcome. Kotloff and associates compared a series of patients from the University of Pennsylvania who underwent volume reduction via sternotomy with a group undergoing the procedure via a VATS approach. Patients who underwent a bilateral VATS procedure fared as well as those undergoing sternotomy in terms of functional improvement. There were fewer postoperative deaths in the VATS group, but the difference was not statistically significant. The National Emphysema Treatment Trial (NETT), a multi-center NIH-sponsored trial designed to evaluate the efficacy of lung volume reduction surgery as a treatment for chronic obstructive pulmonary disease, compared outcomes in patients undergoing lung volume reduction by a video-assisted approach versus a sternotomy approach. Median hospital stay was recduced by use of the thoracoscopy approach, whereas complication rates were not signicantly different.

PULMONARY NODULES

The solitary indeterminate pulmonary nodule is a problem confronted routinely by pulmonologists. In light of the emergence of VATS as a minimally invasive procedure that can be performed with low morbidity even in compromised patients, we must examine closely the current management of a patient who presents with an indeterminate nodule. Whereas in the past definitive management required open thoracotomy, with its attendant morbidity, this no longer is the case. Thoracoscopy offers the opportunity both to definitively make the diagnosis and to treat many of these lesions and, therefore, causes a refocus in our thinking.

The salient question posed by the presence of a pulmonary nodule is a very simple one: Is it malignant? If a previous radiograph demonstrates a lesion that has not changed in size over several years, one can be reasonably certain of the benign nature of that lesion. Depending on the series, approximately 40 percent of resected nodules are malignant, and primary carcinoma of the lung accounts for the majority of malignant nodules. A number of factors point to a benign diagnosis, although none are absolute. We may be far less suspicious of a nodule occurring in a nonsmoker, especially if the person is 35 years of age or younger. Lesions larger than 3 cm in diameter are likely to be malignant. Specific patterns of calcification may also be associated with benign lesions, and CT comparison with a phantom of known density may further support a benign diagnosis. Even when all these factors have been taken into consideration, a histologic diagnosis is required in most cases. If benignity cannot be proved, malignancy must be assumed.

The diagnostic procedures available to the pulmonary physician are very good at establishing a diagnosis of malignancy but fall short in obtaining a "positive" diagnosis of benign disease. The diagnostic yield from fiberoptic bronchoscopy varies from 20 to 80 percent, but a specific benign diagnosis is made only 10 percent of the time. With these figures, it is hard to justify the performance of a bronchoscopy if one is looking to make a diagnosis of benign disease. Unfortunately, percutaneous needle aspiration biopsy does not fare much better. Although its sensitivity in making the diagnosis of malignancy is high (64 to 97 percent), a specific benign diagnosis can be made only about as often as the rate achieved bronchoscopically. A "negative" needle biopsy is of no help and necessitates a further diagnostic procedure, whereas a diagnosis of malignancy essentially tells us what we already know: The lesion has to be excised.

Mack and colleagues, in a multicenter study, have looked closely at the role of thoracoscopy in the diagnosis of the indeterminate solitary pulmonary nodule. Over an 18-month period, 242 patients with solitary nodules were treated. A wedge excision of the lesion that included some surrounding normal lung parenchyma was accomplished with an endoscopic stapler alone in most cases. A definite diagnosis was obtained in all cases; there was no mortality or major morbidity, and minor complications (atelectasis, pneumonia, prolonged

air leak) occurred in only nine patients (3.6 percent). In two patients, the nodule could not be located and a thoracotomy was required; otherwise, a benign diagnosis was obtained in 127 patients (52 percent), while malignancy was found in 115 (48 percent). When a primary lung cancer was identified, formal open thoracotomy and anatomic resection were carried out in patients with adequate pulmonary reserve. The average hospital stay for patients undergoing thoracoscopy alone was 2.4 days.

In a series of 771 VATS procedures at the Mayo Clinic, wedge excision of a pulmonary nodule was performed in 234 patients. There were no deaths in this group of patients, and the most common complication was a prolonged air leak, which occurred in 3.0 percent of patients. The median hospital stay was 3 days. The lesion was found to be malignant in 107 patients, and all patients found to have bronchogenic carcinoma underwent an open thoracotomy for anatomic pulmonary resection and lymph node sampling.

It is hard to argue against a technique that has a sensitivity and specificity of 100 percent and can be done with no mortality and minimal morbidity. But is it necessary to excise so many benign lesions? If we could be certain of the benignity of a lesion, there would be no reason to excise it. It is the uncertainty of the benign diagnosis in most cases that presents the most compelling argument for thoracoscopic excision of most solitary pulmonary nodules. All questions are answered and the uncertainty disappears with one procedure.

Certain lesions are not considered for VATS excision. For lesions greater than 3 cm in diameter, the likelihood of malignancy is so high (greater than 90 percent) that in the absence of metastatic disease, thoracotomy and anatomic resection—i.e., lobectomy—should be the first procedure undertaken. The CT scan aids greatly in localizing the nodule, and we have found it to be the only localizing study that is required. Even deep-seated lesions may be palpated and located, a technique that becomes easier with experience. In our experience with 400 thoracoscopic excisions of pulmonary nodules, we have failed to locate the nodule in only four cases, all early in our experience. Our technique relies heavily on instruments, specifically designed for thoracoscopy, that greatly facilitate the procedure, especially in grasping or moving the lung to the palpating finger (Fig. 37-6). Centrally located lesions, which lie in close proximity to hilar structures, are not suitable for VATS wedge excision and require open thoracotomy.

There is some controversy regarding the optimal management of the solitary nodule that proves to be a carcinoma. Is a VATS wedge excision sufficient treatment for a T1 (less than 3 cm) primary lung carcinoma? Based on current knowledge, we believe that wedge excision is not optimal treatment for primary lung cancer, even a small T1 lesion. A wedge excision is a compromise procedure that is acceptable only for the patient who otherwise cannot tolerate a thoracotomy and anatomic resection. Among other factors, a wedge excision removes no regional lymph nodes and thus staging is inadequate. Local recurrence is significantly higher after wedge excision than after lobectomy. Several authors have performed large series of nonanatomic resections for patients with marginal pulmonary function, and VATS excision, with its low morbidity, may offer another alternative. The Lung Cancer Study group addressed the question of limited resection versus lobectomy for T1 N0 lesions in a prospective, randomized trial. In this study of carefully staged patients proven conclusively to have N0 disease, there was a significantly higher incidence of local recurrence in those who underwent limited resection, but at 3 years there was no survival difference between the two groups. However, a reexamination of the data at 5 years showed a statistically significant survival advantage for the lobectomy group. Wedge excision for bronchogenic carcinoma as a definitive procedure, whether carried out via a VATS approach or open thoracotomy, must be considered a compromise and should be reserved for patients whose pulmonary function is so marginal as to preclude lobectomy.

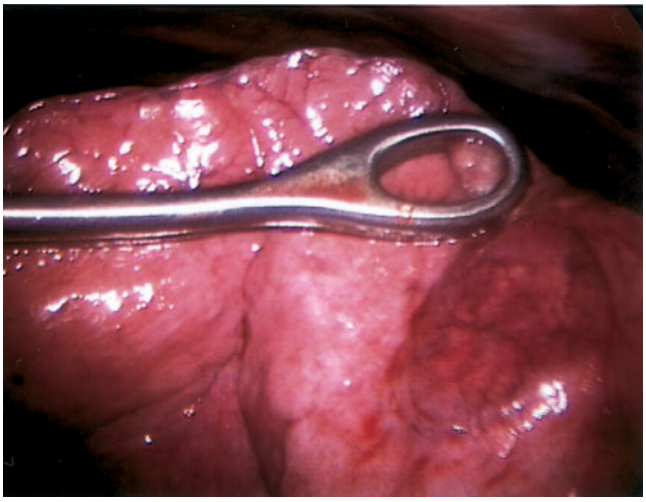

Figure 37-6 A modified ring forceps grasping the lung and moving the lung into position either for wedge excision of a nodule or for palpation of the area to identify the nodule. The forceps is able to grasp the lung without tearing the pulmonary parenchyma, a situation that commonly occurs if the lung is grasped with an instrument with a small surface area.

Anatomic resections (mainly lobectomy) have been performed using a VATS technique that requires a small (6 cm) "utility" incision, but usually without the need for rib spreading—which, theoretically, should minimize postoperative pain (Fig. 37-7). A randomized trial comparing VATS lobectomy with standard muscle-sparing thoracotomy and lobectomy failed to show significant enough differences to justify the routine use of the VATS approach—which probably subjects the patient to a slightly greater risk of intraoperative catastrophe, although no intraoperative deaths have been reported. Roviaro and colleagues performed 52 VATS lobectomies and four pneumonectomies in patients with T1 N0 or T2 N0 lesions. In seven patients it was necessary to convert to an open procedure, three for bleeding during the dissection. There were no deaths related to the procedure. Others have reported the feasibility of performing VATS lobectomy or segmentectomy. A large randomized trial demonstrating

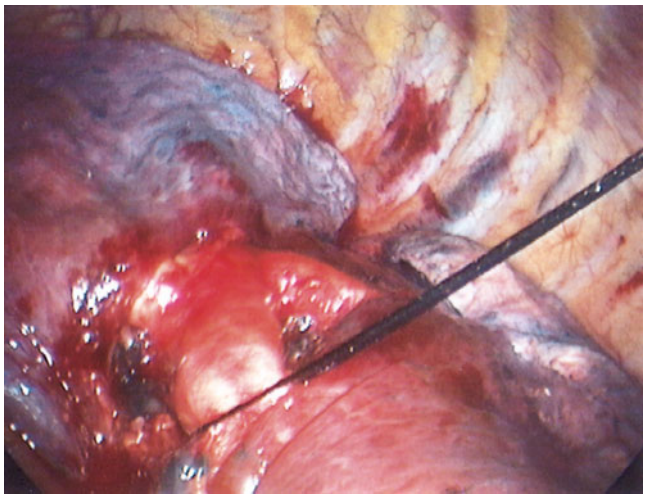

Figure 37-7 View of a video-assisted lobectomy showing the pulmonary artery in the fissure of the left lung. Note the basilar segmental trunk and the branch to the superior segment of the lower lobe. The procedure is performed with visualization provided by the video camera and access via a small utility incision through which regular instruments are inserted but without spreading the ribs.

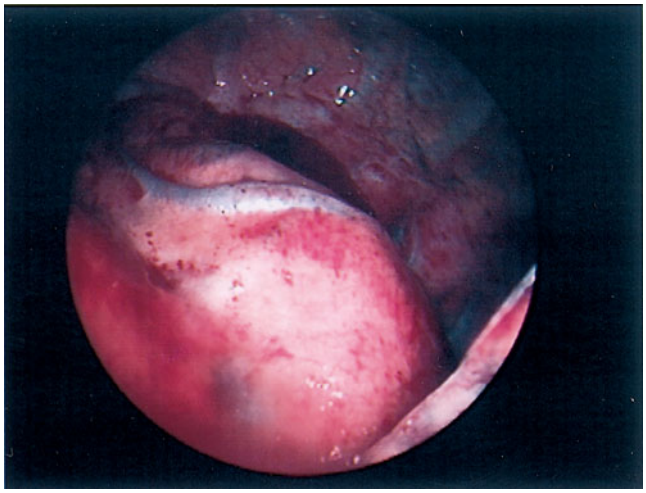

Figure 37-8 The aortopulmonary window, a common site for lymph node involvement when the primary tumor is in the left upper lobe (level 5, subaortic, and level 6, para-aortic). These lymph node locations cannot be reached by standard cervical mediastinoscopy, and videothoracoscopy provides an ideal way both to visualize this area and, when appropriate, to take biopsies.

the superiority of a VATS approach over an open procedure is lacking. VATS lobectomy has not found widespread acceptance, nor is the public demanding it. A few centers continue to perform the procedure regularly.

MEDIASTINAL PROCEDURES

VATS has proved useful as an adjunct to more conventional procedures used in the invasive staging of lung cancer. Mediastinoscopy remains the gold standard for invasive staging of the mediastinum, but lymph nodes in the posterior subcarinal space (level 7) and in the aortopulmonary window (level 5) are not accessible. VATS offers an unmatched ability to visualize the aortopulmonary window and sample lymph nodes in this region (Fig. 37-8). The same is true for the subcarinal space when it is approached from the right side. A VATS staging procedure is not a substitute for mediastinoscopy, but in certain situations directed by findings on the chest CT scan, it may add valuable staging information. This is particularly important because of the interest in preoperative therapy (neoadjuvant) for patients proved to have N2 (mediastinal) lymph node disease.

The utility of VATS is limited for assessing resectability, especially if one is trying to document direct invasion of mediastinal structures (either T3 or T4), but it is of use occasionally. Dissection often proves difficult and potentially hazardous, and there is no substitute for putting one's hand on a lesion of questionable resectability. VATS proves extremely useful, however, in documenting the absence of diffuse pleural metastatic disease if this possibility has been raised (usually by the presence of a pleural effusion).

Many primary lesions of the mediastinum prove to be ideal for VATS management. Lesions in all compartments of the mediastinum are easily accessible, and whether biopsy only or complete excision is the intent, VATS techniques save many patients from having to undergo thoracotomy.

To approach a lesion in the anterior mediastinum, the patient is positioned with the side to be operated on tilted up at approximately 30 degrees instead of in the full lateral position. Often a small inframammary incision is employed. We have utilized a VATS approach to accomplish 15 thymectomies, nine of them for encapsulated thymomas (Fig. 37-9).

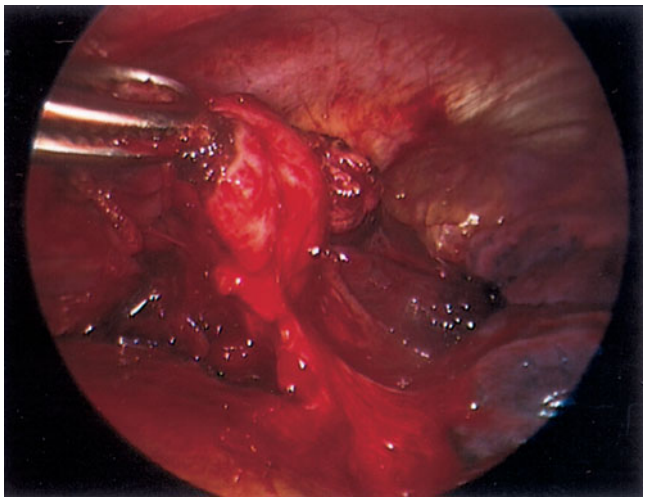

Figure 37-9 A well-encapsulated thymoma being dissected off the pericardium. The cervical portions of the thymus gland have been mobilized by a transcervical approach so that a total thymectomy--the goal of the operation in patients with myasthenia gravis--could be carried out.

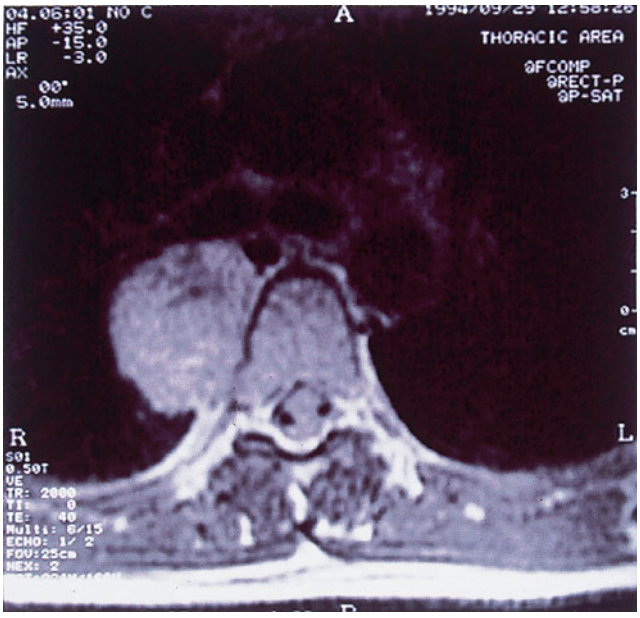

A

B

Figure 37-10 *A*. MRI scan showing a posterior mediastinal mass sitting in a paravertebral location. Lesions in this location usually are neurogenic, and this lesion proved to be a ganglioneuroma. *B*. View at the time of the videothoracoscopy showing the lesion seen in *(A)*. This lesion was able to be completely excised with a videothoracoscopic approach.

A VATS procedure is contraindicated for presumed invasive thymomas. In patients with myasthenia gravis and a thymoma, a total thymectomy is mandatory and may be facilitated by combining a transcervical approach with the VATS exposure. The thymus gland is initially mobilized in the neck, and branches to the innominate vein are divided. The mobilized gland is then tucked down into the mediastinum, the neck closed, and the patient positioned for VATS. The thymoma is mobilized and the dissection completed with the removal of the gland and tumor through one of the chest incisions. Attempting to excise the tumor and perform a total thymectomy with a VATS approach alone is possible but more difficult, because of the need to extend the dissection well up into the neck.

The patient with a large, diffuse mediastinal mass from which tissue is required for diagnosis may also, at times, benefit from a VATS approach. Many of these lesions are more readily accessed for biopsy through an extrapleural, parasternal approach by excision of the costal cartilage (usually the second). Lesions that are not close to the anterior chest wall may be approached and readily sampled with a VATS approach.

The posterior mediastinum is also the site of either solid or cystic lesions that are amenable to VATS resection. We have resected eight posterior mediastinal lesions, including schwannomas (four) and bronchogenic cysts (four) (Fig. 37-10). Incisions used to approach these posterior or mediastinal lesions differ slightly from those used for access to the anterior mediastinum. Overall, we have performed a total of 85 VATS procedures for mediastinal pathology without mortality and with minimal morbidity.

OTHER PROCEDURES

Pericardial Drainage

A pericardial drainage procedure, so-called pericardial window, may be accomplished through either the right or left chest with a VATS procedure. It is, in fact, often easier to perform this procedure from the right side, where a larger area of pericardium is visible and there is more space in which to work. That being said, a subxiphoid approach to pericardial window usually is simpler, less invasive, and more expeditious, and accomplishes the same goals without the need to insert a double-lumen endobronchial tube and place the patient in the lateral decubitus position. If a large window is believed necessary, there may be an advantage to the VATS approach.

Sympathectomy

The sympathetic chain is easily visualized, as it lies along the vertebral bodies (Fig. 37-11). The magnification provided by VATS facilitates the performance of a sympathectomy. Either dorsal or lumbar sympathectomy may be performed, and bilateral procedures may be accomplished under the same anesthetic, with minimal morbidity. Dorsal sympathectomy may be indicated for palmar hyperhidrosis, reflex sympathetic dystrophy, or other upper-extremity pain syndromes. The superior cervical (stellate) ganglion is readily visualized and preserved, in order to avoid producing a Horner's syndrome. Lumbar sympathectomy may be useful for the management of pancreatic pain, particularly when caused by malignant disease. This requires a bilateral procedure to achieve maximal symptom relief.

In the treatment of chylothorax, VATS may be employed to ligate the thoracic duct. The thoracic duct is most readily identified in the right chest just as it courses through the aortic

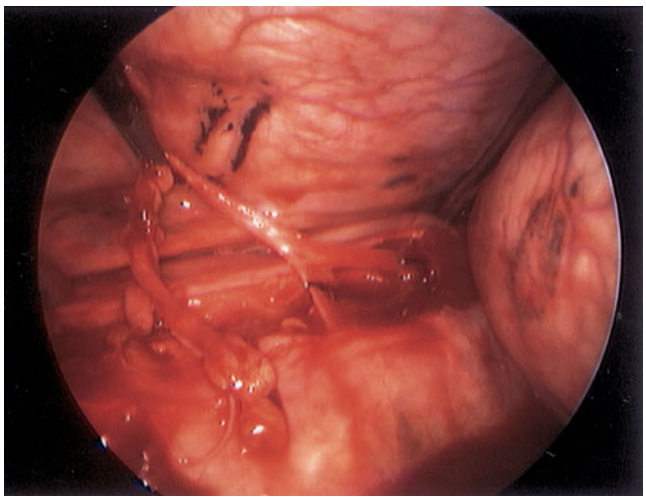

Figure 37-11 The sympathetic chain being mobilized off the vertebral bodies. Ganglia are easily seen as are the various branches of the nerve.

hiatus. In most patients, at this level it is still a single trunk running along the vertebral bodies between the aorta and the esophagus. We have performed 10 thoracic duct ligations for chyle leaks; in two patients, it was necessary to convert to an open procedure to successfully ligate the duct.

VATS provides excellent exposure to the thoracic spine, and procedures such as drainage of abscesses, biopsy of vertebral bodies, discectomy, and anterior releases for kyphoscoliosis have all been carried out successfully, thereby avoiding thoracotomy. Because of the early success and significantly less morbidity in these patients, this technique is becoming the approach of choice in many centers.

COMPLICATIONS

We reviewed the complications that resulted from our initial 266 VATS procedures. There were no deaths, and complications were not life threatening. Ten patients had air leaks lasting longer than 7 days. Eleven patients were electively converted to an open procedure when the intended VATS procedure could not be completed successfully. Bleeding requiring blood transfusion occurred in five patients, and five patients developed superficial wound infections. Data collected on 1358 patients from the VATSG Registry show a similar spectrum of complications, along with 2 percent mortality. As in our series, prolonged air leakage was the most frequent complication; significant bleeding requiring transfusion occurred in only 15 cases (1 percent). To date, no consistent pattern of major complications resulting from VATS has been reported. DeCamp and coauthors list 127 complications occurring in 121 of 595 patients undergoing videothoracoscopy at Brigham and Women's Hospital. Most of the complications were either prolonged air leakage or supraventricular dysrhythmias. We are aware of at least 10 instances of tumor seeding of VATS incisions, and there is at least one report of a death as a result. There appears to be a slightly higher incidence, although still around 3 percent, of recurrent pneumothorax following VATS procedures for spontaneous pneumothorax. Whether this is simply a function of the "learning curve" remains to be determined. The fact that VATS procedures in general have been performed with minimal major morbidity is commendable, since the technology and skills are relatively new to most surgeons.

CONCLUSIONS

Video-assisted thoracic surgical procedures have proved to be extremely useful in the diagnosis and treatment of various thoracic problems. Improvements in video technology have made it feasible for a surgeon and an assistant to work together, and developments in instrumentation, especially staplers, have made many procedures commonplace that previously seemed impossible. Cost issues still need to be carefully examined. Are the more sophisticated techniques and more expensive equipment saving money or expending more resources? If we are expending more resources, is there enough significant benefit to the patient to justify the added expense in this time of cost consciousness? In at least one study, the cost of a thoracoscopic wedge excision ($n = 45$) was less than that of a wedge excision done via thoracotomy ($n = 31$), but the difference was not statistically significant. Disposable instrument costs were significantly higher in the thoracoscopy group. There was no significant difference in the length of hospital stay for the two groups, but in the thoracoscopy group the length of stay was longer than expected. Cost savings potentially should come from a shorter length of stay, and, ultimately, if patients return to work sooner, the overall cost to society should be less, although admittedly this is difficult to measure.

With the tremendous strides made in the development of equipment for videothoracoscopy, there was a great rush on the part of thoracic surgeons to perform as many types of procedures as possible with this new technique. Now that the initial rush is over, we are beginning to appreciate just where these techniques have the greatest application. Some procedures for which there was tremendous early enthusiasm are being performed with less frequency; others have withstood the early shakedown period and have proved their worth over the conventional open procedure, resulting in a benefit to patients.

Perioperative Respiratory Considerations

Horace M. Delisser • Michael A. Grippi

Postoperative pulmonary complications constitute a significant cause of morbidity and mortality following surgery. Managing patients at risk for postoperative pulmonary problems requires an understanding of the predictable changes in pulmonary physiology that occur with surgery and anesthesia, as well as knowledge of factors associated with development of postsurgical respiratory compromise. Despite the availability of several screening tests, a careful history and physical examination continue to be the cornerstone of preoperative pulmonary evaluation. Although a number of measures can be employed before and after surgery to minimize the risk of respiratory complications, close patient monitoring and early detection are essential.

This chapter focuses initially on changes in pulmonary function with surgery. Pulmonary risk factors before, during, and after surgery are reviewed prior to discussion of preoperative evaluation of the patient for surgery, including lung resectional surgery. Finally, recommendations are made regarding preoperative preparation and postoperative prophylactic measures.

CHANGES IN PULMONARY FUNCTION WITH SURGERY

Many postoperative respiratory complications relate to exaggerations of the expected postoperative changes in pulmonary function that occur as a result of the surgery itself, anesthesia, or various pharmacologic interventions. Hence, an appreciation of normal postoperative pulmonary physiology is useful in understanding a number of pulmonary problems

Table 38-1

Changes in Pulmonary Function with Surgery

Reduction in lung volumes
Diaphragm dysfunction
Impaired gas exchange
Respiratory depression due to residual effects of anesthesia or postoperative narcotics
Impaired cough and mucociliary clearance

seen following surgery. Five principal categories of change in pulmonary function with surgery may be considered: (1) lung volumes, (2) diaphragm function, (3) gas exchange, (4) control of breathing, and (5) lung defense mechanisms (Table 38-1).

Lung Volumes

The pattern of pulmonary function abnormalities following thoracic and abdominal surgery is restrictive, characterized by moderate to severe reductions in vital capacity (VC) and smaller, but more important, reductions in functional residual capacity (FRC). The degree of impairment is similar after upper abdominal and thoracic surgery. Smaller changes in VC and FRC are noted with lower abdominal surgery; superficial or extremity surgery is usually unassociated with any significant or persistent changes in lung volumes. During the first 24 h following upper abdominal surgery, VC and FRC may be reduced by more than 70 percent and 50 percent, respectively, and they may remain depressed for more than a week. Consequently, it is not surprising that pulmonary complications are seen more often with thoracic and upper abdominal procedures than with surgery involving the lower abdomen or extremities (see "Intraoperative Risk Factors" below).

Reductions in other lung volumes, including total lung capacity (TLC), inspiratory capacity (IC), expiratory reserve volume (ERV), and residual volume (RV) have been noted. While the forced expiratory volume in 1 second (FEV_1) is decreased, the ratio of FEV_1 to the forced vital capacity (FEV_1/FVC%) remains unchanged, indicating that major airway obstruction does not occur.

Since patients undergoing superficial or extremity surgery do not experience major changes in lung volumes, residual or carryover effects from general anesthesia do not appear to play a primary role in this regard. In fact, studies show that in many patients, FRC in the early postoperative period is unchanged from baseline. An alternative proposal for the reduction is that postsurgical pain and associated muscle splinting may impair lung mechanics. However, since effective pain control using epidural anesthesia or intercostal nerve block fails to fully restore VC or FRC to preoperative levels, other causes must be operative. A growing consensus is that diaphragm dysfunction is an important contributing factor (see below).

The reduced FRC is of major physiological significance postoperatively. Its importance can be understood when the phenomenon of airway closure and the concept of closing capacity (CC) are considered. FRC is the lung volume at the end of a normal tidal expiration. CC is the lung volume at which small airways in the lung bases begin to close during expiration because of a reduction in airway radial traction. The relationship between the two is a key factor in the development of postoperative changes in lung function (Fig. 38-1).

In a normal lung, FRC is always greater than CC, and the airways remain open throughout a tidal breath. However, when CC is greater than FRC, lung volume fails to increase sufficiently during tidal breathing to open all the airways and, consequently, some alveolar units remain closed during a breath. Such regions constitute areas of atelectasis. An intermediate state exists when CC exceeds lung volume for part of the time during each tidal breath. Under these circumstances, the airways open for only a portion of the respiratory cycle, creating areas of low ventilation relative to perfusion. In summary, any circumstance that reduces FRC below CC or that increases CC above FRC produces regions of reduced ventilation and atelectasis (Table 38-2).

Diaphragm Function

Diaphragm dysfunction has been recognized as an important factor contributing to the postoperative reduction in lung volumes. In patients undergoing cholecystectomy, the diaphragm's contribution to quiet tidal breathing after surgery is reduced. This impairment is not due to postoperative pain. Measurements of transdiaphragmatic pressure during maximal phrenic nerve stimulation following upper abdominal surgery indicate that decreased central nervous system output to the phrenic nerves, possibly as a result of inhibitory reflexes arising from sympathetic, vagal, or splanchnic receptors, may be the important etiological factor.

Gas Exchange

Postoperative hypoxemia occurs commonly. There are two phases in its development. The initial phase occurs in the first several hours following anesthesia and surgery. The underlying mechanisms are related largely to the residual effects of the anesthesia and include ventilation-perfusion mismatch, anesthetic-induced inhibition of hypoxic pulmonary vasoconstriction, right-to-left shunting, alveolar hypoventilation, depressed cardiac output, and increased oxygen consumption

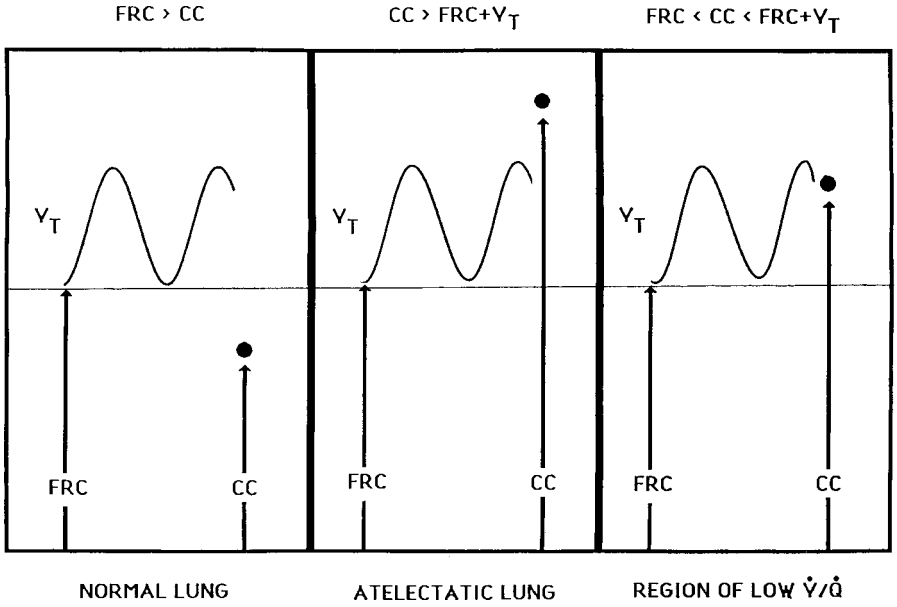

Figure 38-1 The relationship between functional residual capacity (FRC) and closing capacity (CC). See text. *(From Goldmann DR, Brown FH, Guarnieri DM (eds): Perioperative Medicine. New York, McGraw-Hill, 1994, with permission.)*

by peripheral muscle. This phase resolves within 24 h following superficial surgery.

A second phase of hypoxemia that may persist for several days or weeks is seen after thoracic and upper abdominal surgery. This phase correlates with reductions in FRC and changes in the FRC-CC relationship. Although alterations in the FRC-CC relationship predominate, other processes may contribute to late postoperative hypoxemia: (1) alveolar hypoventilation (see "Control of Breathing" below); (2) increased dead space ventilation due to rapid, shallow breathing; and (3) decreased mixed venous oxygen tension due to increased oxygen consumption, impaired cardiac output, and reduced oxygen carrying capacity.

Table 38-2

Conditions That Alter the Relationship between Functional Residual Capacity (FRC) and Closing Capacity (CC)

Decrease FRC	Increase CC
Supine position	Advanced age
Obesity	Smoking
Pregnancy	Chronic obstructive pulmonary disease (COPD)
General anesthesia	Pulmonary edema
Abdominal pain	

Source: From Goldmann DR, Brown FH, Guarnieri DM (eds), Perioperative Medicine. *New York, McGraw-Hill, 1994, with permission.*

Control of Breathing

Respiratory depression is a common feature of the postoperative period. Two factors are responsible. First, residual effects of preanesthetic or anesthetic agents inhibit respiratory drive and reduce the ventilatory response to hypercapnia, hypoxia, and acidemia. Second, narcotics given for postoperative analgesia depress both hypercapnic and hypoxic ventilatory drives, resulting in decreased tidal volume, reduced minute ventilation, and increased Pa_{CO_2}. Narcotics also alter the pattern of breathing, reducing the frequency of sighs or eliminating them entirely; in susceptible patients, narcotics may precipitate sleep apnea.

Lung Defense Mechanisms

Several mechanisms protect the lung from environmental and infectious insults. Two of the most important—cough and mucociliary transport—are compromised after surgery, contributing to an increased risk of pulmonary infection. Postoperative pain or the excessive use of narcotics may inhibit coughing; in addition, altered lung mechanics decrease the expulsive force generated with each cough. Mucociliary clearance is impaired for up to a week following upper abdominal surgery. Although an ineffective cough reflex contributes significantly to reduced mucociliary clearance, several additional mechanisms are involved. These include: (1) cilia damage from endotracheal intubation and inhalation of dry, hyperoxic gas mixtures; (2) reduced tracheal mucus velocity due to the presence of an endotracheal tube; (3) anesthetic-induced inhibition of mucociliary transport; and (4) atelectasis.

Table 38-3

Pulmonary Complications Associated with Thoracic Surgery

Procedure	Complication	Incidence
Coronary artery bypass grafting	Phrenic nerve damage	10%
	Late pleural effusions (arising after discharge)	Not reported in literature
Thoracotomy with lung resection	Bronchopleural fistula or empyema*	5–20%
Median sternotomy	Sternal wound infection (mediastinitis or osteomyelitis)	1–2%
Esophagectomy, gastrectomy	Anastamotic leak	3–6%

** Higher for patients with sarcoidosis and aspergilloma.*

PULMONARY COMPLICATIONS

The criteria used for defining postoperative pulmonary morbidity have varied considerably in published reports, although it is clear that, from a broad perspective, five major categories of complications may be considered: (1) atelectasis; (2) infection, including acute tracheobronchitis and pneumonia; (3) exacerbation of underlying chronic lung disease; (4) prolonged mechanical ventilation and respiratory failure; and (5) thromboembolic disease. With thoracic surgery, several additional unique problems have been noted (Table 38-3).

The variability in defining postoperative pulmonary complications has resulted in reported incidences in the literature ranging from 5 to 90 percent. In general, a healthy, young nonsmoker of normal weight has a very low risk of postoperative pulmonary complications (1 percent or less). However, a number of factors have been identified that are associated with the development of postoperative pulmonary complications (Table 38-4). They include preoperative factors (chronic lung disease, smoking, general state of health, age, obesity, nutritional status, and antecedent respiratory tract infection), intraoperative factors (type and duration of anesthesia, surgical site of operation, and type of surgical incision), and postoperative factors (immobilization and inadequate pain control).

PREOPERATIVE RISK FACTORS

A number of patient-related factors have been implicated in the development of postoperative respiratory complications.

Table 38-4

Factors Associated with Development of Postoperative Pulmonary Complications

Preoperative	Intraoperative	Postoperative
Chronic lung disease	Type of anesthesia	Immobilization
Smoking	Duration of anesthesia	Inadequate pain control
General state of health	Surgical site	
Age	Type of surgical incision	
Obesity		
Nutritional status		
Antecedent respiratory tract infection		

Chronic lung disease (particularly obstructive airway disease), cigarette smoking, and the patient's overall state of health are the most important preoperative risk factors. In addition, age and obesity are relatively minor factors. The precise risks associated with malnutrition and recent viral infections are unknown.

Chronic Lung Disease

The following discussion focuses on the operative risks in patients with three common categories of chronic lung disease: (1) chronic obstructive pulmonary disease, (2) restrictive lung diseases, and (3) pulmonary vascular diseases.

Chronic Obstructive Pulmonary Disease

Since chronic obstructive pulmonary disease (COPD) is the most common chronic pulmonary disorder, most studies addressing the impact of preexisting lung disease on surgical risk have focused on this entity. The reported incidence of postoperative pulmonary complications in patients with COPD varies from 25 to 100 percent and is influenced by type of surgery, magnitude of preexisting respiratory impairment, and criteria used to define complications. Although not precisely quantified in the literature, the risk for postoperative respiratory complications appears to increase significantly (greater than 50 percent) when the FEV_1 is below 65 percent of predicted. The risk is also increased in patients who are hypercapnic.

In patients with severe disease, an important issue is whether a critical level of lung function exists below which the risk of developing a major, potentially life-threatening pulmonary complication is so high as to make anesthesia and surgery too dangerous. In the 1950s, such a prohibitive threshold or level was proposed. Subsequent studies, however, have failed to support this hypothesis. Patients with an FEV_1 as low as 450 ml have been found to tolerate surgery safely. Hence, patients should not be denied necessary operative procedures solely on the basis of marginal lung function. As with all medical interventions, the potential benefits of the operative procedure must be weighed against the operative risk.

The increased incidence of postoperative pulmonary complications in patients with COPD is due, in part, to an increase in the CC, favoring the development of areas of low ventilation-to-perfusion ratios and atelectasis. In addition, in patients who continue to smoke, impaired ciliary function and chronic tracheobronchitis may be contributing factors.

Restrictive Lung Diseases

The risk of pulmonary complications in patients with restrictive lung diseases who undergo surgery is unknown. Although some experience has been reported with patients undergoing thoracic and corrective orthopedic surgery (see below), very little data exist with regard to abdominal and extremity surgery. One might expect a higher incidence of postoperative respiratory complications in these patients for two reasons: (1) FRC is reduced, favoring the formation of areas of poor ventilation and atelectasis; and (2) coughing, and thus the ability to clear respiratory secretions, is impaired.

Experience with postoperative pulmonary complications has been reported in three relatively common situations for patients with restrictive disorders: (1) sarcoidosis complicated by aspergilloma and hemoptysis; (2) corrective surgery for kyphoscoliosis; and (3) myasthenia gravis with associated thymoma.

Sarcoidosis may progress to diffuse interstitial fibrosis and cavitary changes, primarily involving the upper lobes (see Chapter 67). These cavities are prone to infection with *Aspergillus* species and aspergilloma formation, with subsequent development of recurrent and, at times, life-threatening hemoptysis. These patients generally have very poor lung function and, hence, are managed conservatively. However, if supportive medical therapy fails, patients may require thoracotomy and lung resection. Unfortunately, the postoperative course is rarely problem-free and is often complicated by the development of a bronchopleural fistula or empyema.

Corrective surgery in patients with kyphoscoliosis may involve anterior or posterior spinal fusion procedures or a combination of the two. In addition to correction of the primary orthopedic abnormality, an important indication for performing these procedures is progressive deterioration of pulmonary function. Postoperative respiratory complications have been reported in up to 20 percent of these patients, with pleural space-related processes (e.g., pneumothorax, pleural effusion, bronchopleural fistula, and empyema) among the most common. Important risk factors include: (1) nonidiopathic scoliosis, (2) open anterior spinal fusion procedures, (3) age greater than 20 years, (4) mental retardation, (5) preoperative hypoxemia, and (6) obstructive pulmonary function tests. Video-assisted thoracopic (VAT) approaches have emerged as alternatives to open thoracotomy, and initial studies indicate that outcomes of anterior fusion by a VAT procedure and thoracotomy are similar.

Most patients with myasthenia gravis will, during the course of their disease, undergo thymectomy. Risk factors for postoperative pulmonary complications include chronic myasthenia gravis (greater than 6 years), severe bulbar weakness, preexisting respiratory illness, need for large doses of pyridostigmine, and reduced maximal static expiratory pressure (less than 50 cm H_2O or 66 percent of predicted). The preoperative VC has not been found consistently to be a significant predictor of respiratory morbidity following thymectomy. Historically, up to 30 percent of these patients required mechanical ventilation for more than 3 days following the surgery. However, more recent routine use of plasma exchange in patients with bulbar or generalized myasthenia gravis has significantly reduced the duration of postoperative ventilatory support and time in the intensive care unit. Virtually all patients with the disorder are treated with anticholinesterases, which are usually discontinued prior to surgery in order to minimize tracheobronchial secretions. However, controversy exists regarding whether these agents should be restarted immediately after surgery or withheld for 24 to 48 h following thymectomy.

Pulmonary Vascular Diseases

The risk of postoperative pulmonary complications in patients with underlying pulmonary vascular disease and intact respiratory mechanics is not known. However, one might anticipate an exaggeration of, or prolongation in, the hypoxemia seen postoperatively (see "Gas Exchange" above). In addition, pulmonary reserve in these patients is usually reduced; hence, additional pulmonary insults are less likely to be tolerated.

Smoking History

Smoking increases the risk of postoperative respiratory complications, independent of the association of smoking with COPD. Given the well-documented adverse changes in respiratory epithelium and pulmonary function that correlate with the degree of tobacco consumption, such an association is not surprising. In individuals undergoing coronary artery bypass graft surgery, the risk of smoking becomes significant when tobacco use exceeds 20 pack-years. A statistically significant reduction in complications occurs only when patients discontinue smoking for at least 8 weeks prior to surgery. This finding is consistent with studies showing that abnormalities in pulmonary function may persist up to several months after smoking cessation.

Although smoking cessation of more than 2 months is associated with a decreased risk of postoperative respiratory complications, some initial retrospective studies actually showed a paradoxical increase in pulmonary complications in patients who stopped smoking only a few weeks or days prior to surgery. However, a more recent prospective analysis found no evidence for increased pulmonary complications in patients who quit smoking within 2 months prior to a thoracotomy.

General State of Health

Overall clinical status, as categorized by the American Society of Anesthesiologists' (ASA) classification (Table 38-5), correlates with development of postoperative pulmonary complications. For patients undergoing abdominal surgery, an ASA classification of II or higher is a powerful predictor of increased risk of respiratory problems after surgery.

Age

Based primarily on retrospective data from the 1950s and 1960s, advanced age has long been considered a major risk factor for postoperative pulmonary complications. However, recent work suggests that age may not be as significant as originally believed, once other confounding variables are controlled. For example, in a study of 520 patients undergoing elective thoracic or abdominal surgery, no association between age and postoperative pneumonia was found. These findings appear to hold true even when lung tissue is resected. In addition, in a study of patients undergoing thoracotomy for lung cancer, despite a somewhat higher 30-day postoperative mortality in patients over age 70 years, the incidences of postoperative pulmonary complications and hospital stay were not increased, and actual survival was not decreased in the older group.

Table 38-5

American Society of Anesthesiologists' (ASA) Clinical Classification

ASA I:	Otherwise healthy patient undergoing elective surgery
ASA II:	Patient with single system or well-controlled disease which does not affect daily life
ASA III:	Patient with multisystem or well-controlled major system disease which limits daily activity
ASA IV:	Patient with severe, incapacitating disease which is poorly controlled or end-stage
ASA V:	Patient who is in imminent danger of death and is not expected to survive 24 h

Obesity

A number of changes in respiratory mechanics and pulmonary function occur with obesity. The accumulation of fat in the chest wall, diaphragm, and abdomen may reduce total respiratory compliance by more than 60 percent—a change that is amplified when the patient assumes the supine position. The reduced compliance, in turn, increases the work of breathing. Consequently, minute ventilation, oxygen consumption, and carbon dioxide production are further increased beyond baseline values, which are already elevated as a result of increased metabolic demands imposed by the obese state.

Normally, spirometry in obese patients does not indicate airway obstruction. However, a reduction in ERV is found consistently. The magnitude of the reduction correlates with the degree of obesity. Areas of low ventilation relative to perfusion and atelectasis are seen (see "Lung Volumes" above). In addition to these mechanical changes, obese patients appear to have a larger gastric volume and lower pH than do non-obese patients and may be predisposed to aspiration.

Despite what might be predicted based on the changes in lung function described above, retrospective reviews of obese patients undergoing abdominal surgery do not show an increased incidence of pneumonia or atelectasis compared to non-obese patients undergoing similar procedures. The few prospective studies on the risk in obesity of postoperative pulmonary complications have yielded conflicting results. However, in these studies, small numbers of patients have been

studied, liberal definitions of obesity have been employed, patient height has not been routinely considered, and the degree of obesity has not been noted precisely. In studies showing a correlation between obesity and postoperative respiratory morbidity, the principal complication has been atelectasis. Thus, although obesity may increase the risk of some postoperative pulmonary complications, the precise magnitude and significance of the risk are unknown. However, since respiratory complications (e.g., bacterial pneumonia, acute respiratory failure, or prolonged mechanical ventilation) occur in only 4 to 7 percent of morbidly obese patients undergoing gastric bypass surgery, in the absence of other cardiopulmonary disease, the risk of postoperative pulmonary complications associated with obesity appears not to be excessive.

Obesity is, however, clearly a risk factor for obstructive sleep apnea syndrome, which may be unmasked or exacerbated because of use of postoperative analgesics or narcotics. Since sleep apnea occurs in individuals of normal weight, all patients should be questioned about symptoms of the disorder (see Chapter 97).

Nutritional Status

The effects of malnutrition and severe starvation on the respiratory system include a reduced ventilatory response to hypoxia, decreased diaphragmatic muscle function, impaired cell-mediated and humoral immunity, and alterations in the elastic properties of the lung (see Chapter 154). Some evidence of malnutrition can be found in many hospitalized patients, but it is unclear whether the degree of malnutrition usually noted produces clinically significant changes in pulmonary function. In addition, although patients whose nutritional status is compromised may be at higher risk for developing postoperative pulmonary complications, aggressive preoperative nutritional support has not been shown to decrease postsurgical pulmonary morbidity.

Antecedent Respiratory Tract Infection

Enhanced airway reactivity and increased airway resistance may persist for several weeks beyond resolution of the acute symptoms of a viral respiratory tract infection. In addition, diaphragmatic dysfunction has been shown to be impaired during viral infections. Although no published studies have addressed the effect of concurrent viral infections on postoperative pulmonary morbidity, a delay in elective surgery is generally advised, given the changes in airway reactivity and diaphragm function in this setting.

INTRAOPERATIVE RISK FACTORS

Several intraoperative factors have been associated with the development of pulmonary complications after surgery. These include the type of anesthesia, the length of the procedure (as determined by the duration of anesthesia), the surgical site, and the type of surgical incision.

Type of Anesthesia

The pulmonary effects of general anesthesia are addressed in detail elsewhere (see Chapter 147). They include impairment of oxygenation and carbon dioxide elimination. These effects result from anesthetic-induced changes in the shape and motion of the chest wall and diaphragm, which, in turn, lead to increases in alveolar dead space, shunt fraction, and ventilation-perfusion mismatching. The alterations in lung function may contribute to pulmonary morbidity.

Because of the effects of general anesthesia on gas exchange, regional anesthesia has been used as an alternative in patients with underlying pulmonary disease. Indeed, epidural anesthesia to a T4 sensory level does not appear to alter FRC, VC, FEV_1, the alveolar-arterial oxygen gradient, shunt fraction, or cardiac output. Many clinicians have the impression that these strategies lower the incidence of postoperative respiratory complications. However, with the exception of several reports showing a reduced risk of postoperative thromboembolism, studies to date have not been well designed and have not consistently demonstrated that regional anesthesia results in a lower incidence of other postoperative pulmonary complications.

Duration of Anesthesia

The incidence of pulmonary complications increases significantly for procedures lasting longer than 3 to 4 h. Patients whose procedure lasts 4 h or more are five times more likely to suffer postoperative pneumonia than those whose procedures last less than 2 h.

Surgical Site

The development of postoperative pulmonary complications correlates strongly with the anatomic site of operation. The complication rate (excluding thromboembolic disease) is less than 1 percent for non-thoracoabdominal procedures, less than 5 percent for lower abdominal surgery, and greater than 5 percent for upper abdominal surgery (with reported complication rates ranging from 7 to 76 percent). For thoracotomy with lung resection, the complication rate also depends on a number of other factors, including: (1) the presence of underlying lung disease, (2) the amount of functional lung removed, and (3) the extent to which the "bellows" function of the lung is impaired (see "Evaluation for Lung Resection" below).

Type of Surgical Incision

For abdominal procedures, vertical laparotomy incisions carry a higher incidence of postoperative complications than do horizontal incisions. Abdominal laparoscopic procedures and thoracoscopic lung resection have gained widespread acceptance because of reduced patient discomfort, shortened length of hospitalization, and faster patient return to full activity. Since the magnitude of incisional pain is usually less, and since patients typically ambulate sooner, the incidence

of postoperative respiratory problems associated with these less invasive procedures is likely to be reduced. Thus, not surprisingly, laparoscopic cholecystectomy, compared with open cholecystectomy, demonstrates better preservation and faster recovery of lung volumes, less postoperative pain and analgesia use, and higher arterial oxygen saturations.

POSTOPERATIVE RISK FACTORS

Inadequate pain control, prolonged bed rest, and inactivity contribute to the development of respiratory complications following surgery.

Inadequate Postoperative Analgesia

Effective pain control is vital in the early postoperative period, since pain inhibits coughing and deep breathing and discourages early mobilization—factors that contribute to an increased risk of pulmonary complications. Obstacles to good postoperative analgesia include hesitancy of the patient to report pain for fear of being labeled a "bad" patient and anxiety of caregivers in administering narcotics because of side effects.

Immobilization

Prolonged bed rest and inactivity following surgery impact the risk of postoperative respiratory complications in several ways. FRC decreases by 500 to 1000 ml in moving from the upright to the supine position, favoring the development of atelectasis. Increased ambulation is associated with better patient mobilization and clearance of secretions. As discussed elsewhere (see Chapter 82), lack of patient movement in the postsurgical period is a major risk factor for deep venous thrombosis and pulmonary embolism.

PREOPERATIVE EVALUATION

The principal elements in preoperative evaluation of the surgical patient are: (1) the history and physical examination, (2) the chest radiograph, (3) arterial blood-gas analysis, and (4) pulmonary function tests (Fig. 38-2).

History and Physical Examination

A careful history is an essential component of the preoperative evaluation. The following issues should be reviewed: (1) smoking history; (2) history of respiratory symptoms (e.g., cough, chest pain, dyspnea), including symptoms of sleep apnea; (3) extent of preexisting lung disease; and (4) history of recent respiratory tract infection. The physical examination is rarely helpful in identifying pulmonary risk factors. When the history is negative, the physical examination is typically unremarkable. However, the initial physical examination supplements the history and provides a baseline for future comparisons.

Chest Radiograph

The preoperative chest radiograph is usually unrevealing if risk factors and abnormal physical findings are absent. Although the admission or screening chest radiograph is more likely to show an abnormality in individuals with known cardiopulmonary disease, the study usually simply confirms the presence of previously known abnormalities; only occasionally does it result in an alteration in management. Thus, a preoperative chest radiograph is indicated when there are new or unexplained symptoms or signs, when there is a history of underlying lung disease and no recent chest radiograph, or when thoracic surgery is planned.

Arterial Blood-Gas Analysis

Since an elevated Pa_{CO_2} is associated with an increased incidence of postoperative respiratory morbidity in patients with significant chronic lung disease, an arterial blood-gas analysis should be done preoperatively in these patients. It is also recommended that an arterial blood-gas specimen be obtained in patients who, by either history or physical examination, have a new significant pulmonary process or who are undergoing lung resection. Data do not support use of arterial blood-gas analysis as a routine preoperative screening test.

Pulmonary Function Tests

An increased risk of respiratory complications has been demonstrated only in the obstructive category of pulmonary disorders. Although there are theoretical reasons to expect a higher incidence of postoperative respiratory problems in patients with restrictive lung diseases (see "Preoperative Risk Factors" above), currently, no data correlate the degree of restriction (as assessed by lung volumes) with subsequent pulmonary morbidity. Hence, although a complete battery of pulmonary function tests is useful in evaluating suspected restrictive lung disease, spirometry to evaluate for airway obstruction is all that is required to screen patients at risk.

Indications for preoperative pulmonary function testing include the presence of cough or unexplained dyspnea, a history of chronic lung disease, a history of cigarette smoking (greater than 20 pack-years), and planned lung resection (discussed below). Current data do not support the routine use of these studies to evaluate the pulmonary risks of advanced age, obesity, malnutrition, or abdominal surgery. Finally, normal pulmonary function tests do not guarantee a complication-free postoperative course and do not lessen the need for diligent and attentive respiratory care following surgery.

EVALUATION FOR LUNG RESECTION

In evaluating patients for lung resection, the clinician must consider two issues: (1) What are the surgical morbidity and mortality for the patient with significant underlying chronic lung disease? (2) Will postoperative lung function be adequate? A number of approaches have been used over the years

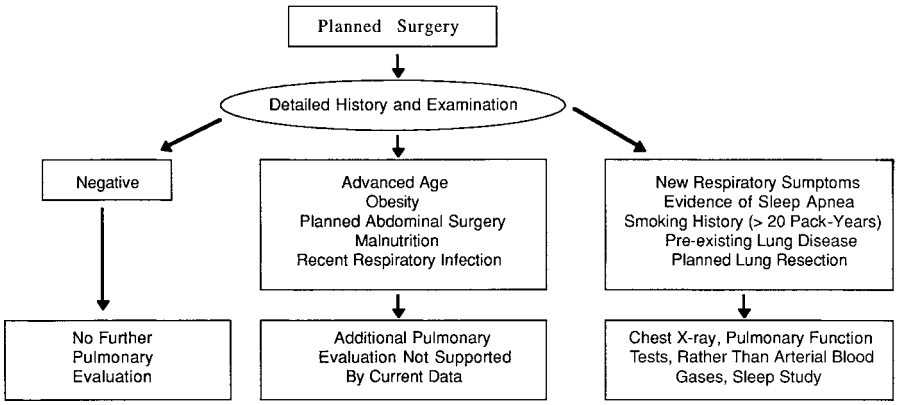

Figure 38-2 Algorithm for preoperative pulmonary evaluation. See text for discussion.

to address these questions. Several, including pulmonary function tests, lung scans, and arterial blood-gas analyses are used routinely; others are used less commonly.

Pulmonary Function Tests, Lung Scans, and Arterial Blood-Gas Analyses

Studies have shown that the risk of postoperative respiratory complications following lung resection (especially pneumonectomy) increases significantly when the FEV_1 is less than 2 L or when the FVC or maximal voluntary ventilation (MVV) is less than 50 percent predicted. For these "high risk" patients, a number of additional tests have been used to estimate postoperative pulmonary function. The most helpful have been quantitative perfusion and ventilation scintigraphy.

Ventilation and perfusion lung scans are equally accurate in calculating the postoperative FEV_1, although perfusion scanning is more commonly used because it is technically easier to perform. These scans measure the relative blood flow or ventilation to one lung or lung region and can be used to predict postoperative FEV_1.

For pneumonectomy, the predicted postoperative FEV_1 is calculated as:

$$\text{Predicted postoperative } FEV_1 = \text{preoperative } FEV_1 \times \text{percent perfusion to remaining lung} \quad (1)$$

For lobectomy, regional quantitative perfusion scans may be used. Alternatively, the postoperative FEV_1 may be predicted using the following equation:

$$\text{Predicted postoperative } FEV_1 = \text{Preoperative } FEV_1 \times (\text{number of lung segments remaining after resection divided by total number of segments in both lungs}) \quad (2)$$

Equation (2) appears to provide information as accurate as that obtained from perfusion studies. When these calculations are inaccurate, they tend to *underestimate* the predicted postoperative FEV_1.

A predicted postoperative FEV_1 of 800 ml has been used as a cutoff for withholding resectional lung surgery, based on the clinical impression that below 800 ml many patients are disabled and develop carbon dioxide retention. Indeed, studies employing this threshold report "acceptable" surgical and postoperative morbidity and mortality. However, no prospective studies have confirmed the significance of this value. Furthermore, the physiological implications of an FEV_1 of 800 ml depend upon a number of factors, including the patient's body size. Therefore, calculation of percent predicted FEV_1 might be of greater value in determining operability. A predicted postoperative FEV_1 of greater than 40 percent predicted has been proposed as a safe criterion in patients undergoing pulmonary resection. Finally, recognizing that most patients who undergo resectional lung surgery have lung cancer and that this malignancy has virtually a 100 percent mortality without surgery (for non–small-cell tumors), caution must be exercised in applying exclusionary criteria.

Finally, as noted previously, hypercapnia in the setting of chronic lung disease is associated with a higher incidence of postoperative respiratory morbidity. Hypoxemia is, however, not as good a predictor of subsequent pulmonary morbidity. In fact, resection of areas of the lung having significant ventilation-perfusion mismatch may *improve* the level of oxygenation postoperatively. A preoperative arterial blood-gas analysis should be obtained in all patients with preexisting lung disease undergoing pulmonary resection. Although supportive data are lacking, it is common practice to obtain an arterial blood-gas sample in all patients undergoing resectional surgery, even those without significant underlying lung disease. This determination serves as a basis for comparison with subsequent intra- and postoperative measurements.

Additional Tests for Evaluating Patients for Lung Resection

Several additional tests, including measurement of diffusing capacity, assessment of exercise capacity, bronchospirometry, the lateral position test, and unilateral pulmonary artery occlusion have been advocated in preoperative evaluation of the candidate for lung resection.

Studies on the predictive value of the preoperative diffusing capacity in assessing operative risk have yielded conflicting results. However, determination of predicted

postoperative D_{LCO} using a formula similar in concept to Eq. (1) may be useful. A predicted postoperative D_{LCO} less than 40 percent of the predicted normal value appears to be associated with a high risk of operative morbidity and mortality.

A number of investigators have found measurement of maximal oxygen consumption during cardiopulmonary exercise testing ($\dot{V}O_2max$) to be useful in predicting postoperative morbidity and mortality. A $\dot{V}O_2max$ less than 15 to 20 ml/kg/min is associated with an increased incidence of postoperative complications. In addition, exercise-induced arterial oxygen desaturation (greater than 2 percent decline) appears to predict postoperative complications, including death and respiratory failure.

The 6-minute walk test and stair climbing are technologically simpler approaches than cardiopulmonary exercise testing and have been used clinically to evaluate the exercise capacity of patients undergoing lung resection.

Studies in patients evaluated for lung volume reduction surgery indicate that those unable to complete a 6-minute walk of more than 500 feet are unacceptable candidates for lung resection. However, for those who maintain an oxygen saturation greater than 90 percent on 2 L of supplemental oxygen while exceeding 700 to 900 feet during a 6-minute walk, morbidity and mortality with lung resectional surgery are less than 10 percent and 1 percent, respectively.

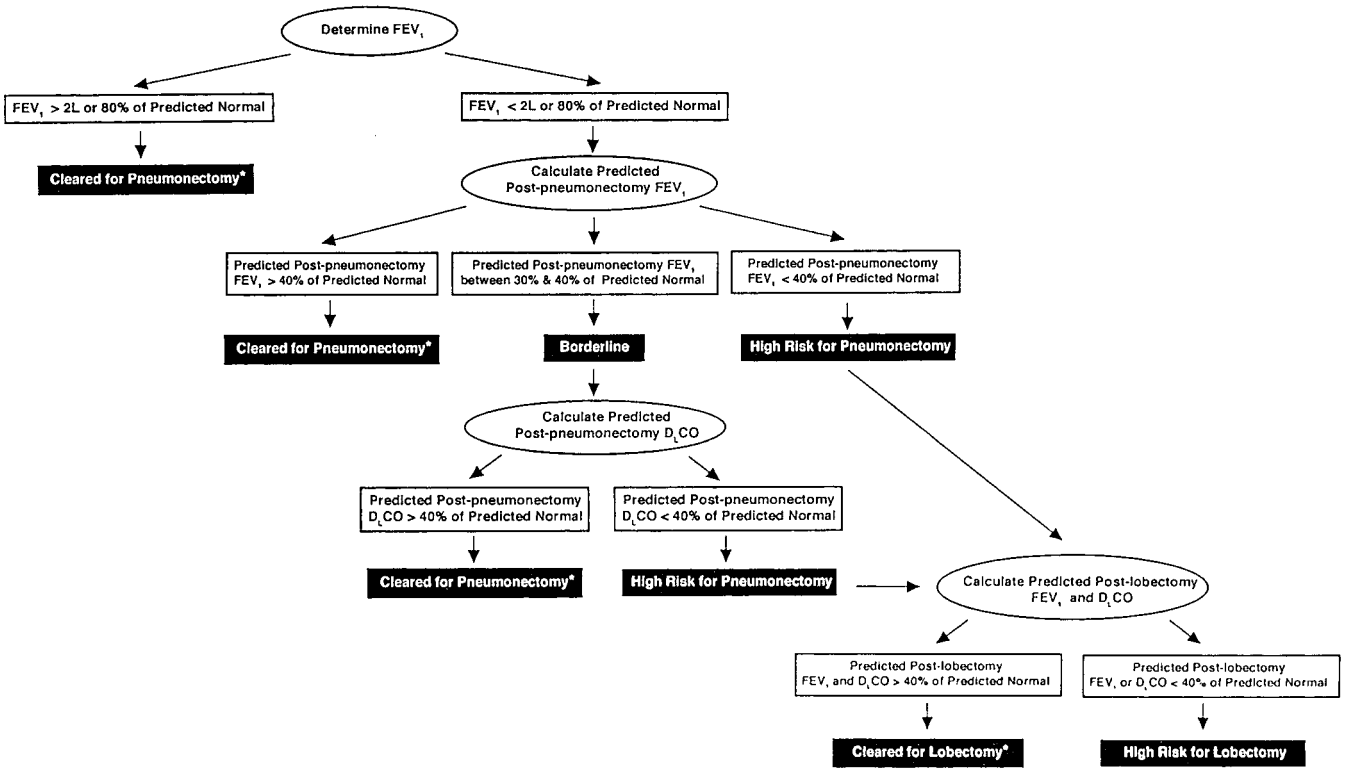
Retrospective studies have demonstrated a significant risk of postoperative pulmonary complications in patients who are unable to climb two flights (where one flight is the equivalent of 12 steps).

Bronchospirometry (the measurement of oxygen uptake in each lung, individually), the so-called lateral position test, and measurement of pulmonary artery pressure during temporary, unilateral pulmonary artery occlusion are techniques used in the past to assess the risk of thoracotomy in borderline patients. These tests are now of historical interest because of technical problems and concerns over reproducibility of results.

Recommended Approach

In evaluating patients for lung resection, the following approach should be considered (Fig. 38-3).

Operability for pneumonectomy is determined in the event that this procedure should become necessary, either to remove the tumor completely or because of an intraoperative complication. If the preoperative FEV_1 is 2 L or greater, or at least 80 percent of the predicted normal value, the patient is "cleared" for pneumonectomy; no further testing is required. If the preoperative FEV_1 is less than these values, the predicted post-pneumonectomy FEV_1 should be determined. The patient is cleared for pneumonectomy if the predicted



*If confirmatory evidence of operability is required, an exercise test can be performed.

Figure 38-3 Algorithm for preoperative evaluation for lung resection. See text for discussion.

postoperative FEV_1 is at least 40 percent of the predicted value. The patient is considered borderline if this number is between 30 and 40 percent of the predicted value; the patient is considered to be at high risk for pneumonectomy if the value is below 30 percent.

For the borderline patient, or for the patient with radiographic evidence of interstitial lung disease or significant dyspnea despite an "operable" FEV_1 or predicted postoperative FEV_1, the predicted post-pneumonectomy D_{LCO} should be determined. The patient is cleared for pneumonectomy if this value is at least 40 percent of the predicted value.

If confirmatory evidence of operability is required, particularly for the borderline patient, an exercise test should be performed. The patient is cleared for pneumonectomy if the $\dot{V}O_2$max is at least 15 to 20 ml/kg/min and arterial oxygen saturation declines less than 2 percent.

If the patient cannot tolerate a pneumonectomy but, from a technical standpoint, appears to be a good candidate for lobectomy, the appropriate steps in Fig. 38-3 should be followed for calculation of the predicted post-lobectomy FEV_1 and D_{LCO}.

Importantly, for selected borderline patients with emphysema and potentially resectable lung cancer, consideration should be given to combined cancer resection and lung volume reduction. This is particularly worth considering if the emphysema is heterogeneous and primarily involves the lobe to be resected.

When respiratory insufficiency occurs as a result of pulmonary resection, it is manifest early (i.e., within the first several weeks following operation). After 3 months, respiratory insufficiency directly attributable to the surgery is rare.

PREOPERATIVE PREPARATION

Surprisingly, few studies have specifically addressed the question of whether aggressive, preoperative pulmonary preparation decreases postoperative pulmonary morbidity and mortality. Although data on preoperative preparation are limited, for patients with significant obstructive airway disease, intensive preoperative respiratory therapy (bronchodilators, corticosteroids, antibiotics, and chest physiotherapy) does appear to reduce the incidence of postoperative respiratory complications by more than 50 percent.

Several preoperative prophylactic measures should be considered in patients undergoing elective surgery (Table 38-6).

Pulmonary function in patients with obstructive airway disease should be optimized. Therapy may include any or all of the following: bronchodilators, corticosteroids, antibiotics (when there is evidence of infection), and chest physiotherapy (if excessive secretions are present). When possible, these interventions should be implemented 48 to 72 h prior to surgery.

Ideally, for at least 8 weeks prior to surgery, smoking should be discontinued. As noted previously, recent data indicate that complication rates are not increased by shorter periods of abstinence; therefore, even when 8 weeks of abstinence is not possible, patients should still be advised to quit smoking prior to surgery.

In severely obese patients, if patient compliance can be achieved, weight reduction should be attempted.

Finally, patient education on the importance of coughing and pain control, proper use of an incentive spirometer, and deep breathing exercises should take place preoperatively.

Table 38-6

Preoperative Pulmonary Preparation

Optimization of airway function in patients with obstructive lung disease (bronchodilators; corticosteroids, antibiotics, and chest physiotherapy, when indicated)
Smoking cessation (ideally, a minimum of 8 weeks prior to surgery)
Weight reduction for severely obese individuals
Patient education (deep breathing exercises, importance of coughing and pain control, use of incentive spirometry)

POSTOPERATIVE PROPHYLACTIC MEASURES

Several postoperative measures may be employed in an attempt to prevent respiratory complications (Table 38-7).

Table 38-7

Postoperative Measures for the Prevention of Respiratory Complications

Early patient mobilization and ambulation
Prophylatic lung expansion maneuvers (incentive spirometry, deep-breathing exercises, continuous positive airway pressure [CPAP]
Provision of adequate analgesia (including patient-controlled analgesia, intercostal nerve blocks, and epidural anesthesia)
Prophylaxis against thromboembolism

Early patient mobilization and ambulation should be encouraged. As noted previously, these measures are important postoperatively in reducing the incidence of atelectasis, in promoting the clearance of secretions, and in decreasing the risk of thromboembolic disease.

Prophylactic lung expansion maneuvers should be initiated. Two equally effective measures are deep breathing exercises and incentive spirometry. Intermittent positive pressure breathing (IPPB) is generally ineffective and costly and is associated with several adverse effects. Reports of intermittent continuous positive airway pressure (CPAP) applied by face mask indicate that it is at least equivalent to deep breathing exercises and incentive spirometry in preventing and treating atelectasis. However, while CPAP may be useful in the patient who cannot cooperate with inspiratory maneuvers, its role in the management of patients capable of taking deep breaths is unclear.

Adequate analgesia should be provided. Traditionally, parenteral narcotics have been used for postoperative analgesia, despite the risk of respiratory depression. Unfortunately, concerns over adverse respiratory effects may lead to inadequate dosing and inadequate pain relief. To overcome this problem, alternative approaches, including use of patient-controlled analgesia, epidural analgesia, and intercostal nerve blocks, have been employed. These alternative techniques provide analgesia equivalent or superior to parenteral narcotics, but published data conflict as to how effective they are in reducing postoperative pulmonary complications.

Prophylaxis for thromboembolism is an important consideration, as discussed in Chapter 82.

Finally, careful monitoring for postoperative complications constitutes a key element in all surgical patients.

Several postoperative interventions have been shown to be ineffective, including the use of "blow bottles," carbon-dioxide–induced hyperventilation, chest physiotherapy in the absence of excessive secretions or sputum production, and routine application of positive end-expiratory pressure in mechanically ventilated patients.

Evaluation of Impairment and Disability Due to Lung Disease

Paul E. Epstein

Evaluation of disability due to pulmonary impairment is performed for a variety of reasons, including assessment of eligibility for government entitlement programs, litigation following a workplace injury, and evaluation of fitness for placement in a specific job. For purposes of the discussion that follows, the term *impairment* is used to denote a measurable decrease in normal organ function. The term *disability* is used to indicate the total effect that decreased function has on that person's ability to carry out activities of daily living, including the ability to work.

Most evaluations of pulmonary impairment are initiated when a worker complains that he or she can no longer perform the duties of a particular job that were previously accomplished without difficulty. Self-assessment of inability to work is almost always too subjective to be useful to organizations or government agencies that award disability benefits, and the subjective impression of the worker must be verified by a knowledgeable examiner. The worker's treating physician often provides important information about physical impairment, but it is common practice to seek additional evaluation from a specialist or subspecialist who performs an independent medical examination.

The information required for determining the degree of impairment and disability status depends on the purpose of the evaluation. For those seeking benefits under government-sponsored disability programs, the question is

simply whether or not the individual is able to take part in gainful employment. For litigation purposes, the critical questions are whether an employee has been injured on the job (and, if so, what is the severity and permanence of the injury), whether the injury has been totally disabling or whether another type of work is possible, and whether or not workplace restrictions are needed if work is resumed. For workers attempting to be placed in a particular job, the question is whether or not respiratory function is sufficient to perform the job successfully. Each of these questions should be answered as carefully as possible on the basis of objective data.

The need for independent medical assessment arises from a concern that many factors are in play when a claim for disability is filed. Some of these concerns arise because there is a need for standardization of disability criteria in fairness to others who are seeking disability benefits. To deal effectively with this concern, various professional organizations have published standards that are commonly used to estimate an applicant's degree of impairment and to assess the risks involved in performing a particular job.

Another reason for requiring independent assessment is that both the worker and the employer may bear significant financial impact from a determination of disability, and it is the physician's responsibility to provide an unbiased opinion of the severity of impairment.

Finally, claims of disability frequently arise from a workplace injury and evoke anger and other emotions that have little to do with the physical effects of the injury. Legal proceedings that often follow such an injury require that the evaluator identify the portion of the impairment that is attributable to loss of function and separate it from other extraneous issues. The physician must approach the evaluation process as an impartial observer whose primary role is to provide a scientific basis on which disability determination can be made. The physician must avoid taking the role of advocate for one party or another.

Pulmonary physicians play an important, but limited, role in disability evaluation that is confined to determining the worker's degree of pulmonary impairment. Clearly, there are gradations of impairment, and not all impairment leads to disability. In fact, disability determination requires knowledge not only of the impaired person's physical abilities, but also his or her education, skills, job experience, and the availability of appropriate work. Finally, determination of disability depends on the laws and regulations governing the award of benefits. Physicians are not usually expert in the entirety of this knowledge base.

This chapter reviews an approach to the evaluation of pulmonary impairment, the types of information that should be collected in an attempt to answer the pertinent questions, the standards used by various professional organizations to quantify the degree of impairment, and the major programs that use this information in coming to a determination of disability.

METHODS OF EVALUATING IMPAIRMENT

While the claimant or worker initiates the process of disability evaluation, the physician sets the framework for assessment of the degree of impairment. The primary goal in evaluating physical impairment is to provide an objective, valid, reliable, repeatable, and reproducible appraisal of the individual's respiratory condition. In this context, validity means that measurements made in the process of evaluation actually test meaningful aspects of physical capability. Reliability means that changes in the individual's condition will be accurately reflected in the results of appraisal. Repeatability means that there will be close agreement of results when successive measurements are performed using the same instrument, at the same sitting. Reproducibility means that if the tests are repeated by other observers at other times, the results will be similar (or at least within acceptable limits of variability).

The concept that a physician can evaluate an individual in a medical office and perform laboratory tests that provide meaningful information about his or her ability to perform specific tasks in the workplace makes many assumptions that are not strongly evidence-based. Ideally, the physician might achieve the best understanding of the claimant's physical capability by observing him or her perform the tasks necessary to carry out a particular job. Unfortunately, that type of observation is not practical and can not be standardized. For these reasons and others, it is important to understand that many compromises must be made in the evaluation procedure. While some government entitlement programs prescribe arbitrary criteria for eligibility for benefits, in general, the process of impairment evaluation is at least partially based on judgment that requires concordance of several lines of investigation. In the case of pulmonary evaluation, these include history and symptom review, physical examination, radiographic examination, and pulmonary function testing.

Medical History

In addition to documentation of prior medical conditions, an important part of the medical history, in the context of impairment/disability evaluation, is an applicant's occupational and exposure history. The examiner must carefully collect a chronological history of jobs held, specific job duties, time spent in each position, specific chemical or dust exposures encountered at each job site, and an accounting of accidental exposures or physical injury on the job. Many work-related abnormalities resemble other diseases and cannot be diagnosed correctly without a validated exposure history. Industrial facilities are required by the Occupational Safety and Health Administration (OSHA) to maintain material safety data sheets (MSDSs) on all chemicals used in the manufacturing process and to make them available to the employee upon request. These MSDSs can provide valuable help to the physician in evaluating the cause of pulmonary dysfunction.

Table 39-1

Medical Research Council Breathlessness Scale

Grade 1	Are you ever troubled by breathlessness except on strenuous exercise?
Grade 2	*If yes:* Are you short of breath when hurrying on the level or walking up a slight hill?
Grade 3	*If yes:* Do you have to walk slower than most people on the level? Do you have to stop after a mile or so (or after 30 min) on the level at your own pace?
Grade 4	*If yes to either:* Do you have to stop for a breath after walking about 100 yards (or after a few minutes) on the level?
Grade 5	*If yes:* Are you too breathless to leave the house or breathless after undressing?

Table 39-2

American Thoracic Society/Division of Lung Diseases Respiratory Symptoms Questionnaire

Mild	Do you have to walk more slowly on the level than people of your age because of breathlessness?
Moderate	Do you have to stop for a breath when walking at your own pace on the level?
Severe	Do you ever have to stop for a breath after walking about 100 yards or for a few minutes on the level?
Very Severe	Are you too breathless to leave the house or breathless on dressing or undressing?

The most common symptoms that lead to pulmonary impairment/disability evaluation are dyspnea, cough, and wheezing. Dyspnea is entirely subjective and is, therefore, difficult to quantitate. Nonetheless, it is of such importance that a number of dyspnea severity scales have been devised for its evaluation. Measurement of dyspnea is an attempt to discriminate between feelings of breathlessness that are experienced by normal people in performing physical tasks and the heightened feelings of air hunger experienced by people with disordered physiology performing the same tasks. One of the earliest and most useful dyspnea scales is the Medical Research Council Breathlessness Scale, which designates five progressively more severe grades of dyspnea based on the answers to questions about common activities of daily life (Table 39-1).

Another instrument that is widely used for evaluating the severity of dyspnea is based on the American Thoracic Society/Division of Lung Diseases Respiratory Symptoms questionnaire, shown in Table 39-2.

The usefulness of scales such as these is limited because of their frankly subjective nature, but the intensity of dyspnea should be consistent with other, more objective measures of respiratory impairment.

In the context of disability evaluation, cough and sputum production must be viewed as acute, subacute, or chronic, depending on the duration of the symptoms. By definition, acute cough lasts up to 4 weeks; subacute cough lasts between 4 and 12 weeks; and chronic cough lasts more than 12 weeks. Only the chronic forms of cough and sputum production are relevant with regard to disability evaluation.

Recognizing the fact that these symptoms can be important concomitants of disabling disease, two features must be recognized. First, it is difficult to quantitate the severity of cough and sputum production and, therefore, it is not easy to integrate them into a system of progressive gradation of disability. Second, they often accompany objectively quantifiable diseases such as asthma, chronic obstructive pulmonary disease (COPD), interstitial fibrosis, or diseases that are characterized by abnormalities on imaging studies, such as bronchiectasis, suppurative lung disease, or neoplasm. As a result, cough and sputum production should not be used as independent indicators of disability, but rather as signposts that help the physician identify what kind of objective evaluation will most likely lead to appropriate classification.

A history of wheezing, on the other hand, can provide important context for the evaluation of impairment. The temporal characteristics of the onset of wheezing, as well as its association with the workplace (or with particular exposures), often helps identify a specific cause of impairment. Wheezing that occurs primarily on workdays and improves during weekends or during vacations is highly suggestive of work-related asthma. The examiner should also be aware that some workplace exposures produce not only wheezing during work but may also cause repetitive nocturnal wheezing after the day's work has been completed. A history of wheezing that begins immediately after starting a new job implies a different kind of respiratory tract abnormality than a history that is characterized by a latency period between the date of employment and onset of wheezing. Each of these patterns can help the physician identify a particular cause of wheezing and can indicate methods appropriate for protecting the worker from ongoing respiratory tract injury.

Physical Examination

Even though the results of physical examination are less precise and less quantifiable than other techniques used in impairment/disability evaluation, for a variety of reasons this method of assessment retains value even in "high-tech" settings. First, the physician has a unique opportunity to assess the applicant's ability (and willingness) to function in normal circumstances and is better able to verify the reasonableness of laboratory findings. Since financial considerations are usually at stake in determinations of disability, physical examination provides an opportunity for the physician to identify malingering as a possible cause of abnormal test results. Second, physical examination often provides clues to alternative explanations for abnormal laboratory results that might be missed if only laboratory test results and imaging studies were considered. For example, a finding of conjunctival pallor on physical examination may lead to reevaluation of the significance of a diminished diffusing capacity on pulmonary function testing. Since pallor suggests anemia (a common, reversible cause of diminished diffusing capacity), as opposed to intrinsic pulmonary disease (commonly due to irreversible causes of decreased diffusing capacity, such as pulmonary fibrosis or emphysema), physical examination may add value to pulmonary function testing. Third, physical examination can help direct attention to additional causes of physical impairment that were previously unrecognized. Careful cardiac assessment often uncovers evidence of extrapulmonary disease that helps explain complaints of dyspnea. On the other hand, pursed-lip breathing, a barrel-shaped chest, inspiratory crackles, expiratory wheezing, and digital clubbing remain valuable diagnostic observations that help verify the pulmonary origin of respiratory complaints and abnormal pulmonary function test results.

Imaging Studies

A routine chest radiograph remains the most widely used and universally accepted imaging study in the diagnosis of pulmonary impairment resulting from pneumoconiosis, despite the fact that radiographic findings correlate poorly with physiological abnormalities or functional ability. The International Labor Organization (ILO), a specialized agency of the United Nations, first published the ILO International Classification of Radiograph of Pneumoconioses in 1950 as an epidemiologic tool to standardize radiographic interpretation of dust-related lung diseases. This classification system was subsequently revised in 1980 and in 2000. It has been adopted as a standard for the presence and severity of pneumoconiosis by many government disability programs, both in the United States and in other countries. The National Institute of Occupational Safety and Health (NIOSH) offers a certification examination to practitioners wishing to qualify as experts in the ILO system (B Reader certification).

Computed tomography of the chest is generally accepted as more sensitive in detecting both pleural and pulmonary parenchymal abnormalities than plain films of the chest. However, it is much more expensive and administers a higher radiation dose than plain film radiography. High-resolution computed tomography (HRCT) of the chest has proven to be extremely helpful in the differential diagnosis of interstitial lung disease. Like the plain film, correlation between HRCT findings and functional measures are not strongly evidence-based. Despite its clear-cut diagnostic value, HRCT has not been adopted as a standard for disability evaluation.

Pulmonary Function Testing

Most of the standard evaluation schemes for impairment/disability evaluation depend on relatively simple pulmonary function testing. Spirometry and diffusing capacity measurements are generally accepted as appropriate criteria upon which functional judgments are made, since the severity of airways obstruction and abnormalities of gas transfer have been most reliably associated with decreased ability to function in activities of daily living and in the ability to work. Furthermore, these simple tests fulfill requirements that equipment used for testing be widely accessible and that adequate standards for repeatability and reproducibility be met. The American Thoracic Society (ATS) periodically publishes requirements for standardization of equipment and test interpretation. The most recent ATS statements were published in association with the European Respiratory Society (ERS) and have gained worldwide acceptance.

In addition to standardization of both the equipment and techniques of test administration, an important issue in pulmonary function interpretation is the choice of an appropriate normal reference population against which the test taker is compared. Many large populations of normal subjects have undergone pulmonary function testing and have been used to develop reference values for this purpose. Current recommendations of the ATS/ ERS task force suggest that prediction values be chosen on the basis that the reference population is of a similar age range and has the same anthropometric, racial, ethnic, socioeconomic, and environmental characteristics as the individuals being tested. The individual being tested should be asked to self-identify his or her own racial or ethnic group. Although it is most desirable to match the person being tested to an ethnically similar reference group, if none is available an adjustment factor, based on published data, may be used for volume measurements. Various adjustment factors have been recommended for use in these circumstances, since African Americans and Asians have been noted in a number of large surveys to have somewhat smaller lung volumes than Caucasians (about 12 percent and 6 percent smaller, respectively). Hence, individuals may be incorrectly classified as having abnormal pulmonary function as a result of the wrong reference values having been chosen. No race adjustment should be made for the ratio of forced expiratory volume in 1 second to the forced vital capacity percent (FEV_1/FVC%) prediction.

Arterial Blood Gas Analysis

Arterial blood gas testing is rarely used by itself as a criterion of impairment since the test is more invasive than other, more common methods of evaluation. Furthermore, abnormalities of pulmonary function are usually present in association with blood gas abnormalities. Resting hypoxia is sometimes used as a modifying factor in adjusting the assessment of severity of impairment. If arterial blood gas analysis is used as a criterion of disability (as in the Black Lung program), the altitude at which the measurements are made must be specified and abnormal studies must be repeated at an interval of at least 3 to 4 weeks.

Cardiopulmonary Exercise Testing

Cardiopulmonary exercise testing (CPET) is sometimes helpful in evaluating impairment, particularly in individuals whose pulmonary function is moderately abnormal, but whose symptoms are more severe than would be expected from the results of routine testing. Both the ATS and the American Medical Association (AMA) support use of CPET in selected circumstances and provide criteria for impairment based on the results. CPET is seldom helpful when routine pulmonary function tests are either normal or severely abnormal, since the results do not affect determination of disability.

The other circumstance in which CPET is helpful is in assessing the ability of the subject to perform a specific job. Maximum oxygen uptake ($\dot{V}_{O_2max}$) measured during CPET is used to determine the maximum peak exercise level that the individual can achieve. Many experts assume that a worker can perform sustained exertion to a level of approximately 35 to 40 percent of their $\dot{V}_{O_2max}$, although this assumption is not firmly evidence-based. A number of investigators have published estimates of the energy requirements for various jobs, and these can be used to judge the likelihood that an individual is able to perform a specific occupational function. A full description of performance techniques and methods of interpretation of CPET is provided in Chapter 35. The ATS and the American College of Chest Physicians have published a joint consensus statement on the subject.

Bronchoprovocation Testing

Bronchoprovocation testing is a method of evaluating bronchial hyperreactivity in individuals who are suspected of having asthma. The method is important in impairment/disability evaluation because occupational asthma, the presence of which may have significance in judging ability to continue certain types of employment, may not be apparent on routine pulmonary function testing performed between attacks. Evaluation schemes of both the AMA and the ATS take bronchial hyperreactivity into account in assessing impairment. The ATS has published guidelines for performing methacholine bronchial challenge studies and interpretation of the results (see Chapter 34).

AMA GUIDES TO THE EVALUATION OF PERMANENT IMPAIRMENT

The American Medical Association (AMA) has developed guidelines for assessing physical impairment that are widely accepted by governments and legal systems as the standard of evaluation for loss of physical function. These guidelines are continually updated by expert panels that are convened by the AMA and published periodically in book form under the title, "Guides to the Evaluation of Permanent Impairment." Most state workers' compensation programs in the United States, as well as the federal governments of many other countries, use the AMA standards in assessing an individual's ability to work.

According to the AMA Guides, impairment is defined as "a loss, loss of use, or derangement of any body part, organ system, or organ function." It should be obvious from such a broad definition of impairment that not all impairments lead to inability to perform activities of daily living or inability to take part in occupational activities. However, identification of a specific impairment allows the evaluator to initiate an impairment rating that estimates the percentage of loss of function of a particular organ.

Varying percentages of lost function are grouped into four severity classes. Class 1 constitutes 0 percent functional loss (for instance, an observable abnormality caused by an anatomic variation); class 2 indicates that there is objective evidence for a 10 to 25 percent impairment of the whole person as result of organ dysfunction; class 3 indicates a 26 to 50 percent impairment of the whole person; and class 4 is 51 to 100 percent impairment of the whole person. In other words, according to the AMA Guides, impairment rating requires that the evaluator first recognize that an abnormality is present, then identify the cause of the abnormality and objectively evaluate the severity of deviation from normal function, and finally, translate the severity of dysfunction into a numerically based classification that estimates how much of an effect the organ dysfunction has on the individual's ability to carry on the activities of daily living.

Evaluation of the severity of impairment is largely based on results of easily obtainable pulmonary function tests that include spirometry and diffusing capacity. Studies must be performed after the individual has achieved maximal medical improvement and is judged to be in stable condition. If possible, respiratory medications are discontinued 24 hours prior to testing. Spirometry is performed initially; if the $FEV_1/FVC\%$ is below 70, the test is repeated following administration of an inhaled bronchodilator. The equipment, its calibration, test performance, and methods of interpretation must conform to recommendations of the ATS Statement on Standardization of Spirometry. Diffusing capacity measurement is also performed according to ATS recommendations. Physicians evaluating physical impairment using the AMA Guides may also use cardiopulmonary exercise studies. Levels of oxygen consumption required to perform various intensities of work have been published and are used in

Table 39-3

Impairment Classification for Respiratory Disorders

Pulmonary Function Test	Class 1 0% Impairment of the Whole Person	Class 2 10%–25% Impairment of the Whole Person	Class 3 26%–50% Impairment of the Whole Person	Class 4 51%–100% Impairment of the Whole Person
FVC	≥ lower limit of normal	≥60% of predicted and < lower limit of normal	≥51% and ≤59% of predicted	≤50% of predicted
FEV_1	≥ lower limit of normal	≥60% of predicted and < lower limit of normal	≥41% and ≤59% of predicted	≤40% of predicted
FEV_1/FVC%	≥ lower limit of normal	N/A	N/A	N/A
$D_{L_{CO}}$	≥ lower limit of normal	≥60% of predicted and < lower limit of normal	≥41% and ≤59% of predicted	≤40% of predicted
$\dot{V}_{O_2max}$	≥ 25 ml/kg/min or >7.1 METS	≥20 and < 25 ml/kg/min or 5.7–7.1 METS	≥15 and < 20 ml/kg/min or 4.3–5.7 METS	<15 ml/kg/min or <1.05 L/min or <4.3 METS

FVC, forced vital capacity, FEV_1, forced expiratory volume in 1s; D_{LCO}; diffusing capacity of the lung for carbon monoxide; $\dot{V}_{O_2max}$, maximum oxygen uptake.

the AMA Guides to classify levels of impairment. Table 39-3 shows the rating impairment method based on AMA Guides. Several specific pulmonary disorders merit special consideration with regard to the Guides.

Asthma

Standard criteria for classification of respiratory impairment are most easily developed for diseases that cause a fixed level of lung damage, producing decrements in pulmonary function that can be measured reproducibly by serial pulmonary function testing. However, asthma is a disorder that is defined by variability over time, with airflow obstruction that may revert toward normal, either spontaneously or as a result of medication administration. As a result, individuals with even moderately severe asthma may appear normal by pulmonary function testing during periods between exacerbations. This unique variability in lung function in asthma creates difficulty for the physician attempting to evaluate a particular level of impairment caused by the disease, especially if the evaluation is performed during a period of quiescence.

Asthma occupies a unique niche among the disorders which prompt an assessment of respiratory impairment and disability evaluation. Asthma affects about 5 percent of the entire population of the United States and is responsible for substantial amounts of time lost from work and school. The attendant economic impact is huge. No matter what the underlying cause of asthma, frequent attacks degrade quality of life and are a common cause of inability to work.

Workplace exposures frequently exacerbate an underlying asthmatic condition (work-related asthma) or cause sensitization of the respiratory tract to materials found uniquely in the workplace (occupational asthma). Previous attempts to classify the level of impairment caused by asthma have depended on historical assessment of the number of exacerbations per year, as indicated by hospitalizations or unscheduled visits to the physician's office. Unfortunately, this type of assessment introduces extraneous variability into the objective process of standardization of disease severity that results from differences in the patient's ability to self-manage exacerbations, the primary care physician's knowledge, and the emergency room's guidelines for managing acute asthmatic attacks.

In the interest of standardizing evaluation of asthma severity, the AMA Guides incorporate the objective evaluation criteria previously published by the ATS. The AMA Guides assign percentage impairment ratings according to the criteria. In addition to providing more objective standards for judgment, the new AMA classification system for asthma offers the additional advantage that evaluation can be performed during periods of stability, even if spirometry is normal at the time of testing.

Table 39-4

Impairment Classification for Asthma Severity

Score	Postbronchodilator FEV_1	% FEV_1 changes after bronchodilator	PC_{20} (mg/ml)	Minimum Medication Needed
0	≥ lower limit of normal	<10%	>8 mg/ml	No medication
1	≥70% of predicted	10%–19%	8 mg/ml to >0.6 mg/ml	Occasional, but not daily, bronchodilator and/or occasional, but not daily, cromolyn
2	60%–69% of predicted	20%–29%	0.6 mg/ml to ≥0.125 mg/ml	Daily bronchodilator, and/or daily cromolyn, and/or daily low dose inhaled corticosteroid (≤ 800 μg of beclomethasone or equivalent)
3	50%–59% of predicted	≥30%	<0.125 mg/ml	Bronchodilator on demand and daily high-dose inhaled corticosteroid (> 800 μg of beclomethasone or equivalent), or occasional course (1–3 courses per year) of systemic corticosteroid
4	< 50% of predicted	N/A	N/A	Bronchodilator on-demand and daily high-dose inhaled corticosteroid (> 1000 μg of beclomethasone or equivalent), and daily or every-other-day systemic corticosteroid

FEV_1, forced expiratory volume in 1 s; PC_{20}, concentration of methacholine required to decrease FEV_1 by at least 20%.

Using the AMA Guides, four types of information are evaluated in assessing impairment from asthma: (1) postbronchodilator FEV_1, (2) percentage change in FEV_1 following bronchodilator administration, (3) results of bronchoprovocation testing, and (4) assessment of the minimal amounts of medication required to keep the patient's asthma under control.

Postbronchodilator FEV_1 values denoting levels of increasing severity of asthma are shown in Table 39-4 and range from the lower limit of normal to less than 50 percent of predicted. If the FEV_1 is less than 70 percent of predicted, additional evaluation is based on the percentage of reversibility of FEV_1 following bronchodilator administration.

When the FEV_1 is greater than the lower limit of normal, bronchoprovocation testing is performed. Both the ATS and AMA methods of evaluating asthma severity take advantage of the fact that even when there is no active bronchospasm, asthmatic airways show nonspecific hyperresponsiveness to irritant materials, including dust, smoke, and certain chemicals (e.g., methacholine and histamine).

If the results of spirometry are initially normal, methacholine bronchoprovocation testing is performed and the degree of bronchial hyperresponsiveness classified according to the concentration of methacholine required to decrease the FEV_1 by at least 20 percent—a measurement known as the PC_{20}.

A final criterion for asthma severity depends on the minimum amount of medication required to keep the disease under control. Disease requiring higher amounts of medication and systemic corticosteroids is considered more severe.

The evaluating physician calculates an asthma impairment score by adding the numerical values assigned to the results of measurements of postbronchodilator % change in FEV_1 (or PC_{20}), and minimum medication requirement. The total score is used to assign an impairment class, as shown in Table 39-5.

Classification of Impairment Resulting from Other Pulmonary Diseases

Special criteria are applied by the AMA Guides to certain pulmonary diseases that are influenced by factors other than decrements in pulmonary function.

Table 39-5

Impairment Rating for Asthma

Total Asthma Score	Impairment Class	% Impairment of the Whole Person
0	I	0
1–5	II	10–25
6–9	III	26–50
10–11, or asthma not controlled despite maximal treatment (i.e, $FEV_1 < 50\%$ despite use of prednisone at >20 mg/day)	IV	51–100

Lung Cancer

Patients with lung cancer are presumed to be severely impaired (class 4) for at least 1 year following diagnosis, even if surgical resection appears to have been successful in curing the disease. If, 1 year after diagnosis, the patient continues to show no evidence of persistence or recurrence of the disease, reevaluation according to the criteria provided in Table 39-5 may lead to reclassification at a lower level of impairment. Any evidence of recurrence of lung cancer mandates retention of a classification of severe impairment.

Hypersensitivity Pneumonitis

Hypersensitivity pneumonitis may produce no permanent pulmonary impairment if the disease is recognized early in its course and the affected person is removed from exposure to the causative material (usually a high-molecular-weight organic dust, but occasionally, a low-molecular-weight chemical). Even when there has been timely resolution of the pulmonary function abnormality, individuals with a history of hypersensitivity pneumonitis should be permanently removed from exposure. Subacute and chronic forms of the disease caused by repeated exposures often produce pulmonary fibrosis that results in restrictive lung disease. An obstructive component in the subacute and chronic forms of the disease may also be observed. Abnormalities may become permanent features of impairment and should be assessed according to the criteria provided in Table 39-3.

Pneumoconiosis

Pneumoconiosis resulting from exposure to a variety of inorganic dusts that produce pulmonary fibrosis (e.g., asbestos, silica, or coal dust), or those producing granulomatous disease and fibrosis (e.g., beryllium), usually alter pulmonary function in a manner that can be assessed by pulmonary function testing and are classified according to criteria provided in Table 39-3.

Although not all cases of pneumoconiosis are associated with physiological impairment, the AMA Guides suggest that recognition of a pneumoconiosis should prompt the physician to recommend limitation of further exposure to the causative material. In the cases of silicosis and coal workers' pneumoconiosis, development of disease depends on the dust burden in the lung and pathological progression that occurs long after exposure has ceased. In fact, the latency period between exposure and disease manifestation is measured in decades, rather than years, so that failure to remove a worker from further exposure to the responsible dusts may progressively increase the risk of worsening disease. Therefore, in order to avoid further accumulation of dust in lung tissue, recognition of radiologic manifestations of these diseases should prompt removal from mining employment, particularly in relatively young individuals.

Berylliosis

Chronic beryllium disease causing pulmonary fibrosis is mediated by an immune process and is not necessarily dependent on total dust burden in the lung. Regardless of whether a beryllium worker has abnormalities of pulmonary function that fulfill AMA criteria for impairment, once a diagnosis of chronic beryllium disease is made, the evaluating physician should recommend complete cessation of beryllium exposure, since even small amounts may cause further pulmonary fibrosis.

Obstructive Sleep Apnea

Although individuals with obstructive sleep apnea characteristically have daytime somnolence and may have cognitive defects that make adequate work performance difficult, well-documented criteria that provide guidance in determining fitness for employment are lacking. The AMA Guides recommend that impairment determination be left to the judgment of a sleep specialist.

AMERICAN THORACIC SOCIETY CRITERIA FOR EVALUATION OF IMPAIRMENT OR DISABILITY

The American Thoracic Society (ATS) has published a series of guidelines and official statements regarding performance and interpretation of pulmonary function testing. The last ATS statement that was specifically devoted to the general subject of impairment/disability criteria was published in 1986. Since that time, several updates of portions of the statement dealing with the evaluation of pulmonary function test interpretation and asthma, partially in the context of the evaluation

of disability, have been published. In general, the AMA has adopted standards of impairment that have been published by the ATS.

The ATS assigns severity ratings to specific results of spirometry and diffusing capacity, but it does not assign percentage impairment ratings. According to ATS criteria, pulmonary impairment is considered mild if the FEV_1 is greater than 70 percent predicted (but less than the lower limit of normal, based on 95 percent confidence intervals); moderate if it is 60 to 69 percent predicted; moderately severe if it is 50 to 59 percent predicted; severe if it is 35 to 49 percent predicted; and very severe if it is less than 35 percent predicted. On the other hand, FEV_1% predicted does not correlate well with the severity of upper-airway obstruction and may underestimate the severity of obstruction in very severe COPD. Furthermore, FEV_1% predicted correlates poorly with symptoms.

The degree of severity of a decrease in diffusing capacity is judged to be mild if the value obtained is less than the lower limit of normal, but greater than 60 percent predicted; moderate if it is between 40 and 60 percent predicted; and severe if it is less than 40 percent predicted. The ATS acknowledges the fact that, in general, the level of pulmonary function is related to the ability to work and function in daily life. The level of pulmonary function is also recognized as having an association with morbidity and prognosis.

Standards of impairment evaluation for asthma published by the ATS in 1993 form the basis for impairment ratings adopted in the AMA Guides in 2000. Since that time, the ATS has updated its own guidelines for assessing and managing asthma.

DISABILITY EVALUATION UNDER SOCIAL SECURITY

The United States Social Security Administration has two programs that provide financial and rehabilitative benefits to disabled individuals. Both programs require objective demonstration of disability using medical standards set forth in the Social Security Act. Importantly, the standards for disability required by the Social Security Administration are not necessarily the same as those required by other federal programs. Furthermore, while Social Security criteria for disability are uniform across all states, they differ markedly from the criteria developed by each individual state in regard to workers' compensation programs. In addition, they are quite different from those endorsed by insurance companies from which many people purchase policies.

The Social Security Act provides two pathways by which individuals can access disability benefits. The first is through Title II of the act (known as Social Security disability insurance); this is a program that is available to individuals who are insured as a result of their contributions to the Social Security trust fund (through taxes on employment earnings during their work careers). The second is through Title XVI of the act (known as supplemental security income, or SSI); this program is available to disabled individuals who have limited income or resources but, who, for one reason or another, are not covered by contributions to the Social Security trust fund.

For adults, the definition of disability is the same whether application for benefits is made under Title II or Title XVI of the Social Security Act. The Social Security Administration defines disability as "the inability to engage in any substantial gainful activity by reason of any medically determinable physical or mental impairment(s) which can be expected to result in death or which has lasted or can be expected to last for a continuous period of not less than 12 months."

The methods used for disability evaluation under Social Security are important for the physician to understand for two reasons: first, because it is a common and important source of financial support for many patients who are under the care of pulmonary physicians, and second, because the pulmonary physician often takes an active role in helping determine eligibility. Unlike workers' compensation programs, the cause of disability is not relevant in awarding benefits. The sole criterion for granting benefits is whether or not the claimant is able to participate in gainful employment.

Evaluation of disability under Social Security is a staged process, beginning with application to a local Social Security field office or the Office of Disability Determination Services (DDS). The DDS gathers objective medical information primarily from the treating physician (who is the preferred source of medical evaluation). If the available information is insufficient to make a determination of disability, the DDS may purchase additional testing and examination from a consultative examiner (CE), such as a pulmonary physician.

The Social Security Administration has decided that certain specific impairments of each major body system are severe enough to prevent a person from engaging in any gainful employment and, therefore, serve as prima facie evidence that disability exists. These impairments have been codified and are known as the Listings of Impairments. Listings include specific severities of abnormalities for various diseases, including COPD; chronic restrictive ventilatory disease; chronic impairment of gas exchange; asthma; cystic fibrosis; pneumoconiosis; bronchiectasis; mycobacterial, mycotic, and other chronic persistent infections of the lung; and cor pulmonale due to chronic pulmonary vascular hypertension.

If a claimant cannot meet the severity criteria of the Listings, he or she may still receive award of benefits by presenting the medical information pertinent to his or her case to the DDS. An initial judgment may then be made by the DDS, but the claimant has the right to challenge an unfavorable decision and to have it reviewed by other members of the DDS staff. If the decision is still unfavorable, the claimant may appeal to the Office of Hearings and Appeals for review by an administrative law judge, who may request expert physician testimony before making a decision. Once again, the claimant can request that an unfavorable decision be reviewed by an appeals council.

SOCIAL SECURITY LISTINGS

An examination of the criteria that determine eligibility for Social Security benefits according to the Listings is helpful in understanding the process.

Chronic Obstructive Pulmonary Disease

In order for COPD to fulfill criteria for the Social Security Listings, the measured FEV_1 must fall at or below the values shown in Table 39-6.

Asthma

Claimants with asthma can meet the Listings criteria either on the basis that they fulfill the pulmonary function abnormalities noted previously for COPD, or because the severity of their disease is such that it requires physician intervention at least six times a year, despite following a prescribed therapeutic regimen. Inpatient hospital treatment lasting more than 24 hours is viewed as equal to two attacks requiring physician attention.

Restrictive Lung Disease

For chronic restrictive ventilatory disease, the FVC must be equal to or less than the values shown in Table 39-7.

Abnormalities of Gas Exchange

In order to reach the severity required for inclusion under the listings for chronic abnormalities of gas exchange, the single breath D_{LCO} must be less than 10.5 ml/min/mmHg or less than 40 percent of the predicted normal value.

Arterial blood gas abnormalities are also considered valid indicators for Social Security Listings, as long as they are performed in the prescribed manner and indicate the required severity of pulmonary disease. Simultaneously, measurements of Pa_{O_2} and Pa_{CO_2} using arterial blood gas analysis must be performed with the claimant at rest and in stable condition. He or she must be awake and in a sitting or standing position. Furthermore, arterial blood gas analysis must be performed on two occasions which are at least 3 weeks apart but within 6 months of one other. The arterial blood gas results must also be interpreted with recognition of the altitude at which they were obtained. With these requirements in mind, a claimant will meet the Listings if arterial blood gas findings are equal to or less than those shown in Table 39-8. Of note is the fact that according to the Listings, measurement of pulse oximetry is not accepted as prima facie evidence of severe pulmonary disease.

Pneumoconiosis

In order for a person to meet the Listings criteria for pneumoconiosis, a radiographic diagnosis must first be made according to appropriate imaging techniques. The severity of the disease is then judged on the basis of the functional deficits shown in Tables 39-6, 39-7, and 39-8, for obstructive disease, restrictive disease, or abnormal gas exchange.

Cystic Fibrosis

Patients with cystic fibrosis qualify for benefits under the Listings if they have an FEV_1 that is less than or equal to the

Table 39-8

levels listed in Table 39-9; or if they have episodes of bronchitis, pneumonia, hemoptysis, or respiratory failure that require physician intervention at least six times annually (one hospitalization for more than 24 hours counts as two outpatient visits); or if there is persistent pulmonary infection with symptomatic episodes requiring intravenous or nebulized antibiotic therapy at least every 6 months.

Cor Pulmonale Due to Chronic Pulmonary Vascular Hypertension

Qualification for benefits under the listings for patients with cor pulmonale requires clinical evidence of the disease and either a measured mean pulmonary artery pressure greater than 40 mmHg or arterial hypoxemia to the levels shown in Table 39-8.

Mycobacterial, Mycotic, and Other Chronic Persistent Infections of the Lung

These diseases meet standards for inclusion under the listings only when the degree of functional abnormality reaches the levels outlined previously for obstructive disease, restrictive disease, or abnormalities in gas exchange (Tables 39-6, 39-7, and 39-8).

STATE WORKERS' COMPENSATION PROGRAMS

Until the early part of the twentieth century, US federal and state-based programs to compensate workers for injuries sustained on the job did not exist. The only legal recourse available to a worker injured on the job was to sue his or her employer through the usual tort system of the courts. Such legal proceedings were often heavily weighted in favor of the employer. Worse still, the legal concept of occupation-related disease (as opposed to occupational injury) was not widely recognized by the courts at that time.

As the Industrial Revolution became progressively more established in Europe and the United States during mid- and late nineteenth century, however, the problem of workplace injuries and occupation-related diseases became ever more important as large numbers of workers left the farm for urban employment in factories and other industrial environments where they were frequently adversely affected by working conditions. By the late nineteenth century, Great Britain had passed legislation that afforded some protection to injured workers, and a few decades later the United States followed suit by passing legislation modeled on the British system. However, because the US Supreme Court at that time interpreted the US Constitution as forbidding federal legislation from covering private-sector employers, the federal government kept workers' compensation legislation at arms' length, leaving each state to work out its own solution to the

problem. As a result, significant variations occurred from state to state in the details of coverage and management systems for workers' compensation, with legislation that was enacted at varying times in a pattern that formed what was essentially a patchwork quilt that eventually covered all 50 states.

Despite the history of independent development of legislation in each state, certain unifying concepts emerged in the way state programs were crafted. In each state, concepts of coverage were hotly contested on the one hand by powerful industrial concerns and on the other hand by labor unions which had recently found their voice in the formation of a strong labor movement. One of the concepts, finally accepted by all stakeholders, marked a dramatic change in the way claims were handled.

In what amounted to an epiphany of understanding between the parties, the interaction between the employer and the injured employee changed from a frankly adversarial relationship to a no-fault system that focused on providing help to the injured employee without consideration of which party was at fault in causing the injury. Both the employer and the employee had to give up certain rights in order to develop a system that would fairly serve all parties. The employee gave up almost all rights to sue the employer for workplace injuries, but, in return, received automatic acceptance of the right to receive free medical care for the immediate injury, cash benefit payments during the period of disability, and rehabilitation services to facilitate a return to work. These services are commonly provided through insurance carriers that sell workers' compensation policies to employers.

Most states require the employer to purchase insurance coverage for their workers, although some states maintain a workers' compensation pool (which the employer can purchase from the state), and some states allow large companies to self-insure. The employer usually has the right to maintain a panel of physicians who evaluate injured employees. In most states, the employee has the right to choose his or her treating physician, but the rates of payment to the physician may be set by law. If the employee has lost time from work as a result of injury, cash benefits are paid for temporary disability according to a formula that varies from state to state with regard to payment size and period of time allowed for each type of disability. Benefits may be awarded for temporary total disability, permanent partial disability, or permanent total disability. Some cash payments are known as "scheduled" losses if they involve injuries, such as loss of arms, hands, fingers, legs, feet, toes, eyes, and ears, while others are "nonscheduled," such as injuries to lungs, heart, back, and so forth. Most states use the classification system of the AMA Guides to the Evaluation of Permanent Impairment (described in detail above) to determine the severity of nonscheduled losses.

FEDERAL WORKERS' COMPENSATION

The first legislation to providing workers' compensation for civilian federal employees to pass the test of constitutionality by the US Supreme Court was signed into law by President Theodore Roosevelt in 1908. However, this program was extremely limited in both scope and benefits and was restricted to very hazardous jobs. Not until 1916 was more comprehensive legislation covering civilian government employees passed in the form of the Federal Employees' Compensation Act. The legislation is administered by the Office of Workers' Compensation Programs. Subsequently, a few additional federal programs were passed by Congress, including the Merchant Marine Act, Longshore and Harbor Workers' Compensation Act, Black Lung Benefits Act, and Energy Employees' Occupational Illness Compensation Program Act. The last two programs are of particular interest to pulmonary physicians because the programs deal specifically with occupational lung diseases, and because the criteria for awarding benefits are radically different from one another.

BLACK LUNG BENEFITS

The federal Black Lung program grew out of the federal Coal Mine Health and Safety Act of 1969. This act was modified by the Black Lung Benefits Act in 1972, which set eligibility criteria for the award of benefits; the act since has been amended several times. While providing funding for benefits is primarily the responsibility of the mining company responsible for the injury, it is not unusual in the coal mining industry to find that either the company had gone out of business or that no specific mine can be identified as responsible. The Black Lung Benefits Revenue Act, therefore, set up a trust fund, funded by an excise tax on coal that was mined and sold in the United States. Eventually, management of the Black Lung program became the responsibility of the US Department of Labor, administered through the Office of Workers' Compensation Programs, Division of Coal Mine Workers' Compensation.

A coal miner applying for Black Lung benefits must supply to the Division of Coal Mine Workers' Compensation medical evidence of pneumoconiosis, including the following: a chest radiograph, along with a report of the findings using the International Labor Organization (ILO) classification system; a report of physical examination detailing the occupational and medical history as well as all manifestations of chronic respiratory disease; pulmonary function test results; and arterial blood gas results. The submitted chest radiograph should fulfill the ILO criteria for radiographic quality and must be interpreted as showing at least category 1/0 pulmonary parenchymal interstitial abnormalities, indicating pneumoconiosis (according to the ILO International Classification of Pneumoconioses). Preferably, the chest radiograph should be interpreted by a NIOSH-certified B Reader or a board-certified or board-eligible radiologist. Pulmonary function tests, recorded as flow-volume loops, must provide measurements of FVC and FEV_1 and calculation of the FEV_1/FVC ratio. Measurements of maximal voluntary ventilation (MVV) may also be used to support a claim for disability. Arterial blood gas analysis is initially performed at

rest, but if the results do not fulfill criteria for disability, the study may be repeated during exercise.

The Department of Labor has published detailed tables of spirometric and arterial blood gas values delineating criteria for total disability. For example, according to the tables, a 55-year-old male who is 5' 10" tall is considered totally disabled if the FVC is less than or equal to 2.71 L, or the FEV_1 is less than or equal to 2.14 L. At any age or height, the applicant is considered totally disabled if the FEV_1/FVC% is less than or equal to 55 percent, or the $PaO_2$is 60 mmHg or less (at sea level, with the $PaCO_2$ between 40 and 49 mmHg).

Importantly, for the purposes of the Black Lung Benefit Act, pneumoconiosis is defined as "a chronic dust disease of the lung and its sequelae, including respiratory and pulmonary impairments arising out of coal mine employment." Included in this definition are not only the diseases that chest physicians usually consider as pneumoconioses (e.g., coal workers' pneumoconiosis, anthracosis, anthracosilicosis, massive pulmonary fibrosis, silicosis, or silicotuberculosis), but also what the act notes as "legal pneumoconiosis" (i.e., any chronic restrictive or obstructive pulmonary disease arising out of coal mine employment).

ENERGY EMPLOYEES' OCCUPATIONAL ILLNESS COMPENSATION PROGRAM ACT

The Energy Employees' Occupational Illness Compensation Program Act (EEOICPA) was signed into law in 2000 and provides benefits to workers who have acquired disease in the course of their work in the nuclear defense industry. This includes employees and former employees of the Department of Energy at nuclear weapons factories, as well as private contractors and subcontractors who supplied the facilities. The two major toxic exposures encountered by these workers include beryllium (used in the manufacture of ballistic missile nose cones) and radiation. Chronic beryllium disease, as a result of exposure to beryllium dust, produces a granulomatous disease of the lungs that commonly causes progressive pulmonary fibrosis. Radiation exposure is a major cause of cancer, including lung cancer. In contradistinction to Black Lung evaluation, the EEOICPA has adopted the standards of the AMA Guides to the Evaluation of Permanent Impairment as the method of rating impairment and disability.

AMERICANS WITH DISABILITIES ACT

Although many physicians think of impairment assessments as inquiries that follow an injury or are conducted at the end of employment, in reality, some of the most important assessments of physical abilities are made at the start of a job. Until relatively recently, people with any type of physical impairment were excluded from employment because of unreasonable fear that an impaired employee would be a detriment in the workplace. The Americans with Disabilities Act (ADA), which was enacted in 1992, produced a fundamental change in the way physical impairments are viewed within the business and legal communities.

Many of the regulations established by the ADA deal with the removal of physical barriers that prohibit impaired workers from entering and functioning within the workplace. Others are specifically directed at removing bias and prejudice from the opportunity to enter the workforce itself. While the ADA has not altered the methods of impairment evaluation used by physicians, it does have a substantial impact on the timing of evaluations and the way these evaluations are reported and used. For instance, while pre-employment physical examinations were commonly requested by industrial and commercial firms prior to enactment of the ADA, they are no longer allowed, due to the perceived risk that a qualified individual might be excluded from employment because of an impairment that has little or nothing to do with the requirements of the job. Prior to making a job offer, employers are no longer allowed to ask if a prospective employee has a physical impairment, although they may ask if he or she can perform the duties of the job. Once a job offer is made and accepted, physical examination is permissible to confirm that the job can be performed in a safe and acceptable manner. In fact, the employer is legally permitted to make a job offer conditional on the applicant passing a physical examination, as long as the same physical requirements are required for every employee in the same job category. These examinations, known as pre-placement physicals, must deal only with job-related issues and must be consistent with business necessity.

The other major change in the determination of work-related physical fitness is that businesses are required to make reasonable accommodation for physical impairments as long as the impairments do not interfere with the essential requirements of the job.

The two concepts of forbidding non–job-related impairment to preclude employment and of making reasonable accommodation for the presence of a non-essential disability can be illustrated in the following scenarios.

Consider a prospective employee who has severe COPD, with an FEV_1 of 50 percent predicted and D_{LCO} of 59 percent predicted; the individual has no history of recurrent infections or excessive absences from work. On the basis of his physical condition, this individual cannot be excluded from a job as an accountant, but he might legally be denied a physically demanding job, such as a firefighter, who must regularly carry heavy equipment into smoke-filled buildings and climb many flights of stairs. The essential work of an accountant does not involve physical exertion, and the applicant's physical condition would not adversely affect his performance in the workplace. On the other hand, the work of a firefighter would be dangerous to a person with severe pulmonary disease.

As a second example, consider a prospective employee who has the same pulmonary function tests as noted in the first scenario. The individual applies for a position in a factory

where the main job responsibility is watching the flow of products on a conveyor belt and pressing a stop button if a malfunction arises. Once a day, the employee is required to lift to shoulder height a 75-pound bag. While it would be difficult for the employee to perform the lifting activity, a reasonable accommodation would be either to provide help from another employee, or to install a hydraulic lifting device. Employers are not, however, required to make unreasonably extensive changes to a work area or to undertake "action requiring significant difficulty or expense" in order to accommodate an otherwise qualified applicant.

CHAPTER

Pathologic Features of Chronic Obstructive Pulmonary Disease: Diagnostic Criteria and Differential Diagnosis

Joanne L. Wright • Andrew Churg

Chronic obstructive pulmonary disease (COPD) is a general name for the chronic airflow obstruction that develops most often as a result of chronic tobacco smoking. The pathology of COPD encompasses a variety of pathologic lesions in the airways, lung parenchyma, and pulmonary vasculature, and these lesions can be correlated, to a greater or lesser degree, with changes in pulmonary function tests and clinical appearances. In general, although the mechanisms involved are complex, airflow obstruction can be attributed largely to a marked increase in airways resistance secondary to a variable mix of structural abnormalities involving all or many of the compartments of the airway. However, in individual cases, it

may be difficult to prove associations between physiological abnormalities and pathologic changes. The recently developed Global Initiative on Obstructive Lung Disease (GOLD), classifies patients with COPD purely upon indices of airflow and thus far there is only limited integration with pathologic findings.

This chapter presents the pathologic features of COPD and how these findings can be differentiated from other lesions associated with airflow obstruction.

HISTORY OF PATHOLOGIC DESCRIPTIONS OF COPD

The word emphysema is derived from Greek and means "to blow into," hence "air-containing" or "inflated." Although "voluminous lungs" and lungs "turgid particularly from air" were described respectively by Bonet in 1679, and Morgagni in 1769, the first description of enlarged airspaces in emphysema in the human, together with illustrations, was furnished by Ruysh in 1721, followed by Matthew Baillie in 1807, who not only clearly recognized and illustrated emphysema, but also pointed out its essentially destructive character.

Laennec, writing in the early 1800s, made a number of seminal contributions to the basic descriptions of pathologic changes in COPD. He was the first to make a clear-cut distinction between interstitial emphysema and emphysema proper, and related the enlarged airspaces to the clinical syndrome of emphysema. He also recognized that air trapping and increased collateral ventilation were features of emphysematous lungs, and that the peripheral airways were the primary site of obstruction in emphysema. Furthermore, he noted that airspaces enlarged with increasing age, and he distinguished these changes from emphysema. He was the first to describe an association of emphysema with chronic bronchitis and to clearly describe the pathology of bronchiectasis.

Little of major importance was added to the gross descriptive morphology of emphysema for almost the next 150 years. The foundation of modern knowledge of the pathologic anatomy of pulmonary emphysema was laid by J. Gough in 1952 when he described centrilobular emphysema and distinguished it from panlobular emphysema. The paper section technique developed by Gough and Wentworth was largely responsible for this advance, as it made examinations of sections of entire inflated lungs possible and simple (Fig. 40-1). A comprehensive microscopic description of emphysema was then provided by McLean, who demonstrated the relationship of destruction to inflammatory alterations of the bronchioles, and also discussed alterations of the vasculature.

Figure 40-1 Gough sagittal section. Paper mount. Normal lung. *(This section and subsequent sagittal sections courtesy of Dr. S. Moolton.)*

LESIONS OF THE LUNG PARENCHYMA IN COPD: EMPHYSEMA

A major problem in describing the pathologic features of emphysema has been the lack of a generally accepted and easy to apply definition. In 1959, a Ciba Guest Symposium defined emphysema in anatomic terms as "a condition of the lung characterized by increase beyond the normal of airspaces, distal to the terminal bronchiole, either from dilatation or from destruction of their walls." Subsequent definitions differed in that destruction of respiratory tissue became a requirement: "Emphysema is a condition of the lung characterized by

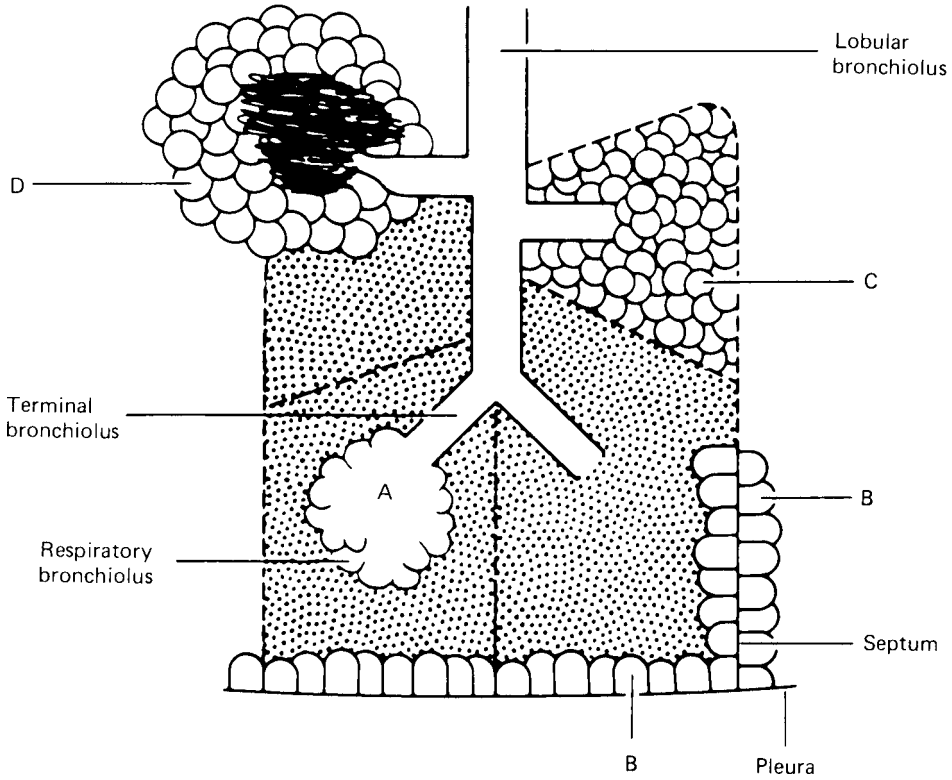

Figure 40-2 Anatomic varieties of emphysema. *A*. Centriacinar (centrilobular). *B*. Paraseptal (distal acinar). *C*. Panacinar (panlobular). *D*. Irregular (scar). The dashed lines mark the edge of the acinus. Only centriacinar and panacinar emphysema are commonly observed in COPD.

abnormal, permanent enlargement of the airspaces distal to the terminal bronchiole, accompanied by destruction of their walls." This requirement separates emphysema from enlargement of airspaces unaccompanied by destruction, the latter now being termed overinflation.

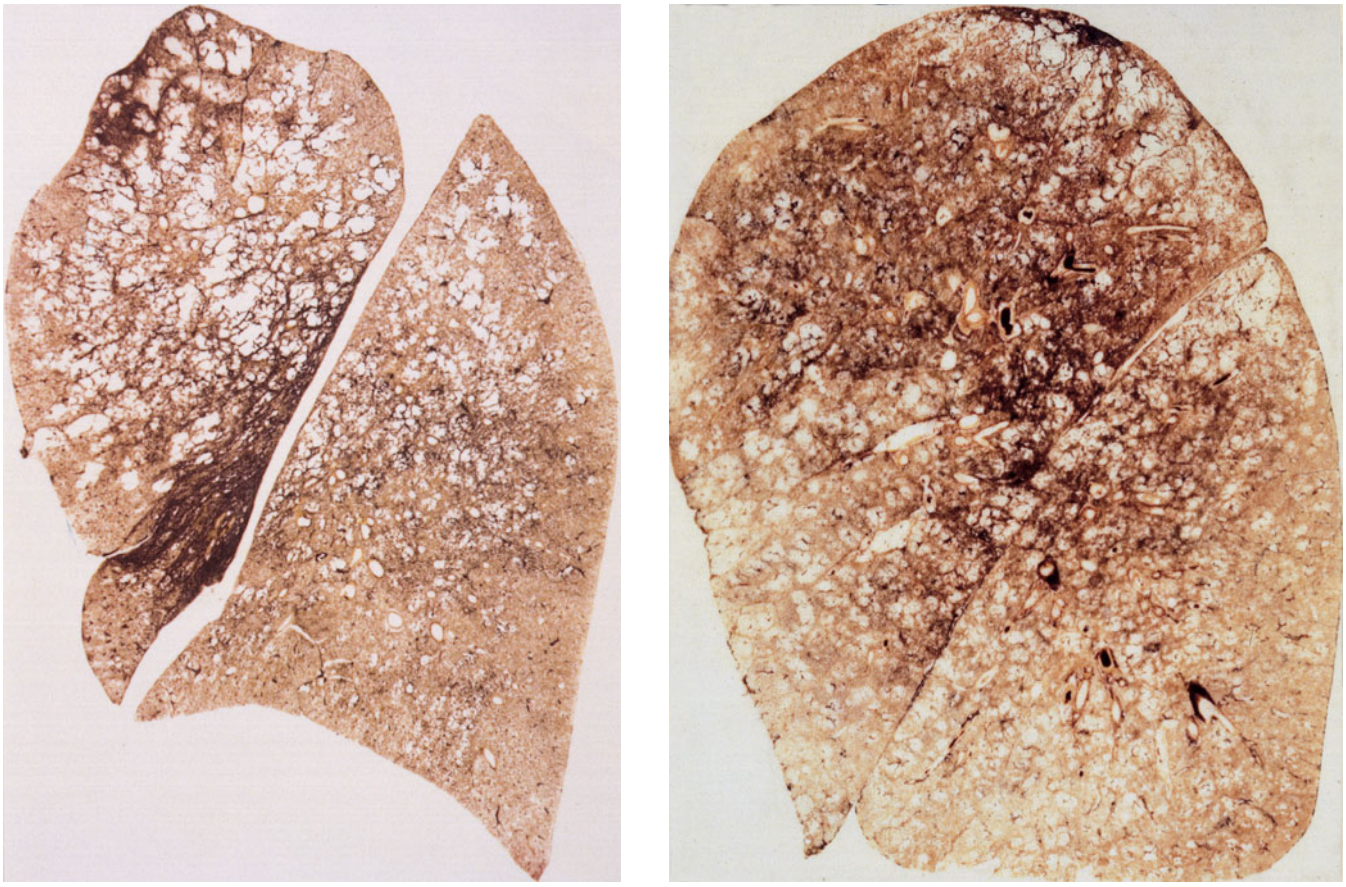
Destruction has been similarly difficult to define in an unambiguous way. A committee of the National Institutes of Health proposed that destruction was present when "there was nonuniformity in the pattern of respiratory airspace enlargement so that the orderly appearance of the acinus and its components is disturbed and may be lost." They recognized that emphysema was a subset of airspace enlargement defined as "an increase in airspace size as compared with the airspace of normal lungs. The term applies to all varieties of airspace enlargement distal to the terminal bronchioles, whether occurring with or without fibrosis or destruction." While these definitions, when strictly applied, would eliminate airspace enlargement due to overinflation or failure of septation, they would not eliminate airspace enlargement due to reorganization of the airspaces, such as is found in honeycomb lung.

Classification of Emphysema

Not only is emphysema defined in terms of lung structure, it is also classified in similar terms; therefore, several anatomic definitions are important. The part of the lung involved in emphysema is the acinus, which is defined as the unit of lung structure distal to the terminal bronchiole (final generation membranous bronchiole) and that consists of three orders of respiratory bronchioles: a single order of alveolar ducts, followed by the alveolar sacs, and finally the alveoli. Alveolar ducts are entirely alveolated and characteristically contain smooth muscle around the mouths of their alveoli. While the walls of alveolar sacs are also formed entirely by alveoli, muscle is absent. Alveolar pores of Kohn (also known as vents, stomata, or fenestrae) are normal components of adult alveoli, responsible for collateral ventilation. However, they may also be an initial site of destruction in the development of emphysema, particularly centriacinar emphysema.

The acinus is a three-dimensional anatomic structure, but it cannot be easily identified by gross examination. What can be seen instead on the surface of lung slices is the secondary lobule of Miller, defined as the tissue bounded on four sides by interlobular septa or pleura. Lobules vary tremendously in size, but are generally 2 to 4 cm on a side, and contain between three to five acini. The terminal bronchiole and subtending respiratory bronchioles tend to be situated in the center of the lobule. For this reason "centrilobular" emphysema and "panlobular" emphysema are reasonable and widely used approximations for the more accurate "centriacinar" and "panacinar" emphysema (see below) (Fig. 40-2).

The ways in which the acini are involved determine the classification of emphysema. There are four recognized patterns (Fig. 40-2). The acinus (and lobule) may be more or less uniformly involved; this is panacinar (panlobular) emphysema. The proximal portion of the acinus (center of the lobule) may be dominantly involved; the best term for this lesion is proximal acinar emphysema, although the usual term



A *B*

Figure 40-3 Pathologic subtypes of emphysema. *A*. Predominantly centriacinar emphysema. Emphysema is more severe in upper lobes. *B* . Predominant panacinar emphysema. Emphysema is more severe in the lower lobes.

is centrilobular or centriacinar emphysema. Alternately, the proximal portion of the acinus may be normal, and the distal part (alveolar sacs and ducts) may be dominantly involved. This is distal acinar emphysema, more commonly referred to as paraseptal emphysema since the lesion is accentuated along lobular septa where the peripheral parts of the acini lie. Finally, the acinus may be irregularly involved, producing irregular emphysema or paracicatricial emphysema, so called because it is usually associated with obvious scarring.

Morphology of Emphysema

Centrilobular Emphysema

This destructive lesion of the respiratory bronchioles has a number of characteristic features on gross examination of the lung. In the *classical* lesion, the enlarged, destroyed respiratory bronchioles coalesce in series and in parallel to produce sharply demarcated emphysematous spaces, separated from the acinar periphery (the lobular septa), by intact alveolar ducts and sacs of normal size. The walls of the emphysematous spaces and adjacent tissue characteristically contain variable amounts of black pigment.

The lesions vary qualitatively as well as quantitatively even within the same lung. There is striking irregularity of involvement of lobules, and even within the same lobule. The lesions are usually more common and become more severe in the upper than in the lower zones of the lung (Fig. 40-3 *A*, Fig. 40-4*A*,*B*). Most affected are the upper lobe, particularly the posterior and apical segments, and the superior segment of the lower lobe. In cases of severe CLE, the destruction proceeds toward the periphery of the lobule, and the distinction between CLE and PLE becomes blurred.

In CLE, alveolar pores are abnormal in size and shape, and occasionally contain epithelial debris and macrophages. Although there are numerous pores of variable size in the emphysematous areas, there are also increased numbers of pores in the grossly normal areas, and accentuation of these changes in the center of the lobule. Thus, it appears that in CLE the pores of Kohn are possibly the initial site of destruction.

There is increased cellularity in the alveolar walls of cigarette smokers, and when this has been quantified, the parenchyma in severe emphysema has increased numbers of neutrophils, macrophages, eosinophils, and both CD4 and CD8 T lymphocytes. There is also a significant inflammatory cell infiltrate in the airspaces in severe emphysema, with the same cells types increased. Although not readily apparent grossly or on standard histological stains, use of histochemical stains or biochemical analysis demonstrates that collagen is increased in both centrilobular and panlobular emphysema.

Cut surface from a lung with centriacinar emphysema showing holes in the center of lobules surrounded by relatively normal parenchyma. The severity varies among lobules. *B*. Microscopic section showing that the airspace enlargement in centriacinar emphysema is most marked adjacent to the abnormal respiratory bronchiole, corresponding to the center of the lobule. Also, some of the alveolar walls of the abnormal airspaces are thickened and fibrotic (H&E × 16). *C*. Cut surface of a lung slice showing how the entire lobule is uniformly affected in panacinar emphysema. *D*. Microscopic section demonstrating that in panacinar emphysema, the airspaces adjacent to the lobular septa are enlarged to the same degree as those in the center of the lobule (H&E × 16).

Panlobular Emphysema

The recognition of mild panlobular emphysema is very difficult. The normal lung has a very characteristic appearance when seen through a dissecting microscope: The multifaceted alveoli form a contrast to the larger, cylindrical conducting structures that are alveolar ducts and respiratory bronchioles. In panlobular emphysema the distinction between alveolar ducts and alveoli becomes lost as alveoli lose their sharp angles, enlarge, and then lose their contrast in size and shape with the ducts, resulting in simplification of the lung architecture, with formation of small box-like structures. As the process becomes worse, the architectural derangement becomes more obvious, with progressive effacement and loss of the orderly arrangement of the lung until little remains other than the supporting framework of vessels, septa, and bronchi. The best way to see panlobular emphysema grossly is to examine lung slices immersed in a water or fixative bath and then immediately after removal from the bath. The immersed specimen shows enlarged airspaces and, when the slices are lifted from the bath, panlobular emphysema can be suspected because the lung parenchyma "falls away" from the supporting structures and protrudes slightly above them. In contrast to centrilobular emphysema, panlobular emphysema is usually worse in the lower lobes (Fig. 40-3*B*).

Histological examination is a sensitive method of recognizing panlobular emphysema. The pattern is again one of simplification with diminishing contrast between alveoli and alveolar ducts (Fig. 40-4*C,D*). Despite the greater extent of tissue destruction, in panlobular emphysema the pores of Kohn are more uniform and inconspicuous than those found in centrilobular emphysema.

Panlobular emphysema is the characteristic lung lesion seen in α-1-antitrypsin deficiency. Panlobular emphysema may also occur as a consequence of permanent obliteration of airways (obliterative bronchiolitis, constrictive bronchiolitis). Most often, obliteration of airways results in collapse of the distal lung parenchyma and dilatation of the bronchi proximal to the obliterated airways. This is the sequence of events in postinfective bronchiectasis. In some instances, however, the lung parenchyma does not collapse, but remains fully expanded or becomes emphysematous. The parenchymal sequel to bronchial and bronchiolar obliteration depends on the extent of the obliteration and the amount of collateral ventilation between adjacent airspaces distal to unobstructed airways. If collateral ventilation is present, then the units distal to the obliterated airways will remain expanded by virtue of the air reaching them by collateral ventilation, producing overexpansion and destruction of lung parenchyma beyond the obliterated airways. The terms Swyer-James or MacLeod's syndrome are applied when this process affects most of one lung but spares the other.

Distal Acinar Emphysema: Paraseptal Emphysema

The original description of distal acinar emphysema is generally credited to Loeschcke, who described collections of subpleural bullae. It was Heard, however, who first noted that the lesions could extend into the substance of the lung, where they lay along the septa, and coined the term "paraseptal" emphysema. Since the distal part of the acinus (alveolar sacs and ducts) is dominantly involved, emphysema is most striking adjacent to the pleura (superficial emphysema or mantel emphysema), along lobular septa (paraseptal emphysema), at the margins of lobules and acini (periacinar emphysema), and along vessels and airways, which, when cut longitudinally, display a linear pattern. The characteristic morphology is that of multiple contiguous, enlarged airspaces, varying from <0.5 mm to >2 cm in diameter.

Paraseptal emphysema is usually limited in extent, and is found most commonly along the anterior and posterior parts of the upper lobe and along the posterior surface of the lower lobe. When extensive, it is usually more severe in the upper half of the lung. Gough has stressed that it is associated with fibrosis of the tissue between the enlarged airspaces, and this is certainly a common finding.

Irregular Emphysema

Irregular emphysema is logically named, because the acinus is indeed irregularly involved in it. Irregular emphysema is almost invariably adjacent to a scar, giving name to the synonyms scar or paracicatricial emphysema. Most scars within the lung are usually small and the emphysema is limited in extent. The severity of irregular emphysema depends on the extent of damage to lung tissue, and multiple scars through the lung may lead to multiple foci of irregular emphysema.

Differential Diagnosis of Emphysema (Table 40-1)

Gas Trapping

The lungs of an asthmatic who has succumbed during an attack are usually characterized by gas trapping, and thus

Table 40-1

Differential Diagnosis of Airspace Enlargement

	Distribution	Enlarged Structure
Centrilobular emphysema	Upper lobes, center of lobule	Alveolar ducts, alveoli
Panlobular emphysema	Lower lobe, uniform in lobule	Alveoli
Paraseptal emphysema	Apical, adjacent to septum	Alveoli
Irregular emphysema	No typical site, adjacent to scars	Alveoli
Aging	Uniform in lung	Alveolar ducts
Compensatory alterations	Uniform in lung	Alveoli
Obstructive alterations	Affected area	Alveoli
Genetic alterations	Uniform in lung	Lack of septuation
Asthma	During acute attack	Alveoli
Honeycomb lung	Variable—often subpleural	Total remodeling

remain inflated, with focal areas of atelectasis. In a patient with longstanding asthma who has died from other causes, or has had a lung resection, there may still be areas of atelectasis. Focal bronchiectasis can be found also, particularly in the anterior segment of the upper lobe. However, parenchymal destruction is not a feature of asthma, and thus gross, microscopic, and morphometric analyses will all be normal in the chronic asthmatic.

Nonemphysematous Airspace Enlargement

Although not part of the differential diagnosis of COPD, nonemphysematous airspace enlargement also occurs in infancy. In congenital lobar hyperinflation (emphysema), the lobes are overinflated rather than emphysematous, but in some instances they may be polyalveolar. Some other genetic abnormalities will also give enlarged airspaces, but this is due to failure of septation with a simplified rather than a destroyed alveolar framework.

At the other side of the age spectrum, the term senile emphysema was once used to describe the enlarged airspaces found in the aged. On gross examination, lungs round out with increasing age. An analysis of Gough sections showed increases in anteroposterior distance, height, perimeter, and area of the lung up to the age of 59 years. After this age, only the anteroposterior diameter continued to increase significantly, thus "rounding" the lung dimensions. This change is due to an increase in the volume proportion of alveolar duct air, with shallower and flatter alveoli, a process termed ductectasia. There is no evidence of lung destruction; thus, the condition does not fulfil the criteria for emphysema.

If a part of the lung collapses or is removed, the remaining lung can expand to fill the increased amount of space available, a process known as compensatory overinflation. The exact way that this happens and the limits of the process are unknown. However, no tissue destruction has occurred and, by definition, this is not emphysema. It is not clear how much larger the overinflated lung can become, or how it expands to reach the new and larger volume. It is generally thought that the possible extent of overinflation is modest and that all the parts of the acinus are equally expanded.

Obstructive overinflation can occur in adults, and two mechanisms may be involved. In one, the obstruction in the bronchus may act as a ball valve, so that air enters on inspiration but does not leave on expiration. Alternatively, the bronchus may be completely obstructed and air may be trapped behind channels of collateral ventilation. Whatever the mechanism, the affected part of the lung can expand considerably. Obstructive overinflation differs in a number of ways from compensatory overinflation, although, in both, the lung contains too much air per unit of lung and lung tissue.

Honeycomb Lung

The airspace enlargement that occurs in cryptogenic fibrosing alveolitis (usual interstitial pneumonia) and other fibrotic lungs diseases could possibly be confused with emphysema. While honeycomb spaces are enlarged airspaces, they are the result of parenchymal remodeling with formation of new airspaces, rather than destruction of normal airspaces, and thus have thickened and irregular walls with none of the structure of an acinus. They are lined by bronchiolar epithelium, and often contain mucus; the walls have abundant and well collagenized connective tissue, which may also contain impressive amounts of muscle and sometimes fat. There is usually interstitial inflammation in the form of varying degrees of lymphocytic and plasma cell infiltration.

LESIONS OF THE LARGE AIRWAYS IN COPD

The majority of studies in this area have focused upon the lesions present when the clinical signs and symptoms of chronic bronchitis are also present.

Gross Findings

Gross lesions in the large airways are few and subtle. Bronchial pits are the dilated openings of one or more mucous glands into the epithelium. They are most often found along the margins of the cartilaginous rings and at the bifurcations of the airways. In nonbronchitis the pits can be seen using a hand lens or a dissecting microscope, but in chronic bronchitis, the ducts may be distended with mucus and the mucus may protrude into the lumen of the bronchus and be visible grossly. It is not correct to refer to these as diverticula. First, these are protrusions of normal ducts; and second, they do not extend through all of the muscle coats of the bronchial wall.

While enlarged bronchial pits are the most obvious gross lesions in COPD, careful examination of lung specimens will show that the bronchi do not taper progressively as they approach the pleura, and they also display prominent circular ridges, probably due to bands of hypertrophic smooth muscle. Mucus may be present in the airway lumen, particularly in subjects with chronic bronchitis.

Microscopic Findings

The intraluminal mucus found in the airways of subjects with COPD contains a mixed population of epithelial cells and acute and chronic inflammatory cells; large numbers of neutrophils can be found during an exacerbation.

Detailed microscopic analysis of the large airways in COPD reveals alterations in the entire airway wall (Fig. 40-5). Epithelial changes are mild in degree and are not necessarily consistent from patient to patient. Epithelial sloughing can occur, but in most instances the epithelium is generally intact and shows only mild goblet cell or squamous cell metaplasia, both of which appear to be more marked if the subject has symptoms of chronic bronchitis. The reticular basement membrane thickness is within the normal range.

The thickness or area of mucous glands in subjects with COPD in general, or chronic bronchitis in particular, is increased over a population mean, but has a distribution that extensively overlaps that of normals and asthmatics.

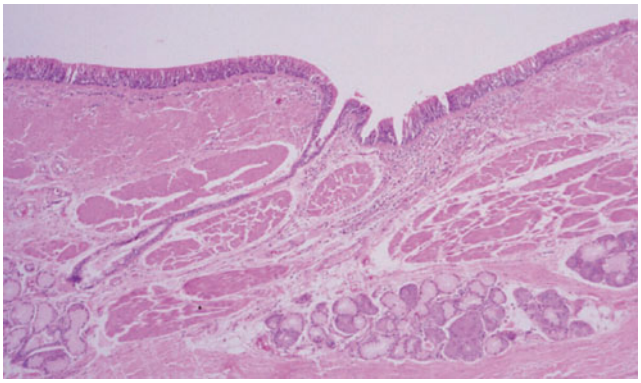

Figure 40-5 Large airway from a subject with chronic bronchitis. The overall wall is thickened with inflammation and fibrosis, and there is prominence of the smooth muscle in addition to the bronchial mucous glands.

Interestingly, there appears to be a decreased percentage of serous acini in these glands, a feature that apparently does not occur in asthma.

Thickening of the inner wall (area internal to the muscular layer) appears to be the most consistent component of airway wall thickening in the large airways of subjects with COPD, and appears to be generalized. This increase in thickness can be partially attributed to edema and hyperemia of the bronchi, but is also due to an increase in fibrous tissue or other matrix proteins.

In the large airways of subjects with COPD, increases in the thickness of the muscular layer have not been consistently identified. Although some studies have found that the average proportion of muscle in main, lobar, and segmental bronchi was approximately doubled in patients with chronic bronchitis and airflow obstruction, others have found that a substantial number of patients fell within the normal range.

Alteration in the amount of cartilage in COPD does not appear to be a consistent finding. While some studies described cartilage atrophy in chronic bronchitis and/or emphysema, or circumferentially arranged cartilage that extended farther distally in nonbronchitis than bronchitis, this was not supported by other reports. However, histological signs of cartilage damage, as judged by loss of cellular or pericellular metachromasia and vacuolated or empty lacunae can be consistently identified.

The large airways in COPD show a mild, usually mixed, inflammatory infiltrate. Bronchus-associated lymphoid tissues (BALT) is not consistently found, but its frequency appears to be considerably higher (82 percent) in smokers than nonsmokers (14 percent). Bronchial biopsy analysis consistently shows an increase in CD8 T cells, with eosinophils and neutrophils found during exacerbations. Chronic inflammation can also be found around the bronchial glands, particularly in subjects with chronic bronchitis.

Differential Diagnosis (Table 40-2)

Asthma

In asthma the large airways are not dilated, but mucus plugs are classically identified in the large airways of subjects with fatal or near-fatal asthma, and the mucus may be continuous with that present in the ducts of the mucus glands. Visible bronchial pits are not a standard feature of asthma, and although the airway wall may be thickened, this is usually not apparent grossly.

In the large airways of subjects with asthma, desquamation of the epithelium is a common feature, and this may be worse in people who have persistent rather than intermittent activity. Sloughing of cohesive epithelial clusters produces the Creola bodies found in cytology specimens. Goblet cell metaplasia can be marked in both asthma and bronchiectasis, but there is a considerable degree of variability, so that this feature cannot be used in isolation to distinguish among the airways of subjects with COPD, asthma, and bronchiectasis. These epithelial cell changes result in an overall thickening of the epithelium in asthma, but not in COPD. In asthma, the reticular basement membrane (lamina reticularis) is characteristically thickened. This alteration occurs early in the course of disease, and remains even when the asthma is mild or well controlled.

The airways of asthmatics demonstrate a greater severity of inner wall thickening, with values double those found in patients with COPD. The increase in thickness is due to variable increases in fibrous tissue, inflammatory cells, edema fluid, and vascular prominence. Analysis of the muscular wall in subjects with severe or fatal asthma compared with normals or those with COPD shows a marked increase in amount of muscle, with a lesser increase in asthmatics who died *with* rather than *from* their asthma There has also been a suggestion that the increase in muscle mass may occur relatively early during childhood.

Neutrophils are the predominant cell present in the mucus of patients with bronchiectasis, while eosinophils and accompanying Charcot Leyden crystals are the hallmark of asthmatic mucus. As noted, the cartilaginous destruction present in polychondritis is severe and associated with chronic inflammation, thus easily distinguishing the two processes. Depending upon the severity of the inflammation in bronchiectasis, there may be significant cartilaginous destruction.

Airways from fatal and near-fatal asthma also contain isolated aggregates of lymphoid cells, roughly in the same proportion as that present in COPD. However, in asthma, by contrast to COPD, there is an inflammatory infiltrate consisting of activated eosinophils, and activated CD4 T cells in the submucosa, and both mast cells and neutrophils within the glands. There is little in the literature regarding the inflammatory cell infiltrates present in the airway walls in bronchiectasis. Compared with asthma, there appear to be fewer eosinophils, but a similar population of CD 45 (as opposed to any specific subtype) lymphocytes, with both cell types having a greater density in the inner, as opposed to the outer aspect of the airway.

Bronchiectasis

In bronchiectasis, there is by definition an abnormal and permanent dilatation of the bronchi, and this is usually present to a much greater degree than is found in COPD, and is often

Table 40-2

Pathologic Differential Diagnosis of Large Airway Lesions in COPD

	Dilatation	Structural Distortion	Pits	Glands	Submucosal Fibrosis	Basement Membrane	Epithelium	Lumenal Mucus	Cartilage	Muscles

Tracheomegaly	√	X	Diverticula	X	X	X	X	X	X	X
Relapsing polychondritis	√	√	X	X	X	X	X	X	√	X

Check mark indicates that the feature is present; X indicates that the feature is absent.

accompanied by airway distortion. There is exaggeration of the muscular ridges and the presence of multiple bronchial gland–based pits. The large airway walls can be thickened and/or irregularly thinned as a result of inflammation and fibrosis, and there is often inspissated mucus or actual purulent material.

Miscellaneous Conditions

Tracheobronchomegaly (Mounier-Kuhn syndrome) is characterized by a marked dilatation of the trachea and major bronchi, with diameters 5 to 10 cm above normal values. In this condition there are multiple true diverticula, with outpouchings formed of membranous tracheal tissue between the cartilaginous rings, with atrophy or absence of elastic fibers.

Patients with tracheobronchopathia osteoplastica have an obstructive pulmonary function pattern; however, unlike the trachea and large airways in COPD, cartilaginous and bony nodules are present in the subepithelial space (submucosa). Relapsing polychondritis shows variable dynamic expiratory and/or inspiratory obstruction depending on the size and location of the airways involved. In this disease, however, the obstruction is due to impaired airway clearance of inflammatory debris, and an ineffective cough because of dynamic upper airway collapse. The airways are dilated and the walls are thickened because of the extensive fibrosis and chronic inflammation due to the immunological nature of this condition. In particular, the cartilaginous plates show extensive destruction.

LESION OF THE SMALL AIRWAYS IN COPD

In the context of COPD, small airways refer to airways with an internal diameter of 2 mm or less. In COPD, intraluminal mucus can be found in the small airways, and there appears to be an overall relationship between the degree to which the airways are occluded by mucus and the FEV_1. Goblet cells are rare in normal small airways, but goblet cell metaplasia is a frequent finding in the airways of patients with COPD.

Similar to the large airways, there is alteration of the all of the small airway wall compartments in patients with COPD (Fig. 40-6). These changes result in an overall decrease in the internal bronchiolar diameter and, as assessed by a conformity index, produce significant deformity. Similar results are obtained from three-dimensional reconstructions. Detailed measurements of the airway walls show that the increased wall thickness is due to increases in the epithelium, subepithelial fibrous tissue compartment (submucosa, lamina propria), smooth muscle, and adventitia. Although the adventitia is thickened, there is a loss of alveolar attachments to the airway wall, an important process because it allows early airway collapse on expiration.

One of the earliest histological abnormalities that can be detected in cigarette smokers is the presence of macrophages in the lumen of the respiratory bronchioles. However, an inflammatory infiltrate can also be identified within the walls

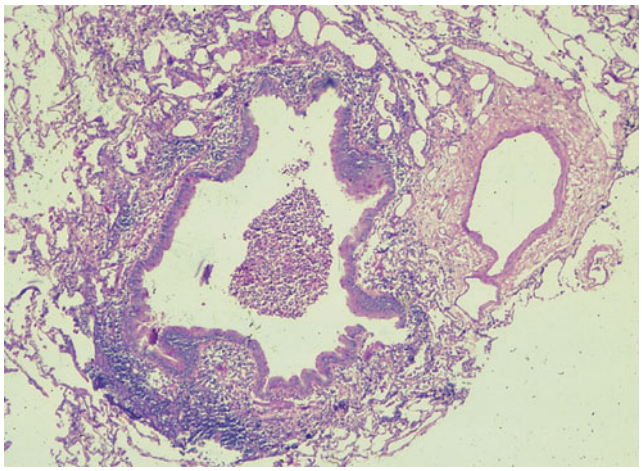

Figure 40-6 A small airway from a subject with COPD. The lumen contains mucus and inflammatory debris. There is goblet cell metaplasia of the epithelium. The subepithelial (submucosal) layer is increased in thickness due to an increase in fibrous tissue and inflammatory cells.

of both membranous and respiratory bronchioles in subjects with COPD. When examined in conjunction with the GOLD (Global Strategy for the Diagnosis, Management, and Prevention of Chronic Obstructive Pulmonary Disease) stage, the proportion of airways which had measurable neutrophils appear to be increased in GOLD stages 2 to 4, and airways with measurable macrophages show a progressive increase from GOLD stage 0 to 4, while there does not seem to be any alteration in the percentage of airways that contain eosinophils among the GOLD stages. The percentage of airways with CD4, CD8, and B cells also increase with GOLD stage, but when these data are expressed as total accumulated volume, only the B cells and CD8 cells show progressive increases. The presence of lymphoid follicles is markedly increased in GOLD stages 3 and 4.

Differential Diagnosis

Asthma

Mucous plugs and goblet cell hyperplasia are markedly increased in the small airways of asthmatics and this increase is generally much greater than is seen in COPD. In addition, the basement membrane thickness is approximately 20 percent greater than that found in either normals or patients with COPD. The peripheral airways of asthmatics have an inflammatory infiltrate that features lymphocytes and eosinophils, with many of the inflammatory cells in the adventitial, as opposed to the submucosal compartment. The data regarding the vessels in the submucosa are controversial, with some studies suggesting that they are congested, but not increased in number, in asthmatics compared with COPD, and others demonstrating an increased number of vessels, but a lesser total area in asthma compared with COPD. Although smooth muscle is increased in asthmatics, the increase is not as great as that present in the large airways. Moreover, the distribution of smooth muscle increase in the bronchial tree may be quite different, with some patients displaying a generalized

increase, while in others the increase is restricted to the larger airways. Overall, the small airways in asthmatic subjects who have died because of their disease have a greater area of subepithelial fibrous tissue, smooth muscle, and adventitial fibrous tissue than do subjects who died with their disease, which in turn have a greater area than do the airways of subjects with COPD. Thus, although the same qualitative changes are present in both asthmatics and COPD, they are more severe in asthmatics and most severe in cases of fatal asthma. Interestingly, there appears to be a loss of alveolar attachments in cases of fatal asthma, although this is less than that present in the airways of patients with COPD.

Follicular Bronchiolitis

Follicular bronchiolitis is characterized by narrowing of the bronchioles due to adventitial and subepithelial lymphoid follicles, and accompanied by a lymphoplasmacytic inflammatory infiltrate. The condition is classically found in patients with rheumatoid arthritis or those with IgA deficiency. This process can mimic severe COPD small airways disease, but the inflammatory infiltrate is generally magnified compared to COPD, while there is little goblet cell metaplasia in the airway epithelium.

Panbronchiolitis

The presence of foamy macrophages in the airway wall and lumen and extending down into the alveolar ducts and alveoli is a feature of the condition known as panbronchiolitis, originally described in Japan but now known to occur worldwide. Follicular hyperplasia of the peribronchiolar lymphoid tissue is frequent, and bronchiolectasis is found in the more advanced lesions.

Constrictive Bronchiolitis

The term constrictive bronchiolitis appears to have been coined by Gosink et al. In constrictive bronchiolitis, the airway lumen is occluded by a progressive thickening of the subepithelial (submucosal) space. Both the membranous and respiratory bronchioles are involved, and show transmural inflammatory cell infiltrates, occasionally with epithelial necrosis. Mucous plugs can also be identified. As the process evolves, the inflammatory infiltrate wanes, and greater amounts of fibrous tissue can be demonstrated both in the peribronchial and subepithelial portions of the airway, acting to narrow or obliterate the airway lumen. Lesions of constrictive bronchiolitis, particularly in the organized phase, may be difficult to demonstrate, and may require elastic stains to outline the obliterated airway. Thus, the lesions in COPD differ from constrictive bronchiolitis only in degree.

Mineral dust–induced airways disease is a distinctive type of constrictive bronchiolitis, characterized by a stereotypic response of the small airways to high doses of particulate, regardless of the specific mineral dust involved. The lesions consist of fibrosis and thickening of the walls of both the membranous and respiratory bronchioles, sometimes extending down the alveolar ducts, the latter finding providing diagnostic discrimination from tobacco smoke–induced airways disease, which tends not to involve the alveolar ducts. Pigment deposition is highly variable, and is not a diagnostic feature.

Proliferative Bronchiolitis

The lesions of proliferative bronchiolitis have been elegantly described and illustrated. Within the lumens of the membranous and respiratory bronchioles are plugs of organizing fibroblastic (granulation) tissue. Occasionally, ulceration of the epithelium can be seen, and early lesions may have fibrin. The granulation tissue is formed of a pale matrix with proliferating spindle cells, accompanied by chronic inflammatory cells. As the lesions age, the granulation tissue usually shrinks and contracts. However, in a certain proportion of cases, the bronchiolar cells proliferate over the granulation tissue, and incorporate it into the subepithelial space, leaving an irregular airway lumen.

Although acute bronchiolitis, be it bacterial or viral in nature, is usually easily distinguished from the lesions of COPD by the presence of extensive epithelial damage, healed lesions may show nonspecific airway fibrosis and chronic inflammation, or the residua of proliferative bronchiolitis. Interestingly, latent adenoviral infection has been suggested as a contributor to airflow obstruction in adults by amplifying the inflammatory response in the bronchioles of cigarette smokers. Airway disease complicating other diseases may also need to be distinguished from that of COPD. For example, post-transplant bronchiolitis or airways disease in patients with inflammatory bowel disease (both Crohn's disease and ulcerative colitis) include both proliferative and constrictive bronchiolitis. Inflammatory bowel disease may also have large airway involvement.

LESIONS OF THE VESSELS IN COPD

There are no consistent alterations in the large elastic pulmonary arteries of subjects with COPD. Atheromata can be found, but unless there is pulmonary hypertension, the incidence is probably not greater than that found in a carefully matched population.

Cigarette smokers, with or without pulmonary hypertension, have an increase in arterial muscle media thickness as well as intimal fibrosis in the muscular arteries, and progressive muscularization of the small arterioles. Increases in intimal thickness with longitudinal muscle formation are a common feature in lungs of patients with COPD (Fig. 40-7). There appears to be a progressive increase in the numbers of smaller muscularized arteries, percent medial thickness, and percent intimal thickness of muscularized arteries from nonsmokers, to smokers without obstruction, to smokers with airflow obstruction.

The lesions of primary pulmonary hypertension and hypertension secondary to vascular shunting also include intimal fibrosis and increased muscular media thickness. Intimal fibrosis is often cellular in its early phases, but progresses to concentric laminar fibrosis, which can almost totally obliterate the vessel lumen. These changes are of much greater

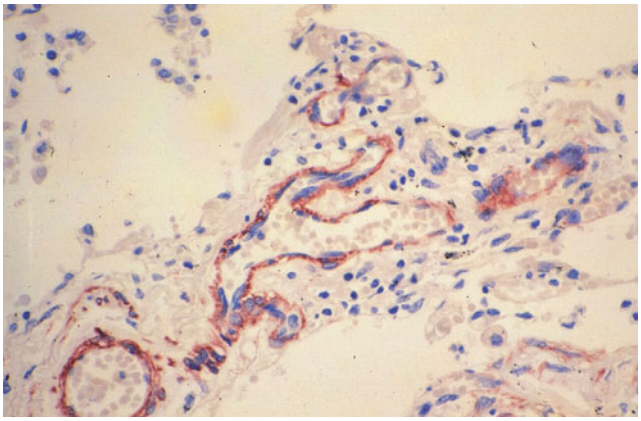

Figure 40-7 A small pulmonary artery from a subject with COPD. These vessels, situated adjacent to the alveolar ducts, are normally poorly muscularized, but in this case, the vessel has a distinct circumferential muscular layer.

severity than those identified secondary to COPD. Vasculitis, fibrinoid necrosis, and plexiform lesions are never found in COPD. Lesions of chronic thromboembolic disease include eccentric intimal thickening, and the occasional formation of webs due to recanalization of the thrombi.

SUMMARY

There are a number of pathological alterations of the lung in COPD. These involve almost all of the lung compartments, including the parenchyma, vasculature, and large and small airways. These changes can overlap the pathologic findings present in other diseases associated with airflow obstruction, or other diseases that are manifested in the lung. It is important to be able to make the distinction among these diseases. Although the pathologic alterations roughly correlate to alterations in pulmonary function, it is important to remember that their individual contributions are not well worked out. Thus, it may be difficult on an individual patient basis to proceed from a clinical classification such as the GOLD classification to a mechanistic/pathologic explanation of the airflow obstruction.

Chronic Obstructive Pulmonary Disease: Epidemiology, Pathophysiology, and Pathogenesis

Robert M. Senior • Jeffrey J. Atkinson

For many years, chronic obstructive pulmonary disease (COPD) was defined as "a disease state characterized by the presence of airflow obstruction due to chronic bronchitis or emphysema; the airflow obstruction is generally progressive, may be accompanied by airway hyperreactivity, and may be viewed as partially reversible." In the past few years a new definition has been presented by the Global Initiative on Obstructive Lung Disease (GOLD) and by a Task Force of the American Thoracic Society (ATS) and the European Respiratory Society (ERS). Both GOLD and ATS/ERS state that "COPD is a disease state characterized by airflow limitation that is not fully reversible. The airflow obstruction is usually both progressive and associated with an abnormal inflammatory response of the lungs to noxious particles and gas." The ATS/ERS definition also states that COPD is both preventable and treatable and that COPD is a systemic disease. A secondary feature of both the GOLD and the ATS/ERS definitions is a scoring system for staging the severity of COPD based upon the post-bronchodilator forced expiratory volume in the first second (FEV_1) (see Chapter 42).

EPIDEMIOLOGY

COPD occurs worldwide, but it is a major health problem principally in societies where cigarette smoking is common and the average life span extends into the sixth decade or

beyond. Although COPD occurs predominately in smokers, nonsmokers also develop COPD. In a survey of COPD deaths in the United States in 1993, 16.7 percent of individuals who died with COPD were never-smokers (smoked fewer than 100 cigarettes during their lifetime) of whom approximately one-third, an estimated 12,900, had COPD listed as the primary cause of death. A history of asthma was significantly associated with death from COPD in nonsmokers. In undeveloped countries, burning biomass for heating and cooking results in COPD among nonsmokers.

COPD has a prevalence of 4 to 10 percent in adults in populations in whom lung function has been measured. The National Health Interview Survey, an annual survey of approximately 40,000 United States households, has yielded an estimate of 10 million adults in the United States with a physician-based diagnosis of COPD. Other estimates, such as that from the Third National Health and Nutrition Examination Survey (NHANES III), that included spirometry along with questionnaires and a physical examination, done between 1988 and 1994, have yielded even more impressive prevalence figures. According to NHANES III, COPD affects 23.6 million adults in the United States, of whom 2.4 million have severe disease. Thus, approximately 10 percent of the United States adult population might be classified as having COPD, and of this group about 10 percent have advanced disease. Impressive as these figures are, they are reasonable considering the estimates for COPD-related physician visits, emergency department visits, hospitalizations, and deaths. Indeed, these prevalence figures may be underestimates since COPD is likely unrecognized in some groups such as elderly persons with low incomes. Irrespective of the precision of the prevalence estimates, it is clear that COPD is a major health burden.

The death rate from COPD in the United States has been rising in recent decades in contrast to falling death rates from heart and cerebrovascular diseases over the same interval. COPD is now the fourth most common cause of death in the United States, accounting for approximately 4.5 percent of all deaths. Moreover, COPD is a contributory factor in another 4.3 percent of deaths. Currently, men still have a higher mortality rate from COPD than women (83 vs. 57 per 100,000), but the mortality rate is rising in women and is stable in men. Among women, the death rate from COPD has more than doubled in the past 20 years, and in the year 2000 more women than men died from COPD.

The percentage of smokers in the adult population in the United States has dropped over the past several decades from more than 50 percent to about 25 percent. The drop has been most striking among men. Accordingly, morbidity and mortality from COPD may decline in the years ahead, reflecting these favorable trends in smoking practices in recent decades. However, COPD is certain to remain a major health problem in the United States into the foreseeable future since there are an estimated 48 million smokers in the United States and smoking is common in young people. Among high school students 23 percent are current smokers, with a slightly higher incidence for boys (25 percent) than girls (21 percent), while among middle-school children 10 percent are smokers, equally so among boys and girls. The problem of COPD worldwide is destined to be profound in the future. The World Health Organization reports that 15 billion cigarettes are smoked daily worldwide and predicts that COPD will rank fifth in life-years lost to premature death and disability in 2020.

RISK FACTORS

Risk factors for the development of COPD may be broadly divided into those related to environmental exposures and those that are host-based (Table 41-1). Smoking and alpha 1-antitrypsin (α_1-AT) deficiency are risk factors for which the data are most compelling, but even for these risk factors much remains to be determined about the specific mechanisms involved. Some factors listed may be a composite of other individual risk factors. A low socioeconomic status, for example, is notable in this regard as it might be linked to COPD through deficient medical care for respiratory infections, occupational exposure to inhaled particulates, and exposure to household allergens. The following sections consider smoking, occupational exposures, childhood lower respiratory infections, airway hyperresponsiveness, and genetic factors other than α_1-AT deficiency which is discussed separately later in the chapter.

Environmental

Smoking

Smoking tobacco accounts for 80 to 90 percent of the risk of developing COPD in the United States. Accelerated deterioration of ventilatory function is common among smokers. However, its magnitude is relatively small in most smokers. In males, the loss of FEV_1 in excess of the normal decline

Table 41-1

Risk Factors for COPD

Environmental	Host-based
Smoking	Genetic factors
Occupational exposures	Asthma/airway hyperreactivity
Air pollution	
Childhood respiratory infections	
Low socioeconomic status	

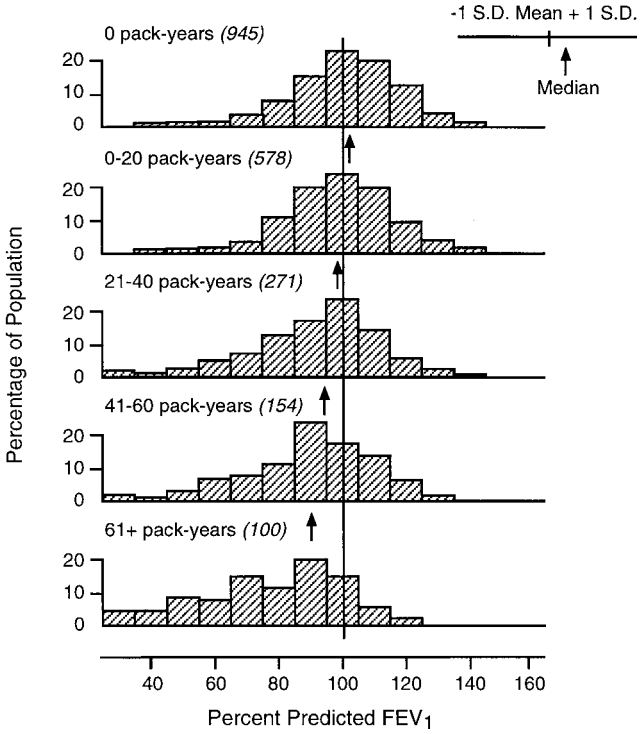

Figure 41-1 Distribution of percent predicted FEV_1 in adults with varying pack-years of smoking. Subjects with "respiratory trouble" before age 16 are excluded. The proportion of smokers with normal expiratory airflow decreases with increasing pack-years. Nevertheless, many smokers have a normal FEV_1 despite large cigarette-smoking histories. Means, medians, and ± standard deviation of the data for each group are shown in the abscissas. The numbers in parentheses are the numbers of subjects. *(From Burrows B, Knudson RJ, Cline M, et al: Quantitative relationships between cigarette smoking and ventilatory function. Am Rev Respir Dis 115:195–205, 1977, with permission.)*

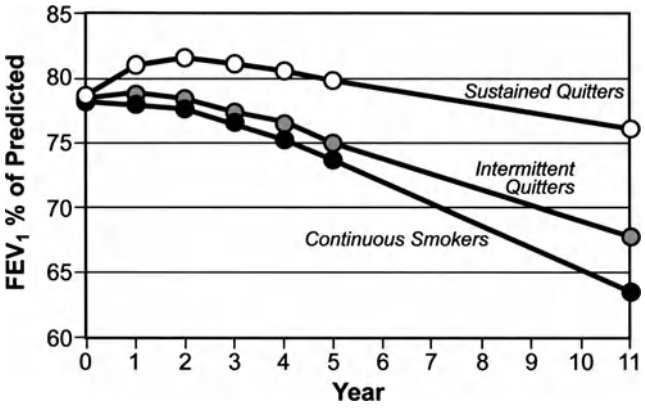

Figure 41-2 Mean post-bronchodilator FEV_1 for participants in the Lung Health Study during 11 years of follow-up in relation to smoking history. Sustained quitters (open circles) and continuous smokers (closed circles). Smokers show progressive deterioration. *(From Anthonisen NR, Connett JE, Murray RP: Smoking and lung function of Lung Health Study participants after 11 years. Am J Respir Crit Care Med 166:675–679, 2002, with permission.)*

with aging is 9 ml per year for each pack-year of smoking; in females, the excess rate of decline is 6 ml. Based on these rates of decline, a man who has smoked one pack daily for 30 years will have an FEV_1 that is 270 ml less than it would have been had he not smoked. However, the relationship between amount of smoking and risk of COPD is unpredictable on an individual basis. Many people with a high number of pack-years still have a normal or near-normal FEV_1, while some people have a reduced FEV_1 with a modest smoking history (Fig. 41-1).

Among smokers who have already sustained reductions in FEV_1, the consequences of continued smoking on ventilatory function are much more impressive than when all smokers are lumped together. The Lung Health Study revealed that among middle-aged smokers with an FEV_1 between 55 and 90 percent of predicted, differences of about 200 ml in FEV_1 developed within 5 years between those who quit and those who did not quit and this difference between smokers and quitters doubled over the next 6 years (Fig. 41-2). Thus, not surprisingly, in smokers who have demonstrated an increased susceptibility to the effects of smoking on ventilatory function, the rate of decline of FEV_1 is much larger than that seen in the average middle-aged smoker who has normal or near-normal ventilatory function. Further evidence of the harmful effects of smoking in susceptible smokers is apparent from the trends in ventilatory function among those who stop smoking. Their rate of decline of FEV_1 reverts to that of nonsmokers.

Occupation

The fact that occupation-related chronic inhalation of particulates and gases carries a risk for COPD has been slow in gaining acceptance. The delay is understandable, since ascertaining the risk of COPD in relation to occupation may be difficult for several reasons. The high prevalence of smoking among workers in certain occupations has been a major confounding factor. Also, workers beginning jobs with a high risk of causing lung disease typically have better lung function than normal (the "healthy worker" phenomenon), obscuring work-related effects among relatively young workers. In addition, among cohorts of workers, those with COPD may drop out, causing an underestimate of risk in follow-up studies confined to those still working.

Despite these difficulties, studies from different groups around the world, urban and rural, workforce-based and community-based, clearly implicate occupations producing exposures to dusts, gases, and fumes as risk factors for COPD. The American Thoracic Society states that 15 percent is a reasonable estimate of the occupational contribution to the population burden of COPD.

Dusts appear to be most significant. Similar to the experience with tobacco smoke, the presence or absence of chronic cough and sputum does not necessarily imply the presence or absence of airflow obstruction. The risk generally relates to the intensity of exposure, but there is considerable individual variability, pointing to the importance of host factors in determining susceptibility. Apart from the recognized

risk in occupations involving exposure to organic and inorganic dusts, many less obviously "risky" occupations may carry an increased risk of COPD. A recent analysis of data from NHANES III, in which smoking and other confounders were taken into account, uncovered slightly increased incidences of COPD in many occupations, including construction, plastics manufacturing, and utility work. The impact of an adverse occupation is likely to be particularly important in individuals who have other factors that raise their risk for COPD. An example of this occurrence was found among agricultural workers with α_1-AT deficiency who had never been regular smokers. These individuals showed significantly reduced FEV_1 values compared to nonsmoking α_1-AT-deficient individuals not involved in agricultural work.

Childhood Lower Respiratory Tract Infections

Childhood lower respiratory tract infections (lower respiratory tract infections) are commonly regarded as a risk factor for COPD. Since lung growth and alveolar development continue into early childhood it is plausible that lower respiratory tract infections during childhood might produce permanent damage or impair lung growth and development. However, although correlations have been found between early (up to around age 2) childhood lower respiratory tract infections and reduced lung function later in life, there is not a correlation with airflow obstruction as judged by the FEV_1/forced vital capacity (FVC) ratio. Furthermore, even in the setting of COPD, LRTIs seem to have only a minor lasting effect on the obstruction. In the Lung Health Study COPD exacerbations in smokers were associated with an additional loss of FEV_1 of 7 ml per year for those having one exacerbation per year. Among nonsmokers exacerbations had no apparent effect on the FEV_1.

HOST FACTORS

Genetic Background

Aggregation of COPD in families and concordance of pulmonary function in twin studies have established a role for genetic predisposition to COPD. The occurrence of reduced maximal expiratory airflow among nonsmoking first-degree relatives of individuals with early onset COPD provides further support. Perhaps most compelling is the marked variability in development of COPD among smokers. However, dissecting specific genetic factors that increase the risk of COPD has proven difficult. α_1-AT deficiency illustrates this difficulty. Even among individuals with this clearly identified genetic risk factor, there is wide, unexplained, variability in the occurrence of COPD.

Polymorphisms of genes involved in protease-antiprotease balance, antioxidant function, inflammation, and immune responses have been implicated in COPD. However, none of these polymorphisms could be confirmed in a recent genetic association analysis of families identified through patients who developed severe COPD at an early age (without α_1-AT deficiency). Failure of confirmation may indicate flaws in previous studies, but differences in COPD phenotypes, ethnic background, or other factors might explain the discrepancies between previous studies and the recent data. A polymorphism in elastin that results in an amino acid substitution and altered elastic fibers has been uncovered in approximately 1 percent of individuals with severe COPD and emphysema. Thus, future studies of the genetic aspects of COPD should extend to extracellular matrix.

Two basic approaches are used to identify the genetic determinants of apparently complex genetic disorders such as COPD: candidate gene analysis and positional cloning. Both rely on polymorphisms in the populations studied and careful characterization of the disease phenotype being targeted. Unfortunately, characterization of the COPD phenotype has been variable, involving parameters of airflow obstruction and/or radiographic evidence of emphysema.

The advantages of a candidate gene approach are that the selection of genes can be guided by information from mouse models or expression profiling experiments. Since only a limited number of genetic variants are typically tested, associations can be uncovered with relatively small populations. However, the disadvantages are that the small sample size can miss associations due to inadequate power and associations discovered may represent linkage to a polymorphism in a neighboring gene, not the gene of interest. These candidate gene association studies are likely more powerful if performed on a relatively genetically isolated and uniform population, but use of isolated populations decreases the ability to generalize findings to other populations. Some polymorphisms change amino acid sequence of a protein, but polymorphisms in the promoter region are often evaluated, so that confirmation of alteration in protein production or activity is necessary. Since many of these studies attempt to examine multiple polymorphisms in the same sample population, adjustment for multiple statistical testing should be applied. As noted above, candidate genes for COPD have been from categories proposed to be involved in the pathogenesis of COPD, such as proteases-antiproteases, antioxidants, and mediators of inflammation, so this approach will not uncover novel mechanisms.

Unlike the candidate gene approach, the positional cloning approach has traditionally been performed in families of affected individuals, using linkage analysis to determine if affected relatives share a region of the genome significantly more often than expected based on random chance. Broad mapping with a genome-wide set of genetic markers is performed on all individuals to evaluate linkage of the phenotype to pieces of chromosomal DNA. The disadvantage of positional cloning is the intensive labor required for the collection, phenotyping, and mapping of a large population of families. The result of linkage analysis is usually identification of a large area on a chromosome rather than a distinct gene. However, unlike the candidate gene approach, linkage analysis can discover unknown or formerly unrecognized genes involved in COPD pathogenesis. Some linkage analysis studies demonstrate that even in the absence of smoking, lung function parameters show heritability, suggesting that some

of the risk for COPD development may be attributable to genetic control of lung development.

In one study a combination of both candidate gene and positional cloning approaches was used. A domain in chromosome 19q that was linked to pre-bronchodilator FEV_1 in smokers in the Boston Early-Onset COPD study was evaluated for single nucleotide polymorphisms (SNPs) in and around the transforming growth factor-β1 (TGF-β1) gene. This study then confirmed the candidate gene findings in a second cohort of patients in the National Emphysema Treatment Trial (NETT), which includes not only the initial phenotype of low pre-bronchodilator FEV_1, but also the presence of radiographically confirmed emphysema. These NETT cases were compared to population-based control subjects. It seems likely that combining both approaches of genetic analysis together with better phenotypic characterization of COPD traits will expand knowledge of the genetic factors affecting the risk of developing COPD. Progress in SNP identification and genotyping technology has made genome-wide association studies possible, which may allow the advantages of both the candidate gene and positional cloning approaches to be applied comprehensively to complex diseases like COPD.

Airway Hyperresponsiveness

Airway hyperresponsiveness (AHR) refers to an acute decline in maximal airflow in response to inhaling potential bronchoconstricting agents such as methacholine or histamine. In COPD, AHR is associated with accelerated decline of FEV_1 and therefore is a negative prognostic marker. Intriguingly, however, AHR does not predict whether there will be some bronchodilator reversibility nor does bronchodilator responsiveness have favorable prognostic significance. The pathological features and mechanistic basis for AHR in COPD are not known, but smoking cessation is associated with reduced AHR.

AHR leads to consideration of the "Dutch hypothesis," which ascribes a role of allergy in the risk of developing COPD. What makes this area problematic is whether AHR, which is common in COPD, precedes or follows the development of COPD. An observation that argues against a causal relationship is that smokers typically do not show AHR until their baseline FEV_1 is already reduced. Confounding an analysis of the relationship is that smoking is common among asthmatics so that asthmatics are likely to be included in groups regarded as COPD.

PATHOPHYSIOLOGY

Many pulmonary function abnormalities occur in COPD, but persistent reduction in maximal forced expiratory flow is the defining physiological feature. Increased airway resistance, increased residual volume, increased residual volume/total lung capacity ratio (RV/TLC), decreased inspiratory capacity, maldistribution of ventilation, and ventilation-perfusion mismatching are also typical features.

Airflow Obstruction

Persistent reductions in FEV_1 and FEV_1/FVC are the characteristic physiological abnormalities of COPD. Measurement of the FVC at 6 seconds (FEV_6) may be an adequate and safer equivalent of measuring the FVC in individuals with severe obstruction. The reduced FEV_1 is not reversible with inhaled bronchodilators, although improvements up to 15 percent are common. In this respect, COPD differs from asthma in which large improvements in airflow with inhaled bronchodilators are characteristic. Maximal inspiratory flow may be relatively well preserved in the presence of a markedly reduced FEV_1. Such discrepancies between inspiratory and expiratory flow suggest that the reduction in forced expiratory flow in COPD is not due to fixed narrowing or obliteration of airways, but instead that there is airway instability with narrowing during forced exhalation.

Airflow during forced exhalation is the result of the balance between the elastic recoil of the lungs promoting flow and the resistance of the airways that limits flow. In normal lungs, as well as in lungs affected by COPD, maximal expiratory flow diminishes as the lungs empty because the lung parenchyma provides progressively less elastic recoil and the cross-sectional area of the airways falls so that resistance to airflow increases. The decrease in flow, coincident with the decrease in lung volume, is readily apparent on the expiratory limb of a flow-volume curve (Fig. 41-3). In the early stages of COPD, the abnormality in airflow is evident only at lung volumes at or below functional residual capacity, appearing as a "scooped out" lower part of the descending limb of the flow-volume curve. In more advanced disease, the entire curve demonstrates decreased expiratory flow.

The relative contributions of diminished elastic recoil and increased airway resistance in reducing maximal expiratory airflow can be quantified from flow-pressure curves (Fig. 41-4). With decreased elastic recoil the curve has a normal slope, but it terminates prematurely. In contrast, with increased airway resistance the slope becomes less steep, reflecting the necessity for increased driving pressure for any level of airflow. In theory, therefore, it is possible to distinguish between emphysema ("decreased elastic recoil") and small airway pathology ("increased airway resistance") as the cause for the reduced FEV_1. The situation is more complex, however, because most people with COPD have both emphysema and small airway pathology. Moreover, elastic recoil and airway resistance are not necessarily separable. Elastic recoil affects the stiffness of small airways. When elastic recoil is reduced, the curve may be shifted to the right because of increased airway collapsibility. Because flow-pressure data are difficult to collect and interpret and are of little help in patient management, sorting among decreased elastic recoil, airway collapsibility, and increased airway resistance as the mechanism of airflow obstruction in COPD is rarely done in clinical practice. Moreover, other data, such as the diffusing capacity

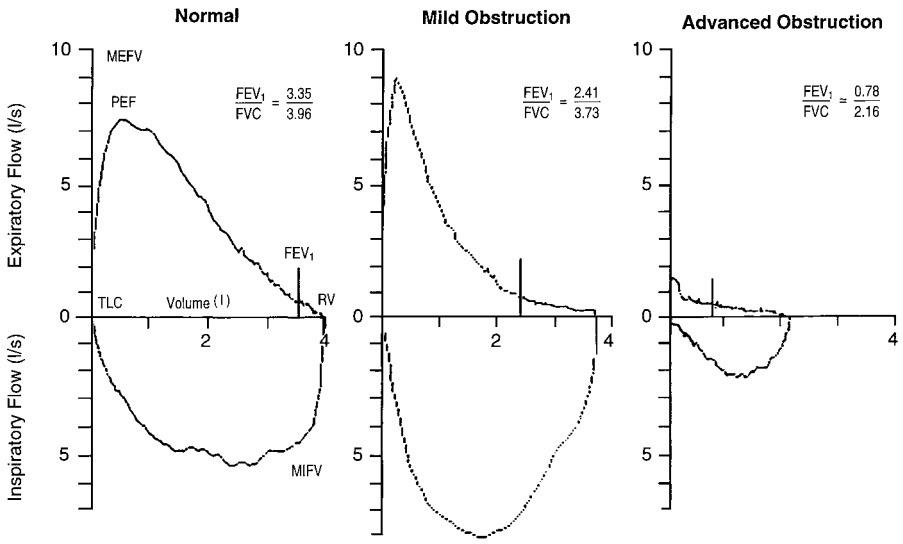

Figure 41-3 Maximum expiratory and inspiratory flow-volume (MEFV, MIFV) curves in a normal subject (left), a subject with mild airway obstruction (middle) due to COPD, and a subject with advanced obstruction (right) due to COPD. The FEV_1 is indicated on the volume axis by a vertical bar. TLC = total lung capacity; RV = residual volume; FVC = forced vital capacity. Note the development of convexity of flow to the volume axis in mild obstruction, despite preservation of a large peak expiratory flow, a normal FVC, and only a small reduction in FEV_1/FVC ratio. Inspiratory flow is normal. In advanced COPD there is marked decrease of FEV_1, FVC, and maximal expiratory airflow generally. Inspiratory flow is also markedly reduced, but spared relative to expiratory flow. *(From Pride NB, Milic-Emili J: Lung mechanics, in Calverley PMA, Pride NB [eds], Chronic Obstructive Pulmonary Disease. London, Chapman & Hall, 1995, pp 135–160, with permission.)*

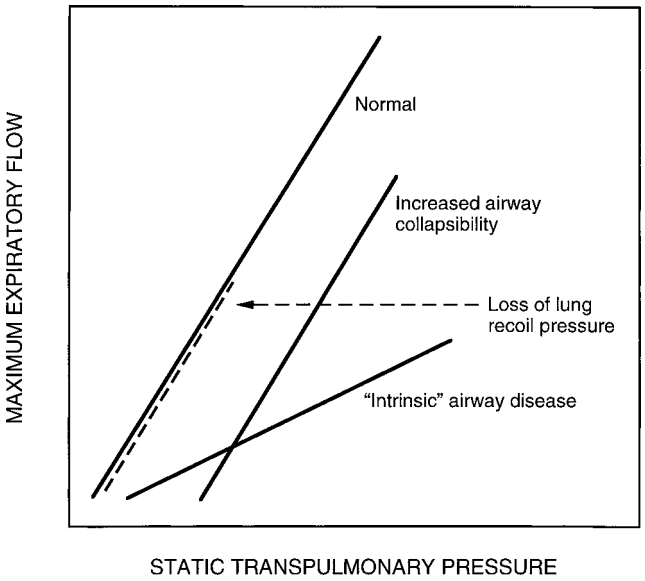

Figure 41-4 Analysis of reduced maximum expiratory flow in COPD from maximum expiratory flow vs. lung recoil pressure curves. With loss of lung recoil pressure–-i.e., "emphysema" (heavy interrupted line)–-the slope of the flow-pressure curve remains normal, but the curve terminates at lower pressure than normal. With intrinsic airway obstruction–-i.e., "bronchitis"–-the slope is reduced. Increased airway collapsibility, which may be a result of decreased elastic recoil, causes the curve to be displaced to the right. Commonly in COPD, the flow-pressure curve has premature termination and a decreased slope and is shifted rightward, indicating that decreased elastic recoil, increased airway resistance, and increased airway collapsibility are all involved in causing the reduced maximum expiratory flow. *(From Pride NB, Milic-Emili J: Lung mechanics, in Calverley PMA, Pride NB [eds], Chronic Obstructive Pulmonary Disease. London, Chapman & Hall, 1995, pp 135–160, with permission.)*

and chest computed tomography may provide estimates of the severity of emphysema. As discussed below, the correlation between FEV_1 is better with small airway pathology than with emphysema.

Although there is considerable variability in the relationships between the FEV_1 and other physiological abnormalities in COPD, certain generalizations may be made. The arterial oxygen tension (Pa_{O_2}) usually remains near normal until the FEV_1 is decreased to about half of the predicted level; even a much lower FEV_1 may be associated with a normal Pa_{O_2}, at least at rest. An elevation of arterial P_{CO_2} (Pa_{CO_2}) is not expected in COPD until the FEV_1 is less than about one-fourth of predicted; even then an elevation in arterial carbon dioxide tension (Pa_{CO_2}) may not occur. Pulmonary hypertension due to COPD that is severe enough to cause cor pulmonale and right ventricular failure occurs only in persons who have a marked decrease in FEV_1 (one-fourth of predicted or less) and chronic hypoxemia (Pa_{O_2} under 55 mmHg), although some elevation of pulmonary artery pressure, particularly with exercise, is common with less advanced COPD.

Maldistribution of Ventilation and Ventilation-Perfusion Mismatching

Maldistribution of ventilation and ventilation-perfusion mismatching are characteristic of COPD and reflect the heterogeneous nature of the disease process as it affects the airways and lung parenchyma. Nitrogen washout during breathing of 100 percent oxygen is delayed because of regions that are poorly ventilated, and the profile of the nitrogen washout curve is consistent with many parenchymal compartments

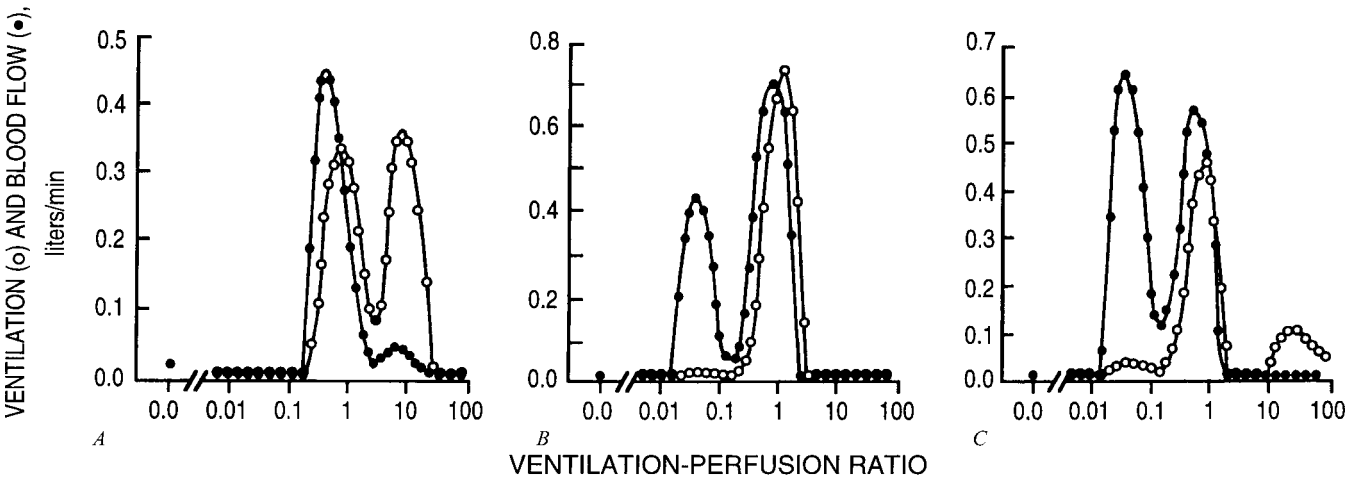

Figure 41-5 Ventilation-perfusion distributions in three persons with COPD determined by the multiple inert gas elimination technique (MIGET). *A*. Regions of high ventilation-perfusion characteristic of "emphysematous," type A COPD. *B*. Regions of low ventilation-perfusion characteristic of "chronic bronchitis," type B COPD. *C*. Regions of both high and low ventilation-perfusion characteristic of many people with COPD. In the normal person, not shown, ventilation-perfusion virtually overlaps and peaks at about a ventilation-perfusion ratio of 1. *(From Wagner PD, Dantzker DR, Dueck R, et al: Ventfl ation-perfusion inequality in chronic obstructive pulmonary disease. J Clin Invest 59:203–216, 1977, with permission.)*

having different washout rates because of regional differences in compliance and airway resistance. Radioisotopic ventilation scanning with ^{133}xenon reveals regional heterogeneity of ventilation in COPD.

The multiple inert gas elimination technique (MIGET), which enables quantification of the ventilation-perfusion profile, has demonstrated different ventilation-perfusion patterns among patients with advanced COPD (Fig. 41-5). In one pattern, so-called type A ("pink puffer") COPD, there is a substantial amount of ventilation distributed to high ventilation-perfusion regions. In a second pattern, called type B ("blue bloater") COPD, there is a substantial amount of pulmonary blood flow perfusing low ventilation-perfusion regions. There are important limitations to this simple classification. First, persons with the clinical features of type A or type B (that is, emphysema or chronic bronchitis) do not necessarily have the expected ventilation-perfusion pattern. Of perhaps greater importance, most people with COPD are not easily classified as either type A or type B. They have both high and low ventilation-perfusion regions. MIGET has also revealed that an increased dispersion of ventilation-perfusion values is already present in the early stage of COPD.

Ventilation-perfusion mismatching accounts for essentially all of the reduction in Pa_{O_2} that occurs in COPD; shunting is minimal. Thus, modest elevations of inspired oxygen are effective in treating hypoxemia due to COPD. If hypoxemia is difficult to correct other problems such as pulmonary emboli or right to left intracardiac or intrapulmonary shunting need to be considered.

Hyperinflation

Hyperinflation, defined in various ways (increased functional residual capacity, increased residual volume to total lung capacity, increased total lung capacity, or decreased inspiratory capacity to total lung capacity) is common in COPD of moderate severity or worse. Hyperinflation might be beneficial as it favors preservation of maximum expiratory airflow because as lung volume increases, elastic recoil pressure increases, airway lumens enlarge, and airway resistance decreases. However, hyperinflation has adverse effects on the mechanics of the thorax, increasing the work of breathing and eliciting dyspnea.

Hyperinflation displaces the diaphragm into a flattened position and, thereby, creates a number of adverse effects (Fig. 41-6). First, because the zone of apposition between the diaphragm and the abdominal wall is lost, positive abdominal pressure during inspiration is not transmitted as effectively to the chest wall, hindering rib cage movement and impairing inspiration. Second, because the muscle fibers of the flattened diaphragm are shorter than those of a more normally curved diaphragm, they are less capable than normal of generating inspiratory pressures. Third, the flattened diaphragm must generate greater tension to develop the transpulmonary pressure required to produce tidal breathing. This follows from Laplace's law, $P = 2T/r$. As the radius of diaphragm curvature (r) increases with diaphragm flattening, the tension (T) required to develop a transpulmonary pressure (P) to generate tidal breathing must increase. Also, with hyperinflation, the thoracic cage, in general, must operate at a mechanical disadvantage. Because the thoracic cage is distended beyond its normal resting volume, during tidal breathing, the inspiratory muscles must do work to overcome the resistance of the thoracic cage to further inflation instead of gaining the normal assistance from the chest wall recoiling outward toward its resting volume. Typically hyperinflation increases further on exercise because airflow obstruction limits lung emptying during rapid breathing. This additional hyperinflation,

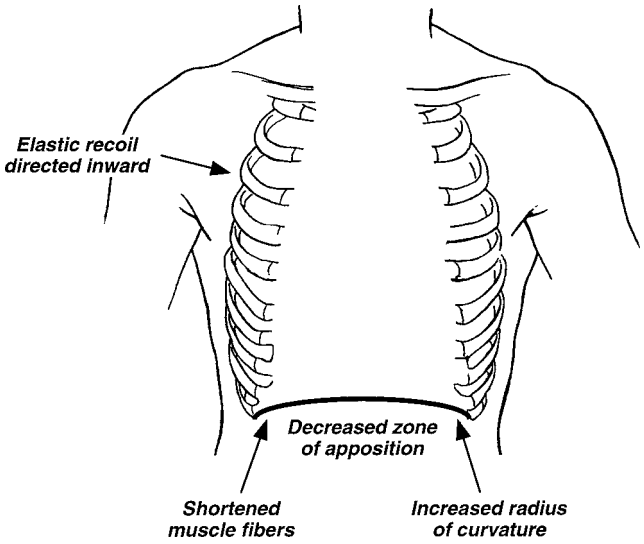

Figure 41-6 Detrimental effects of hyperinflation on diaphragmatic function. Hyperinflation causes flattening of the diaphragm, which (1) decreases the zone of apposition between the diaphragm and the abdominal wall, hindering rib cage movement; (2) shortens diaphragmatic muscle fiber length, decreasing the force that can be generated by the diaphragm; (3) increases the radius of curvature of the diaphragm, thereby decreasing transpulmonary pressure (at constant tension); and (4) directs diaphragmatic muscle fibers medially, impairing inflation with diaphragmatic contraction. In addition, hyperinflation prevents the thorax from assisting inspiration during tidal breathing because the resting volume of the thorax is above the volume at which the rib cage recoils outward during inspiration. *(From Yusen RD, Lefrak SS, and the Washington University Emphysema Surgery Group: Evaluation of patients with emphysema for lung volume reduction surgery. Semin Thorac Cardiovasc Surg 8:1–12, 1996, with permission.)*

designated dynamic hyperinflation, adds to the load on the inspiratory muscles while further reducing their mechanical advantage. The net effect is increased work of breathing, diminished capacity for exercise, and increased dyspnea.

Coincident with hyperinflation, the inspiratory capacity (IC) is commonly reduced in COPD. Reduction of the IC has prognostic significance that is independent of FEV_1. In a study of subjects with moderate to very severe COPD, survival was markedly shorter in 286 individuals whose IC/TLC was less than 25 percent compared to 403 individuals whose IC/TLC was greater than 25 percent, even though the two groups had comparable severity of COPD based on percent predicted FEV_1.

Dyspnea

People with COPD typically seek medical care because of dyspnea. Dyspnea compromises their activities and quality of life. Dyspnea is seldom a complaint until the FEV_1 has fallen below about 60 percent of predicted; however, the correlation between FEV_1 and exercise limitation is not strong. Some individuals with COPD are relatively free of dyspnea despite impressively low levels of FEV_1.

The mechanisms of dyspnea in COPD are not fully understood. Neural signals relating to abnormalities of chest wall and airway mechanics appear to be important. Specifically, an increased sense of effort relating to the pressures needed from the respiratory muscles relative to their maximum pressure-generating capacity is thought to be one factor in producing dyspnea. Signals of "length-tension inappropriateness" from the respiratory muscles due to hyperinflation constitute another. Also, impulses from airways undergoing abnormal dynamic compression during exhalation have been described. Hypercapnia and hypoxemia play only a small role, except in acute situations. Oxygen administration may decrease breathlessness by reducing ventilation during exertion and through poorly understood direct effects not associated with changes in ventilation.

Physiological-Pathological Correlations

Approximately 40 years ago Hogg and colleagues discovered that airways 2 mm or less in internal diameter normally contribute only a minor part of the total airway resistance, but that these airways become the principal sites of increased airway resistance in COPD. Although it is well accepted that the functional obstruction to airflow in COPD is in the small airways, the relative importance of emphysema vs. intrinsic abnormalities of the small airways as the physical basis for the obstruction is still under investigation. Emphysema and small-airway pathology are both present in most persons with COPD so that their relative contributions to obstruction might vary from one patient to another. However, correlations between emphysema severity and airflow obstruction are poor (Fig. 41-7), while a recent analysis found good correlations exist between airway pathology and GOLD classes. Thus, it appears that airflow obstruction in COPD is especially associated with structural abnormalities in the small airways.

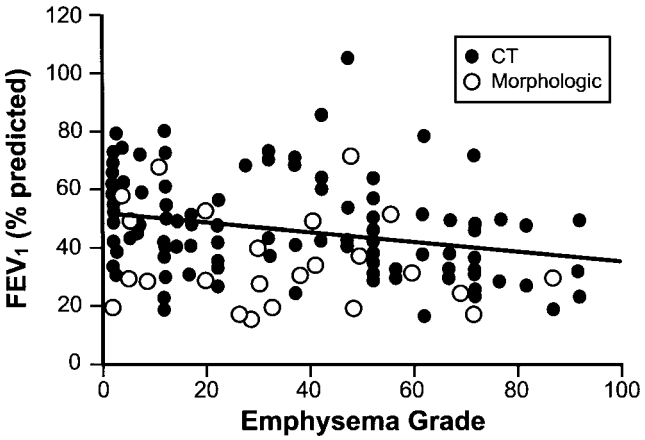

Figure 41-7 Emphysema score vs. FEV_1 (% predicted). Emphysema graded either by direct examination of lung tissue or by chest computed tomography. There is no correlation between emphysema severity and FEV_1. *(From Gelb AF, Hogg JC, Schein M: Contribution of emphysema and small airways in COPD. Chest 109:353–359, 1996, with permission.)*

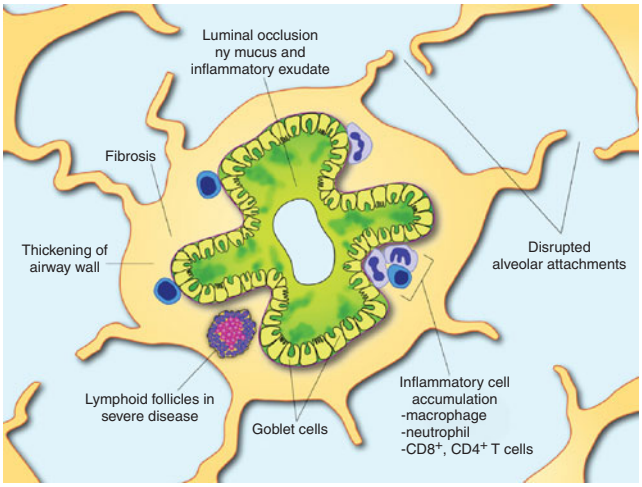

Figure 41-8 Small airway pathology in COPD. Multiple pathological lesions can be found. In some studies, but not all, quantification of these abnormalities correlates with the reduction in FEV_1. *(Reproduced with permission from Senior RM, Silverman EK: XXII Chronic Obstructive Pulmonary Disease. 14 Respiratory Medicine. ACP Medicine. Dale DC, Federman DD, eds. WebMD Inc., New York, 2007 [www.acpmedicine.com].)*

Small airways in the lungs of individuals with COPD typically show multiple abnormalities that include goblet cell metaplasia, replacement of surfactant-secreting Clara cells with mucus-secreting cells, and infiltration of the walls by inflammatory cells that, in severe disease, may include lymphoid follicles (Fig. 41-8) (see Chapter 40).These changes are accompanied by increased connective tissue and mesenchymal cells in the subepithelial and adventitial compartments of the airway walls. Alveolar tissue surrounding small airways normally provides radial traction on bronchioles at points where alveolar septa attach. Loss of these bronchiolar attachments as a result of proteolytic destruction may contribute to airway distortion, narrowing, and instability.

PATHOGENETIC PROCESSES

COPD represents the clinical expression of complex alterations in structure and function of alveolar tissue and small airways. Many processes at the tissue and cellular levels can be implicated, including inflammation, cell proliferation, apoptosis, altered phenotype of lung cells, and remodeling of the extracellular matrix. Numerous mediators, most notably proteinases, oxidants and cytokines, are involved in these processes. Studies in genetically altered mice have proven invaluable in helping to elucidate the pathogenesis of COPD, especially emphysema.

Inflammation

As reflected in the definition of COPD, inflammation occupies a central role in current thinking about the pathogenesis of COPD. The inflammation paradigm is that smoking and other types of inhaled irritants lead to recruitment of inflammatory cells to the lungs and airways and that products of these recruited cells injure lung tissue and disrupt normal mechanisms of lung repair. Indeed, inflammation is prominent in airways and lung parenchyma in biopsies, surgical specimens, and postmortem material from individuals with COPD. Other indicators of inflammation are increased inflammatory cells in bronchoalveolar lavage fluid (BALF) and sputum and increased volatile products of inflammatory cells in exhaled breath. Inflammatory cells associated with COPD include neutrophils, eosinophils, macrophages, and lymphocytes. Once the inflammatory process is initiated by smoking the process may persist long after smoking has stopped.

Unlike nonsmokers, macrophage accumulations are found in respiratory bronchioles in smokers, and BALF from smokers contains many fold increases in macrophages compared to the numbers in BALF from nonsmokers. Besides releasing proteinases that might degrade the extracellular matrix of the lung, alveolar macrophages in COPD make chemotactic factors that recruit other inflammatory cells to the lungs. Likewise, structural cells of the lungs in COPD produce proteinases and chemotactic factors for inflammatory cells. Expression of interleukin-8 (IL-8), macrophage inflammatory protein-1α (MIP-1α), and monocyte chemoattractant protein-1 (MCP-1), for example, are up-regulated in bronchiolar epithelium in COPD. T cells from COPD lungs produce cytokines that stimulate production of matrix metalloproteinases by macrophages. Peptides of elastin are chemotactic for inflammatory cells and, in some experimental models of emphysema the elastin peptides present in the lung are crucial to the inflammatory process, suggesting that destruction of the lung's extracellular matrix may be a self-perpetuating process. In mice, genetically induced overexpression of cytokines such as IL-13 or γ-interferon by lung cells leads to emphysema that is mediated by proteinases from inflammatory cells.

Cellular and humoral immunity may be involved in emphysema pathogenesis. CD4+ and CD8+ T cells and B cells accumulate in alveolar and airway tissue in COPD and form bronchus-associated lymphoid tissue (BALT) in the walls of small airways, and an increasing BALT in small airways correlates with increasing GOLD stage. In mice, exposure of antibodies to endothelial cells elicits alveolar septal cell destruction. Speculation about antigens for immunologically driven emphysema in patients include microbial pathogens, material contained in tobacco smoke, and peptides released from lung extracellular matrix.

Proteinase-Antiproteinase Imbalance

Proteinases of several biochemical classes, and requiring different inhibitors, are implicated in the pathogenesis of emphysema. Serine proteinases, especially neutrophil elastase, and several matrix metalloproteinases (MMPs), especially MMP-1 (collagenase), MMP-9 (gelatinase B), MMP-12 (macrophage elastase), and MMP-14 (MT1-MMP, membrane-type 1 MMP), have been the classes and specific proteinases for which there are the most data.

For many years neutrophils and macrophages were considered to be the exclusive sources of proteinases involved in COPD. Now it is appreciated that other types of inflammatory cells and even structural cells of the lungs may produce proteinases that promote emphysema. Besides degrading matrix proteins, proteinases may exert other effects that relate to the pathogenesis of COPD, such as releasing cell-bound and matrix-bound chemokines, activating growth factors, and inducing expression of mucin genes. However, α_1-AT deficiency is still the only situation of proteinase-antiproteinase imbalance in COPD in which both the proteinase (neutrophil elastase) and its inhibitor (α_1-AT) have been definitively established. It must be emphasized that little is known about proteinases in the pathogenesis of the small-airway pathology of COPD. Virtually all of the information about proteinases in COPD pertains to emphysema. Accordingly, we discuss proteinases below in the context of the pathogenesis of emphysema.

Oxidant-Antioxidant Imbalance

Reactive oxygen species in cigarette smoke or released by inflammatory cells and structural cells of the lungs in response to smoke may lead to lung injury (see Chapter 25). Up to 20 mg of tar may be deposited in a smoker's lung per cigarette smoked. This tar contains more than 10^{17} stable, long-lived radicals per gram. The gas phase of tobacco smoke contains 10^{15} organic radicals per puff of smoke, although in general these small oxygen- and carbon-centered species are more short-lived and reactive than the radicals in the particulate phase. Tobacco smoke appears to "prime" neutrophils and alveolar macrophages to generate elevated amounts of reactive oxygen species, such as hydrogen peroxide, hydroxyl radicals, and superoxide radicals. The lung tissue of smokers also contains significantly more iron than that of nonsmokers, providing a catalyst for the production of hydroxyl radicals from H_2O_2. Additionally, smokers demonstrate increased production of neutrophil myeloperoxidase, which is capable of yielding oxidized halogens such as hypochlorous acid (HOCl). Oxidants can modify and inactivate proteins, protease inhibitors (such as α_1-AT and secretory leukoprotease inhibitor [SLPI]), and histone deacetylase 2 (HDAC2), which is involved in glucocorticoid mediated anti-inflammatory responses. Oxidants can also affect lipids and DNA, and some specific end products, such as 4-hydroxy-2-nonenal (4-HNE) and 8-hydroxy-2′-deoxyguanosine (8-OHdG), may be markers of COPD.

Directly relevant to the inflammatory hypothesis of COPD, oxidants can promote inflammation and proteinase expression via intracellular signaling pathways that involve mitogen-activated protein kinases (MAPK), nuclear factor (NF)-κB, and other pro-inflammatory signaling molecules (Fig. 41-9). Oxidants can induce apoptosis. Oxidants may also facilitate proteinase-mediated extracellular matrix degradation by enhancing matrix molecule susceptibility to proteolytic cleavage, and may participate in nonenzymatic degradation as in the case of the effects of hydroxyl radicals on type I collagen. In experimental animals the combination of cigarette smoke and elastase leads to greater emphysema than either insult alone, suggesting that these insults do not elicit identical responses.

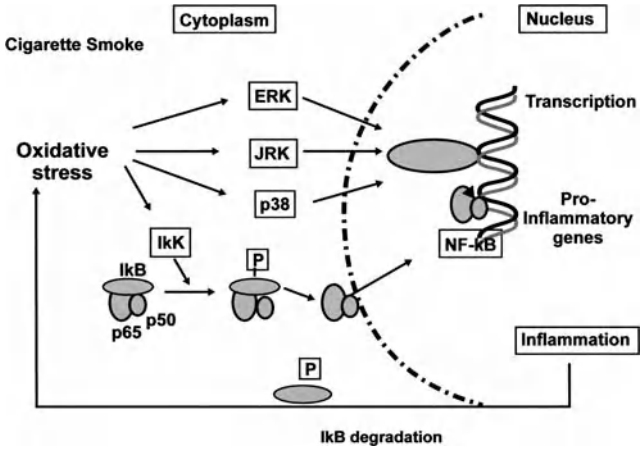

Figure 41-9 Activation of signal pathways by oxidative stress. Ap-1 = activating protein 1; erk = extracellular signal-related kinase; ikk = inhibitor kb kinase; jnk = c-jun n-terminal kinase; nf-b = nuclear factor b; p = phosphate. *(From MacNee W: Pulmonary and systemic oxidant/antioxidant imbalance in chronic obstructive pulmonary disease. Proc Am Thorac Soc 2:50–60, 2005, with permission.)*

A number of antioxidant enzymes protect against oxidative injury. Intracellular oxidant concentrations are controlled by copper- and zinc-dependent superoxide dismutases in the cytoplasm and a manganese-dependent form in mitochondria. H_2O_2 is eliminated by catalase and glutathione peroxidase. Additional antioxidants include α-tocopherol and ascorbate, which are enriched in epithelial lining fluid. Gene profiling of airway epithelium in long-time smokers suggests that the glutathione pathways are induced, but the catalase and superoxide dismutases are not. Experimental evidence for the importance of the antioxidant system in protection against cigarette smoke– induced damage is apparent in mice lacking the master antioxidant regulator, nuclear factor E2-related factor (Nγf-2). When these mice are exposed to cigarette smoke they develop emphysema whereas identical mice that have normal Nγf-2 are resistant to the development of emphysema. Interestingly, the underlying mechanisms for emphysema vary between mouse strains. The capacity to mount antioxidant responses appears to influence the capacity to generate antiproteases as Nγf-2– deficient mice develop more severe emphysema in response to intratracheally administered elastase than controls. Thus, it appears that Nγf-2 protects against the development of emphysema not only by regulation of oxidant/antioxidant balance, but also by influencing inflammation and protease/antiprotease balance.

Although the antioxidant defense system may be compromised by the oxidative stress imposed by smoking, this has not been proven. In fact, some evidence suggests that

protective mechanisms are enhanced. The antioxidant capability of alveolar macrophages from smokers is increased and glutathione levels in alveolar lining fluid are elevated. Ascorbate and α-tocopherol levels in smokers are difficult to interpret, with increased levels in macrophages and decreased levels noted in serum and alveolar lining fluid.

Apoptosis

An early theory of emphysema development was that alveolar vascular destruction preceded loss of alveolar tissue. Recent data suggest that this speculation may have merit since blockade of vascular endothelial growth factor (VEGF) signaling in alveolar endothelial cells or genetic down-regulation of VEGF production in alveolar epithelium produces apoptosis and noninflammatory emphysema in rodents. The same result can be achieved by instilling the pro-apoptotic protein caspase-3 into the lungs. These experimental studies may actually have relevance to human emphysema as apoptotic cells can be found in emphysematous lungs and smokers' lungs but not in nonsmokers' lungs. In vitro, cigarette smoke induces apoptosis of several lung cell types. The mechanisms by which apoptosis leads to emphysema are still not well understood, but in the caspase-3 study mentioned above apoptotic alveolar type II cells degraded elastin. An important feature of experimental models of emphysema due to apoptosis is that there is minimal inflammation. In contrast to the expanding body of information linking emphysema to apoptosis, there is only scant information about apoptosis of the cells of small airways in COPD. Much remains to be learned about apoptosis in the context of COPD.

Mucus Hypersecretion

Airway mucus is a normal protective barrier that is constantly replenished and cleared in health (see Chapter 8). Mucin glycoproteins, the main components of mucus, have a core protein rich in serine and threonine, to which carbohydrates and cysteine residues are attached. It is secreted from submucosal glands and airway goblet cells. In COPD there is hyperplasia of goblet cells and hypertrophy of glands with an increase in the ratio of glandular mucus cells to serous cells. The changes in COPD are associated with an alteration of the mucus proteins (MUCs) to favor a predominance of MUC5B over the typical MUC5AC form, and an increase in the MUC2 form, which is uncommon in normal lung mucus. Other alterations in the mucus layer in COPD include greater acidity, less mucin glycosylation, and decreased antimicrobial peptides. Mediators responsible for mucus hypersecretion include proteinases (neutrophil elastase and MMP-9), cytokines (tumor necrosis factor α, TNFα), oxidants, dual oxidase, TNFα-converting enzyme (TACE), and epidermal growth factor receptor (EGFR) ligands.

Determining the relationship between chronic cough and sputum in patients with COPD and the natural history of COPD has been elusive. Reports vary from finding weak to strong correlations between cough and sputum production and COPD progression, COPD exacerbations, and mortality. A relationship between chronic mucus hypersecretion in small airways and adverse outcomes is plausible as histological analysis of small-airway pathology in COPD demonstrated that the extent of small-airway luminal obstruction by mucus correlated with the GOLD stage. However, the correlation with the GOLD stage was stronger for inflammatory cell infiltration into the walls of the small airways than the luminal mucus obstruction.

PATHOGENESIS OF EMPHYSEMA

General Concepts

The standard definition of emphysema is "a condition of the lung characterized by abnormal, permanent enlargement of airspaces distal to the terminal bronchiole, accompanied by destruction of their walls, and without obvious fibrosis." Although overt fibrosis may not be a finding, studies since this definition was enunciated indicate increased collagen per unit volume of airspace wall in emphysematous lungs associated with active synthesis of extracellular matrix. Also, emphysematous tissue has been found to exhibit both apoptosis and proliferation of alveolar cells. Accordingly, emphysematous lung tissue should be viewed as undergoing remodeling rather than simply a destructive process.

The pathogenesis of emphysema was obscure until 1963 when Laurell and Eriksson reported an association between deficiency of serum α_1-AT and chronic airflow obstruction with emphysema. At approximately the same time Gross and associates described the first reproducible model of emphysema by injecting the plant proteinase papain, a potent elastase, into the lungs of rats via the trachea. Together, these observations led to the proteinase-antiproteinase hypothesis of emphysema which has been the prevailing concept of the pathogenesis of emphysema ever since.

According to the proteinase-antiproteinase hypothesis, there is normally a steady or episodic release of proteolytic enzymes into the lung parenchyma, principally from inflammatory cells. Under normal conditions plasma proteinase inhibitors, especially α_1-AT, permeate lung tissue and prevent proteolytic enzymes from digesting structural proteins of the lungs. Proteinase inhibitors synthesized locally in the lungs also contribute to the antiproteinase "shield". Emphysema results when there is an imbalance between proteinases and antiproteinases in favor of proteinases due to an augmentation of proteinase release in the lungs, a reduction in the antiproteinase defense within the lungs, or a combination of both increased proteinase burden and decreased proteinase inhibitory capacity. It is important to appreciate that proteolytic injury to the extracellular matrix of the lung does not necessarily operate throughout the lungs as a whole. In fact, proteolytic events are tightly controlled and occur at or near the surface of cells. Thus, "imbalance" between proteinases

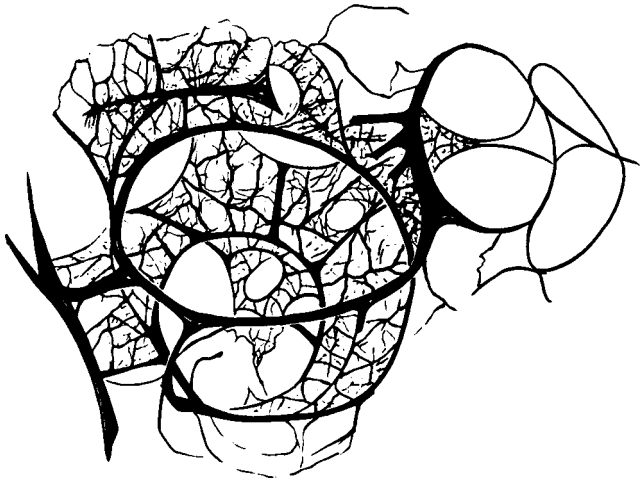

Figure 41-10 Alveolar elastic fiber network. Artist's sketch of the elastic fibers in the parenchyma of human lung showing how elastic fibers form a helix encircling the alveolar ducts and penetrate into alveolar septae. *(From Pierce JA, Ebert RV: Fibrous network of the lung and its change with age. Thorax 20:469–476, 1965.)*

and their inhibitors probably should be viewed as operating in microenvironments immediately surrounding cells.

Lung Elastic Fibers

The original observations linking proteinases and emphysema led to the concept that destruction of alveolar elastic fibers is a key to emphysema development. Indeed the proteinase-antiproteinase hypothesis of emphysema pathogenesis became, in fact, the "elastase-antielastase hypothesis".

Structurally, the extracellular matrix of the lung is organized into three interdependent cable systems: (1) an axial system that extends from the central airways through the peripheral airways to the alveolar ducts; (2) a parenchymal system that comprises the matrix of the alveolar septae; and (3) a peripheral system that arises from the visceral pleura and extends into the interlobular septae, forming a fibrous sac around the lung. Distal to the respiratory bronchioles, the axial system forms a helix encircling the alveolar ducts, extending into the interstitium of alveolar walls. Elastic fibers, of which elastin is the main component, loop around alveolar ducts, form rings at the mouths of the alveoli, and penetrate as wisps into the alveolar septae, where they are concentrated at bends and junctions (Fig. 41-10). Elastic fibers, which possess rubberlike reversible extensibility, come under tension and provide elastic recoil throughout the respiratory cycle. Unlike elastic fibers, the interstitial collagen fibers in alveolar septa are nondistensible and have high tensile strength. They can be thought of as relaxed ropes that straighten during inspiration and become taut at total lung capacity.

Elastin is resistant to many proteinases, most notably the collagenases that cleave interstitial collagens. However, there are a number of enzymes that may come in contact with the lung that can degrade elastin (Table 41-2). Elastic fibers in the lung normally last a full human life span. There is virtually no elastin synthesis in the normal adult lung, but animal studies indicate that elastin synthesis can be reinitiated in the adult lung.

Table 41-2

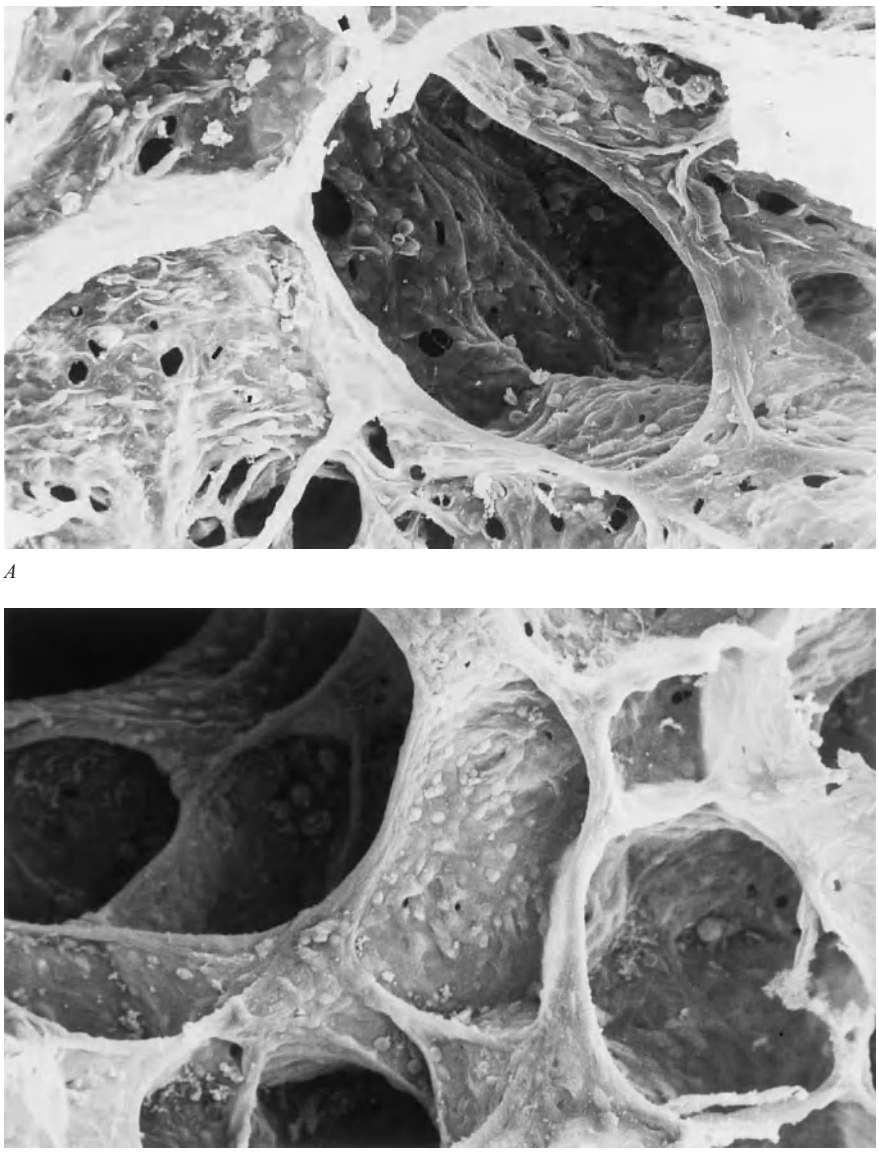
Elastolytic Proteinases that May Affect the Lung Parenchyma

Proteinase	Cell of Origin
Neutrophil elastase	Neutrophil (Monocyte)
Proteinase 3	Neutrophil (Monocyte)
Cathepsin G	Neutrophil (Monocyte, mast cell)
MMP-9 (Gelatinase B)	Macrophage, neutrophil, eosinophil, fibroblast, epithelial cell
MMP-12 (Macrophage elastase)	Macrophage
Cathepsin L	Macrophage
Cathepsin S	Macrophage

Note: Parentheses denote minor cellular sources.

Histological studies of emphysematous lung tissue support the hypothesis that elastic fibers are perturbed in emphysema. There are fragmented elastic fibers in α_1-AT deficiency and poorly formed elastic fibers and clumps of elastin in smokers with centriacinar emphysema. The latter changes appear to be from aberrant synthesis of new elastin and resemble the findings in the lungs in emphysema induced experimentally with elastase.

What little is known about lung repair in response to elastolytic proteinases derives from animal research. After an intratracheal injection of human neutrophil elastase into an experimental animal, acute depletion of elastin occurs, followed by a burst of synthesis of extracellular matrix including elastin. Over a few weeks, the elastin content of the lungs returns to normal, although the lungs display emphysema. The elastic fibers, like the elastic fibers in human emphysema, appear disorganized. Thus, even if elastin expression can be reinitiated in the adult human lung, the production of normal elastic fibers is not achieved. This is not surprising as production of elastic fibers entails temporally and physically coordinated expression of the many components of the elastic fiber. One way in which smoking may impair lung elastic



A

B

Figure 41-11 Holes in alveolar walls in early emphysema. Scanning electron micrographs of alveolar walls from surgically resected specimens: lung with mild emphysema (*A*) and non-emphysematous lung (*B*). Holes are more numerous in alveolar walls in the emphysematous lung than in the normal lung. Original magnification ×250. *(From Nagai A, Inano H, Matsuba K, et al: Scanning electron microscopic morphometry of emphysema in humans. Am J Respir Crit Care Med 150:1411–1415, 1994, with permission.)*

fiber synthesis is by inhibiting lysyl oxidase, the enzyme that catalyzes the first step in the conversion of tropoelastin monomers to the elastin polymer.

Lung Collagen Turnover

Although elastases and elastic fiber destruction dominate thinking about the pathogenesis of emphysema, degradation of alveolar wall collagen and aberrant collagen deposition in alveolar tissue may also be involved. Indeed, collagen destruction may be the critical event in some forms of experimental emphysema. Mice genetically engineered to harbor a transgene that leads to expression of human MMP-1 (collagenase) in lung tissue develop enlarged alveoli, bullous lesions, and reduced collagen fibers in alveolar walls and pleura. Depending on the level of transgene activity the lung lesions can start early after birth or later, indicating that the emphysema is post-developmental. Besides showing that collagenase activity can lead to emphysema, results with these mice also indicate that proteinases causing emphysema can be from structural cells of the lungs, as there is minimal inflammation in the lungs, and that emphysema can occur without obvious disruption and faulty resynthesis of elastic fibers as the elastic fibers in these lungs look normal.

In emphysematous lungs the pores of Kohn are larger and more numerous than in normal lungs (Fig. 41-11). Because interstitial collagens and basement membrane collagens are prominent in alveolar walls, it seems plausible that collagenous structures undergo degradation in the process of increasing the number and size of these interalveolar pores.

Proteinases

The high risk of emphysema among smokers with severe α_1-AT deficiency is the most compelling evidence linking a

proteinase, in this case neutrophil elastase, to emphysema. Thus far, gene profiling of emphysematous lung tissue has shown only limited changes in proteinases and proteinase inhibitors compared to control lung tissue. Success in protecting mice from smoke-induced emphysema through knockouts of proteinase genes or by treatment with proteinase inhibitors has reinforced the proteinase-antiproteinase hypothesis. Neutrophil elastase and several MMPs, some released by neutrophils, and others produced by alveolar macrophages and structural cells of the lungs have been the predominant proteinases implicated in emphysema.

Neutrophil Elastase

Ever since the discoveries of α_1-AT deficiency and neutrophil elastase, this proteinase has been prominent in the consideration of emphysema pathogenesis. Neutrophil elastase is a serine proteinase. Like other serine proteinases it has conserved histidine, asparagine, and serine residues that form a charge relay system that functions by transfer of electrons from the carboxyl group of asparagine to the oxygen of serine. The serine then becomes a powerful nucleophile that is able to attack the carbonyl carbon atom of the peptide bond of the substrate. It is synthesized as a pre-proenzyme in the endoplasmic reticulum, processed by cleavage of the signal peptide (pre-) and removal of a dipeptide (pro-) by cathepsin C. Its synthesis occurs in the bone marrow during a very specific stage in myeloid development and it is stored in azurophil granules as an active packaged protein. It has activity against elastin and other extracellular matrix proteins, as well as many non-matrix substrates. Because neutrophils can concentrate it on their plasma surface, it may function in the extracellular environment despite large excesses of α_1-AT and other inhibitors.

Following the early connection of α_1-AT and neutrophil elastase, later evidence implicating neutrophil elastase in the pathogenesis of emphysema has included: (1) increased presence of neutrophil elastase, both free and in complex with α_1-AT, in BALF of people with emphysema; (2) the presence of neutrophil elastase in emphysematous lung tissue; and (3) finding that mice lacking neutrophil elastase ("knockouts") show significant protection from the development of emphysema in response to chronic inhalation of cigarette smoke. Although neutrophil elastase may be the predominant elastase associated with emphysema, other enzymes in the lung have elastase activity (Table 41-2).

Matrix Metalloproteinases (MMPs)

For many years neutrophil elastase dominated thinking about proteinases and emphysema. In recent years, however, MMPs have become a focus. MMPs are a family of neutral proteinases that degrade extracellular matrix and modify many other substrates. This enzyme family can be subdivided based on secretion vs. membrane association. Membrane-type MMPs are linked to the cell surface and are more resistant to inhibition by secreted antiproteinases than MMPs in pericellular spaces. MMPs are secreted as inactive proenzymes, which are activated at the cell membrane surface or within the extracellular space by proteolytic cleavage of the N-terminal domain. Catalytic activity is dependent on coordination of a zinc ion at the active site and is specifically inhibited by members of another gene family, tissue inhibitors of MMPs known as the tissue inhibitor of metalloproteinases (TIMPs) (see below). Although the name implies that MMPs are directed at extracellular matrix, MMPs may exert proteolytic activity against other substrates such as α_1-AT and various cytokines. Accordingly, MMPs may promote the development of emphysema in diverse ways.

Individual members of the MMP family can be loosely divided into groups based on their matrix-degrading capacity. As a whole, they are able to cleave all extracellular matrix components at neutral pH. The collagenolytic MMPs have the unique capacity to cleave native triple helical interstitial collagens, but have a restricted substrate specificity and are unable to degrade elastin or basement membrane molecules. In lung tissue exhibiting emphysema, various cell types express MMP-1 (collagenase 1), MMP-2 (gelatinase A), and membrane-type 1 MMP (MT1-MMP; MMP-14). In other types of analyses, MMPs associated with COPD include MMP-8 (collagenase 2) and MMP-9 (gelatinase B) in BALFs and MMP-12 (macrophage elastase) in alveolar macrophages.

MMP-8 (neutrophil collagenase) and MMP-9 (gelatinase B) are stored within specific granules in neutrophils from which they are readily released by a variety of stimuli. Alveolar macrophages produce multiple MMPs, including 2, 9, 12, and 14. However, MMPs are scarcely expressed in normal lung tissue. Their production and activity are carefully controlled during normal repair and remodeling processes. With chronic inflammation, regulation of MMPs may go awry, and MMPs may be overexpressed and produced at inappropriate sites. MMP-12 is up-regulated in alveolar macrophages of cigarette smokers. Elimination of MMP-12 by gene targeting protects mice from emphysema induced by cigarette smoke. As already noted, overexpression of MMP-1 in the lungs of transgenic mice leads to enlarged airspaces characteristic of emphysema. In advanced emphysema, alveolar type II cells produce MMP-1 and smoke exposure induces MMP-1 expression by human airway epithelial cells and lung fibroblasts in cell culture. Accordingly, there is considerable evidence implicating both elastolytic and collagenolytic MMPs in the pathogenesis of emphysema.

Cysteine Proteinases

Human alveolar macrophages can produce multiple cysteine proteinases, including cathepsins L and S which have large active pockets with relatively indiscriminate substrate specificities that include elastin and other matrix components. These enzymes have their maximum activity at acidic pH, but cathepsin S retains about 25 percent of its elastolytic capacity at neutral pH, making it approximately equal to neutrophil

Table 41-3

Proteinase Inhibitors in the Lung Parenchyma

Inhibitor	Cell of Origin	Class of Proteinases Inhibited
α_1-antitrypsin	Hepatocyte (Mononuclear phagocyte)	Serine*

elastase. Thus, these enzymes have the capacity to cause lung destruction if they are targeted to the cell surface or extracellular space, especially if macrophages can acidify their microenvironment.

Proteinase Inhibitors

Considerations of proteinase inhibition in COPD have tended to focus on α_1-AT. However, other inhibitors may serve important antiproteinase functions in lung tissue (Table 41-3).

Inhibitors of Serine Proteinases

Low-molecular-weight serine proteinase inhibitors are abundant in airway fluid and, hence, are thought to represent the primary defense against proteinase-mediated airway damage. Secretory leukoprotease inhibitor (SLPI) is a 12-kDa protein produced by mucus-secreting and epithelial cells in the airway, as well as type II pneumocytes. SLPI inhibits neutrophil elastase and cathepsin G and many other serine proteinases, but not proteinase 3. Elafin, also produced by airway secretory and epithelial cells, is released as a 12-kDa precursor that is processed to a 6-kDa form that specifically inhibits neutrophil elastase and proteinase 3. These inhibitors are able to inhibit neutrophil elastase bound to substrate, giving them an added dimension that α_1-AT lacks.

Airway mucus contains several other substances that partly inhibit neutrophil elastase, including polyanionic molecules, such as mucins, other glycosaminoglycans, and fatty acids. DNA, released from inflammatory leukocytes, binds to SLPI, greatly enhancing its rate of association with neutrophil elastase. The relative contribution of each of these molecules to proteinase inhibition is unknown.

Tissue Inhibitors of Matrix Metalloproteinases (TIMPs)

TIMPs are a family of four proteins that form tight noncovalent bonds with all MMPs. All TIMPs inhibit all MMPs, except TIMP-1 which does not inhibit membrane type (MT)-MMPs. Structurally TIMPs have a wedge-shaped N-terminal domain that competes with substrate for the catalytic site; however, the C-terminal domain can bind to specific pro-MMPs without inhibiting pro-MMP activation. TIMP-2 is secreted complexed to pro-MMP-2 in fibroblasts and interacts with MT1-MMP in the activation of pro-MMP-2.

TIMPs are secreted from many cell sources and are abundant in tissues. Cell-specific production and microenvironment localization appear to play an important role in the balance between MMPs and TIMPs. TIMP-3 is more highly glycosylated and interacts with matrix and cell-surface proteoglycans while the other TIMPs are secreted and

freely diffusible. TIMP-1 is the most highly inducible whereas TIMP-2 expression is more constitutive.

Alveolar macrophages secrete TIMP-1 and TIMP-2. Cytokines, such as interferon-γ, inhibit MMP-1 and MMP-12 expression in macrophages, with little effect on TIMPs; while TGF-β induces TIMP-1 expression and inhibits MMP production. Thus, MMPs and TIMPs may be coordinately regulated, perhaps limiting tissue injury during normal remodeling associated with inflammation. Alternatively, regulation may become discoordinate, leading to proteolysis of extracellular matrix or fibrosis.

In COPD, TIMP-1 is elevated in sputum and tissue homogenates, but may not be in excess of MMPs. Other TIMPs have been less well studied, but TIMP-3 knockout mice have enhanced pulmonary inflammation and impaired lung development that resembles emphysema. A TIMP-2 polymorphism associated with COPD has been uncovered in a Japanese population, but it is unclear if this polymorphism has any effect on TIMP-2 protein expression.

Cystatins

Cystatins represent families of cysteine proteinase inhibitors, some of which are strictly intracellular, while others such as cystatin C possess a signal peptide and are secreted by a variety of cells. Cystatin C, composed of a single, non-glycosylated, chain (13 kDa), forms reversible 1:1 complexes with enzymes. It is the most ubiquitous cystatin. It has been found in all human tissues and body fluids, providing protection against tissue destruction by intracellular cathepsin enzymes leaking from cells. It is produced by alveolar macrophages.

Overall View of the Pathogenesis of Emphysema

Degradation of lung elastin by elastase activity from inflammatory cells is probably the predominant mechanism for emphysema in most smokers. However, the biology of emphysema is clearly complex and still incompletely understood. It includes inflammatory cell recruitment, proteinase-antiproteinase imbalance, oxidant-antioxidant imbalance, and responses of lung cells to proteinases and oxidants from inflammatory cells and to constituents of tobacco smoke (Fig. 41-12). It may also involve humoral and cellular immunity. Degradation of extracellular matrix components besides elastin, particularly collagens, may be an important feature. In some situations apoptosis of lung cells may precede degradation of extracellular matrix. Senescence of lung cells, a recently identified phenomenon in emphysema, has unclear implications, but suggests that lung repair mechanisms are depressed.

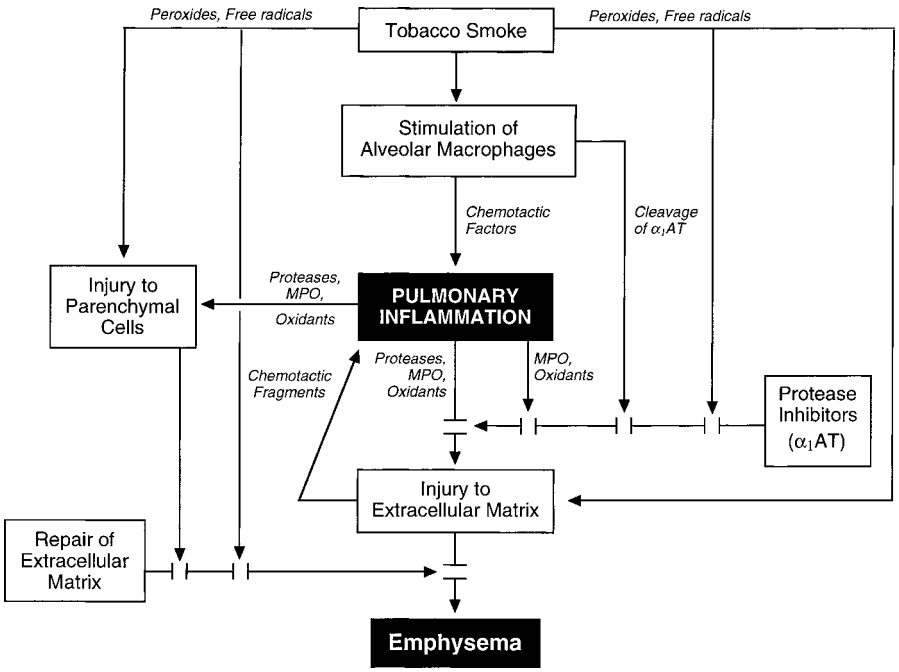

Figure 41-12 Schematic of concepts of the pathogenesis of emphysema due to smoking. Smoke leads to induction and release of chemotactic factors by alveolar macrophages and resident structural cells causing an accumulation of several types of inflammatory cells in the lungs. Smoke-stimulated resident cells and the recruited cells release proteinases and oxidants that damage or degrade extracellular matrix in the walls of alveoli, alveolar ducts, and respiratory bronchioles. Smoke also induces senescence and apoptosis of structural cells (injury to parenchymal cells) which leads to release of products that injure tissue and reduces the capacity of the tissue to repair. Smoke further affects lung homeostasis by inactivating proteinase inhibitors, such as α_1-AT. Peptides released from damaged extracellular matrix, notably from elastin, are chemotactic for inflammatory cells so that degradation of the extracellular matrix leads to a feedback loop that perpetuates inflammation. Not shown is the possibility that cellular and humoral immune processes are also involved.

ALPHA 1-ANTITRYPSIN DEFICIENCY

Background

Human plasma contains at least six proteins that function as proteinase inhibitors. Together, they make up about 10 percent of the total plasma protein. At a concentration of 150 to 350 mg/dl, alpha 1-antitrypsin is present in the highest concentration of all of the plasma proteinase inhibitors. α_1-AT is a member of a family of serine proteinase inhibitors called serpins.

α_1-AT is a glycoprotein of 52 kDa synthesized primarily by the liver. Mononuclear phagocytes are a secondary source. It consists of a single polypeptide chain of 394 amino acids. Carbohydrate side chains account for 12 percent of the molecular mass. The 12.2-kb gene that encodes α_1-AT is on the proteinase inhibitor (PI) locus on chromosome 14. This site is near the gene for α1-antichymotrypsin, the inhibitor for cathepsin G which, like neutrophil elastase, is a proteinase contained in the azurophil granules of neutrophils. The α_1-AT gene has seven exons and six introns. Exons four through seven code for the mature protein. Of note, the first two exons and a segment of the third exon are encoded in the transcript expressed in macrophages, but not in hepatocytes. α_1-AT is an acute-phase reactant. Plasma levels rise with trauma, estrogen therapy, use of birth-control pills, and during pregnancy, however the levels do not rise to normal among individuals with severe deficiency.

Proteolytic inhibition of neutrophil elastase and other serine proteinases by α_1-AT involves cleavage by the proteinase of the reactive site of α_1-AT between methionine[358] and serine[359]. The result is an altered, "relaxed" α_1-AT conformation in complex with the proteinase. Formation of the complex renders the proteinase inactive, and because the complex is quite stable, inactivation is essentially permanent. α_1-AT inhibits many serine proteinases and does so at a 1:1 molar basis. However, α_1-AT associates with neutrophil elastase much faster than with trypsin or other serine proteinases. Indeed, the association with neutrophil elastase is so fast in comparison with other serine proteinases that inhibition of neutrophil elastase is almost certainly the primary function of α_1-AT. The capacity of α_1-AT to inhibit neutrophil elastase and other serine proteinases besides trypsin has led some authors to prefer the designations α_1-PI or α_1-antiproteinase, but the name α_1-AT has become a fixture.

From the genetic standpoint, α_1-AT is transmitted in a co-dominant fashion. Thus, the gene product from each parent is expressed in the offspring. More than 100 different α_1-AT alleles are known, most of which are SNPs that do not alter expression of the protein or its function and, therefore, have no clinical significance.

The nomenclature for α_1-AT polymorphisms uses letters to specify the allelic variants. The original letters were chosen to reflect electrophoretic mobility: F = fast, M = medium, S = slow, and Z = ultraslow. The normal allele, M, exists in more than 95 percent of the US population, with the S and Z alleles being the next most common, having frequencies of 3 percent and 2 percent, respectively. Homozygosity for the Z allele, Pi ZZ, is associated with severe deficiency of α_1-AT (less than 15 percent of normal) and accounts for virtually all of the individuals with severe α_1-AT deficiency. In the United States its incidence is about 1 in 3000 people. It is rare in Asians and infrequent in African Americans.

Heterozygosity of the M allele with either the S or Z allele is very common. There are an estimated 15 million MS and 7 million MZ individuals, respectively, in the United States and comparable numbers in Europe. Despite numerous studies, it is still not yet clear whether the Pi MZ phenotype carries an increased risk of COPD. If there is an increased risk it appears to be small or is limited to an as yet undefined subset of MZ individuals. The MS phenotype does not carry an increased risk, but SZ heterozygosity is associated with increased risk.

The abnormality in the Z protein is a point mutation in a single nucleotide at codon 342 that results in coding for lysine instead of glutamic acid. This amino acid substitution changes the charge attraction between the amino acids normally present in positions 342 and 290 in α_1-AT and prevents the formation of a fold in the molecule. With this change in tertiary structure, the molecule is susceptible to dimerization with another α_1-AT molecule; the dimerization can result in polymerization of α_1-AT in the endoplasmic reticulum that impedes secretion of the protein from the cell (Fig. 41-13). Inability to secrete α_1-AT from the hepatocyte explains the low levels of the protein in plasma and other body fluids. Polymers may also form in the lung. α_1-AT polymers are chemotactic for inflammatory cells which may help to explain the marked accumulation of inflammatory cells in the lungs of individuals with α_1-AT deficiency.

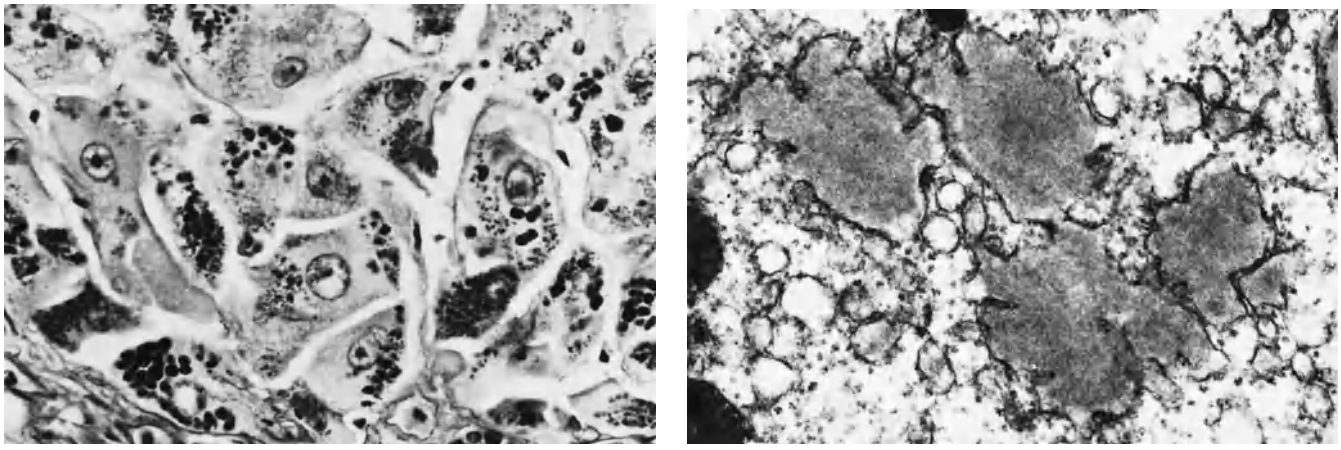
The Z form of α_1-AT has a much slower rate of association with neutrophil elastase than the association rate of normal α_1-AT with neutrophil elastase. Thus, not only do persons with the Pi Z phenotype have a deficiency of α_1-AT protein, but their α_1-AT is less effective than normal α_1-AT as an inhibitor of neutrophil elastase.

In contrast to the Z variant, the S variant of α_1-AT, which involves a single nucleotide substitution of glutamic acid[264] with valine, does not accumulate in the liver. This protein is less stable, presumably owing to loss of a salt bridge between the glutamic acid in position 264 and the lysine in position 387, and it polymerizes more slowly than the Z protein.

Quantification of serum α_1-AT concentration is done routinely by immunoassay. To confirm an immunoassay showing severe deficiency phenotyping is done in specialized laboratories by isoelectric focusing in the pH range of 4.0 to 5.0 (Fig. 41-14). Typing with molecular probes may be performed to definitively identify α_1-AT genotypes, but there is seldom an indication for this procedure to be performed in clinical practice.

Clinical Aspects

Alpha 1-antitrypsin deficiency may be suspected in adults as a result of respiratory symptoms, evidence of liver disease, or



A *B*

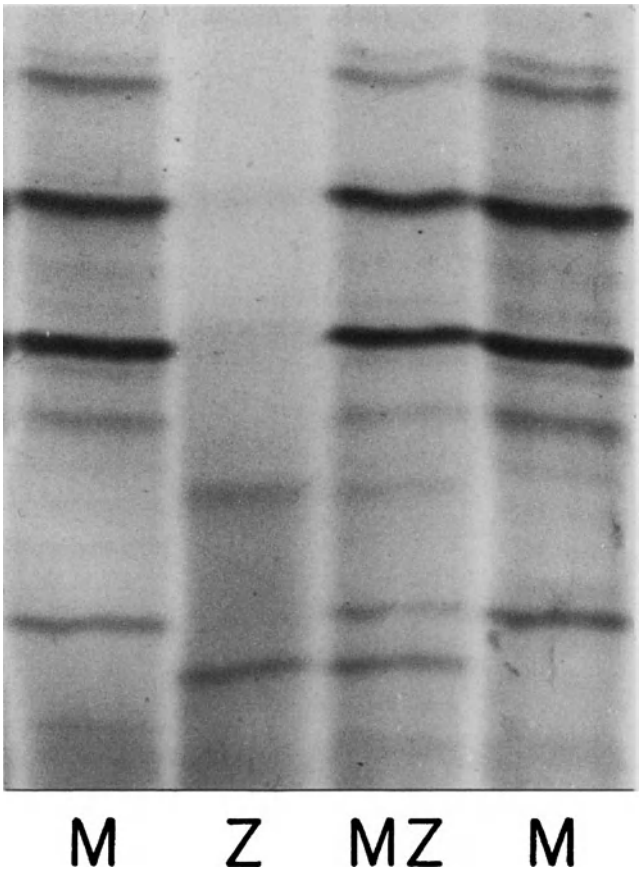

Figure 41-14 Patterns of Pi M, Pi Z, and Pi MZ α_1-AT on isoelectric focus. By this analysis, α_1-AT has microheterogeneity and thus appears as multiple bands. Pi M and Pi Z have distinctly different band patterns, while Pi MZ has a pattern that combines the patterns of both Pi M and Pi Z. (*Courtesy of John A. Pierce, M.D.*)

rare clinical manifestations such as panniculitis. In practice, however, most (about 80 percent) patients are discovered because of chronic respiratory symptoms and most of the rest are detected from screening for α_1-AT deficiency prompted by finding the deficiency in a family member. Liver disease is the mode of presentation in only a small percentage of adults with α_1-AT deficiency. Because of its infrequency in the practice of most physicians, the diagnosis of α_1-AT deficiency may not be suspected for a number of years after the onset of chronic respiratory symptoms, and often the patient has been seen by several physicians before the diagnosis is established.

Lung Disease

In the classic situation, the patient with Z type α_1-AT deficiency presents with the typical symptoms of COPD, especially shortness of breath, but is atypical on the basis of being rather young, often around age 40. The patient has hyperinflation, an increased total lung capacity, a decreased diffusing capacity, and radiographic changes consistent with emphysema that include hyperlucent lower lung fields reflecting the pathology (Fig. 41-15). This classic patient reports a mild smoking history relative to the severity of his/her COPD and may describe other family members with chronic respiratory symptoms.

In fact, however, there are many exceptions to this classic picture of α_1-AT deficiency. Wheezing, cough and sputum mimicking asthma, or chronic bronchitis that is poorly responsive to standard therapy may be the predominate symptoms. Evidence of emphysema may be minimal relative to the severity of the airflow obstruction. Finally, no other family members may have chronic respiratory symptoms, including siblings or other close relatives, even some who also have severe deficiency.

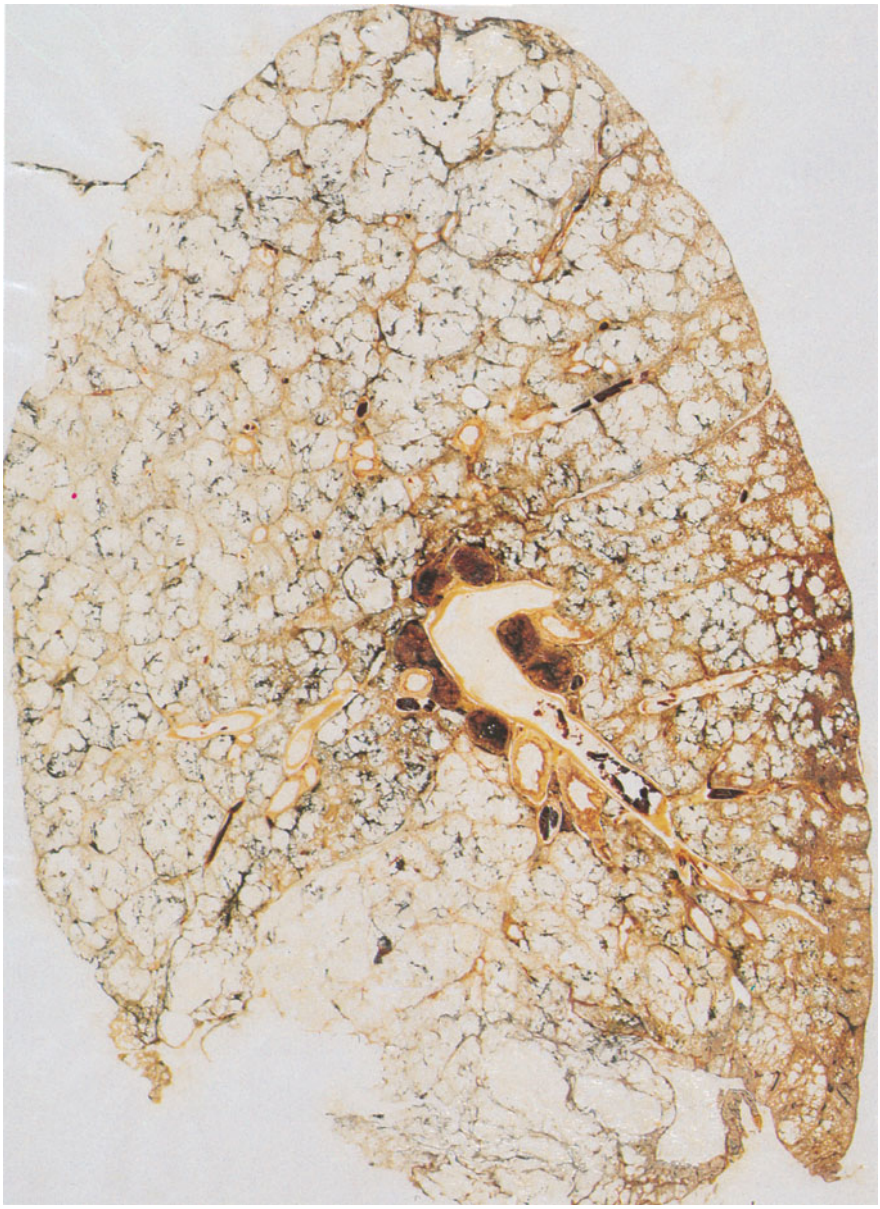

Figure 41-15 Lung pathology of Pi Z-type α_1-AT deficiency. Panacinar emphysema that is worst in the lung base. Paper-mounted whole lung section.

Because the presentation of α_1-AT deficiency can deviate so much from the classic presentation, some experts in this field advise that everyone diagnosed with COPD be screened for α_1-AT deficiency by the routine immunoassay. Other indications for screening include asthma that is not fully reversible despite aggressive therapy, recurrent bronchitis with or without bronchiectasis, a family history of the deficiency, and chronic liver disease without apparent risk factors. It is estimated that there are approximately 100,000 Pi Z individuals in the United States, of whom only around 10,000 are known, in part because they have few or no symptoms that lead to medical attention or, as noted above, clinicians do not think of the diagnosis.

Smoking is highly deleterious and hastens the development of COPD in most people with the deficiency. The typical Pi Z individual who smokes has respiratory symptoms by age 40, about 15 years earlier than equally deficient individuals who have never smoked. However, some Pi Z individuals reach advanced age with minimal respiratory symptoms.

Liver Disease

α_1-AT deficiency can present as liver dysfunction in infancy in various forms ranging from asymptomatic jaundice to frank liver failure. In most instances the clinical manifestations are mild and resolve. However, α_1-AT deficiency represents one of the main indications for liver transplantation in children. In adults, liver abnormalities may be limited to tests of liver function. Clinical manifestations seldom present before middle age. However, among Pi Z individuals who live beyond age 60, liver abnormalities are common and may overshadow respiratory symptoms. Indeed, among those individuals who

have not smoked and for other unexplained reasons avoid significant pulmonary function deterioration, hepatic cirrhosis and associated complications is the predominant terminal illness. In such individuals there is also a high incidence of hepatic cell carcinoma.

Alpha 1-antitrypsin deficiency is a paradoxical situation in which there is a severe systemic deficiency of α_1-AT despite substantial production of α_1-AT by the liver. The distinction between what is happening in the liver and what is happening systemically is clinically important. Infusions of α_1-AT, or other techniques under investigation for boosting systemic α_1-AT levels, can compensate for a severe systemic α_1-AT deficiency and so help protect the lung, but these approaches do not correct or ameliorate problems associated with the accumulation of abnormal α_1-AT in liver cells. At present, liver transplantation is the only treatment for the liver defect.

CONCLUDING COMMENT

Better understanding of COPD is imperative. This potentially disabling and fatal disease is already epidemic in many countries and appears destined to become epidemic worldwide in coming decades given trends of smoking prevalence.

Chronic Obstructive Pulmonary Disease: Clinical Course and Management

Robert A. Wise

In past decades, the treatment of COPD has been approached by many physicians and patients alike with a nihilistic attitude, assuming that the disease was progressive, incurable, and untreatable. More recently, as our understanding of the clinical epidemiology and value of therapy of COPD has improved, this attitude has changed. Physicians have come to approach COPD in the same way as other chronic diseases, such as diabetes, rheumatoid arthritis, and coronary artery disease. With modern comprehensive treatment, the diagnosis of COPD is compatible with prolonged survival, good quality of life, and independent functional status for many who have this illness. The purpose of this chapter is to summarize the current understanding of the course of COPD and best approaches to treatment.

OVERVIEW OF COPD

Chronic obstructive pulmonary disease (COPD) is a disorder that is characterized by slow emptying of the lung during a forced expiration. In practice, this is measured as the FEV_1/FVC ratio, and the arbitrary definition of airflow obstruction is generally taken to be an FEV_1/FVC ratio lower than 0.70. Because the rate of emptying of the lung falls with advancing age, many elderly individuals demonstrate airflow obstruction even in the absence of a clinical diagnosis of COPD. Several disorders cause chronic airflow obstruction: long-standing asthma, cystic fibrosis, bronchiectasis, bronchiolitis obliterans, lymphangioleiomyomatosis,

panbronchiolitis, silicosis, Sjögren's syndrome, and diffuse interstitial processes such as eosinophilic granuloma and sarcoidosis. The diagnosis of COPD is usually limited to individuals who have chronic airflow obstruction associated with tobacco smoke or some other noxious inhalant, and it is usually not difficult to distinguish it from other causes of chronic airflow obstruction. The most commonly associated clinical disorders associated with COPD are emphysema and chronic bronchitis. *Emphysema* is defined anatomically by airspace enlargement due to disappearance of alveolar septae (see Chapter 40). This leads to the characteristic loss of elastic recoil, which, in turn, causes slowing of airflow from the lungs, hyperinflation, and air-trapping (see Chapter 41). *Chronic bronchitis* is characterized by chronic cough and sputum production, which is present in about one out of three people with early COPD. Chronic cough and sputum production in cigarette smokers is often, but not always, associated with chronic airflow obstruction. When chronic mucus hypersecretion is associated with airflow obstruction, it is often called *chronic obstructive bronchitis*. The anatomic correlates of chronic bronchitis are mucus gland hyperplasia and goblet cell metaplasia in large and medium-size airways. Patients with COPD also have *small and medium-size airway involvement* with inflammation, narrowing, tortuosity, and fibrosis that contributes to the airflow limitation. Some patients with a long-standing history of asthma develop airflow obstruction that is not completely reversible, episodes of cough and wheeze, and chronic sputum production. These individuals are often classified as having *chronic asthmatic bronchitis* and tend to have a somewhat better prognosis for survival than those with typical tobacco-related COPD. Physicians have a tendency to classify women as having asthma and men as having COPD despite similar medical histories.

NATURAL HISTORY OF COPD

COPD results from an increase in the rate of decline in lung function over time. Normal nonsmoking adults lose FEV_1 at a rate of 30 ml/y, thought to be the consequence of the aging-related loss of elastic recoil of the lung. Persons who develop COPD may start in early adulthood with lower levels of lung function and also have increased rates of decline. Studies of patients with COPD show an average annual decline in FEV_1 of 45 to 69 ml/y (Fig. 42-1*A*). This leads to the insidious loss of ventilatory reserve capacity that often is asymptomatic and unrecognized by patients and physicians alike. Chronic bronchitis may be dismissed as an innocent "smoker's cough" because patients fail to understand that it is abnormal to produce daily sputum. As ventilatory reserve decreases, people with mild COPD tend to limit strenuous activities, so breathlessness with activities of daily living is not ordinarily an early symptom of the disease. When the ventilatory reserve decreases to the extent that mild exertion such as climbing stairs, bed making, or carrying groceries is limited, patients tend to seek medical advice. In some cases, the first clinical presentation of disease is an acute episode of bronchospasm, dyspnea, or even respiratory failure in association with a respiratory infection or exposure to respiratory irritants. Thus, the onset of COPD may appear precipitous

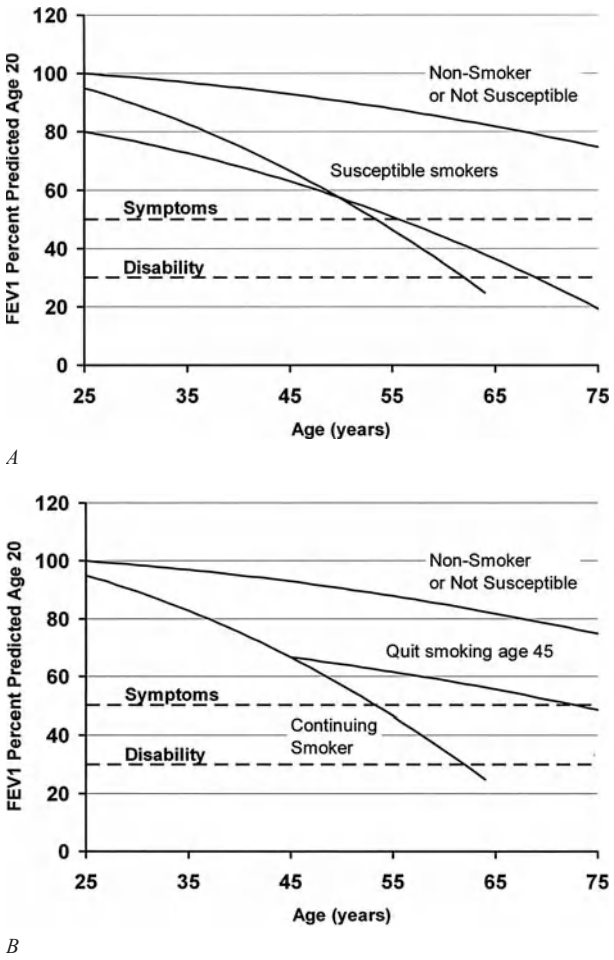

Figure 42-1 *A*. The natural history of COPD is presented for three hypothetical individuals. Pulmonary function is plotted as the percent of predicted lung function for a young adult who has attained maximal lung growth. Those who do not smoke, or are not susceptible to cigarette smoke typically lose about 25 percent of their young adult lung function throughout life. Individuals are susceptible to the adverse effects of smoking because of increased decline of lung function, or low lung function in young adult life. Although the abnormality of lung function is detectable for many years, symptoms do not develop until there is loss of approximately 50 percent of lung function (upper dashed line), which occurs in middle age or later. If the disease progresses, it may lead to substantial disability within a decade of the onset of symptoms (lower dashed line). *B*. The natural history of COPD is displayed for a hypothetical continuing smoker, and an individual who quit smoking at age 45. The axes are identical to those in (*A*). If an individual ceases smoking in the asymptomatic phase of COPD, the rate of decline of lung function reverts toward normal. In this example, the detection of abnormal lung function and cessation of smoking has a substantial effect of delaying the onset of respiratory symptoms. This plot is modified from the work of Fletcher and Peto and is commonly referred to as Fletcher curves. *(From Fletcher C, Peto R. The natural history of chronic airflow obstruction. Br Med J 1:1645–1648, 1977.)*

even though it is the cumulative result of decades of progression.

People who discontinue smoking with mild to moderate degrees of airflow obstruction cease the rapid decline in FEV_1, and have better survival (Fig. 42-1*B*). The improvement in survival depends largely upon the stage of disease. Persons who quit smoking with earlier disease have better outcomes compared with those who continue to smoke or those who quit smoking later in the disease. Once the disease is advanced, the inflammatory response persists and the rate of decline of lung function tends to progress. Because there are many years of asymptomatic decline in lung function, it is possible to diagnose COPD with forced expiratory spirometry before the disease is apparent and implement aggressive smoking intervention programs. There is no consensus whether it is necessary to screen for COPD among all cigarette smokers. Opponents of using spirometry for case-finding argue that the finding of a normal test would not alter physician behavior because all smokers should be encouraged to quit. It has also been argued that a normal spirometry test might provide a false sense of complacency for active smokers. Moreover, current evidence does not support the idea that drug treatment of asymptomatic individuals provides any benefit. Those who support the use of spirometry for COPD case-finding argue that early detection and aggressive smoking intervention have been proved to halt disease progression, and the finding of abnormal spirometry may encourage patients and health care professionals to be more aggressive with smoking cessation.

With the progression of COPD comes progressive exercise limitation. This is due to the increased work of breathing as ventilation increases with exercise. With increased respiratory rate, patients develop dynamic hyperinflation—a condition in which the end-expiratory lung volume does not return to the static end-expiratory volume of functional residual capacity (FRC). The hyperinflation that occurs causes increased work of breathing and exacerbates dyspnea. An indicator of dynamic hyperinflation is the inspiratory capacity (IC), which progressively falls with increasing ventilation. Measures that reduce dynamic hyperinflation, increasing IC, can improve exercise capacity. These include alterations in breathing pattern, oxygen supplementation, helium inhalation, and use of inhaled bronchodilators.

As COPD progresses, ventilation-perfusion inhomogeneity causes an increase in the alveolar-arterial oxygen difference. Eventually, alveolar hypoxemia leads to pulmonary hypertension, which becomes manifest as cor pulmonale. The alveolar hypoxemia may be compounded by alveolar hypoventilation—manifest by arterial hypercapnia. Physical findings indicative of cor pulmonale are venous engorgement, edema, and physical findings of pulmonary hypertension and right ventricular failure. Chest imaging shows central enlargement of the pulmonary arteries. Once cor pulmonale is clinically apparent, survival is markedly reduced in proportion to the elevation of pulmonary artery pressure. Chronic respiratory failure is defined by chronic hypoxemia (sea-level resting $Pa_{O_2} \leq 60$ mmHg or 8 kPa) with or without attendant hypercapnia ($Pa_{CO_2} > 45$ mmHg).

Patients with advanced COPD may restrict their activities to a bed-and-chair lifestyle because of severe exercise incapacitation. This limitation can lead to social isolation, depression, and skeletal muscle deconditioning which, in turn, further restrict activity and impair quality of life. Protein and calorie malnutrition occurs as the consequence of impaired nutritional intake caused by dyspnea. Malnutrition is augmented by increased metabolic demands caused by increased basal oxygen consumption, inefficient skeletal muscle oxygen utilization, and cachexia-producing cytokines such as tumor necrosis factor alpha.

DIAGNOSIS OF COPD

Physical examination and chest imaging are insensitive methods for diagnosis of COPD. Physical findings of hyperinflated lungs such as low-lying diaphragms, decreased breath sounds, and hyperresonant chest percussion are highly specific for COPD, but usually only in advanced disease. One study has suggested that a distance between the thyroid cartilage and the sternal notch less than 4 cm in a smoker older than age 45 is highly indicative of the presence of COPD. Clubbing of the fingers is not common in COPD and, if present, suggests another diagnosis such as bronchiectasis, asbestosis, or lung cancer. High-resolution computed tomography (HRCT) of the lung, analyzed by quantitative measures of lung density, is a promising technique for early detection of emphysema, but the role of HRCT in early detection and monitoring of COPD is not established at present. α_1-Antitrypsin deficiency is an uncommon, but not rare, condition associated with premature emphysema. Testing for α_1-antitrypsin deficiency is indicated in those most likely to have the disorder (see Chapter 41 and Table 42-1). Although controversial, some experts advocate that all patients with COPD should be tested for α_1-antitrypsin deficiency. HIV/AIDS is also associated with premature emphysema, and screening for HIV should be performed for persons with emphysema and HIV risk factors such as intravenous drug use or high-risk sexual activity.

The diagnosis of COPD, classification of its severity, and progression of the disease can be monitored with spirometry, a simple, noninvasive, and inexpensive test. The FEV_1/FVC ratio, reflecting the rate of emptying of the lung, is used to define the presence of an obstructive ventilatory defect, commonly defined as a ratio less than 0.70. Once airflow obstruction is established, the severity of the disease is classified by the reduction of FEV_1 compared with a healthy reference population. Table 42-2 shows the widely used GOLD classification of COPD severity based on the FEV_1. Lung volume measurements, by plethysmography, helium dilution, nitrogen washout, or single-breath methods typically show hyperinflation (elevated TLC) and air trapping (elevated residual

Table 42-1

c-ANCA positive vasculitis (e.g., Wegener's granulomatosis)
Family history of early onset emphysema or non-smoking–related emphysema
Bronchiectasis without other etiology

volume [RV]), and thus are useful to exclude restrictive lung diseases. The carbon monoxide diffusing capacity (D_{CO}) is an indicator of emphysema and is roughly inversely correlated with the anatomic extent of emphysema in patients who have an FEV_1 greater than 1.0 L.

PROGNOSIS OF COPD

After COPD becomes clinically apparent, the median survival is about 10 years. The prognosis may vary widely, however, and physicians are poor prognosticators of survival in COPD. In part, this is because the disease is one of widely varying rates of progression, and, in part because death is often due to susceptibility to intercurrent illness and other smoking-related illness such as lung cancer rather than progressive respiratory failure.

Several factors have been identified that predict poor survival in COPD. These include low FEV_1, active smoking status, hypoxemia, poor nutrition, the presence of cor pulmonale, resting tachycardia, low exercise capacity, severe dyspnea, poor health-related quality of life, anemia, frequent exacerbations, co-morbid illnesses, and low carbon monoxide diffusing capacity. Patients with an FEV_1 less than 35 percent predicted have about 10 percent mortality per year. If a patient reports that they are unable to walk 100 meters without stopping because of breathlessness, the 5-year survival is only 30 percent. A multidimensional prognostic index that takes into account several indicators of COPD prognosis is the BODE index (*b*ody mass index [BMI], *o*bstructive ventilatory defect severity, *d*yspnea severity, and *e*xercise capacity). See Table 42-3 for calculation of the BODE prognostic score. The components are derived from measures of the body mass index (weight in kg/height m^2), FEV_1 percent predicted, and the modified Medical Research Council dyspnea score (Table 42-4). A BODE score greater than 7 is associated with a 30 percent 2-year mortality; whereas a score of 5 to 6 is associated with 15 percent 2-year mortality. If the BODE score is less than 5, the 2-year mortality is less than 10 percent.

Table 42-2

Classification of COPD Severity

Stage	Characteristics
I Mild COPD*	FEV_1 80% predicted
II Moderate COPD*	FEV_1 50%–79% predicted
III Severe COPD*	FEV_1 30% to 49% predicted
IV Very Severe COPD*	FEV_1 <30% predicted or <50% predicted with room air Pa_{O_2} <60 mm Hg (8.0 kPa)

* *Postbronchodilator FEV_1/FVC 0.70.*

TREATMENT OF STABLE COPD

The goals of treatment of COPD are to prevent progression and complications of the disease, relieve symptoms, improve exercise capacity, improve quality of life, treat exacerbations, and improve survival.

Education

The diagnosis of COPD can be a life-changing event for people, so understanding the nature and prognosis of the disease is an important and underemphasized aspect of care. There is a wide divergence of understanding of the implications of having COPD, and many patients do not understand that COPD comprises both the diagnoses of emphysema and chronic bronchitis. Table 42-5 lists topics that should be discussed with COPD patients. It is neither possible nor effective to cover all of these topics in a single session, so several sessions with repetition and expansion of the educational messages is necessary. Supplemental written materials or referral to a health educator is also necessary for many patients. Local and national volunteer health organizations provide useful educational materials and group educational sessions. Special counseling is needed for patients with α_1-antitrypsin

Table 42-3

Calculation of the BODE Index*

	Points on the BODE Index			
Variable	**0**	**1**	**2**	**3**
FEV_1 (% predicted)	≥65	50–64	36–49	≤35
Distance walked in 6 min (meters)	≥350	250–349	150–249	≤149

Advanced directives for end-of-life care

be prepared to deal with patients' sense of guilt, as many view COPD as a self-induced disease. Caregivers need to address the reality that COPD is often stigmatized by patients, their families, and other health care providers. The physician should let the patient understand that nicotine dependence is a strong physical addiction and difficulty quitting smoking is not a measure of moral weakness or lack of will. The general message provided should be realistic, but positive. Current treatments for COPD can usually improve quality of life, restore activity levels, maintain social interactions, and reduce the frequency of complications.

Prevention of COPD Progression and Complications

Presently, there are no proven treatments that prevent the progression of COPD in patients who continue to smoke cigarettes. *Smoking cessation,* however, does prevent the excessive decline in lung function and should be a primary goal for physicians caring for COPD patients. Patients with mild or moderate COPD may not know that they have underlying lung disease that can be halted by smoking cessation, or may adopt a fatalistic attitude that it is too late for help. Even severely impaired patients who are dyspneic at rest or use continuous oxygen may continue to smoke cigarettes or relapse after quitting. A smoking history should be obtained at each patient encounter because many patients fail to volunteer the extent of their smoking or report a smoking relapse following cessation. In patients who do smoke, achieving cessation should be a primary and persistent goal of treatment. Approaches to smoking cessation are given in detail in Chapter 43. For patients who do smoke, a direct, unambiguous, and personalized smoking cessation message should be given by the physician. The message should emphasize the harm of continued smoking, the benefits of cessation in terms of activities that are meaningful for the individual, and the understanding that smoking cessation is a realistic and achievable goal. Assistance with pharmacologic adjuncts such as nicotine replacement therapy, varenicline, or bupropion and referral to smoking cessation groups should be offered. Follow-up of smoking status and repeated smoking cessation messages should be performed at each encounter.

Exposure to respiratory irritants should be avoided in the workplace as well as the home. Although heavy occupational dust exposure rarely is the primary cause of COPD, exposure to dusty occupational jobs in smokers can increase the lung function deterioration from smoking and increase symptoms of cough and sputum. Respiratory protective equipment should be worn by COPD patients exposed to heavy dust concentrations. There is no level of FEV_1 that absolutely prohibits the use of respiratory protective equipment, but patients with COPD often experience untoward breathlessness with these masks because of the increased dead space and increased inspiratory resistance. Thus, many COPD patients need to change their work environment if they cannot tolerate protective devices. If COPD is complicated by allergy or overlaps with allergic asthma, environmental control measures should be instituted to the extent that these strategies are helpful. Smoking of marijuana and cocaine may cause airway irritation, and although there is no convincing evidence that they contribute to progression of COPD, their use ought to be discouraged.

Pneumococcal vaccination is recommended, although the evidence of its particular efficacy in COPD is lacking. Annual *influenza immunization* can prevent or attenuate this potentially fatal infection. The killed vaccine is preferred, as cold-attenuated live influenza vaccines have not been approved for use in older patients and those with underlying lung disease. For individuals who are not immunized, prophylaxis with amantadine or rimantadine during an influenza epidemic can often prevent infection with influenza A, although recent reports have shown increasingly resistant strains of influenza and side-effects may limit usefulness. During influenza epidemics, the use of neuraminidase inhibitors such as zanamivir and oseltamivir can minimize severity of infection if taken within 48 hours of onset of illness and are useful against both influenza A and B, and may limit the spread of infection.

Replacement therapy with α_1-antitrypsin should be considered for those individuals with severe deficiency. Observational studies suggest that individuals with moderate degrees of impairment (FEV_1 35 to 65 percent predicted) appear to benefit most in terms of preservation of lung function and improved survival. The human plasma-derived preparation of α_1-antitrypsin is administered intravenously in a dose of 60 mg/kg weekly. Although the replacement treatment is derived from pooled human plasma, the risk of viral transmission is low and immunization for hepatitis B is not required prior to initiating therapy. Monitoring of immunoreactive serum levels of α_1-antitrypsin does not accurately reflect the enzymatic activity in the blood or alveolar lining fluid and is not necessary to adjust treatment dose. Alternative dosage schedules, use of recombinant preparations, specific protease inhibitors, or aerosolized preparations may be available in the future.

Exercise and Rehabilitation

Regular prudent self-directed exercise is recommended for all individuals with COPD to prevent the muscle deconditioning that often accompanies the disorder. Individuals should be encouraged to perform at least 20 to 30 minutes of constant low-intensity aerobic exercise such as walking at least three times per week. Even the most severely impaired patients with COPD can usually attain an exercise regimen of 30 minutes of walking at 1 mph (i.e., one-half mile in 30 minutes). It is important to instruct patients that they should exercise to a level of dyspnea that is tolerable for the entire exercise period. Patients should understand that dyspnea, by itself, is not injurious to the heart or lungs, but patients should pace themselves to avoid severe dyspnea that disrupts activity, can lead to panic reactions, and is distressing to onlookers. Patients who demonstrate desaturation with exertion may be prescribed supplemental oxygen for exercise. Some may

benefit in terms of exercise capacity and training effect even if they do not have demonstrable oxygen desaturation. Many patients, particularly those with marked hyperinflation, find that they can ambulate better with the use of a rolling walker that supports the arms, improving the mechanical advantage of the accessory muscles in the neck.

Formal rehabilitation programs offer a comprehensive approach to exercise training, patient education, nutritional counseling, group support, and psychological support that cannot be efficiently provided in the physician's office. Rehabilitation programs are established as an effective component of COPD management and should be offered to patients who have substantial limitation in daily activities. A detailed discussion of rehabilitation is provided in Chapter 44.

Nutritional Support

In patients with very severe COPD (FEV_1 less than 35 percent predicted) about half show protein-calorie malnutrition. Reasons for this include increased resting metabolic demands, inadequate caloric intake due to dyspnea and anorexia, and possibly elaboration of cachexia-associated inflammatory cytokines such as TNF-α, IL-1, and IL-6. Patients with a BMI of less than 90 percent of normal have increased mortality and decreased exercise capacity. Muscle wasting and loss of bone mass may be present even in patients who have normal BMI. Although clinical trials of nutritional supplementation have been disappointing, it is prudent to monitor body weight in COPD patients and encourage caloric supplementation as needed since those patients who do gain weight show improved survival. High-fat diets have the theoretical advantage of offering higher caloric content with lower CO_2 production than high carbohydrate diets, but there is no convincing evidence that this strategy is clinically superior to a well-balanced diet. For patients with less advanced disease, a balanced diet with avoidance of overweight or underweight is a rational goal. In particular, patients with mild to moderate disease who quit smoking tend to gain excessive weight which might adversely affects lung function.

Sleep Disorders in COPD

Sleep disturbances, including insomnia and daytime hypersomnolence, are common symptoms in patients with COPD, and are often overlooked because of the focus on breathlessness and exercise intolerance. The causes for sleep symptoms are multifactorial and include anxiety/panic disorder, depression, resting hypoxemia, nocturnal bronchospasm, sleep apnea, and nocturnal oxygen desaturation. Patients with COPD often relate insomnia to a fear of suffocation or death during sleep, a situation that may respond to repeated reassurance, cognitive therapy, or small doses of anxiolytics or antidepressants. Patients with resting hypoxemia treated with low-flow nasal oxygen often report improved sleep quality. Nocturnal bronchospasm, more common among those with an asthmatic component to their disease, may respond to longer-acting bronchodilators, or rearrangement of the dosing schedule to provide nocturnal coverage. In some cases, treatment for gastroesophageal reflux by elevation of the head of the bed and prescription of acid suppressant drugs can help. Sleep apnea syndrome, probably not more common in COPD patients than the general community, has particularly severe complications in COPD. Patients with COPD and sleep apnea, the so-called "overlap syndrome" are prone to develop pulmonary hypertension and daytime hypercapnia. Accordingly, symptoms of sleep apnea such as snoring, intermittent nocturnal breathing, and daytime hypersomnolence should be sought in patients with COPD. If present, then formal sleep studies and treatment with continuous positive airway pressure (CPAP) are indicated. Nocturnal oxygen desaturation (NOD) is common during rapid eye movement sleep in patients with COPD. The causes are not entirely understood, but contributing factors include hypoventilation, ventilation-perfusion mismatch, respiratory muscle dysfunction, and increases in upper airway resistance. NOD is thought to be associated with poorer sleep quality and pulmonary hypertension. It is controversial whether NOD is associated with poorer survival. However, small studies have shown inconclusive results about the utility of treating nocturnal oxygen desaturation.

Current guidelines do not recommend that all patients with COPD have nocturnal oxygen monitoring, nor do they recommend treatment with supplemental oxygen or nocturnal ventilation if NOD is found. Many physicians, though, will prescribe these diagnostic studies and treatments for selected symptomatic patients, and most insurance companies will provide reimbursement for such treatment. Patients who have resting room air daytime hypoxemia should be prescribed nocturnal oxygen at the same flow rate as used during the day, and it is usually not necessary to monitor nocturnal oxygen saturation in such patients.

Air Travel

Patients with COPD should not avoid air travel, but must be aware of the medical and regulatory issues that are involved. Modern airplanes are pressurized to an equivalent altitude of approximately 5000 to 8000 feet, but may, on occasion, pressurize to an equivalent altitude of 10,000 feet without providing emergency oxygen. Many patients with COPD who do not use sea-level oxygen can tolerate short flights without supplemental oxygen. As flight distance becomes longer, the flying altitude becomes higher and the cabin pressure becomes lower, so transcontinental or transoceanic flights should prompt medical advice. The general rule of thumb used by the commercial airline industry is that patients who can ambulate 50 meters without stopping are safe for air travel. A more conservative approach is to estimate the Pa_{O_2} during air travel by performing a high altitude simulation test. High altitude simulation can be performed by administering 15 percent oxygen via a face mask or by using 100 percent nitrogen in a 40 percent Venturi mask. If the oxygen saturation falls below 86 percent or 50 mmHg, then supplemental oxygen is recommended. Formulas are available to estimate

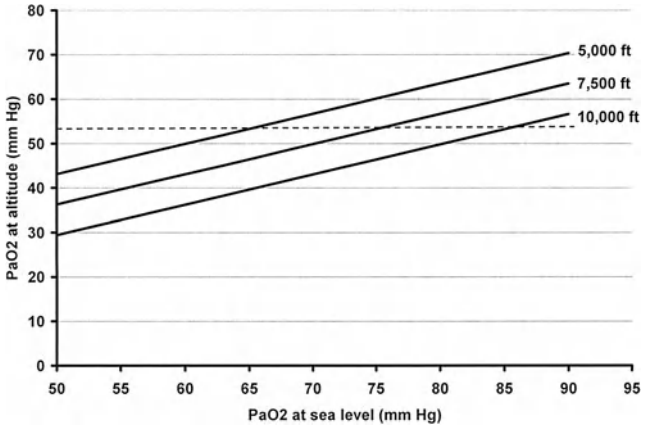

Figure 42-2 Estimated Pa_{O_2} at altitude based on resting sea level arterial oxygen tension. Isopleths are drawn for the range of cabin pressures that occur on commercial aircraft. The dashed line is drawn at 54 mmHg, which indicates a threshold for prescribing supplemental oxygen for air travel. The nomogram is derived from the data of Gong et al. *(Gong H Jr, Tashkin DP, Lee EY, et al: Hypoxia-altitude simulation test. Evaluation of patients with chronic airway obstruction. Am Rev Respir Dis 130:980–986, 1984.)*

altitude hypoxemia from sea-level room air blood gases. Figure 42-2 provides a nomogram for estimating altitude Pa_{O_2} from sea-level room-air arterial oxygen tensions. If estimated altitude Pa_{O_2} is used, it is prudent to prescribe oxygen for estimated altitude Pa_{O_2} of 54 mmHg or lower. Patients who use oxygen supplementation at sea level should increase their resting oxygen prescription by a flow rate of 2 L/min. For patients with COPD who travel by air frequently, low-cost finger pulse-oximeters that are marketed to airplane pilots can be used to adjust their oxygen flow.

Airlines have inconsistent policies with respect to providing supplemental oxygen for travelers, so it is important to check with the airline service desk prior to booking travel. In the past, it was required that airlines provide compressed oxygen tanks for travelers. Recently the United States Federal Aviation Administration has promulgated regulations that permit some approved portable oxygen concentrators to be carried on board by passengers as personal luggage with a physician's statement of need.

Long-Term Oxygen Therapy

In addition to smoking intervention in early COPD, treatment of resting daytime hypoxemia with oxygen is a treatment that prolongs survival. The two strongest indications for prescription of long-term oxygen therapy are: (1) resting room-air $Pa_{O_2} \leq 55$ mmHg or oxygen saturation ≤ 88 percent while a person is in usual state of health; and (2) resting room-air Pa_{O_2} 56 to 60 mmHg or oxygen saturation 88 to 89 percent with supporting evidence of chronic hypoxemia such as polycythemia, pulmonary hypertension, cor pulmonale, or psychological impairment. Oxygen is usually administered by nasal cannula, with the flow rate adjusted to maintain a resting saturation greater than 90 percent. The usual starting flow rate is 2 L/min, although some patients with severe hypercapnia require lower flows. A few patients, particularly those with concomitant interstitial pulmonary disease or cardiac disorders, require higher flow rates.

The most convenient and cost-effective oxygen source at home is usually a concentrator device that uses a molecular sieve to extract oxygen from room air. For ambulation, small compressed air cylinders or liquid oxygen reservoirs that can be carried provide patients with the ability to leave their homes. Conserving devices such as reservoirs or demand valves permit portable ambulatory oxygen tanks to last up to 10 hours at flow rates of 2 L/min. Compressed oxygen cylinders or liquid oxygen reservoirs should be provided to patients who use electrically driven oxygen concentrators for emergency use in the event of a power failure. Ideally, oxygen should be used constantly 24 hours per day. At least 18 hours of oxygen per day, however, has been show to have substantial benefit over 12 hours per day. If continuous oxygen supplementation is prescribed following an exacerbation of COPD, it is recommended to check arterial oxygen levels in 6 months, as many patients will no longer require oxygen.

Nasal drying or congestion is a common symptom for those who use continuous oxygen. This may be alleviated to some extent by alternating the nasal cannula from one nostril to the other or placing it in the mouth for periods. Copious watery nasal secretions often respond well to ipratropium nasal spray, and dry, crusted nasal mucosa is treated with hourly instillations of saline nasal spray. Other nasal disorders that are aggravated by oxygen, such as allergic rhinitis or vasomotor rhinitis, should be considered and treated with appropriate therapy such as intranasal corticosteroids or cromolyn.

Smoking or exposure to any open flame, of course, is prohibited by the danger of fire and airway burns in those who use oxygen. This is a surprisingly common cause of burns in the United States, with estimates that up to 50 percent of patients on oxygen continue to smoke to some extent. Accordingly, it is safer to counsel patients to discontinue oxygen while smoking or cooking over an open flame if they insist on doing these imprudent activities. Patients at particular risk are those who live alone, have cognitive impairment, and do not have functioning smoke detectors.

Transtracheal oxygen administered via a percutaneous catheter is useful for patients who need high oxygen concentrations or in whom use of a nasal cannula is not tolerated because of local nasal adverse effects or cosmetic preference. Transtracheal oxygen has the advantage of decreasing effective dead space ventilation and permitting lower flow rates to provide high oxygen concentrations. However, the catheter and insertion site require meticulous care to prevent complications such as local infection or mucus concretions. On occasion, the catheter insertion site may lead to a pneumothorax or pneumomediastinum. High flow rates with humidified oxygen via transtracheal catheters may augment ventilation and reduce hyperinflation.

Ambulatory oxygen, although not shown to improve survival, may be provided for patients who desaturate with exertion. Some, but not all, patients show improved exercise

capacity and reduced breathlessness. There is a growing body of evidence that suggests that oxygen supplementation may also benefit COPD patients who do not have exercise desaturation by reduction in minute ventilation and diminution of dynamic hyperinflation. Because it permits greater exercise intensity, oxygen supplementation is also a useful adjunct for aerobic conditioning during pulmonary rehabilitation.

Treatment of Anemia

Anemia, usually mild, is present in about 10 percent of patients with severe COPD, similar to other chronic inflammatory diseases, and is a poor prognostic indicator. Although there is no evidence that COPD, per se, causes anemia, patients with COPD have a lower erythropoietic response to hypoxia than healthy people at altitude. For patients who are anemic and breathless, restoration of normal hemoglobin content reduces resting minute ventilation and work of breathing, which presumably improves exercise capacity. Thus, pending definitive clinical trials, it is prudent to test for anemia and treat it appropriately in patients who are markedly symptomatic.

Drug Therapy

Over the past several decades, the evidence base for use of drug therapy in COPD has expanded, and provides an objective and generally optimistic picture that such treatment is effective. Bronchodilators and anti-inflammatory agents are used in COPD to reverse bronchoconstriction and improve airflow limitation. The goals of drug therapy are not only to improve lung function, but also to improve quality of life, exercise capacity, and prevent exacerbations. No drug treatment is known to diminish the decline in pulmonary function with continued smoking, or substantially reduce mortality, but large and long-term clinical trials needed to definitively determine this have not yet been done for newer agents. Recent evidence however suggests that a combination of inhaled steroids and long-acting bronchodilators may improve survival as well as reduce exacerbations. Proposed future drug treatments that might alter progression of COPD are under active investigation, including inhibitors of cytokines, proteases, and oxidative stress. There is a poor correlation between the effect of bronchodilating drugs on lung function and symptom relief, so monitoring of treatment requires attention to patient-centered outcomes as well as lung function. Small amounts of bronchodilation can cause considerable improvement in functional capacity through decrease in dynamic exercise hyperinflation; and reduction in days of exacerbation can make considerable improvement in patients' quality of life.

The usual approach to drug treatment for COPD is to sequentially add agents using the minimum number of agents and the most convenient dosing schedule, starting with the agents having the greatest benefit, best tolerance, and lowest cost. One approach to step-up therapy is provided in Figure 42-3. Inhaled bronchodilators are the foundation

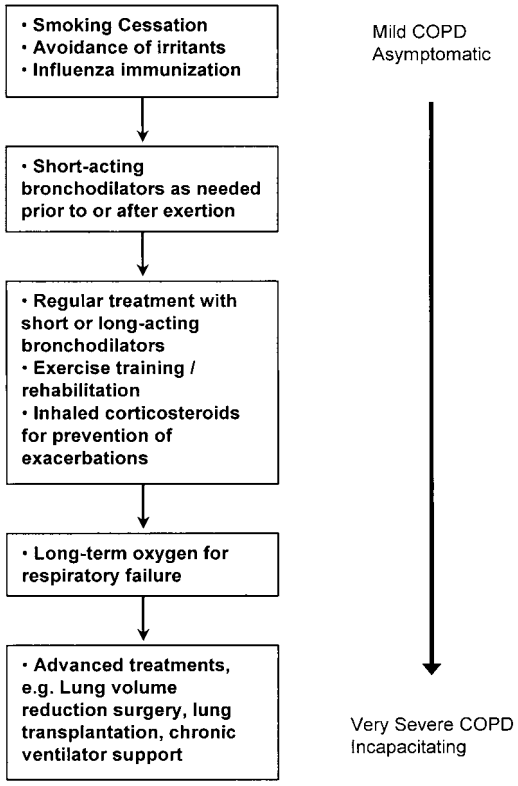

Figure 42-3 Step-care approach to treatment of COPD. Treatments are sequentially added to maximize functional status and minimize symptoms. Patients with greater impairment receive more advanced treatments. At each phase of treatment, assessment of lung function, symptoms, and functional status are used to evaluate need for additional treatments. If patients are stable for 6 to 12 months, consideration should be given to trial reductions of treatment.

of treatment for COPD. They are given on a regular basis to maintain bronchodilation and on an as-needed basis for relief of symptoms. Most breathless patients benefit from regular use of a maintenance bronchodilator. Both beta-agonist and anticholinergic classes are available in short duration (4- to 6-hour) and long-duration (12- to 24-hour) forms (Tables 42-6 and 42-7). The choice of bronchodilator class and duration of effect depends upon the preference of the patient and the cost of the preparation. Combination of different classes of bronchodilators is often more effective than increasing the dose of a single agent, and combination inhalers can simplify treatment regimens. Patients with advanced COPD often use a combination of bronchodilators, including long-acting maintenance anticholinergics and beta agonists as well as symptomatic use of shorter-acting bronchodilators. Individuals with frequent exacerbations often benefit from a combination inhaler of corticosteroids and long-acting bronchodilator. Long-acting oral preparations of theophylline are useful adjuncts in cases in which inhaled medication is too expensive or not acceptable for the patient. Chronic use of systemic corticosteroids should be reserved for individuals with very frequent or life-threatening exacerbations who cannot tolerate their discontinuation. Response to treatment is judged by symptomatic improvement, functional status,

Table 42-6

β-Sympathomimetic Agonists

Drug Name	Onset of Action (min)	Inhalation Peak Effect (min)	Duration of Effect (h)	Dosage Form
Metaproterenol	1–5	30–60	2–5	Metered-dose inhaler, 650 μg/puff
				Nebulized solution, 5%, or premixed 0.4%–0.6% ampules
Terbutaline	1–5	—	2–5	Oral tablets 2.5 or 5.0 mg
				Injection, 1 mg/ml
Pirbuterol	5	30–60	4–5	Metered-dose inhaler, 200 μg/puff
Albuterol	5–15	60–90	3–6	Metered-dose inhaler, 90 μg/puff
				Nebulized solution 0.5% or premixed 0.083% ampules
	30	—	6–12	Oral tablets 4.0 to 8.0 mg, rapid and slow-release forms
Levalbuterol				
Salmeterol	10–20	180	12	Metered-dose inhaler, 25 μg/puff
				Dry powder inhaler, 50 μg/dose
Formoterol	2–10	120	12	Dry powder inhaler, 12 μg/dose

frequency of exacerbations, and spirometry. If patients are doing well for 6 to 12 months on a stable treatment regimen, then it is reasonable to see if a trial withdrawal of one of the drug components can be tolerated.

Inhaled agents are administered by metered dose inhaler (MDI), dry powder inhaler (DPI), or as a nebulized solution. The selection of route of administration is made by cost and convenience of the device because all are similarly effective if used properly. Many patients find that it is difficult to coordinate an MDI, and addition of a spacer device is helpful. There are many forms of DPI, some more intuitive to use than others, so specific instruction and demonstration is required by most patients. Nebulizers are easier for patients to coordinate, but each treatment takes longer to complete, and they require additional effort to maintain cleanliness. Although nebulized medications are more expensive overall, the cost of the medication is often covered by insurance, so many patients prefer nebulizers for financial considerations.

Table 42-7

Anticholinergic Bronchodilators

Generic Name	Onset of Action (min)	Inhalation Peak Effect (min)	Duration of Effect (h)	Dosage Form
Ipratropium	30	60	6–8	HFA or CFC metered-dose inhaler 17–18 μg/puff
				Nebulized solution 0.02% (500 μg in 2.5-ml vial)
Tiotropium	60	120	>24	Dry powder inhaler 18 μg/dose

Adherence with inhaled medication, particularly when it does not provide immediate symptom relief is poor. Typically about half of patients do not take their medication in the dose or quantity prescribed. Reasons for this include a lack of understanding of the role of the medication, failure of the medication to provide meaningful benefit, complexity of the treatment program, and expense of the treatment. Many patients do not want to confide poor adherence to their physician, so it is important for the physician to ascertain this information in a way that does not interfere with the relationship with the patient. For example, a physician could inquire, "It is often difficult for patients to remember to take all of their medications. Has this been a problem for you?" or "Are you able to afford all your medication?" or "Do you think that your medicines are working for you?" If nonadherence is a problem, the treating physician can undertake actions to improve adherence, such as simplification of the medication program, education about the benefits of treatment, linking drug use to established habits such as meals or tooth brushing, or prescribing less costly drugs.

Proper use of MDIs is difficult for many patients to learn and retain. Repeated review and training of patients in MDI use is an important component of treatment of COPD and asthma. The inhaler should be held about 4 cm from the mouth to minimize deposition of larger droplets in the mouth. The patient should exhale to functional residual capacity and take a slow inhalation to TLC over about 5 seconds. The slow inhalation diminishes impaction of particles in the mouth and larynx. At the initiation of inspiration the patient should actuate the MDI one time. After full inspiration, the patient should hold the breath for about 10 seconds to permit deposition of particles in the distal airspaces. If the patient finds that hoarseness or mouth irritation occurs with inhaler use, this can often be corrected by use of a spacer, slowing the rate of inspiration, and rinsing the mouth after each inhaler use. Although waiting a period of time between inhalations or between different MDIs is sometimes recommended for optimal effect, the benefit is small compared with the inconvenience and risk of worsening adherence. Therefore, it is usually appropriate to permit the patient to take additional inhalations as soon as he or she has rested a few seconds.

If the patient has difficulty coordinating the actuation of the MDI with inspiration, a spacer device or holding chamber can be used. This device is placed directly in the mouth and the MDI can be actuated prior to inspiration. In some circumstances, it is necessary for patients to use a breath-actuated MDI or nebulizer to achieve optimal benefit from inhalational medication. Dry powder inhalers usually require less coordination than MDIs, but there are many different devices, some rather complicated to use. Therefore, each device requires individual instruction and review of technique. (For a compendium of patient instructions, see http://www.ginasthma.com/OtherResources.asp.

Ipratropium bromide is an inhaled anticholinergic drug that causes 4 to 8 hours of bronchodilation through inhibition of vagal stimulation of the airways. Although it is more expensive than beta agonists, it is often used as first-line therapy. The dosage is started at two MDI inhalations three times daily, and can be increased to six inhalations four times daily. Adverse effects are minimal, even with relatively high doses, so the maximum dose is limited by cost and convenience. Local side effects include mouth irritation and cough, which can be diminished by good inhaler technique or use of a spacer. Supraventricular tachyarrhythmias may occur more frequently in patients using ipratropium but are rare. Urinary retention or acute narrow-angle glaucoma are potential but exceedingly rare complications of inhaled ipratropium. Although ipratropium provides sustained benefit in patients with moderate disease, it does not inhibit progression of the disease if smoking is continued.

Tiotropium is an anticholinergic bronchodilator that has the benefit of once-daily dosing, and is more effective than usual doses of ipratropium in bronchodilation, quality of life, and reducing exacerbations. Exercise capacity is improved by reduction in dynamic hyperinflation. Tolerance does not develop with prolonged use. First morning spirometry is improved after long-term use of tiotropium, but it is not yet known whether this reflects sustained improvement in lung function, or it is residual bronchodilation due to the very long duration of action. It is inhaled once daily from a capsule inserted into a dry powder inhaler. Tiotropium is most useful in patients with moderately symptomatic disease who find frequent use of bronchodilators inconvenient or those who have nocturnal or early morning symptoms. Because of the slower onset of bronchodilation, some individuals do not recognize the efficacy of this drug, and use additional short-acting agents for symptomatic use. Proper instruction is needed in use of the inhaler, but the dry powder inhaler does not require as much coordination as a metered dose inhaler. Some patients with mild disease prefer to use once-daily tiotropium rather than as-needed short-acting bronchodilators as initial therapy, which is a reasonable treatment approach.

Short-acting β-adrenergic agonists are used at dosages comparable to those used in asthma. Selective beta$_2$ agonists should be administered by the inhaled route and oral forms reserved for the occasional person who cannot or refuses to take inhaled drugs. Oral beta agonists, although longer-acting, tend to have more side effects such as tremor, tachycardia, and hypokalemia. Albuterol is the most widely prescribed selective beta$_2$- adrenergic bronchodilator and is available in MDI formulations with either CFC or HFA propellants. The typical dose is two inhalations every 4 to 6 hours as an as-needed or regular agent. Pirbuterol has similar pharmacologic properties, but is supplied in a breath-actuated MDI that is easier for discoordinated patients to use effectively without a spacer.

Long-acting inhaled beta agonists such as salmeterol or formoterol are useful because of the long duration of action and documented benefit on quality of life and exercise tolerance. Monotherapy with a long-acting beta agonist is discouraged in treating patients with asthma, but has been used effectively in patients with COPD. Both salmeterol and formoterol are available in dry powder inhaler formulations.

Formoterol has a quicker onset of action and is sometimes used for intermittent symptom relief, but does not permit as frequent re-dosing as short-acting agents. Increasing doses beyond the recommended dose adds little to the bronchodilator effect, but does increase the risk of adverse effects such as hypokalemia, tremor, and tachycardia. Therefore, it is usually advised that patients started on long-acting beta agonists also be provided with a short-acting bronchodilator for as-needed treatment of symptoms.

Combination inhaler therapy with a beta agonist and a short-acting anticholinergic provides better bronchodilation than either agent alone and the simplified treatment regimen may improve adherence. Combinations of inhaled corticosteroids and long-acting bronchodilators provide more bronchodilation than either alone in patients with chronic bronchitis and airflow obstruction.

Theophylline is taken as a long-acting oral preparation once or twice daily. Although it is possible to monitor blood levels, because the drug is protein bound there is a poor correlation between efficacy or adverse effects and serum levels. Theophylline is a bronchodilator; it improves arterial oxygenation and exercise tolerance. If typical side effects such as nausea, vomiting, tremor, or tachyarrhythmias occur, the dose should be adjusted irrespective of serum levels. Prescriptions for theophylline for COPD have diminished in recent years because of the availability of long-acting inhaled agents, but it is still an effective second-line drug for patients who show benefit or prefer inexpensive oral medications. Theophylline has other putative pharmacologic actions that might be beneficial for the COPD patient: improvement in diaphragm contractility, prevention of respiratory muscle fatigue, increased ventilatory drive, potentiation of catecholamine function, prevention of microvascular permeability, increased mucociliary clearance, prevention of late-phase antigen responses, inhibition of mast cell histamine release, and suppression of leukocyte activation. Recent evidence has suggested that the anti-inflammatory effect of theophylline is mediated by augmentation of steroid effects through activation of histone deacetylase (HDAC), an effect that is of particular importance in COPD patients who have lower HDAC activity. Newer agents that are more specific inhibitors of phosphodiesterase-4 have been developed but are not yet marketed in the United States, and hold the promise of similar efficacy as theophylline with lower toxicity.

Oral corticosteroids are effective for treatment of COPD exacerbations. About 10 to 20 percent of chronic symptomatic patients show substantial short-term improvement in pulmonary function, but it is not possible to identify these patients based on clinical characteristics alone. Because of the well-defined long-term adverse effects of systemic corticosteroids, and the ill-defined long-term benefits, most patients should not be maintained on long-term oral or systemic corticosteroids. Patients with COPD who are on chronic corticosteroids can most often taper the dose at the equivalent of 5 mg of prednisone per week, and exclusively reserve their use for exacerbations. Long-term low doses of oral corticosteroids are occasionally needed by patients who cannot afford or tolerate inhaled agents, and who suffer frequent exacerbations. Patients on long-term systemic steroids should receive prophylaxis for osteoporosis with calcium and vitamin D or bisphosphonates, and should be instructed about the need for stress-dose steroids for acute illnesses.

Inhaled corticosteroids do not effectively alter the progression of COPD in those who continue to smoke. Inhaled corticosteroids are most useful in patients who have an overlap between asthma and COPD and those with more advanced disease who have frequent exacerbations. Inhaled corticosteroids can reduce the frequency of exacerbations, improve airways reactivity, and slow the decline in quality of life. In patients with chronic bronchitis and obstructive lung disease, inhaled corticosteroids improve pulmonary function, and the results are additive to those achieved with long-acting bronchodilators. The efficacy of inhaled corticosteroids cannot be predicted based on the response to oral corticosteroids, so it is not necessary to conduct an oral steroid trial prior to initiating this treatment. Combined corticosteroid and long-acting bronchodilator inhalers are available in the United States and throughout the rest of the world and can simplify the treatment regimen. Inhaled corticosteroids, although poorly absorbed, probably do contribute to steroid side effects such as cataracts, capillary fragility, and osteoporosis in susceptible individuals. In most cases, the risk is low compared to the benefit of treatment, but it is prudent to prescribe the lowest effective dose. In patients who are at risk for osteoporosis (i.e., older age, cigarette smoking, low exercise) as most patients with COPD are, it is prudent to recommend prophylactic treatment such as calcium supplements and vitamin D. In those with established osteoporosis, bisphosphonates are advised. Monitoring for osteoporosis with DEXA bone scans is guided by the overall clinical situation and is not required for all patients using inhaled corticosteroids.

Mucolytic agents to control mucus hypersecretion with the use of expectorants and physical means such as high-frequency chest wall oscillation is not of proven benefit in improving lung function, although symptoms are sometimes improved. N-acetyl cysteine a mucolytic with antioxidant properties does not prevent exacerbations, nor does it alter the decline in FEV_1.

TREATMENT OF COMPLICATIONS

Patients with advanced COPD are prone to develop secondary complications of the disease. The goal of treatment is to restore functional status as quickly and as much as possible and to alleviate distress and discomfort.

Treatment of COPD Exacerbations

COPD exacerbations are characterized by worsening dyspnea, cough, and increased sputum production. There are several formal definitions of a COPD exacerbation, but a useful working definition is that a COPD exacerbation is a worsening of

dyspnea, cough, or sputum production that exceeds day-to-day variability and persists for more than a day or two. On average, patients with COPD have two to three exacerbations per year, but there is wide variation, and the frequency of exacerbations is only roughly correlated with severity of airflow obstruction. The best predictor of future exacerbations is a past history of frequent exacerbations, and these are more common in patients with chronic cough and sputum production. Only half of COPD exacerbations come to the attention of treating physicians, and many of these eventually resolve without specific treatment. Precipitating events include respiratory and nonrespiratory infections, exposure to respiratory irritants and air pollution, or co-morbid conditions such as heart failure, pulmonary embolism, myocardial ischemia, or pneumothorax. The management of these exacerbations depends upon the severity. Indications for hospital evaluation or hospitalization are listed in Table 42-8. Arterial blood gas studies and chest radiographs are useful for evaluating etiology and severity of acutely ill patients. Spirometry during the acute exacerbation is usually not helpful in predicting the severity or duration of the exacerbation. In selected patients with frequent or life-threatening exacerbations, monitoring of FEV_1 with inexpensive home spirometers may facilitate early recognition of exacerbations and communication with health care providers.

For patients treated at home, increasing the frequency and intensity of inhaled short-acting bronchodilators for several days is effective in mild exacerbations. A handheld inhaler and spacer are usually effective, but a nebulizer may be needed for those who cannot coordinate well or who have severe dyspnea. Increasing dyspnea accompanied by a change in the quantity or color of phlegm is usually an indication of bacterial infection and should prompt initiation of antibiotics. The choice of antibiotic is determined by severity of the underlying disease, resistance patterns of likely pathogens, and likelihood of treatment failure (Table 42-9). A course of corticosteroids, equivalent to 30 to 60 mg of prednisone for 7 to 14 days, will shorten the duration of symptoms for patients with exacerbations managed as outpatients.

For patients admitted to the hospital, intensification of inhaled bronchodilator treatment, systemic corticosteroids, and antibiotics are administered. Controlled oxygen supplementation should be provided at the lowest level needed to reverse hypoxemia and minimize the induction of hypercapnia. The selection of the oral or intravenous route for antibiotics and corticosteroids is determined by the severity of the illness and the ability of the patient to tolerate oral medication. Evaluation for the cause of the exacerbation does not have to be extensive if it responds to initial treatment and conforms to the patient's usual exacerbation pattern. Sputum culture for resistant bacterial strains, a chest radiograph for exclusion of pneumonia and pneumothorax, and an electrocardiogram for exclusion of myocardial ischemia and arrhythmia are useful tests in all hospitalized patients. Echocardiography for assessment of ventricular function, and Doppler venous flow studies, radionuclide, or computed tomographic lung imaging for evaluation of pulmonary thromboembolism need to be performed only in selected cases. Selection of antibiotics for hospitalized patients should be based on local bacterial antibiotic sensitivities, and guided by culture results. Usually a 2-week course of steroids is sufficient for hospitalized patients.

Treatment in an intensive care setting should be undertaken for patients with severe life-threatening exacerbations or those who require more constant attention (Table 42-8). For patients with respiratory failure, noninvasive mask ventilation has proved to be an effective strategy to avert

Table 42-8

COPD Indications for Hospitalization

Indications for Hospital Assessment or Admission for COPD Exacerbation
Sudden onset of new or severe symptoms (e.g., dyspnea)
Inability to sleep or eat because of dyspnea
Severe or very severe underlying COPD
Onset of new physical findings (e.g., edema, cyanosis, change in mental status)
Failure to respond to initial medical treatment
Associated comorbidities (e.g., cardiac, renal, hepatic failure, or diabetes)
Diagnostic uncertainty (e.g., suspected pneumonia or pulmonary embolism)
Unusual presenting symptoms
Older age or frailty
Inadequate home or social support
History of poor adherence with treatment
Indications for ICU Admission for COPD Exacerbation
Severe dyspnea unresponsive to initial treatment
Change in mental status (e.g., confusion, lethargy, coma)
Persistent or worsening hypoxemia, hypercapnia, or respiratory acidosis
Need for sedation or narcotic pain control

Table modified from 2004 GOLD COPD guidelines (www.goldcopd.com) and 2004 ATS/ERS Standards for treatment of COPD.

Table 42-9

Risk Stratification for COPD Exacerbation and Suggested Antibiotic Treatment

Group	Basic Clinical State	Symptoms and Risk Factors	Probable Pathogens	First-Choice Alternatives for Treatment Failure
0	Acute tracheobronchitis	Cough and sputum without other pulmonary disease	Usually viral	If symptoms persist for >10–14 days, then macrolide or tetracycline
I	Chronic bronchitis without risk factors (simple)	Increased cough and sputum, sputum purulence and increased dyspnea	Haemophilus influenzae, Haemophilus spp., Moraxella catarrhalis, Streptococcus pneumoniae	Second-generation macrolide, ketolide, fluoroquinolone, second- or third-generation cephalosporin, β-lactam + β-lactamase inhibitor, doxycycline, trimethoprim/sulfamethoxazole, amoxicillin
II	Chronic bronchitis with risk factors (complicated)	As in group I plus one of the following: FEV_1 <50% predicted, >4 exacerbations/year, cardiac disease, home oxygen use, chronic oral steroid use, or antibiotic use in past 3 months	As in group I plus *Klebsiella* + other gram-negatives. Increased probability of β-lactam resistance	Fluoroquinolone, β-lactam +β-lactamase inhibitor
III	Chronic suppurative bronchitis	As in group II with constant purulent sputum or bronchiectasis. FEV_1 < 35% predicted, or multiple risk factors (e.g., frequent exacerbations and FEV_1 <50%)	As in group II plus *Pseudomonas aeruginosa* and multiresistant *Enterobacteriaceae*	Tailor treatment based on pathogen and sensitivities. For *Pseudomonas* spp., ciprofloxacin is preferred. Hospitalized patients may need intravenous antibiotics.

Adapted from: Balter MS, La Forge J, Low DE, et al: Canadian guidelines for the management of acute exacerbations of chronic bronchitis. Can Respir J *10:3B–32B; 2003.*

endotracheal intubation, shorten duration of illness, and improve outcomes. Institution of mask ventilation requires specialized skills of trained respiratory therapists. Attention needs to be paid to selecting and fitting a comfortable well-sealed mask, and providing a ventilator that minimizes the patient's work of breathing and triggering effort. When noninvasive mask ventilation is not successful in sustaining ventilation, or the patient is too ill to use the mask, endotracheal intubation and mechanical ventilation are needed to treat respiratory failure. The mechanical ventilator should be set to provide minute ventilation that does not overventilate the patient and cause alkalemia, which may ultimately impede liberation from the ventilator. The inspiratory flow rates and inspiratory to expiratory time ratios should be adjusted to provide a prolonged duration of expiration to minimize dynamic hyperinflation (auto-PEEP), which can lead to dyspnea, discoordination, and barotrauma. Weaning and liberation from mechanical ventilation can be hindered by anxiety, oversedation, mucus secretions, intravascular volume overload, myocardial ischemia, or respiratory muscle deconditioning. Survival after an episode of acute respiratory failure for COPD is about 50 percent at 2 years after discharge, with about half of the patients being re-admitted to the hospital within 6 months.

Pneumothorax

COPD is thought to be the most common cause for secondary spontaneous pneumothorax. A pneumothorax can either cause an acute symptomatic exacerbation of COPD

from rupture of a bleb, or may occur during the course of an exacerbation as a consequence of hyperinflation or mechanical ventilation. Because this is a life-threatening but quickly treatable cause for worsening respiratory failure in COPD, it should always be considered in the differential diagnosis for worsening dyspnea in COPD. The physical examination can be misleading because diminished breath sounds are a component of the underlying disease. Imaging studies are usually diagnostic, but at times it can be difficult to distinguish a pneumothorax from an overdistended bulla. If the patient's clinical situation can tolerate it, imaging with inspiratory and expiratory views, or chest computed tomograms can be helpful. In the intensive care unit, upright and supine views sometimes show mobility of the pleural air.

Urgent treatment for the patient *in extremis* is performed by aspirating the pleural space at the second intercostal space anteriorly in the mid-clavicular line. Definitive emergency treatment is placement of a thoracostomy tube, which should be done with care to avoid laceration of a bulla and creation of a broncho-pleural fistula. In patients with advanced COPD, recurrence of a pneumothorax can be life threatening, so definitive pleural sclerosis with surgical or medical thoracoscopy should be strongly considered. Whether one adopts a surgical or medical approach to pleural sclerosis depends upon the clinical situation and preference of the treating physicians.

Cor Pulmonale

Pulmonary hypertension and consequent right ventricular failure, *cor pulmonale,* are usually the consequence of chronic alveolar hypoxia, with secondary contributions from destruction of the alveolar capillary bed, lung hyperinflation, and increased blood viscosity. Diagnosis of pulmonary hypertension and right ventricular failure can be difficult, as physical findings of venous engorgement, and right ventricular hypertrophy and dilatation are late signs. Peripheral edema is poorly correlated with resting right atrial pressure and may reflect fluid retention from activation of the renin-angiotensin-aldosterone system. Functional imaging studies including echocardiography or radionuclide ventriculography are more probative for evaluation of right ventricular function. Doppler echocardiographic measures of pulmonary artery systolic pressure are often inaccurate and may overdiagnose pulmonary hypertension, but a normal value is reassuring that pulmonary hypertension is not present. Once cor pulmonale is present, survival is diminished. If the pulmonary artery pressure exceeds 45 mmHg, the average 2-year survival is less than 2 years.

The primary treatment of cor pulmonale consists of continuous oxygen to overcome hypoxemia and diuretics to control peripheral edema. Digitalis is useful for rate control of atrial fibrillation. Calcium channel blockers and other vasodilators can dilate the pulmonary circulation, but they worsen hypoxemia and their benefit is not established. Phlebotomy increases exercise capacity when the hematocrit exceeds 55 percent, but persistent erythrocytosis suggests inadequate oxygen supplementation or another cause. Anticoagulation, which is considered beneficial in severe pulmonary vascular hypertension of other causes, is of uncertain benefit in patients with pulmonary hypertension caused by COPD.

Supraventricular Arrhythmias

Supraventricular tachyarrhythmias are common in patients with COPD, as a consequence of right atrial enlargement, increased endogenous adrenergic tone, hypoxemia, and drug treatment—specifically theophylline and anticholinergic bronchodilators. Treatment is similar to that in nonpulmonary patients; however, the presence of COPD should not prevent evaluation for treatable causes of arrhythmias such as pulmonary embolism, hyperthyroidism, or valvular heart disease, which may be difficult to diagnose in COPD patients.

Hypercapnia

Chronic hypercapnia secondary to alveolar hypoventilation can be considered an adaptive response to obstructive lung disease by decreasing the work of breathing, preventing respiratory muscle fatigue, and allowing a diminished sensation of dyspnea. The adverse effect of chronic hypercapnia is the development of alveolar hypoxia and consequent pulmonary hypertension. Accordingly, the approach to chronic hypercapnia is the use of supplemental oxygen in controlled concentrations. In patients who are very sensitive to oxygen, it is preferable to provide oxygen in controlled concentrations with Venturi masks rather than nasal cannulae.

Nocturnal ventilation has been effective in reducing daytime hypercapnia in patients with neuromuscular disease and kyphoscoliosis. Short-term trials have shown divergent effects of nocturnal ventilation in patients with COPD. A 2-year controlled long-term trial of nocturnal ventilation in hypercapnic patients with COPD has shown modest improvement in symptoms and quality of life, and a trend toward reduced hospitalization, but only small improvements in daytime hypercapnia. Thus, based on our current state of knowledge, long-term nocturnal ventilation ought to be reserved for selected symptomatic patients with frequent hospitalizations who can tolerate the treatment.

ADVANCED TREATMENTS

For patients who have far-advanced disease evidenced either by severe breathlessness or short life expectancy, more aggressive treatments should be considered. Undertaking these treatments requires thoughtful consideration by patients and their families, and frank discussion of the risks and benefits by the medical caregivers.

Lung Volume Reduction Surgery

Lung volume reduction surgery (LVRS) is a surgical procedure that involves stapled resection of 20 to 30 percent of

the lung bilaterally, usually from the apices. The procedure is equally safe and effective done by median sternotomy or video-assisted thoracoscopy (VATS). The theory behind this procedure is that the remaining lung expands to fill the thorax, thereby increasing its elastic recoil pressure, which improves expiratory airflow. The reduction of lung volume permits the diaphragm to attain a more normal, domed configuration, which improves its mechanical efficiency. Moreover, the preferential removal of unventilated bullae reduces residual volume, permitting an increase in the vital capacity. While some patients show substantial physiological and symptomatic improvement following LVRS, many do not. An algorithm for selection of patients for LVRS, based on distribution of emphysema and functional measures, is presented in Figure 42-4. Generally, LVRS should not be done on patients with an FEV_1 less than 20 percent predicted and either diffusing capacity less than 20 percent predicted or diffuse homogeneous emphysema on HRCT, because these patients have high surgical mortality. The group of patients who fare best with LVRS are those who have emphysema predominantly in the upper lung zones and low exercise capacity despite pulmonary rehabilitation. These patients have improved survival after LVRS and show improved functional status and quality of life. Conversely, patients without upper lobe predominance (i.e., lower lobe emphysema or homogeneous emphysema) and who have adequate exercise capacity after rehabilitation, have worse outcomes after LVRS. In selected cases, resection of a pulmonary nodule may be accompanied by LVRS as an attempt to improve postoperative functional status. Although LVRS was originally proposed as a temporizing measure while patients were awaiting lung transplantation, most LVRS candidates are not suitable candidates for lung transplantation. However, prior LVRS does not alter the outcome of subsequent lung transplantation.

Surgical resection of a single large bulla is rarely indicated for treatment of COPD. Isolated giant bullae are usually the result of an expanding congenital cyst. The generally accepted indication for resection of a single large bulla is that it occupies more than one-third of the hemithorax and causes compression of normal lung. Some believe that a preserved carbon monoxide diffusing capacity is an indicator of those most likely to improve following a bullectomy.

Preliminary studies with nonsurgical approaches to lung volume reduction using bronchoscopically implantable one-way valves to cause lobar atelectasis are currently being evaluated for safety and efficacy. This or other nonsurgical methods may ultimately provide an alternative approach for patients who are not otherwise surgical LVRS candidates.

Lung Transplantation

In younger patients with advanced disease, lung transplantation should be a treatment consideration. Criteria for lung transplantation referral in patients with COPD are an FEV_1 below 25 percent predicted, severe hypercapnia, or severe pulmonary hypertension in patients under the age of 60 years.

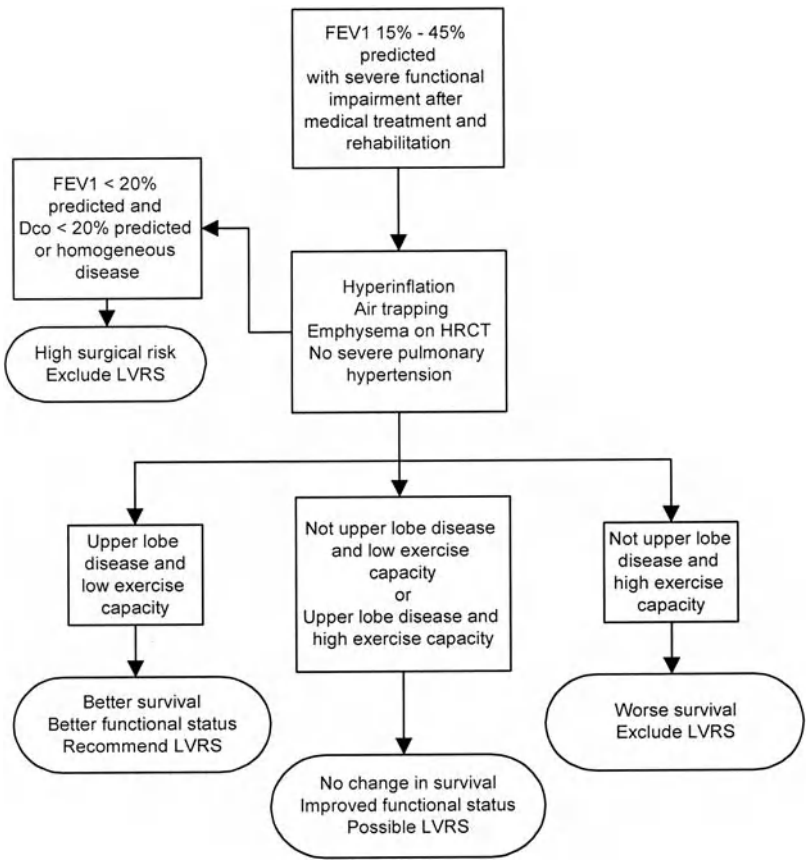

Figure 42-4 Decision tree for selection of candidates for lung volume reduction surgery based on distribution of emphysema on high-resolution computed tomogram and functional impairments.

The traditional recommendation is that patients should be referred for transplantation when their life expectancy is less than 2 years, because this is the average waiting time on a transplant recipient list. In recent years, the waiting time has lengthened to closer to 4 years, so this may influence physicians to make earlier referrals. Other co-morbid conditions such as poor nutritional status, chronic mycobacterial infection, severe osteoporosis, or suboptimal psychosocial support are considered relative contraindications. Current smoking, recent malignant disease, major organ system failure (particularly renal), or chronic hepatitis B or C infections are considered absolute contraindications. Lung transplantation may be either unilateral or bilateral depending upon the availability of donor organs and preference of the transplant surgeon. Generally, younger patients and those with accompanying bronchiectasis are considered better candidates for bilateral lung transplantation.

COPD is the most common indication for lung transplantation, accounting for nearly 40 percent of all lung transplants and about half of single lung transplants. This is accounted for by the high prevalence of COPD as well as the better survival for COPD than other transplant indications while awaiting donor organs. However, newly promulgated criteria for prioritization of transplant recipients, based on diagnosis rather than waiting time alone, are likely to diminish the likelihood that COPD patients will receive donor organs. Early survival for patients with COPD following lung transplant is slightly better than other diagnostic groups in the first few years. Overall, 30-day survival is 93 percent; 3-year survival is 61 percent; and 5-year survival is 45 percent. Evidence suggests that COPD transplant recipients do not have better survival than comparable wait-listed candidates, so the rationale for lung transplantation in COPD, in contrast to other diseases, is the demonstrable improvement in functional capacity and quality of life.

Chronic Ventilator Support

Some patients remain on long-term ventilator support following an episode of acute respiratory failure. Most often these patients are treated in a long-term ventilator unit, but some can be managed at home with adequate support. In some cases, the goal of long-term ventilator support is to provide rehabilitation via respiratory care, nutrition, and exercise to eventually be liberated from the ventilator entirely or for substantial portions of the day. In other cases, the goal of care is to provide comfort and support for terminal care without attempts at rehabilitation. Whatever the goal, a coordinated team of physicians, respiratory therapists, physical therapists, nutritionists, social workers, psychologists, and nurses are needed to undertake the care of these patients. The treatment of long-term ventilator patients differs from the treatment of acute respiratory failure in the intensive care unit. Ventilators are less sophisticated in terms of modes of ventilation and monitoring, but more portable. Ventilation is often performed with an uncuffed tracheostomy with an air leak to avoid complications at the cuff site. Sufficiency of ventilation is judged by noninvasive measures of oxygenation and patient comfort. Narcotics in small doses are administered for relief of dyspnea. Diagnostic studies and invasive testing are performed less frequently than in critical care units. Although the care in long-term ventilator units is complex and expensive, the quality of life experienced by patients in chronic ventilator units is similar to that of patients confined to a bed and chair existence by other chronic maladies. The survival of COPD patients on long-term mechanical ventilation is less than those on such treatment for neuromuscular diseases, in part, because of their older age and co-morbidities.

CONCLUSIONS

COPD develops insidiously. However, the disease can be easily detected with simple spirometric testing before symptoms occur, and cessation of smoking can slow or even halt the disease progression and prolong survival. Once the disease is symptomatic, a coordinated, comprehensive, and individualized approach to treatment, both pharmacologic and nonpharmacologic, can increase functional status, prevent complications, and improve the quality of life. Exacerbations of COPD can range from those that are nuisances to those that are life threatening, but treatment can shorten the duration of illness and improve outcomes. In advanced disease, treatments including surgical approaches are directed toward relief of symptoms and prolongation of survival. Thus, although there is certainly need for improvement in our treatment of symptomatic COPD, current treatments are effective and a nihilistic attitude is not warranted.

Cigarette Smoking and Disease

Stephen I. Rennard • Lisa M. Hepp • David M. Daughton

Native Americans discovered the use of the tobacco plant, *Nicotiana tabacum,* during antiquity. By the time Columbus arrived in America, tobacco use was widespread throughout the western hemisphere and was well integrated into Native American cultures. Production of tobacco and its trade represented a major economic activity in the pre-Columbian Americas. Early European explorers learned of the tobacco plant from Native Americans, and by the mid-seventeenth century tobacco was widely used in Europe.

The most important, but not the only, active psychopharmaceutical drug contained in the leaves of the tobacco plant is nicotine. It is likely that this alkaloid, which represents a major metabolic product of the tobacco plant, evolved as a protection against insect predators, as nicotine is a potent insect neurotoxin. Interestingly, nicotine has been exploited in this regard as a commercial insecticide.

Nicotine is a potent euphoriant. On a molar basis, nicotine is more active than such euphoria-inducing drugs as cocaine, amphetamine, or morphine. Nicotine also has a number of other effects on the central nervous system (CNS). For example, nicotine can improve task performance and attention time by measurable degrees in nonhabituated individuals and may have beneficial effects on cognition. Nicotine can also ameliorate anxiety and depression and induce a sense of well-being while causing a state of arousal. In addition, nicotine can attenuate pain. Unfortunately, nicotine is also highly addictive.

NICOTINE ADDICTION

Nicotine exerts its biologic effects on "nicotinic" receptors, a subset of cholinergic receptors whose endogenous ligand is acetylcholine. Nicotinic receptors are homo- or heteropentamers that bind two ligand molecules and form an ion channel. In humans, 17 genes code for distinct component chains, resulting in a very large number of potential pentamers, although only a relative few are believed to have a biologic role. The $(alpha4)_3(beta2)_2$ receptor is believed to be most important in the addicting effects of nicotine, while the $(alpha7)_5$, for example, is believed to mediate some of the cognitive effects of nicotine. In contrast, the muscarinic receptors, the other major class of cholinergic receptors, are single-chain G-protein–coupled receptors.

Support of the addictive potential of nicotine includes the well-described withdrawal syndrome (Table 43-1), evidence that nicotine withdrawal is associated with

Table 43-1

Nicotine Withdrawal Symptoms (DSM-IV)
Dysphoric or depressed mood
Insomnia
Irritability, frustration or anger
Anxiety
Difficulty concentrating
Restlessness
Decreased heart rate
Increased appetite or weight gain

drug-seeking behavior, and the general dose escalation observed early in the habitual use of nicotine in most individuals. Current concepts suggest that both the psychoactive effects of nicotine and its addiction potential depend on its pharmacokinetics. As with many other addicting drugs, the CNS effects of nicotine depend on both the absolute level of the drug and the rate of drug level increase at the receptors in the brain. Smoking is a particularly effective means of delivering nicotine to induce psychoactive effects. When the drug is inhaled into the lungs its lipid solubility allows it to be rapidly absorbed across the alveolar surface into the pulmonary capillary blood. This results in a very rapid increase in nicotine levels in arterial circulation. Consequently, at the level of receptors in the brain, nicotine concentration rises very rapidly following inhalation of a cigarette. This type of pharmacodynamics maximizes not only the psychoactive potential of nicotine, but is also important in its addictive potential. Alternative forms for delivering nicotine, which do not achieve such rapid rises in blood levels, are associated with less psychoactive effect and less addictive potential. These pharmacodynamic principles are important in the use of nicotine replacement as an aid to smoking cessation, as they underlie the basis for nicotine vaccines and provide part of the rationale for partial nicotine agonist therapy (see below).

Nicotine addiction is primarily a pediatric problem. That is, most individuals who become addicted to nicotine become addicted prior to adulthood. In the United States, the peak incidence for developing a regular nicotine habit is in adolescence. Individuals who do not acquire a nicotine habit prior to age 20 are exceedingly unlikely to do so as adults. The demographics of smoking initiation were well known to the tobacco industry. Marketing campaigns designed to promote the image of specific brands of cigarettes were carefully designed and were exceedingly effective in leading to logo recognition among children as young as kindergartners and contributed to brand selection among American adolescents. The susceptibility of children to these campaigns was a major driver in leading to the current ban on tobacco advertising in media likely to be seen by children.

Most children who begin to smoke do so on an occasional basis. Within a few years, however, a regular habit may develop. Most often this habit is characterized by smoking only a few cigarettes daily. The number of cigarettes smoked, however, generally increases for the first 8 to 10 years. Important variations on this pattern exist, suggesting biologic differences among smokers. Some smokers achieve a "mature addiction" very rapidly. In contrast, as many as 15 percent of smokers, termed "chippers," may continue to smoke episodically and may not be fully addicted. Once a smoker achieves a mature addiction, however, cigarette consumption typically remains very constant. Interestingly, the smoker appears to be adjusting nicotine intake. If supplemental nicotine is administered, smokers often reduce their nicotine consumption. Alternatively, if smoking is restricted (e.g., by decreasing the number of cigarettes available), smokers alter their smoking strategy (e.g., by smoking each cigarette more deeply) in order to maintain a relatively constant nicotine intake.

While the pathogenetic mechanisms underlying withdrawal symptoms are incompletely understood, it is generally believed that some withdrawal symptoms are related to decreases in nicotine blood levels below certain thresholds. Some smokers experience nicotine withdrawal at night when sleep interferes with nicotine intake. The concept that nicotine replacement can help ameliorate withdrawal symptoms by maintaining nicotine blood levels is also an important concept underlying nicotine replacement as an aid to smoking cessation (see below).

Smoking is a perfect example of a gene-environment interaction. Twin studies have established a genetic basis for both smoking initiation and smoking persistence. It is likely that many genes affect smoking behavior, and several candidate genes have been suggested. Among these is CYP2A6, the enzyme that normally metabolizes about 70 percent of nicotine into cotinine. Individuals with a null mutation in CYP2A6 are less likely to become smokers, presumably because they "overdose" when they smoke. If they do smoke, they smoke fewer cigarettes and smoke them less intensely and, as might be expected, are at less risk for smoking-related disease.

Nicotine, through its action on the $(alpha4)_3(beta2)_2$ receptors located on the neurons in the mesolimbic system, is believed to modulate release of the neurotransmitter dopamine. Interestingly, other drugs of addiction, including opiates, alcohol, and amphetamines, also modulate dopamine release. Further supporting a key role of dopamine in mediating the addiction to nicotine is the observation that the dopamine antagonist haloperidol increases smoking behavior while the dopamine agonist bromocriptine decreases smoking. Consistent with this, several candidate genes for smoking behavior have been suggested in the pathways of dopamine signaling and metabolism.

SOCIAL AND CULTURAL ASPECTS OF SMOKING

Social factors also play a vital role in smoking. The experience a child has with the initial attempts at smoking appears to be important, as is an individual's attitude toward smoking (i.e., the "image" of the smoker, peer pressure, parental cigarette use, and availability). Social attitudes can account for very low smoking prevalence in some groups. These observations support attempts to place restrictions on smoking in public places and other efforts to "de-normalize" smoking. Nicotine, moreover, is not the only psychoactive compound in cigarettes. While less well studied, monoamine oxidase inhibitors are present, and these may have either direct effects or interact with other psychoactive drugs. Thus, while it is clear that nicotine is a highly addicting psychoactive substance, smoking is highly complex. This complexity suggests that various smokers may smoke for different reasons; some may be relatively casual smokers, while others may be hard core. Understanding the nature of the addiction is likely to become more important as cessation techniques become more sophisticated.

As in ancient America, the use of tobacco products has become well integrated into modern cultures worldwide. Tobacco is a multi–billion dollar industry. In some regions, tobacco is a crucial cash crop in an agricultural economy. In addition, the manufacture, distribution, marketing, and sale of tobacco products employ many individuals worldwide. Taxation on tobacco products has become an important means for the support of many governments. Thus, any changes in tobacco usage are likely to have economic impacts well beyond any health effects.

The use of tobacco not only has an economic role, but a cultural one as well. In some societies, e.g., certain Native American tribes, tobacco usage has religious significance. In other groups, tobacco usage is associated with a strong cultural image. Often this image may have been created through direct efforts of the tobacco industry to market their product. In this regard, advertising messages promoting the image of the cigarette smoker as rugged, independent, and masculine or as sophisticated, independent, and feminine have been developed. While these images of cigarette smoking have their origins in advertising campaigns, the effectiveness of such marketing programs cannot be underestimated. The portrayal of these images in media such as film may help promote smoking. Whatever the reasons, cigarettes clearly have a cultural significance. The social and economic impact of tobacco usage, therefore, must be considered when attempting to deal with smoking as a public health problem.

MASTER SETTLEMENT AGREEMENT

In an effort to combat the public health ramifications of tobacco usage, the Master Settlement Agreement was signed into effect in 1998. It served as a measure to recuperate what states had lost through Medicaid expenditures due to smoking-related illnesses and as a measure to fine the tobacco industry for deceitful actions. Four major United States tobacco companies awarded 46 states $206 billion dollars to be paid over 25 years and to be utilized as the states saw fit. Four states had previously settled separately. Unfortunately, since its inception, many states have failed to use the funding for tobacco control causes, instead using it to fill budget deficits or support other state programs. Among many other actions, the agreement also prohibited advertisements targeted at youth and permitted access to tobacco industry documents.

SMOKING AS A PUBLIC HEALTH PROBLEM

Cigarette smoking is a major public health problem. In fact, it can be considered *the* major public health problem. The number of deaths attributed to cigarette smoking in the United States has been estimated to be in excess of 400,000 annually. This vastly exceeds deaths attributed to other specific causes. The health burden attributable to smoking parallels smoking prevalence. As a result, smoking-induced disease is becoming more common in the developing world, where smoking prevalence has been increasing. In the United States, where comprehensive tobacco control programs have reduced smoking prevalence, the burden of tobacco-related disease has begun to decrease.

Smoking can cause disease through a myriad of effects. Cigarette smoke contains in excess of 6000 compounds. Detailed toxicity studies have been done on relatively few of these inhaled toxins. Some are present in the tobacco plant; others, including much of the carcinogenic nitrosamines, are generated during the processing of the tobacco leaf, and many more toxins are generated during the pyrolysis of the processed tobacco. While the mechanisms of toxicity are legion, tobacco smoke contains compounds that can disrupt DNA, causing both mutations and altering gene expression, bind to and disrupt proteins, and alter cellular lipids. Obviously, such a diverse group of toxins interacts with many biochemical and cellular pathways. It is not surprising, therefore, that individuals whose biochemistry may differ considerably will be heterogeneous in their response to cigarette smoke. Recognizing that there appears to be a wide range of poorly understood inter-individual susceptibilities, tobacco smoke is associated with an increased mortality from atherosclerotic vascular disease, cancer, chronic obstructive pulmonary disease and is associated with a number of other adverse health effects as well (Table 43-2).

CHRONIC OBSTRUCTIVE PULMONARY DISEASE

Cigarette smoking is the major risk factor associated with the development of chronic obstructive pulmonary disease

Table 43-2

Diseases Associated with Cigarette Smoking

- Cardiovascular
  - Atherosclerotic vascular disease
    - Coronary artery disease
    - Carotid vascular disease
    - Mesenteric, renal, iliac
    - Abdominal aortic aneurysm
  - Peripheral vascular disease
    - Thromboangiitis obliterans (Berger's)
    - Deep venous thrombosis
    - Pulmonary embolus
  - Cardiac disease
    - Angina pectoris
    - Coronary artery spasm
    - Arrythmia
- Malignancy
  - Respiratory tract
    - Lung cancer
      - Squamous cell
      - Adenocarcinoma
      - Large cell
      - Small cell
    - Laryngeal cancer
    - Oral cancer
  - Other tissues
    - Esophagus
    - Pancreas
    - Bladder
    - Uterine cervix
    - Kidney
    - Anus
    - Penis
    - Stomach
    - Liver
    - Leukemia
- Lung disease
  - COPD
    - Emphysema
    - Chronic bronchitis
    - Asthma
  - Other lung diseases
    - Idiopathic pulmonary fibrosis
    - Histiocytosis X
    - Respiratory bronchiolitis
    - Goodpasture's syndrome
    - Sleep apnea
    - Pneumothorax
- Gastrointestinal disease
  - Peptic ulcer disease
    - Gastric
    - Duodenal
  - Gastroesophageal reflux
    - Chronic pancreatitis
    - Chron's disease
    - Colonic adenomas
- Dermatologic disease
  - Skin wrinkling
  - Psoriasis
- Reproductive disease
  - Ovarian failure
  - Pregnancy related
    - Prematurity
    - Premature rupture of membranes
    - Spontaneous abortion
  - Decreased sperm quality
  - Fetal effects
    - Low birth weight
    - Impaired lung growth
    - Sudden infant death syndrome
    - Febrile seizures
    - Reduced intelligence
    - Behavioral disorders
    - Atopic disease/asthma
- Effects on children of parental smoking
  - Asthma
  - Rhinitis
  - Otitis
  - Pneumonia
  - Increased risk to smoke
- Rheumatologic disease
  - Osteoporosis
  - Rheumatoid arthritis
- Psychiatric
  - Depression
  - Schizophrenia
- Oral disease
  - Periodontal disease
  - Loss of taste
- Loss of olfaction
- Infectious disease
  - Tuberculosis
  - Pneumococcal infection
  - Meningococcal infection
- Endocrine disease
  - Altered hormonal secretion
  - Graves' disease
  - Antidiuresis
  - Goiter
- Renal
  - Glomerulonephritis
- Benign prostatic hypertrophy
  - Cataracts

Most of the associations of cigarette smoking and disease are based on epidemiologic studies. While in some cases there is clear evidence of an etiologic role of cigarette smoking, in other cases this relationship is not clear. Cigarette smoking, for example, may be associated with something else that is, in fact, etiologically related to a specific disease. In some cases, for example, depression, cigarette smoking may be therapeutic; thus, the association may not be that the smoking causes the disease, but rather the disease causes the smoking.

(COPD) (see Chapter 41). Approximately 80 percent of patients with clinically significant COPD are or have been smokers. The number of individuals with COPD in the United States is estimated to be as high as 23 million, of whom as many as 10 percent have severe disease. Evidence supporting the relationship between smoking and COPD includes a dose-response effect; that is, heavy smokers are at greater risk of developing COPD. Low doses are also likely hazardous, as symptoms of bronchitis and increased risk for COPD have been associated with passive smoke exposure.

On average, expiratory airflow in cigarette smokers decreases twice as fast in smokers (40 ml/y) than nonsmokers (20 ml/y). Although only a minority of smokers, perhaps 15 percent, who lose lung function faster than the average, are commonly diagnosed with COPD, it is likely that as many as 50 percent of smokers will have at least moderate disease and, upon careful questioning, will have evidence of functional compromise. In addition, COPD is a major risk factor for acute cardiac events with even minor decrements in lung function being associated with increased cardiac risk.

Current understanding of the mechanisms by which cigarette smoke leads to the development of COPD is presented in Chapter 41. A number of interacting mechanisms appear to be involved. Emphysema likely develops from lung damage, which can be a result of direct injury from oxidants in cigarette smoke, and the action of oxidants released by inflammatory cells recruited into the lung as a result of smoke exposure. Smoke-generated oxidants may also disrupt the anti-protease protective mechanisms of the lung, creating a milieu more susceptible to protease-induced damage. When damage induced by smoking is not balanced by appropriate repair mechanisms, emphysema may result. In this context, cigarette smoke may disrupt repair processes. Chronic bronchitis appears to result from similar mechanisms in the airway. Inflammation induced by cigarette smoke appears capable of stimulating both acute production of secretions and inducing long-term anatomic changes in the airway. Changes such as goblet cell metaplasia may predispose to a hypersecretory state. Others, such as peribronchial fibrosis, may result in airflow obstruction. The development of autoimmune processes has been suggested to contribute to disease that persists after smoking cessation. The heterogeneity of clinical COPD likely results from varied host responses to the many pathogenetic pathways initiated by cigarette smoke.

MALIGNANCY

The association of smoking with the development of lung cancer is also well established. The risk for developing lung cancer is increased about 20-fold in smokers compared to nonsmokers. Furthermore, smoking is the major risk factor associated with lung cancer. The attributable risk for the development of lung cancer is estimated to be 79 percent in women and 90 percent in men. In further support of the association of cigarette smoking and lung cancer, as with COPD, epidemiologic evidence supports a dose dependency. Specifically, lung cancer risk increases with amount smoked and, most importantly, with the duration of smoking. The increased risk of lung cancer among passive smokers again is suggestive that even low-dose exposures to cigarette smoke carry significant risk.

A direct etiologic role of cigarette smoke in the development of lung cancer is also supported by considerable evidence. The current model of carcinogenesis is a multistage process in which cigarette smoke plays a role at several stages. Both tumor initiators and tumor promoters are present in cigarette smoke. Although many substances in cigarette smoke likely contribute to carcinogenesis, polycyclic aromatic hydrocarbons and nitrosamines have attracted considerable attention. These toxins can lead to acquired somatic cell mutations and persistently altered cellular function. As a result, smokers frequently have epithelial cell abnormalities, which progress from mild metaplastic changes through severe dysplasia and, it is believed, finally to cancer. These lesions are also often widespread raising the possibility that the development of lung cancer in the smoker may be a multi-focal process. These epithelial cell alterations may also contribute to the pathogenesis of other diseases, such as COPD. Interestingly, the development of cancer may depend on host factors. Some potential carcinogens, for example, must be activated in the lung by mixed function oxidases. These enzymes are themselves under genetic control. It has been suggested that varying capacity to induce such enzymes could contribute to varying cancer risk.

Cigarette smoking is associated with several other nonmalignant lung diseases besides COPD (Table 43-2). Nearly all patients with pulmonary histiocytosis X are smokers, suggesting cigarette smoke may have a pathogenetic role in this illness. Similarly, a large number of individuals with spontaneous pneumothorax are smokers. As a result, it has been thought that cigarette smoke–induced damage may contribute to the development of this condition. Malignancies of both the upper respiratory tract and outside the respiratory tract are also associated with cigarette smoking. Cigarette smoking is a major cause of oral and laryngeal cancer. Cigarette smoking, moreover, has been associated with a number of other malignancies (Table 43-2). The mechanism by which cigarette smoking contributes to the development of these various malignancies is not fully established. Cigarette smoke–derived carcinogens are concentrated in the urine and, as a result, the urinary tract, particularly the bladder, is exposed to high concentrations of these toxins.

CARDIOVASCULAR DISEASE

Cigarette smoking is also a major risk factor for the development of cardiovascular disease. In this regard, the impact

of cigarette smoking is of a similar magnitude to that of the other two major risk factors: hypertension and hypercholesterolemia. As with other smoking-related diseases, the cardiovascular risks correlate with the intensity of smoking. Finally, smoking can contribute to cardiovascular disease by contributing to both the chronic development of atherosclerosis and acute cardiac events.

As with COPD and cancer, the epidemiological associations of cigarette smoking and cardiovascular disease are supported by considerable clinical and experimental evidence. In this regard, cigarette smoking can contribute to the development of atherosclerosis through a variety of mechanisms. For example, endothelial injury is associated with the development of atherosclerosis. Cigarette smoking can cause endothelial injury through direct toxicities. In addition, cigarette smoking is associated with tachycardia. Persistent tachycardia is thought to also cause endothelial injury and thus contribute to the development of atherosclerosis. Cigarette smoke per se is not associated with hypertension, but it is associated with hyperlipidemias. In particular, cigarette smoking appears to contribute to increased levels of oxidized low-density lipoproteins, which are believed to be particularly atherogenic. Smokers also have increased levels of circulating neutrophils, which may contribute to atherogenesis through injury of the vascular wall. Finally, smoking exerts effects on blood coagulability. Specifically, fibrinogen levels are increased, and platelet activation may be present. Activation of coagulation can result in release of cytokines, which is believed to contribute to atherogenesis. Microvascular disease is associated with cigarette smoking. It is the major risk factor associated with thromboangiitis obliterans. Smoking is also associated with an accelerated development of microvascular disease when there is concurrent diabetes mellitus. Abdominal aortic aneurysm is highly associated with a history of smoking.

Cigarette smoke can also contribute to acute cardiac events. While smoking does not increase blood pressure chronically, acute smoking is associated with a transient increase in blood pressure. Combined with tachycardia, therefore, smoking is associated with acutely increased myocardial oxygen requirements. This may be one mechanism by which smoking contributes to acute myocardial ischemia. Cigarette smokers also have increased levels of blood carbon monoxide (CO). This impairs oxygen delivery. Increased CO levels, in addition, may also contribute to the increased red cell mass of smokers, which together with increased fibrinogen levels contributes to increased blood viscosity. These factors in turn contribute to the hypercoagulable state associated with smoking and lead to an increased predisposition for the development of acute thrombosis. Finally, cigarette smoking is associated with acute release of catecholamines and the development of coronary vasospasm. Through such mechanisms, cigarette smoking could contribute not only to acute ischemic events, but also to acute arrhythmias.

OTHER ADVERSE HEALTH EFFECTS OF SMOKING

There are also considerable data associating cigarette smoking with a variety of other diseases (Table 43-2). Adverse effects of smoking during pregnancy, for example, are well recognized. Smoking is associated with a twofold increase in premature deliveries. Smoking also has a dose-dependent association with abruptio placenta, placenta previa and premature rupture of placental membranes. Smoking during pregnancy is associated with increased spontaneous abortion. On average, babies of smokers weigh less than those of nonsmokers. With regard to pulmonary disease, infants whose mothers smoked during pregnancy are more likely to develop both sudden infant death syndrome (SIDS) and asthma than are infants whose mothers did not smoke during pregnancy. Smoking is also related to reduced fertility in women, where it is associated with both secondary amenorrhea and irregular menstrual cycles.

In men, cigarette smoking has been associated with impaired sexual functioning. Some studies of sperm quality have shown slight impairments in smokers, but an association with infertility has not been demonstrated. Sexual activity appears to be relatively normal in smokers. Impotence may be increased in smokers, but is generally associated with the development of significant pelvic atherosclerotic vascular disease.

Considerable epidemiologic and experimental data support an association of smoking with the development of peptic ulcer disease. In this context, smoking has been associated with increased gastric acid output, increased duodenal gastric reflux, and has been suggested to decrease gastric blood flow. Smoking may also decrease the effect of antiulcer medications. Finally, smoking appears to potentiate the development of peptic ulcer disease in individuals taking nonsteroidal anti-inflammatory drugs and individuals colonized with *Helicobacter pylori*.

Cigarette smoking is also associated with a number of other diseases (Table 43-2). While the mechanisms by which cigarette smoke can exert these varying effects are not fully understood, currently available data do make some general suggestions. For example, osteoporosis is increased in smokers, particularly in older women. While the mechanism is not fully understood, mineral content is reduced in older smoking women, an effect that may be dependent on reduced circulating hormones and earlier menopause associated with smoking. Smoking is also associated with a number of inflammatory and destructive diseases such as skin wrinkling, psoriasis, chronic pancreatitis, and glomerulonephritis.

It is interesting to note the mechanistic overlap among smoking-related diseases. Activation of inflammatory processes, for example, appears to play an important role in the development of COPD and atherosclerosis, and may also play a role in the development of ulcers, skin wrinkling, pancreatitis, gingivitis, and so on. The destruction of the connective tissue macromolecular framework, particularly elastin,

is believed to play an important role in the development of pulmonary emphysema. Similar processes may also take part in the development of skin wrinkling and gum disease. Moreover, the release of cytokines driving cell accumulation and proliferation is believed to play an important role in the development of chronic bronchitis and atherosclerosis, but may also play an important role in the development of neoplasia. Finally, cigarette smoking appears to alter the release of regulatory molecules. This could account for a myriad of consequences smoking has on endocrine disease, altered immunity, and the CNS.

In support of this "systemic concept" of cigarette smoking are important epidemiologic associations. Thus, while most smokers have an accelerated decline in lung function, only a small percentage are routinely diagnosed with clinically significant COPD. This observation has been interpreted as suggesting that the effects of smoking are not clinically important with regard to lung function in the majority of smokers. Refuting this concept, however, are epidemiologic data associating an increase in mortality primarily from cardiac disease that may occur with even very modest declines in FEV_1. The important point is that the presence of a smoking-related effect, even if not symptomatically important, clearly defines an increased risk group.

SMOKING CESSATION

Background

Since Dr. Luther Terry released the first Surgeon General's report on smoking and health in 1964, the prevalence of adult smokers in the United States has dropped from 40 percent to close to 20 percent. Antismoking awareness has increased worldwide to the extent that smoking bans have become commonplace in public buildings, workplaces, and public transportation. In 1984, Surgeon General C. Everett Koop proclaimed that the United States' number one health goal was to achieve a "smoke free society by the year 2000." Unfortunately, this goal was not achieved, yet the overall incidence of smokers in the adult population in the United States continues to decrease. A more realistic goal of adult smoking reduction to 12 percent in the United States was put into place through Healthy People 2010. Whether this goal will be obtained remains to be determined; however, it still highlights the importance of a smoke-free society. The greatest reductions in smoking have been in states with the most comprehensive tobacco control programs, supporting the effectiveness of currently available interventions. Comprehensive tobacco control programs, including bans on advertising, restriction of sales to minors, and increased price for cigarettes, also appear to be having an effect in reducing smoking initiation and prevalence among high school students. Nevertheless, smoking remains a highly prevalent disorder. Since more than three-fourths of smokers wish to quit, there is need for effective smoking cessation interventions.

Behavioral Approaches

Behavioral interventions for smoking cessation should be recognized as part of all patient-physician interactions. For example, not inquiring and intervening about smoking is also a message. Current concepts suggest that not addressing smoking, when it would have been relevant, sends three messages: (1) the physician does not care if the patient smokes; (2) the physician does not have an effective intervention to offer; and/or (3) the physician does not think the patient will be able to quit. All of these "non-messages" have negative effects, particularly as smokers gradually make the decision to quit. A sense of empowerment and control over the behavior is vital to making and succeeding in a quit attempt. Inadvertently eroding a patient's sense of mastery is an unanticipated adverse consequence of not asking about smoking. In addition, many patients are unaware of the potential available therapies; appropriate information can increase motivation to engage in quit attempts.

A wide spectrum of behavioral techniques has been used to treat cigarette addiction. These include some that are effective, such as individual and group counseling, and many that are not effective, such as education, aversive conditioning, psychotherapy, transcendental meditation, sensory deprivation, hypnosis, and desensitization. Unfortunately, these latter, some of which have been assessed in detail, have tended to isolate smoking cessation interventions from mainstream medical practice.

Smoking Behavioral Intervention Models

Several models have been proposed to both understand and enhance the quitting process.

Stages of Smoking Cessation

Prochaska and DiClemente described the smoking cessation process as involving five stages: precontemplation, contemplation, preparation, action, and maintenance. These stages are viewed as a continuum, with smokers progressing sequentially through each stage. In the precontemplation stage, smokers are not interested in quitting smoking and will likely be nonresponsive to direct intervention. Smokers in the contemplation stage are considering quitting smoking and may be receptive to a physician's advice about the risks and benefits of quitting. In the preparation stage, smokers are actively preparing to quit. The action stage encompasses both initial abstinence and the 6-month postcessation period. The maintenance period commences after the 6-month abstinence period. It is rare for a smoker to progress successfully through these stages in the initial quit attempt. The cycle will likely be repeated several times before smoking cessation is ultimately achieved.

National Cancer Institute's Model for Smoking Intervention

The National Cancer Institute's (NCI) recommended model for smoking intervention is based, in part, on five NCI-supported trials involving more than 30,000 patients and was

later expanded by the Public Health Service. This approach, popularly referred to as "the five As," emphasizes the role of medical professionals to *ask* patients about their smoking status, *assess* their willingness to make a quit attempt, *advise* smokers to stop, *assist* them in their stop smoking efforts, and *arrange* for follow-up visits to support the patient's efforts. This approach utilizes brief intervention techniques and emphasizes the role of physicians as facilitators in the quitting process. Simple advice has been assessed in a number of studies, and a meta-analysis suggests a small but significant benefit of these limited interventions. Physician advice is effective both in the outpatient and hospital setting and may also be effective when given by letter or telephone.

Group Counseling

Group counseling programs for smoking cessation are offered by several commercial and voluntary health organizations. These programs are similar in content and typically include lectures, group interactions, exercises on self-recognition of one's habit, some form of tapering method leading to a quit day, development of coping skills, and suggestions for relapse prevention. Group counseling programs sponsored by voluntary health organizations, such as the American Lung Association, are generally the best cost value for smokers. However, these programs are generally limited to large metropolitan areas and are offered on a sporadic basis. One-year success rates associated with group counseling programs are typically in the 15 to 35 percent range.

Gradual Reduction vs. Abrupt Abstinence

Gradual reduction or tapering intuitively appears to offer smokers the least abrasive way to stop smoking, and may be effective for some. However, gradually cutting down can be stressful when smokers attempt to reduce their cigarette use below their critical blood nicotine threshold. At this stage, smokers may begin to experience tobacco withdrawal symptoms. Rather than suffer prolonged discomfort, many taperers will gradually return to their customary cigarette levels and will not succeed in quitting. One of the negative consequences of tapering is that this method can strongly reinforce the smoker's belief of the underlying need for cigarettes. Abrupt abstinence is often stressful and can lead to tobacco withdrawal symptoms. However, within a few weeks of total abstinence, complete abstainers experience less frequent cigarette cravings than taperers and are less prone to relapse. Cigarette tapering is often a component of many group programs in which gradual cigarette reduction is used as a preparatory stage leading toward a target quit day. In this circumstance, the tapering approach may prove beneficial to some smokers.

Educational Techniques

For years, cigarette smoking was viewed as largely a social or psychological habit. As such, the ability to quit was viewed as a measure of personal motivation and psychological willpower. Motivation to stop smoking, combined with sufficient psychological resources, was seen as a driving force behind successful cigarette abstinence. Thus, if smokers could be educated about the health risks of cigarette smoking, they could theoretically become sufficiently motivated and psychologically empowered to quit. Unfortunately, anticipated benefits of the smoking cessation value of educational awareness messages were overly optimistic and simplistic. Over 80 percent of current smokers indicate they would like but are unable to quit. Educational programs to aid smoking cessation have produced disappointing results, with high long-term failure rates. Nevertheless, education about smoking is still regarded as a useful activity.

Other Modes

The goal of hypnosis in smoking cessation is to enable the smoker to achieve an altered state of consciousness to enhance the ability to quit. Controlled trials of hypnosis have generally been unable to document long-term smoking cessation efficacy. Aversive conditioning is based on the premise that smoking is a learned response that can be extinguished by creating an association between smoking and a negative sensation. Impressive quit rates are generally not seen unless these techniques are combined with other methods, such as individual or group counseling programs. Acupuncture has been advocated, but controlled trials with "sham" acupuncture have not demonstrated an effect.

Pharmacologic Treatment

Two classes of agents, nicotine replacement and bupropion, are approved to aid smoking cessation. In addition, two other agents, clonidine and nortriptyline, are supported by guidelines for "off-label" use as secondary agents. In addition, several other agents are under active investigation and have shown promise.

Nicotine Replacement Therapies

A wide variety of nicotine replacement formulations have been developed, including tablets, polacrilex (gum), transdermal systems, nasal spray, a variety of inhalers, and nicotine toothpicks. Five formulations are currently approved as aids for smoking cessation in the United States, and three are available over the counter. In clinical trials, all have demonstrated about twofold increases in quit rates above placebo.

Nicotine Polacrilex

Nicotine polacrilex gum was the first nicotine replacement therapy to gain Food and Drug Administration approval. It is now commercially available over the counter in 2- and 4-mg forms. In nicotine polacrilex, nicotine is bound to a resin that contains a buffering agent to improve delivery of nicotine through the buccal mucosa. The rate of chewing can influence the rate of nicotine release, and the pH in the mouth can influence absorption as acid foods or drinks convert nicotine base to salt, which, because of its charge, does not cross the buccal mucosa. Ad libitum use of 2-mg nicotine polacrilex is associated with blood nicotine levels less than 40 percent

of customary smoking. At this level of nicotine replacement, many smokers may still experience discomforting tobacco withdrawal symptoms. A fixed dosage regimen of nicotine gum can produce higher blood nicotine levels than ad libitum use.

Although effective in clinical trials, less successful results have been observed with nicotine gum in general practice and unsupervised settings. This may be due, in part, to the difficulty associated with using this pharmaceutical agent.

Nicotine Polacrilex Lozenge

A nicotine polacrilex lozenge is also approved as an aid for smoking cessation, and is available over the counter. Chewing is not required, but acid food and/or beverages impair absorption.

While the potential to develop addiction to nicotine polacrilex is believed to be low, many smokers who have quit continue to use these formulations chronically. This suggests that the pharmacokinetics of nicotine delivery by nicotine polacrilex, which is substantially slower than that of a cigarette, is insufficient to induce addiction, but may be sufficient to sustain it.

Transdermal Nicotine

The primary advantage of transdermal patch delivery systems are ease of use and controlled drug delivery. Several formulations are available over the counter. In general, they achieve nicotine blood levels roughly 40 to 50 percent of that achieved by customary smoking of about 30 cigarettes daily. Transdermal nicotine systems have been repeatedly found to reduce tobacco withdrawal symptoms and significantly enhance smoking cessation rates. Unlike nicotine polacrilex, transdermal nicotine systems have consistently improved quit rates in primary care settings. This difference is likely due to the ease of patch use in this setting. The recommended use period for patches varies according to product, but a minimum of 4 weeks of therapy is probably required to help achieve long-term abstinence. Patches are most commonly worn at night, which provides a level of nicotine when a smoker awakes. Often this is a time when the individual is at risk to relapse since the low nicotine levels are associated both with withdrawal and increased effect of the smoked cigarette. On the other hand, delivery of nicotine at night may disturb sleep, particularly through vivid dreams. Spontaneous long-term use of the patch has not been observed, suggesting that the very slow kinetics of nicotine delivery with this system is insufficient to sustain addiction effectively. In addition, perhaps due to the partial replacement of nicotine, most smokers on patches still experience some tobacco withdrawal symptoms during the first few days of quitting. While these symptoms will likely be less severe compared to quitting cold turkey, some patients will be tempted to smoke and wear patches. Early concerns about increased cardiac risk among individuals who smoked while wearing the patch have not been substantiated. In fact, reduced smoking may decrease cardiac events. However, individuals who continue to smoke and use patches after the 2-week period are unlikely to achieve abstinence. For this reason, simultaneous nicotine patch wearing and smoking should be discouraged.

Nicotine Inhaler

The nicotine inhaler is a plastic nicotine-containing cartridge that fits on a mouthpiece. Nicotine is released when air is inhaled through the device, which is similar in size to a cigarette. The nicotine is not effectively delivered to the lungs as the particle size is too large. Rather, it is deposited and absorbed through the buccal mucosa, which results in pharmacokinetics that resembles nicotine polacrilex. Blood levels depend on the frequency of inhalations but can be about one-third of conventional smoking. It may cause irritation of the throat and mouth and may precipitate bronchospasm in individuals with reactive airways.

Nicotine Nasal Spray

The nasal spray delivers nicotine to the nasal mucosa through which it is absorbed. It has the most rapid pharmacokinetics of the currently available nicotine replacement formulations. Nasal irritation is very common, particularly when initiating therapy.

Combination Therapy

Although not approved by drug regulatory agencies, various combinations of nicotine replacement may have utility for selected individuals who need higher doses. In addition, combination of a transdermal system with an ad libitum modality (e.g., nasal spray) can increase the control of nicotine levels and may result in increased quit rates.

Bupropion

Bupropion is approved as an antidepressant, and several studies have demonstrated its efficacy as an aid in smoking cessation. It is believed to act by potentiating dopaminergic and noradrenergic signaling. The formulations for depression and smoking cessation have different trade names, which has clinical relevance. First, an appropriate diagnosis is often required for reimbursement. Second, care is needed not to prescribe bupropion under one name to an individual already taking it under its other name, as overdosage can result.

In clinical trials, bupropion approximately doubled quit rates compared with placebo. Subjects with a history of depression, however, appeared to benefit from bupropion but did not with nicotine replacement, suggesting that bupropion may be a superior initial choice in such individuals. Combination of nicotine replacement with bupropion has been assessed and appears more effective than either agent alone.

The currently recommended dose is 150 mg daily for 3 days followed by 150 mg twice daily. The quit date should be after a week of therapy so that blood levels are established. The drug is generally well tolerated, although dry mouth and insomnia may occur. In combination with nicotine replacement, an increase in blood pressure may also occur. A reduction in seizure threshold makes the drug contraindicated

among those predisposed to seizures, or with anorexia nervosa or bulimia. As the 150-mg once-daily dose was nearly as effective as the 150 mg twice daily, many practitioners use the lower dose routinely. The appropriate duration of therapy is not established. Clinical trials that formed the basis for approval treated for 7 weeks. However, with prolonged therapy, there is an increase in secondary quits, and therapy for 1 year resulted in more quits than therapy for 7 weeks.

Off-Label Agents

Clonidine

Clonidine is an α-adrenergic agonist active in the central nervous system that is used to treat hypertension. A number of clinical trials have evaluated its efficacy in smoking cessation and have generally shown a trend toward benefit, although individual trials have generally not been statistically significant. Its use is supported by a meta-analysis, and the DHHS guidelines suggest it can be used by experienced practitioners comfortable with the drug.

Nortriptyline

Nortriptyline is a tricyclic antidepressant that has been evaluated for efficacy in smoking cessation in several studies. Both individual studies and a meta-analysis support its benefit as an aid to smoking cessation, and it is also recommended as a possible second-line agent for practitioners comfortable with its use by the DHHS guidelines.

A number of other agents approved for other uses have also been assessed for smoking cessation. None are currently recommended off-label by established guidelines, although several are under investigation. These include topimirate, an antiseizure medication that has shown promise for combined alcohol and tobacco addiction, and selegiline, an agent used as an adjunct in the treatment of Parkinson's disease that has also shown promise in smoking cessation. Several other agents, including selective serotonin reuptake inhibitors (SSRIs) antidepressants, opiate antagonists, and amphetamines have been demonstrated to be without benefit. Anxiolytics have generally been without benefit, but buspirone remains controversial as studies have been mixed.

Investigational Drugs

Several drugs are under active investigation for smoking cessation. Varenicline is an $(alpha4)_3(beta2)_2$ receptor partial agonist that has looked promising in phase 2 and 3 clinical trials. As a partial agonist, it has the potential to mitigate some of the nicotine withdrawal syndrome. Also, as a partial agonist, it may function as an inhibitor and block some nicotine effects, and thus may prevent full relapse if a smoker "slips." Rimonabant is a CB1 receptor antagonist. It appears to attenuate a wide variety of cravings and has shown promise in clinical trials for smoking and for obesity. The potential to treat smoking and control the weight gain that is often associated would be a great boon.

Nicotine Vaccines

Nicotine vaccines are also under investigation. Antibodies can be made to nicotine, if it is presented bound to an appropriate carrier. The antibodies then bind nicotine reversibly. By slowing the delivery of nicotine to the brain, the vaccine would distort the pharmacokinetics of a cigarette. These investigational agents may have utility for long-term relapse prevention or for prevention of smoking initiation.

Practical Aspects of Intervention

Pragmatic Approaches to Smoking Cessation

There is no single "best" approach for smoking cessation. In the past, 95 percent of all successful quitters stopped smoking on their own without any outside intervention. This should no longer be regarded as the treatment of choice, however. Approximately 25 percent of smokers who spontaneously quit, stop smoking without developing tobacco withdrawal symptoms. Many other self quitters, however, do develop tobacco withdrawal symptoms, but the discomfort is not sufficiently powerful to overwhelm their desire to quit. The two critical factors required for successful abstinence are that smokers must have a *reason for quitting* and the *ability to quit.*

Reason for Quitting

Educational activities related to smoking risks are such that almost any smoker can enumerate a number of reasons for quitting smoking. There are exceptions, however, and the impact of specific reasons can vary greatly from person to person. Appropriate education, therefore, is still vital to smoking cessation. The more important issue is whether the reasons for quitting are sufficient to lead to a quit attempt. Often the motivation to make a quit attempt is driven as much by the sense of control as empowerment to succeed. This leads directly to the second factor.

Ability to Quit

Many smokers take a defeatist approach to smoking cessation that leads to a self-restoring pattern of continued smoking. The availability of effective support and, more importantly, of effective pharmacologic interventions should be known to the smoker, as this will encourage quit attempts.

Evaluation Process

In the evaluation process, patients are assessed regarding their motivation or reason to quit and their ability to stop smoking. For patients who indicate they are not currently interested in quitting, the goal is simple: Provide them with a reason for quitting. For some, this may be information about health risks. For others, it may be information about effective interventions. The second component of the evaluation process assesses the smoker's ability to quit. A simple, easy-to-use measure, the Fagerstrom test for nicotine dependence (Table 43-3), can provide a brief assessment of the patient's nicotine dependence. The most important question is time to first cigarette, and smokers who smoke within 30 minutes of awakening are usually heavily addicted to nicotine. These

Table 43-3

Items and Scoring for Fagerstrom Test for Nicotine Dependence

Questions	Answers	Points
1. How soon after you wake up do you smoke your first cigarette?	Within 5 minutes 6–30 minutes 31–60 minutes After 60 minutes	3 2 1 0
2. Do you find it difficult to refrain from smoking in places where it is forbidden (e.g., in church, at the library, at the mates?)	Yes No	1 0
3. Which cigarette would you hate most to give up?	The first one in the morning All others	1 0
4. How many cigarettes do you smoke per day?	10 or less 11–20 21–30 31 or more	0 1 2 3
5. Do you smoke more frequently during the first hours after waking than during the rest of the day?	Yes No	1 0
6. Do you smoke if you are so ill that you are in bed most of the day	Yes No	1 0

Reprinted with permission from K.O. Fagerstrom. National Cancer Institute. Clearing the Air: Quit smoking today. Washington, DC: National Institute of Health, 2003. NIH publication 03-1647.

patients and those with Fagerstrom scores greater than or equal to 7 comprise a group of individuals likely to benefit from nicotine replacement therapy. In contrast, patients with low Fagerstrom scores who are able to cope with smoke-free environments for an extended time period (greater than 4 hours) without developing discomforting withdrawal symptoms, may not require nicotine replacement therapy. For these individuals, bupropion may be a better choice for pharmacologic support.

Current guidelines suggest that all individuals who are making a serious quit attempt should be given the best chance for success. Thus, in general, pharmacotherapy should be recommended for all individuals who have no contraindications. As noted below, this approach is probably both the most effective and the most cost effective.

Preparing Smokers for Quitting

By anticipating the problems smokers will likely encounter, clinicians can help guide patients through the pitfalls that await them.

Tobacco Withdrawal Period

The first 3 days of abstinence are usually the most difficult. Tobacco withdrawal symptoms (Table 43-1) generally peak during the first 72 hours, and then gradually subside over a 3- to 4-week period. These symptoms can include restlessness, anxiety, difficulty concentrating, irritability, frustration, depression, and almost unrelenting craving for cigarettes. Common suggestions to help smokers cope with these early withdrawal symptoms in addition to nicotine replacement therapy can include: (1) Be active. Increased activity may curtail some of the drive to smoke. (2) Use deep breathing exercises. The simplest breathing exercise involves nothing more than extended breath holding followed by slow exhalation through pursed lips. (3) Avoid high-risk situations for smoking during the first 3 weeks of quitting. (4) Use plenty of cinnamon gum or chewable candies. (5) Combat strong urges to smoke: the urge to smoke will go away whether one smokes or not.

Cravings

Of all the symptoms associated with nicotine withdrawal, cravings to smoke are the most persistent. Unlike the other symptoms, cravings can also recur long after abstinence is achieved. During the second and third week of abstinence, the craving waves usually occur less frequently, but can sometimes catch smokers off-guard because of their unexpected intensity. The decrease in frequency is greater than the decrease in intensity, and cravings can be precipitated months and years after abstinence if precipitated by specific cues. In this context, cravings recapitulate, in some ways, the grief response. Relapse is commonly associated with concurrent alcohol consumption. It is likely that alcohol, and the associated situations in which it is consumed, serves both as a cue leading to craving and decreases the inhibitions that may prevent smoking. Ex-smokers should be aware of these moments of hazard.

Depression

At some time during the first three months of abstinence, some smokers may experience depression. For many this depression is mild and transient. For a small minority of smokers, quitting smoking may produce a clinical depression that may require antidepressant therapy, counseling, or return to smoking.

Weight Gain

One of the most disheartening components of quitting smoking is weight gain. Rapid weight gain is common during the first 6 to 8 weeks of cigarette abstinence. This is followed by a more gradual increase in weight to roughly 4 kg at 6 months. Average weight gain at 10 years following cessation is 4.4 kg and 5.0 kg for males and females, respectively. The health risks associated with postcessation weight gain are unknown

but are likely surpassed by the health benefits of stopping smoking.

Additional resources are now available to clinicians to help prepare smokers for quitting. Toll-free tobacco quit lines are currently provided by many countries, including the United States and Canada. Research has found that telephone counseling is an effective smoking intervention. Thus, clinicians should encourage every smoker who wishes to quit to utilize the National Quit Line (1-800-Quit Now). Additional support can be found via the internet using smokefree.gov. Using this approach, a smoker can choose to talk with a telephone specialist with either internet instant messaging or telephone support. Both methods are designed to provide smokers with a personalized quit plan.

Health Benefits of Smoking Cessation

Data on the health benefits of smoking cessation largely come from studies of former smokers. In many cases, these are individuals who may have quit smoking because of the development of disease; therefore, they represent a highly selected group. Other data are derived from interventional studies. Many times, however, such interventional studies include smoking cessation efforts together with many other interventions. Finally, such studies are generally designed to assess the intervention. In general, such interventions will only be partially successful at achieving smoking cessation, and the control group is likely to also have some quitters. As a result, the effect of the intervention cannot be equated with the effect of cessation. Nevertheless, smoking cessation is clearly associated with health benefits.

All-cause mortality is significantly decreased among former smokers. The decrease in mortality rates, moreover, is observed among all age groups and in both men and women. Thus, there is little doubt that all smokers, regardless of age or gender, are likely to benefit from cessation.

Most of the reduction in mortality is due to decreased mortality from cardiovascular events. Smoking cessation is associated with a very rapid reduction in acute myocardial events. It is also associated with a more gradual reduction in complications of atherosclerotic vascular disease. These effects are consistent with the concept that smoking contributes to cardiovascular disease by several mechanisms. The rapid reduction in acute events may be due to removing the acute stresses smoking places on the heart. The longer-term gradual effects may be associated with alteration of the atherosclerotic disease process.

Smoking cessation is also associated with significantly improved risk of both respiratory tract and nonrespiratory malignancies. The risk for the development of lung cancer appears to decrease gradually following cessation, although it will never reach that of a nonsmoker.

Smoking cessation is associated with improvement in lung function in subjects with relatively mild impairment. Improvements can be observed in the first 6 months to 1 year following cessation in FEV_1, an observation initially made in several smaller trials and subsequently confirmed in the Lung Health Study. This large study (nearly 6000 individuals) assigned individuals to three groups, no special intervention, and a smoking cessation intervention with or without the addition of the bronchodilator ipratropium. Among the individuals who successfully quit in the intervention program, there was a significant improvement in FEV_1 in the first year following cessation that was dramatically different than the continued decline observed in the continuing smokers in the same treatment group. Follow-up evaluation of this group has demonstrated continued benefits for at least 11 years, and a reduction in mortality. While not assessed in the Lung Health Study, smaller studies have also demonstrated that smoking cessation is associated with improvement in measures of small airways function including closing volume, closing capacity, and the slope phase III of the nitrogen washout curve. While more limited, several studies also suggest that smoking cessation may be associated with partial improvement in the impaired diffusion capacity of a lung for carbon monoxide (D_{LCO}) associated with smoking. This physiological effect may have a correlate in the cellular changes associated with smoking cessation.

Smokers have markedly increased numbers of alveolar macrophages recoverable by bronchoalveolar lavage. Following cessation in normal smokers, the numbers of recoverable alveolar macrophages decreases significantly towards normal. Among individuals with more severe COPD, however, cessation may not be associated with a reduction in inflammation. Cross sectional studies have demonstrated similar inflammation among current and ex-smokers. Other prospective studies suggest persistent inflammation following cessation. How these studies relate to the improved clinical status of COPD patients following cessation remains to be delineated.

Smoking cessation is associated with an improvement in nonspecific respiratory symptoms. Individuals with cough, sputum production, dyspnea, and wheeze have all reported improvement in symptoms in long-term follow-up studies, with symptoms often improving in the first few months. Smoking is the major risk factor for respiratory bronchiolitis, and smoking cessation is usually associated with a dramatic improvement in this condition. It seems reasonable to suggest that clinically recognizable respiratory bronchiolitis represents one end of a spectrum, and the physiologic and cellular changes noted above in asymptomatic individuals represent a more common result of similar pathogenetic mechanisms. Histiocytosis X occurs almost exclusively in smokers. Smoking cessation is generally regarded as an important therapeutic goal for such individuals. There are cases of complete roentgenographic resolution of the changes of histiocytosis X with cessation. While the pathogenetic mechanisms underlying histiocytosis X are unknown, such case reports suggest that at least part of the anatomic abnormalities associated with this condition are reversible with cessation of smoking.

The effect of smoking cessation on other diseases associated with smoking is, unfortunately, somewhat limited. Former smokers have a reduced incidence of peptic ulcer disease and a more rapid rate of ulcer healing than do current

smokers. Similarly, women who are former smokers seem to have ovarian function that more closely resembles never smokers than smokers. These observations are consistent with a benefit of smoking cessation.

Risks of Smoking Cessation

Smoking cessation may be associated with some hazards in selected cases. Nicotine and other components of cigarette smoke may have a significant antidepressant effect, and many endogenously depressed individuals may have empirically found smoking helped alleviate their symptoms. Depression is a well-recognized manifestation of the nicotine withdrawal syndrome. At times, this depression can be of major clinical importance. Exacerbations of colitis have also been associated with acute smoking cessation. These potential adverse effects should not minimize the importance of smoking cessation, but the clinician should be prepared to address them when necessary. Anecdotal reports have suggested that asthma may worsen following cessation. Anti-inflammatory action of toxins contained in smoke such as NO or CO has been suggested to account for such an effect.

Smoking as a Chronic Relapsing Disease

With current therapeutic interventions, only a minority of smokers will achieve permanent abstinence. This has led to the concept that smoking should be regarded as a chronic relapsing disease. The goal, therefore, is to induce remissions that are as robust as possible. When relapse occurs, re-induction at the earliest possible time is appropriate.

HARM REDUCTION

A more controversial approach for smokers who are unwilling or unable to quit at all is that the health consequences may be partially addressed by reducing the exposure to smoke-derived toxins. This approach, termed "harm reduction," has been the subject of an Institute of Medicine report. Three general categories of harm reduction are theoretically possible: (1) administration of agents to counteract the effects of cigarette smoking; (2) smoking reduction; and (3) development of a less toxic cigarette.

Since cigarette smoking is thought to cause its effects through pathogenetic mechanisms that are at least partially defined, it is appealing to use such mechanisms as targets for therapeutic intervention. In this regard, antioxidants to ameliorate the oxidant-induced injury caused by cigarette smoke and protease inhibitors to bolster the antiprotease defenses are both potential therapies. While conceptually appealing, no data exist to suggest that any such approach is of benefit in continuing smokers.

Pharmacologic support may facilitate reduction in smoking. The observation that most smokers maintain a relatively constant nicotine intake creates the possibility that nicotine replacement can help sustain smoking reduction. Smoking reduction has also been achieved with several formulations of nicotine replacement, and there is some evidence for physiological benefit. Short-term smoking reduction, facilitated with the use of nicotine polacrilex gum, was associated with improvements in lower respiratory tract inflammation assessed by bronchoscopy and bronchoalveolar lavage in a group of heavy smokers. In patients with cardiac disease who reduced smoking, measurable improvements in cardiac function were associated with improved oxygen delivery to the heart due to reduced carbon monoxide. Bupropion has also been associated with reduction in smoking, suggesting that several pharmacologic approaches may be possible to quantitatively reduce smoking.

Reducing the delivery of cigarette smoke toxins while still providing the smoker with a satisfactory cigarette has been an important commercial goal. This was a major motivation in the development of filtered cigarettes and of low-tar, low-nicotine cigarettes. Unfortunately, these approaches do not reduce, and may actually increase, exposure to smoke-derived toxins. As most smokers maintain constant nicotine intake, many smokers compensate for altered smoke composition by simply smoking more or changing the way in which each cigarette is smoked. By causing an altered smoking strategy, filtered and low-yield cigarettes may actually deliver more toxins.

Many of the cigarette-derived toxins are generated as a result of pyrolysis. As a result, tobacco products that do not burn have the promise to yield fewer toxins. There has been much interest in oral tobacco products in this regard. Moist snuff, which has low nitrosamine content due to its processing, has been widely used for several decades in Sweden. It has been associated with a measurable decrease in a number of tobacco-related diseases among Swedish men. Several cigarette-like devices have been developed with similar goals. Some burn small amounts of processed tobacco together with a carbon heat source in order to have a taste that more closely resembles a cigarette. Others electrically heat the tobacco. These products appear to deliver fewer toxins in standardized smoking regimes. Limited data are available on physiological effects but, in one study, a reduction in lower respiratory tract inflammation and in airway metaplasia was observed among heavy smokers who switched to a harm reduction product. Whether such products are associated with health benefits, however, remains to be determined.

Harm reduction strategies may have unforeseen problems. Reduced risk products or smoking reduction strategies may encourage smokers to continue and thus discourage quit attempts. Available data, however, suggest the opposite. Smokers who switch to harm reduction products or who reduce with pharmacologic support appear to have an increased rate of subsequent quits. It may be that the sense of mastery that comes with the reduction effort helps make smokes able to quit. There are other potential hazards. Reduced risk products, for example, might be particularly appealing for individuals beginning smoking both because they may be easier to smoke and they are not perceived as having significant risks. Finally, if use of reduced-risk products erodes the social

climate that discourages smoking, such products could increase use of conventional cigarettes.

SMOKING PREVENTION

As noted above, smoking initiation is generally a pediatric problem. Precisely why some children begin smoking is not fully understood. More than two-thirds of children experiment with cigarettes, but only half will eventually smoke regularly. A number of factors are believed to contribute, including the child's social environment and attitude toward smoking, which appears to be based, in large part, on the smoking behavior of parents, friends, and peer group role models. The reasons for initiating smoking, however, are not entirely environmental, as twin studies suggest a genetic basis for smoking as well. Interventions aimed at altering the social milieu are of some benefit. Participation in sporting activities is associated with lower rates of smoking initiation, as is control of affective disorders. Attitudes toward smoking appear to be important factors leading to smoking initiation, which may depend, at least in part, on advertising and marketing programs; hence the effectiveness of bans on advertising.

A second approach to limiting smoking initiation is to restrict the sale of tobacco products to minors. Many states have legal restrictions on such sales. In many cases, however, these laws are not enforced. Active enforcement, however, can lead to a decrease in both experimental smoking and regular cigarette use among younger smokers. For such measures to be effective, they must be uniformly enforced in the community, and vending machines must be made inaccessible to minors. Another approach to restrict tobacco usage by minors is taxation. It has been suggested that increasing tobacco taxes will decrease use, and that this effect will be particularly prominent among less addicted smokers. Because adolescents may have less disposable income, the effect may be even greater. While such an approach is appealing, the magnitude of price changes required is unclear.

Measures aimed at restricting tobacco sales to minors may lead simply to a deferral of smoking initiation. Thus, if measures are effective at delaying smoking initiation among children, it may be that parallel measures will also be required to affect smoking initiation among older adolescents and young adults. Currently available data suggest that smoking behavior among high school students has begun to decrease. There does not appear to be a corresponding increase in smoking among older individuals. These changes are associated with comprehensive tobacco control programs, which therefore seem to have measurable benefits.

CONCLUSION

Cigarette smoking is a complex social and medical issue. The physician has a particularly important role in curbing smoking. Not only must the physician participate in efforts to reduce smoking as a citizen, but as a protector of public health and a possessor of specific expertise in health care matters, the physician must take an active role in health promotion. Such a role includes discouraging smoking initiation among younger patients, encouraging and assisting smoking patients to quit, and participating in social efforts designed to reduce smoking at various levels. A number of policy statements have been prepared regarding smoking and the role of the physician. By implementing these recommendations, it is hoped that cigarette smoking, the number one preventable cause of death in the developed world, eventually can be eradicated.

Rehabilitation in Chronic Obstructive Pulmonary Disease and Other Respiratory Disorders

Andrew L. Ries

Rehabilitation for patients with chronic lung diseases is well established as a means of enhancing standard pharmacologic and other therapies in controlling and alleviating symptoms and optimizing functional capacity. The primary goal of any rehabilitation program is to restore the patient to the highest possible level of independent function. This goal is accomplished by helping patients and significant others learn more about the underlying disease, treatment options, and coping strategies. Patients are encouraged to participate actively in providing their own health care, become more independent in daily activities, and be less dependent on health professionals and expensive medical resources. Rather than addressing solely reversal of the disease process, rehabilitation focuses on improving disability from disease.

Historically, pulmonary rehabilitation strategies were developed and have been used primarily for patients with chronic obstructive pulmonary disease (COPD). However, pulmonary rehabilitation has also been applied successfully to patients with other chronic lung conditions, including interstitial diseases, cystic fibrosis, bronchiectasis, and thoracic cage abnormalities. It has been used successfully in the evaluation and preparation of patients for surgery, such as lung transplantation and volume reduction lung surgery, and in maximizing recovery after surgery. Pulmonary rehabilitation has been used to facilitate patient recovery from acute processes such as acute lung injury, or exacerbations of chronic lung disease requiring mechanical ventilation or acute hospital care. Pulmonary rehabilitation is appropriate for any

patient with stable lung disease who is disabled by respiratory symptoms. Even patients with advanced disease may benefit if they are selected appropriately and realistic goals are set.

This chapter defines pulmonary rehabilitation and outlines issues related to patient selection and evaluation. Key components of a pulmonary rehabilitation program are described and results of rehabilitation programs reviewed. Finally, the role of rehabilitation prior to and following lung surgery is reviewed.

DEFINITION

In 1999, the American Thoracic Society adopted the following definition:

> Pulmonary rehabilitation is a multidisciplinary program of care for patients with chronic respiratory impairment that is individually tailored and designed to optimize physical and social performance and autonomy.

This definition focuses on three important features of successful rehabilitation. First, the program is *multidisciplinary.* Pulmonary rehabilitation programs utilize expertise from various health care disciplines that is integrated into a comprehensive, cohesive program tailored to the needs of each patient. Second, the program is tailored to the *individual.* Patients with disabling lung disease require individual assessment of needs, individual attention, and a program designed to meet realistic individual goals. Third, the program addresses both *physical and social function.* To be successful, pulmonary rehabilitation must address the social and emotional problems as well as seek to optimize medical therapy to improve lung function.

The interdisciplinary team of health care professionals in pulmonary rehabilitation may include physicians, nurses, respiratory and physical therapists, psychologists, exercise specialists, and others with appropriate expertise. The specific team make up depends upon the resources and expertise available, but it usually includes at least one full-time staff member. Responsibilities of team members generally cross disciplines.

Within this general framework, successful pulmonary rehabilitation programs have been established in both outpatient and inpatient settings and with different formats. A key to success is a dedicated, enthusiastic staff that is familiar with respiratory problems and can relate well to pulmonary patients and motivate them.

PATIENT SELECTION

Any patient with symptomatic chronic lung disease is a candidate for pulmonary rehabilitation (Table 44-1). Appropriate patients are aware of disability from their disease and are motivated to participate actively in their own care in order to improve their health status. Patients with mild chronic disease may not perceive their symptoms to be severe enough to warrant a comprehensive care program. On the other hand, patients with severe disease who are bed bound may be too limited to benefit greatly.

Table 44-1

Patient Selection Criteria for Pulmonary Rehabilitation

Symptomatic chronic lung disease
Stable on standard therapy
Functional limitation from disease
Relationship with primary care provider
Motivated to be actively involved in and take responsibility for own health care
No other interfering or unstable medical conditions
No arbitrary lung function or age criteria

Criteria based on arbitrary lung function parameters or age alone should not be used in selecting patients. Pulmonary function is not a good predictor of symptoms, function, or improvement after rehabilitation. In general, selection should be based upon a person's disability and functional limitation from respiratory symptoms, potential for improvement, and motivation to participate actively in a comprehensive self-care program. Also, pulmonary rehabilitation is not a primary mode of therapy. Patients should be stabilized on standard medical therapy and should not have other disabling or unstable conditions that might limit their ability to participate fully in the program and to concentrate on the necessary tasks.

The ideal patient for pulmonary rehabilitation, then, is one with functional limitation from moderate to severe lung disease who is stable on standard therapy, not distracted or limited by other serious or unstable medical conditions, willing and able to learn about his or her disease, and motivated to devote the time and effort necessary to benefit from a comprehensive care program.

PATIENT EVALUATION

The initial step is screening patients to ensure appropriate selection and to set realistic individual and program goals. The evaluation process includes the following components: interview, medical evaluation, psychosocial assessment, diagnostic testing, and goal setting (Table 44-2).

Table 44-2

Components of a Comprehensive Pulmonary Rehabilitation Program

- Patient evaluation
  - Interview
  - Medical evaluation
  - Diagnostic testing
    - Pulmonary function
    - Exercise
    - Arterial blood gases/oximetry
  - Psychosocial assessment
  - Goal setting
- Program content
  - Education
  - Respiratory and chest physiotherapy instruction
  - Exercise
  - Psychosocial support

Interview

The screening interview is an important first step. It serves to introduce the patient to the program, review the medical history, and identify psychosocial problems and needs. Family members and significant others should be included. Communication with the primary care physician is important to establish the vital link for the rehabilitation staff to clarify medical questions prior to the program and facilitate subsequent recommendations. Care and attention in this initial evaluation helps in setting goals compatible with everyone's expectations as well as appropriate programmatic objectives.

Medical Evaluation

Reviewing medical history helps to identify the patient's lung disease and assess its severity. Other medical problems that might preclude or delay participation may be identified. Available laboratory data should be reviewed, including pulmonary function and exercise tests, rest and exercise arterial blood gas measurements, chest radiographs, electrocardiogram, and pertinent blood tests. Program staff can then determine the need for any additional information or action before the program begins.

Diagnostic Testing

Planning an appropriate rehabilitation program requires accurate, current information. The complexity of the testing procedures performed depends upon individual patient and program goals as well as the facilities and expertise available.

Pulmonary function testing is used to characterize lung disease and quantify impairment. Spirometry and lung volume measurements are most useful. Other tests (e.g., diffusing capacity, maximal respiratory pressures to assess muscle strength) can be added as needed.

Exercise testing helps to assess the patient's exercise tolerance and to evaluate changes in arterial blood gases (e.g., hypoxemia or hypercapnia) with exercise. This may also uncover coexisting diseases (e.g., heart disease). The exercise test is also used to establish a safe and appropriate prescription for subsequent training.

Maximal exercise of patients with chronic lung disease is limited largely by their breathing reserve. Simple pulmonary function tests such as spirometry can be used to estimate a patient's capacity for sustained breathing (maximal ventilation) during exercise. The forced expiratory volume in 1 s (FEV_1) is most useful in this regard. However, lung function only provides an estimate of an individual patient's maximum work capacity. Exercise tolerance depends also on the patient's perception and tolerance of the subjective symptom of breathlessness. Therefore, it is important to exercise patients to assess their physical function and symptom tolerance.

Exercise evaluation for rehabilitation is most easily performed with the type of activity planned for training (e.g., treadmill for a walking training program). Variables measured or monitored during testing should include workload, heart rate, electrocardiogram, arterial oxygenation, and symptoms (e.g., breathlessness). Other measures, such as ventilation or expired gas analysis to calculate oxygen uptake ($\dot{V}O_2$) and related variables may be obtained depending on the interest and expertise of the program staff and laboratory.

Measurement of arterial blood gases at rest and during exercise is important because of the frequent but unpredictable occurrence of exercise-induced hypoxemia. Arterial blood gas sampling during exercise makes testing more complex. The noninvasive estimate of arterial oxygen saturation by cutaneous (e.g., pulse) oximetry is useful for continuous monitoring, but it has limited accuracy (95 percent confidence limits, $\pm$4 to 5 percent).

Psychosocial Assessment

Successful rehabilitation requires attention not only to the patient's physical problems but also to psychological, emotional, and social issues. Patients with chronic illnesses experience psychosocial difficulties as they struggle to deal with symptoms they may not fully understand.

Neuropsychological impairment is common in patients with chronic lung diseases and cannot be accounted for solely on the basis of age, depression, or organic disease. Commonly, such patients become depressed, frightened, anxious, and more dependent on others to care for their needs. Progressive dyspnea is a frightening symptom and may lead to a vicious "fear-dyspnea" cycle: With progressive disease, less exertion results in more dyspnea, which produces more fear and anxiety, which, in turn, lead to more dyspnea. Ultimately, the patient avoids any physical activity associated with both of these unpleasant symptoms.

In addressing these problems, the initial evaluation should assess the patient's psychological state and pay attention to "psychosocial clues" that may be apparent during the screening interview (e.g., level of family and social support, the patient's living arrangement, activities of daily living, hobbies, and employment potential). Important clues in initial interviews may be evident in nonverbal communication, such as facial expression, physical appearance, handshake, and "body space." Cognitive impairment that may limit the patient's ability to participate fully in the rehabilitation program may be identified. Family members and significant others may provide valuable insight and should be included in the screening process and program whenever possible.

Goals

After a patient's medical, physiologic, and psychosocial state have been evaluated, specific goals should be set that are compatible with his or her disease, needs, and expectations. Goals should be realistic in light of the objectives of the program. Family members and significant others should be included in this process so that everyone understands what can and cannot be achieved.

PROGRAM CONTENT

Comprehensive pulmonary rehabilitation programs typically include several key components: education, instruction in respiratory and chest physiotherapy, psychosocial support, and exercise training (Table 44-2). Often, the various components are provided simultaneously; for example, during an exercise session, a patient may learn and practice breathing techniques for symptom control while being encouraged and supported by staff or other patients.

Education

Successful pulmonary rehabilitation depends upon an understanding of lung disease and active involvement by patients and important others in providing social support. Education is an integral component; even patients with severe disease can gain a better understanding of their disease and learn specific means to deal with problems. Instruction can be provided individually or in small groups, but it should be adapted to different learning abilities. Topics discussed commonly include normal lung function, chronic lung disease, medications, nutrition, travel, stress reduction and relaxation, reasons to call the physician, and planning a daily schedule. Individual instruction and coaching may be provided on the use of respiratory therapy equipment and supplemental oxygen, breathing techniques, bronchial drainage, chest percussion, energy-saving techniques, and self-care tips. The general philosophy is to encourage patients to assume responsibility for their own care and become partners with their physician in providing the care.

Despite the importance of education, it is unlikely that increased patient knowledge alone will lead to improved health status. It is more difficult to change patient attitudes and behaviors. Patients require specific, individualized treatment strategies, instruction, and reinforcement. Thus, education is a necessary but not sufficient component of pulmonary rehabilitation.

Respiratory and Chest Physiotherapy Techniques

Patients with chronic lung disease use, abuse, and are confused about respiratory and chest physiotherapy techniques. In pulmonary rehabilitation, each patient's needs for respiratory care techniques should be assessed and instruction provided in proper use. These techniques may include chest physiotherapy to control secretions; breathing retraining techniques to relieve and control dyspnea and improve ventilatory function; and proper use and care of respiratory equipment, including nebulizers, metered dose inhalers, and supplemental oxygen.

Bronchial Hygiene

Patients with chronic lung diseases frequently have abnormal lung clearance mechanisms that increase problems with retained secretions and infection. Therefore, rehabilitation programs teach a variety of chest physiotherapy techniques for secretion control (e.g., coughing, postural drainage, chest vibration and percussion). These are important for patients who experience excess mucus production during exacerbations as well as for those with chronic sputum production. The use of mucolytic agents to reduce viscosity of secretions is of questionable benefit.

Breathing Retraining Techniques

Pulmonary rehabilitation typically includes instruction in breathing techniques, such as diaphragmatic and pursed lips breathing—techniques aimed at helping patients relieve and control breathlessness, improve their ventilatory pattern (i.e., slower respiratory rate and increased tidal volume), prevent dynamic airway compression, improve respiratory synchrony of the abdominal and thoracic musculature, and improve gas exchange. Review of studies evaluating these techniques indicates that improvement in symptoms (e.g., dyspnea) is a more consistent finding than are measurable changes in physiological parameters. The diaphragmatic breathing technique is a maneuver in which the patient consciously coordinates abdominal wall expansion with inspiration and slows expiration through pursed lips. The primary effect is to slow respiratory rate and increase tidal volume.

Pursed-lips breathing is commonly taught to pulmonary patients, particularly those with COPD. This technique was observed by Laennec as early as 1830 and was advocated as a physical exercise for pulmonary patients in the early part of the twentieth century. As a maneuver assumed

naturally by many patients with respiratory disease, pursed-lips breathing is characterized by tensing the lips and narrowing the mouth opening during expiration. The aim is to slow expiration and maintain positive airway pressure in order to "stent the airways open" and prevent collapse.

Oxygen

When chronic oxygen therapy is required, available delivery methods should be reviewed to help select the best system for the patient's needs. Supplemental oxygen is beneficial for patients with severe resting hypoxemia. Long-term continuous oxygen therapy has been clearly shown to improve survival and reduce mortality and morbidity in hypoxemic patients with COPD. The benefits of supplemental oxygen for nonhypoxemic patients or those with intermittent hypoxemia (e.g., during exercise or sleep) are less clearly defined. Although continuous oxygen therapy is feasible and safe, maintaining patients on supplemental oxygen presents several challenges. Handling equipment is particularly difficult for physically disabled and frail patients. Therefore, it is important to assess each person's oxygen needs and provide appropriate instruction.

Several new developments have improved the efficiency of gas delivery systems and patient compliance with continuous oxygen therapy. Liquid oxygen provides more gas with less weight than tanks of compressed gas, particularly in portable systems. Oxygen conserving devices may increase the efficiency of delivery, reducing flow requirements and prolonging the life span of portable gas sources. Transtracheal oxygen delivery may help to improve compliance and avoid problems with nasal catheters; however, patients must be instructed carefully in caring for the catheter.

Exercise

Exercise is important in pulmonary rehabilitation. Considerable evidence supports favorable responses to exercise training in patients with chronic lung diseases. Benefits are both physiological and psychological. Patients may increase their maximum capacity and endurance for physical activity, even though objective measures of lung function do not usually change. Patients may also benefit from learning to perform physical tasks more efficiently. Exercise training provides an ideal opportunity for patients to learn their capacity for physical work and use and practice methods for controlling dyspnea (e.g., breathing and relaxation techniques). Of all the components in a comprehensive pulmonary rehabilitation program, exercise is probably the most costly and labor-intensive, considering the personnel, equipment, and expertise required. Principles of exercise for patients with lung disease differ from those based on normals or other patient populations because of differences in the limitations to exercise and the problems encountered in training.

Many approaches have been used to train the person with chronic lung disease. To be successful, the program should be tailored to the individual's physical abilities, interests, resources, and environment. For general application, techniques should be simple and inexpensive. As in normals and other patients, benefits are largely specific to the muscles and tasks involved in training. Patients tend to do best with activities and exercises for which they are trained. Walking programs are particularly useful. They have the added benefit of encouraging patients to expand social horizons. In inclement weather, many can walk indoors (e.g., at shopping malls). Other types of exercise (e.g., cycling, swimming) are also effective. Patients should be encouraged to incorporate regular exercise into daily activities they enjoy (e.g., golf, gardening). Since many persons with chronic lung disease have limited exercise tolerance, emphasis during training should be placed on increasing endurance. Changes in endurance with rehabilitation are often greater than changes in maximal exercise tolerance and allow patients to become more functional within their physical limits. Increase in maximum exercise is also possible as patients gain experience and confidence.

Exercise Prescription

Selecting a training target based upon a predetermined percentage of predicted maximal heart rate or ($\dot{V}O_2$) is a well-established practice for normals or patients without underlying pulmonary disease. However, in patients with chronic lung diseases, the best method of choosing an appropriate training prescription is less clearly defined. Exercise tolerance in pulmonary patients is typically limited by maximal achievable ventilation and breathlessness. Such patients frequently do not reach their limits of cardiac or peripheral muscle performance.

Much controversy exists regarding the appropriate training intensity target for patients with chronic lung disease. Use of a target heart rate has been advocated by some, although it is recognized that such a target may not be reliable for patients with more severe disease. Many patients with lung disease can be trained at a high percentage of maximal exercise tolerance, with work levels approaching or even exceeding the maximal level reached on the initial exercise test. In a study of 52 patients with moderate to severe COPD, patients were able to perform endurance exercise testing at an average workload of 95 percent of their baseline maximum. After 8 weeks of training, these patients were training at 86 percent of the baseline maximum. In fact, many patients with severe COPD were exercising at levels exceeding their baseline maximum. In another study that examined 59 patients with moderate to severe COPD who trained at levels near their ventilatory limits, a mean peak exercise ventilation of 100 percent of measured maximal voluntary ventilation was achieved after 12 days of training and at 3 months of follow-up. These findings suggest that even patients with advanced disease can be trained successfully at or near maximal exercise levels.

Based on the findings noted previously, some pulmonary rehabilitation programs define exercise targets and progression during training more by symptom tolerance than heart rate, work level, or other physiological measurements.

Ratings of perceived symptoms (e.g., breathlessness) help teach patients to exercise to "target" levels of breathing discomfort. A typical approach is to begin training at a level that the patient can sustain with reasonable comfort for several minutes and then to increase the time or exercise level according to symptom tolerance. Patients are encouraged to exercise daily and increase exercise duration up to 15 to 30 minutes of continuous activity. This graduated program helps patients to achieve a goal of improved tolerance for tasks of daily living, which often require a period of sustained activity.

Blood-Gas Changes

A major problem in planning a safe exercise program for patients with lung disease is the potential for worsening of hypoxemia with exercise. Patients who are not hypoxemic at rest may develop changes in arterial oxygenation that cannot be predicted reliably from resting measurements of pulmonary function or gas exchange. Normal individuals do not become hypoxemic with exercise. In patients with obstructive lung disease, Pa_{O_2} changes unpredictably during exercise. In patients with mild COPD, Pa_{O_2} typically does not change with exercise; in fact, it may even improve. However, in patients with moderate to severe COPD, Pa_{O_2} may increase, decrease, or remain the same. Patients with interstitial lung disease commonly develop worsening oxygenation with exercise.

Based on these observations, it is important to evaluate a patient's oxygenation status both at rest and during exercise. Such testing is also used to prescribe oxygen therapy at rest and with physical activity. With the availability of convenient, portable systems for ambulatory oxygen delivery, hypoxemia is not a contraindication to safe exercise training.

Other Types of Exercise

Exercise programs for pulmonary patients typically emphasize lower extremity training (e.g., walking or cycling). Since exercise conditioning is largely specific to the muscles and tasks involved in training other forms of exercise may be particularly valuable for persons with chronic lung diseases.

Upper Extremity Training

Many patients with chronic lung disease report disabling dyspnea with daily activities involving the upper extremities (e.g., lifting, grooming) at much lower work levels than with the lower extremities. Upper extremity exercise is accompanied by a higher ventilatory demand for a given level of work than is lower extremity exercise. Given the aforementioned muscle specificity of training, upper extremity exercises may be important in helping pulmonary patients cope better with common daily activities.

Ventilatory Muscle Training

The potential role of ventilatory muscle fatigue as a cause of respiratory failure and ventilatory limitation in patients with chronic lung disease has stimulated attempts to train the ventilatory muscles. Techniques of isocapnic hyperventilation, inspiratory resistive loading, and inspiratory threshold loading have been shown to improve function of the respiratory muscles in both normals and patients. In normals, respiratory muscle function does not limit exercise tolerance; therefore, specific respiratory muscle training is unlikely to be of clinical benefit. In patients with COPD, the patient group most extensively studied, improvement in general exercise performance from ventilatory muscle training alone has not been demonstrated consistently. Thus, the role of respiratory muscle training as a routine component of pulmonary rehabilitation has not been clearly established.

Psychosocial Support

An essential component of pulmonary rehabilitation is psychosocial support, the goal of which is to help patients combat progressive feelings of hopelessness and an inability to cope with chronic, progressive disease. Depression is common in patients with chronic pulmonary disorders, as are anxiety (especially anxiety over dyspnea), denial, anger, and isolation. Patients become sedentary and dependent upon family members, friends, and medical services to provide for their needs. Excessive concern over other physical problems and psychosomatic complaints arise. Sexual dysfunction and fear are common and represent often unspoken consequences of chronic lung disease. Patients may also demonstrate cognitive and neuropsychological dysfunction, possibly related to or exacerbated by the effects of hypoxemia on the brain.

Psychosocial support is provided best by a warm and enthusiastic staff who can communicate effectively with patients and devote the time and effort necessary to understand and motivate them. Family members and significant others should be included in activities so that they can understand the disease and help the patient cope. Support groups are also effective. Patients with severe psychological disorders may benefit from individual counseling and therapy. Psychotropic drugs should generally be reserved for patients with more severe psychological dysfunction.

BENEFITS OF PULMONARY REHABILITATION

A growing body of evidence supports the expected results and benefits of pulmonary rehabilitation in the management of patients with chronic lung disease (Table 44-3). Evidence-based guidelines, published by a joint effort of the American College of Chest Physicians (ACCP) and the American Association of Cardiovascular and Pulmonary Rehabilitation (AACVPR), summarized clinical trials in pulmonary rehabilitation. The rehabilitation components included lower extremity training, upper extremity training, ventilatory muscle training, and psychosocial/behavioral interventions. Outcomes evaluated included dyspnea, quality of life, health care utilization, and survival. Based on this review, the Panel rated the highest level of supportive evidence regarding

Table 44-3

Results of Pulmonary Rehabilitation

Decreases in Medical resource utilization (e.g., hospitalizations, emergency room visits) Respiratory symptoms (e.g., breathlessness) Psychological symptoms (e.g., depression, fear)
Increases in Quality of life Physical activity Exercise tolerance (endurance or maximal level of activities of daily living) Knowledge Independence
Return to work possible
No change in lung function
Possible prolonged survival

documented improvements in lower extremity exercise training and in dyspnea after pulmonary rehabilitation. Other positive recommendations included the inclusion of upper extremity exercise training and the improvements in quality of life and health care utilization after pulmonary rehabilitation.

Two meta-analyses evaluated the effects of respiratory rehabilitation on exercise capacity and health-related quality of life. In a review of 14 randomized controlled trials employing systemic exercise as the primary intervention for at least 4 weeks for COPD patients, Lacasse and coworkers found significant improvements for dyspnea and mastery as two important aspects of health-related quality of life, and for maximal and functional exercise capacity. However, functional exercise capacity demonstrated heterogeneity that could not be explained by the sensitivity analyses performed. Cambach and coworkers reviewed 18 controlled studies evaluating the long-term effects of pulmonary rehabilitation on patients with asthma and COPD. Significant improvements were found for exercise tolerance (6-minute walk) and in dyspnea, fatigue, emotion and mastery measures of health-related quality of life. The authors noted heterogeneous results in improvements in maximal exercise capacity.

Several published randomized trials demonstrate important and significant benefits of pulmonary rehabilitation for patients with COPD, including improvements in exercise performance, symptoms, and quality of life. In a clinical trial of rehabilitation versus an education program in 119 patients with COPD, Ries and coworkers reported a highly significant improvement in exercise endurance after rehabilitation that was maintained up to 18 months later. This was associated with a significant decrease in perceived symptoms of breathlessness and muscle fatigue during exercise as well as improvement in maximum exercise tolerance, breathlessness with daily activities, and self-efficacy for walking. A follow-up trial of maintenance versus routine care after pulmonary rehabilitation was conducted in 164 patients with chronic lung disease. Similar to previous studies, both groups demonstrated decline in benefits over the first year of follow-up, although they remained above pre-rehabilitation levels. In comparison to 81 routine care patients, the 83 patients receiving maintenance care of weekly telephone contacts and monthly reinforcement sessions after pulmonary rehabilitation sustained improvement in maximum exercise tolerance at 1-year follow-up. However, a decline in measures of dyspnea, depression, self-efficacy, quality of life, and health care utilization were also observed in both groups. At 2-year follow-up, with both groups receiving routine care, there was a progressive decline in exercise tolerance and other measures of symptoms and morbidity.

In another randomized trial, Berry and colleagues demonstrated the added benefit of a longer-term exercise (18 months) compared to short-term training (3 months) in 140 patients with COPD. Patients in the long-term training group maintained greater improvements in measures of physical function and self-reported disability.

In a randomized controlled trial of 79 older adults with COPD, Emery and coworkers investigated physiological, psychological, and cognitive outcomes of a 10-week pulmonary rehabilitation program. Significant improvements were observed at program completion among 29 patients receiving exercise training, education, and stress management in measures of cardiopulmonary endurance, anxiety, illness-related physical and emotional impairment, and verbal fluency. These changes were not observed among patients receiving a combined intervention of education and stress management or patients with no intervention at all, suggesting that education without exercise may have limited value for the physical and psychological functioning.

Benefits and cost savings associated with pulmonary rehabilitation have been demonstrated not only in highly specialized centers, but also in community-based settings. A collaborative study of 647 patients in 10 centers in California reported significant improvements in dyspnea and quality of life with substantial reduction in health care utilization over 18 months of follow-up (Fig. 44-1).

PULMONARY REHABILITATION AND LUNG SURGERY

Pulmonary rehabilitation has been applied primarily in the medical management of patients with stable, chronic pulmonary disease. In recent years, surgical options for patients with severe, disabling lung disease have been used more frequently. Lung surgery in these patients represents new challenges and may further compromise already reduced lung

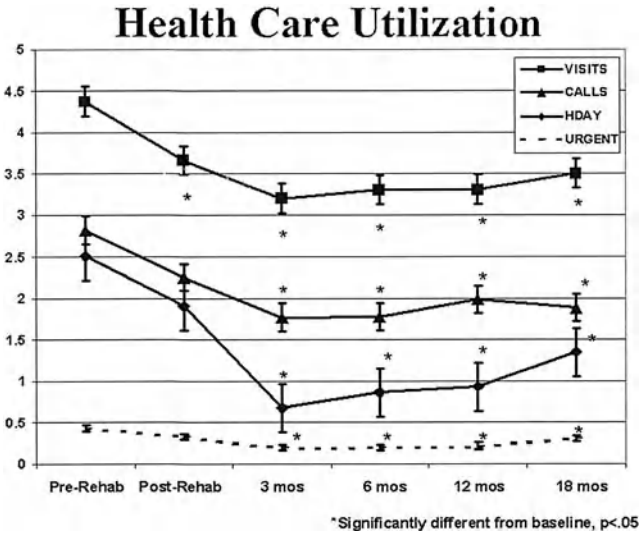

Figure 44-1 Changes in health care utilization over 18 months after pulmonary rehabilitation in a collaborative study of 647 patients in 10 centers in California. Results are presented as mean ± SE. *(From California Pulmonary Rehabfl itation Collaborative Group: Effects of pulmonary rehabfl itation on dyspnea, quality of life and health care costs in California. function. Pulmonary rehabilitation has been found to be a valuable adjunct in preparing the patient for surgery or in postsurgery recovery.

Lung Transplantation

Pulmonary rehabilitation is recommended and used commonly in both the preoperative and postoperative phases of lung transplantation programs. Although the general strategies of rehabilitation may be similar, the individual and program goals and specific program components differ.

Pretransplant Rehabilitation

Patients with advanced lung disease who are candidates for lung transplantation are usually evaluated by the transplant team and then referred for pulmonary rehabilitation after their transplant candidacy is approved. Rehabilitation staff evaluate the patient to assess needs and plan an appropriate program that can be maintained throughout a waiting period, which may last months to years. Since these patients have advanced disease with limited life expectancy, the goals in the preoperative period differ from those that typically apply to rehabilitation in chronic lung disease (Table 44-4).

The overall goals of pretransplant pulmonary rehabilitation are to maintain function, monitor disease progression, prevent complications, provide education about the underlying lung disease and lung transplantation, and offer psychosocial support for patients and families in coping with the stresses of waiting for a potentially life-saving procedure. The exercise training program may be similar to that provided to other chronic lung disease patients, with the exception that

Table 44-4

Goals of Pulmonary Rehabilitation in Lung Transplantation

Pretransplant
- Maintain and increase mobility and exercise tolerance
- Monitor disease progression
- Prevent complications
- Provide education about
  - Underlying disease
  - Transplantation procedures
  - Self-care and self-assessment
- Provide psychosocial support during waiting period for patients and families

Posttransplant
- Improve physical work tolerance
- Monitor clinical status and assess symptoms and oxygenation
- Prevent complications
- Reinforce self-care and self-assessment
- Encourage compliance with medical regimen
- Provide psychosocial support for adaptation to new demands and expectations

patients with primary pulmonary vascular diseases do not typically participate in exercise or other physical activities because of the increased risk of sudden death. Although patients may have some initial improvement in exercise tolerance or endurance as they begin rehabilitation, the primary goal for these patients is to maintain mobility and exercise capacity. Exercise sessions also provide an excellent means to monitor disease progression and to detect, at an earlier stage, problems that commonly occur (e.g., increased breathlessness or reduced arterial oxygenation with exercise).

The goals of education in the pretransplant period are to teach patients about their underlying lung disease, the transplant procedure itself, and expectations following transplantation. Patients can also be taught techniques for self-care and self-assessment that will be useful before and after surgery. The psychosocial stresses of waiting for transplantation are considerable. Many patients feel as though their lives are "on hold." Some may have moved away from family and social support networks to live close to the transplant center. Providing support for patients and families during this time, whether through formal group support sessions or informal contact with supportive staff and other patients, helps patients cope better with these problems.

Posttransplant Rehabilitation

After lung transplantation, patients must learn to cope with a new level of function, new expectations, and a new set of

problems. Rehabilitation for patients in this phase can facilitate physical reconditioning, help implement self-care and assessment techniques, and facilitate coping with the psychosocial adaptations to a new life-style.

Goals of exercise training after rehabilitation are improved physical work tolerance and continued assessment of symptoms and oxygenation as early warning signs of complications, including rejection and infection. Educational goals are focused on self-care and assessment and the importance of compliance with a new medical regimen. Psychosocial support can assist with adaptation to a new set of stresses related to additional demands and expectations from both patients for themselves and significant others. Patients who are used to being sick, disabled, and cared for by others may now be expected to be well, independent, return to work, and provide support for others.

Lung Volume Reduction Surgery

Recently, there has been a resurgence of interest in lung volume reduction surgery (LVRS) in the treatment of patients with severe emphysema. Pulmonary rehabilitation has been recommended as an important modality in the evaluation for and preparation of patients for this procedure as well as in the postoperative recovery phase. Since these patients have severe, disabling chronic lung disease, they are typically good candidates for pulmonary rehabilitation. Enrolling patients in rehabilitation prior to surgery has the advantage of optimizing their functional status, improving physical and psychological symptoms, helping them learn more about their disease and alternative treatment options, and improving their skills for coping and actively co-managing their disease. Patients can then make an informed decision about surgical treatment based upon their optimal level of baseline function. After surgery, similar to the post-transplant period, rehabilitation helps patients to adapt to new levels of function and to reassess symptoms and oxygenation needs.

The National Emphysema Treatment Trial (NETT), a multicenter, randomized clinical trial of medical therapy versus medical therapy plus LVRS, evaluated the benefits and risks of LVRS in patients with severe bilateral emphysema. All patients enrolled in the NETT completed 6 to 10 weeks of pulmonary rehabilitation prior to randomization into medical therapy or medical therapy plus LVRS and participated in a maintenance program of additional rehabilitation after randomization. Results from the prerandomization phase demonstrated significant improvements in exercise tolerance, symptoms and quality of life following pulmonary rehabilitation.

Rehabilitation after Lung Resection

Patients who undergo pulmonary resection frequently experience a significant increase in symptoms and reduced functional status. This is particularly true for patients with underlying chronic lung disease. Most commonly, surgery is used to treat patients with thoracic neoplasms who are deemed to have resectable disease and are operative candidates. Following resection, these patients with already limited lung function have to learn to adapt to a new, lower level of function.

Similar changes may be observed in patients who undergo radiation therapy. Patients in a stable phase of their treatment or in remission may be appropriate candidates for pulmonary rehabilitation. Improvement in health status, physical and psychological symptoms, exercise tolerance, and quality of life—as well as reduced health care burdens—are potential benefits. These patients' survival may be as limited by their underlying lung disease as by their treated malignancy.

SUMMARY AND FUTURE OF PULMONARY REHABILITATION

Pulmonary rehabilitation has been well established as a means of improving functional status and reducing the disability and economic burden of the growing number of patients with chronic lung diseases. In adopting a broad rehabilitation medicine perspective, such programs provide interdisciplinary expertise directed toward the needs of the individual disabled patient.

Much of the experience in pulmonary rehabilitation has been in patients with COPD. However, it is clear that similar benefits can result for patients with other disabling pulmonary conditions. Pulmonary rehabilitation may also play an important role in the preoperative evaluation, preparation, and postoperative recovery of patients undergoing surgical procedures, including lung transplantation, lung volume reduction surgery, and lung resection.

CHAPTER

The Biology of Asthma

Sameer K. Mathur • William W. Busse

Asthma is characterized by intermittent airflow obstruction, airway inflammation, and bronchial hyperresponsiveness. This disorder affects an estimated 5 to 10 percent of the population, and as such is a major health care issue in most Western countries. A precise definition of asthma remains elusive, partly because the cause of this disease has yet to be found. Moreover, it is entirely possible that asthma is not a distinct disease, with a discrete etiology, but rather a "syndrome" with a variety of phenotypes in which various precipitating factors result in similar clinical, physiological, and pathological manifestations. This view of asthma likely explains its varied patterns and presentations, while explaining the common development of intermittent airflow obstruction, airway inflammation, bronchial hyperresponsiveness, and response to treatment.

Twenty years ago, the focus for the study and treatment of asthma had emphasized the mechanisms of acute bronchospasm with the treatment directed toward control of airway smooth muscle tone. With the exception of "severe asthma," the consideration of airway inflammation as an essential component of the disease had been largely neglected. However, with the use of fiberoptic bronchoscopy and biopsy, airway inflammation was found as an underlying feature of asthma and shifted therapeutic emphasis toward

anti-inflammatory medications. This has led to the current belief that bronchoconstriction, airway hyperresponsiveness, and airway inflammation are not mutually exclusive. Rather, acute and chronic inflammation, including airway edema, mucus secretion, and altered bronchial smooth muscle function are important, if not central, to the airflow obstruction and overall reactivity of the airways in asthma. Furthermore, it has been recognized that, although asthma covers a wide spectrum of clinical severity, inflammatory changes may be seen even in the airways of asymptomatic asthmatics. This chapter details our understanding of the mechanisms underlying acute and chronic inflammation in asthma. It focuses on the cellular components of the asthmatic inflammatory response and elucidates how the properties of these cells, and the mediators they produce, contribute to the pathophysiology of asthma.

MODELS OF MECHANISMS OF ASTHMA PATHOGENESIS

The bronchoconstriction and airway inflammation of asthma can be elicited by allergens, respiratory infections, and occupational exposures. Two models have been particularly instructive in the efforts to further understand the pathogenesis of asthma in these settings. They are the late-phase asthmatic response to antigen and the airway changes seen with viral respiratory infections.

Late-Phase Asthmatic Response

Inhalation of antigen can elicit responses to provide insight to allergic airway inflammation. This model for an asthmatic response results in a distinct pattern of airway limitation (Fig. 45-1). In the acute-phase response (APR), inhalation of allergen causes an immediate fall in lung function. This airway response is characterized by wheezing, coughing, and/or shortness of breath. The APR usually resolves within 1 hour and may be followed by a late-phase response (LPR), beginning about 4 to 6 hours after allergen challenge. The LPR often persists for 24 to 48 hours. An isolated LPR is rare and is found primarily in occupational asthma.

Late asthmatic reactions share a number of features with chronic asthma: increased airway responsiveness, decreased responsiveness to bronchodilator therapy, and bronchial inflammation. In asthma patients who exhibit the dual-phase features of an APR followed by the LPR, the LPR is not only more prolonged but also more intense. This is true even though the original apparent stimulus (allergen exposure) for bronchoconstriction has been removed.

The LPR is associated with the recruitment of inflammatory cells into the airway. Many have used bronchoscopy and bronchoalveolar lavage (BAL) to examine the cellular and mediator composition of the airways both before and after allergen challenge. In the past, airway eosinophilia appeared to exhibit the most significant correlation with LPR. However, recent studies with improved detection for basophils indicate that basophil levels correlate more strongly to the LPR in all forms of allergic inflammation, including airway, nasal, and skin (upon skin prick with allergen). Furthermore, in contrast to the BAL fluid from the APR with increased levels of histamine, tryptase, and PGD_2 (prostaglandin D_2) reflecting mast cell activation, the BAL fluid from a LPR contains histamine and tryptase while lacking PGD_2, which is consistent with products from basophil activation. Basophils have also been shown to release Th2 cytokines such as IL-4, IL-5, and IL-13. Thus, although several inflammatory cells including T cells and eosinophils accumulate during the LPR, it is currently thought the basophil is of central importance in mediating the LPR.

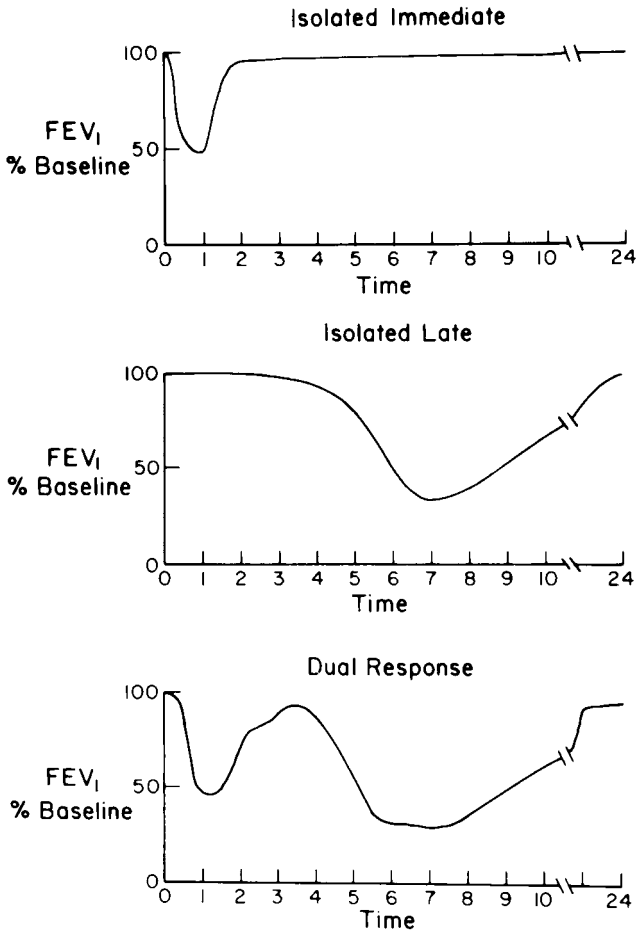

Figure 45-1 Acute and late phases of asthmatic responses (time in hours). (*Based on data from Lemanske RF Jr, Kaliner MA: Late phase allergic reactions, in Middleton E Jr, Reed CE, Ellis EF, et al (eds),* Allergy: Principles and Practice, *vol 1. St. Louis, Mosby–Year Book, 1993, pp 320–361, with permission.*)

Respiratory Viruses and Asthma

Viral respiratory infections increase asthma symptoms in many patients, particularly children. The viruses most typically associated with asthma in epidemiologic studies are respiratory syncytial virus (RSV) and rhinoviruses (RVs). Infection with "cold viruses" normally occurs in the upper airway and entails viral entry into a minority of bronchial epithelial cells. It has been difficult to determine the extent to which

actual viral infection and replication occur in the lower airway or whether viruses adversely affect asthma by indirect means. Experimental infection of subjects with respiratory viruses provides a useful model to establish the mechanisms in the pathogenesis of asthma.

Airway hyperresponsiveness to inhaled histamine may be increased in normal subjects as well as in allergic rhinitis and asthma patients during acute infection with RV, which can persist as long as 4 weeks after virus inoculation. Furthermore, bronchoscopy has shown a prominent acute neutrophilic response to RV infection in normal and allergic subjects. In a subsequent investigation of allergic patients who underwent segmental bronchoscopy and antigen bronchoprovocation 1 month before, during, and 1 month after RV infection, the viral infection also potentiated eosinophilic airway inflammation. Thus, the results of several studies suggest that viral respiratory infections not only increase airway hyperresponsiveness, but also change the pattern of allergic airway response, including the factors responsible for, or contributing to, the neutrophilic and eosinophilic inflammatory responses.

RVs stimulate the production of several mediators from respiratory epithelial cells and mononuclear cells, including IL-8, GM-CSF (granulocyte-monocyte colony stimulating factor), INF-γ (interferon-γ), and RANTES (regulated upon activation, normal T cell expressed). These cytokines and chemokines are important for the recruitment and activation of neutrophils and eosinophils. Thus, viral respiratory infection may modulate the airway environment or the interaction of components of airway inflammation, including cells and mediators, to promote allergic inflammation.

CELLS IN ASTHMA

The inflammatory response in the asthmatic airway is the manifestation of complex interactions between multiple cell types, both resident and recruited, and their molecular mediators. It is characterized by varying degrees of mononuclear cell and eosinophil infiltration, epithelial desquamation, mucus hypersecretion (and airway plugging), smooth muscle hyperplasia, and airway remodeling with subepithelial fibrosis. The presence or recruitment of inflammatory cells into the airway provides the basis for these changes. Each cell type exerts effector and regulatory functions in the pathogenesis of asthma as detailed in this section.

Mast Cells and Basophils

Mast cells are granulocytes generated from a nonmyeloid lineage derived from $CD34^+$ hematopoietic stem cells. Mast cells enter the peripheral circulation in an immature form and differentiate upon localization to a tissue compartment typically adjacent to an epithelial surface such as the skin, lung, and gastrointestinal tract. The differentiation requires IL-3 and the ligand for the c-kit receptor on mast cells, SCF (stem cell factor).

Two types of mast cells are found in humans. The cell subtypes are distinguished primarily by their tissue location and biochemical characteristics: mucosal mast cells (atypical) and connective-tissue mast cells (typical). MCT refers to mast cells containing the neutral protease tryptase alone, while MCTC denotes mast cells containing chymase in addition to tryptase and the other neutral proteases, carboxypeptidase and cathepsin G–like proteins. In the normal human lung, alveoli-associated mast cells are almost exclusively of the MCT type, which also predominate in the subepithelium of the bronchi and bronchioles. In vitro studies indicate that one role for tryptase in asthma pathogenesis includes the increase of airway smooth muscle responsiveness to histamine.

Mast cells are notable for expression of the high-affinity IgE receptor, FcεRI. IgE molecules are constitutively bound to these receptors on the surface of mast cells. Upon encountering an allergen, the antigen-specific IgE molecules are bound with allergen and the subsequent cross-linking of FcεRI receptors activates mast cells. There is the immediate release of preformed mediators including histamine and tryptase. In some mast cells, TNF-α (tumor necrosis factor-α and VEGF (vascular endothelial growth factor) may also be among the preformed mediators. This is followed by the synthesis of leukotrienes (primarily LTC_4), prostaglandins (primarily PGD_2), and cytokines, which all contribute to the inflammatory milieu as discussed below.

Basophils are also derived from $CD34^+$ hematopoietic stem cells via the myeloid lineage; however, in contrast to mast cells, these cells are typically found in the peripheral circulation. Basophils share some common features with mast cells in the expression of FcεRI and tryptase; however, both are expressed at much lower levels than the mast cells. In addition, basophils are also capable of an immediate release of histamine upon activation. It is currently thought that mast cell activation is involved in immediate allergic inflammation, whereas basophils are involved in the late-phase response.

Eosinophils

Eosinophils are granulocytes derived from $CD34^+$ hematopoietic stem cells. The cytokines IL-3, IL-5, and GM-CSF are involved in the stimulation of eosinophil production, growth, and maturation. IL-5 is particularly important in the development and terminal differentiation of eosinophils. Upon exposure to allergen, eosinophils are actively recruited into the airway predominantly by chemokines such as eotaxins. The migration of eosinophils to the airway is dependent on extravasation of peripheral blood eosinophils. This process is highly regulated and occurs via interaction between adhesion molecules on the endothelium (e.g., VCAM-1) and eosinophils (e.g., VLA-4). The activation of these integrins and subsequent recruitment of eosinophils to the airway is the result of cytokine and chemokine signaling, including IL-5, GM-CSF, eotaxin, and RANTES.

Eosinophils have a variety of cell surface receptors, including low-affinity IgE receptors (in contrast to the high-affinity mast cell IgE receptors), cytokine receptors such as the IL-5 receptor (IL-5R), which is thought to be specific for

eosinophils, and receptors for immunoglobulins and complement. Some of these molecules function in the primordial role of eosinophils in host defense against parasitic infectious agents. They are also likely, however, to be important in allergic diseases and asthma.

Upon entry into the airway, eosinophils are able to release numerous mediators including granule proteins, leukotrienes (primarily LTC_4), prostaglandins, and cytokines. Eosinophils contain primary and secondary granules. The primary granules contain Charcot-Leyden crystal protein. The secondary granules contain four principal cationic proteins: MBP (major basic protein) in the dense core, along with the matrix proteins ECP (eosinophil cationic protein), EDN (eosinophil-derived neurotoxin), and EPO (eosinophil peroxidase).

Peripheral blood eosinophilia is a prominent feature of asthma. Autopsy samples from the airways of asthma patients, even those who died of non-asthma causes, and biopsies from asthmatics, even with mild disease, also contain eosinophilic inflammatory cell infiltrates. Similarly, eosinophil numbers are increased in the BAL and tissue after segmental antigen challenge. Immunohistochemical studies have also demonstrated eosinophils and their granule products in the asthmatic airway, and elevated levels of ECP have been found in the BAL and sputum of asthmatics. These observations and several lines of evidence speak to the importance of the eosinophil in the asthmatic process. Among the most compelling are the positive correlation between the levels of blood and airway eosinophilia and the severity of asthma and the subsequent drop in eosinophilia upon effective treatment with corticosteroids.

The specificity of IL-5 for promotion of eosinophil activity led to studies in mice to antagonize IL-5 for the depletion of eosinophils, which resulted in differential effects on airway hyperresponsiveness depending on the mouse strain. The subsequent use of a humanized anti–IL-5 monoclonal antibody in clinical trials succeeded in significantly reducing peripheral blood eosinophil counts with only modest effects (approximately 50 percent reduction) on airway tissue eosinophil counts; however, there was no evidence for improved control of asthma. The lack of efficacy in asthma control has been attributed to deficiencies in experimental design. However, further study of the anti–IL-5 treatment has revealed significant reduction in measures of airway remodeling. Therefore, the role of eosinophils may be in the development of the chronic changes associated with asthma. Recently, two different models of eosinophil deficient mice were created and found to have conflicting results regarding the development of airway hyperresponsiveness upon allergen sensitization and challenge. Thus, the role of eosinophils in acute exacerbations of asthma remains unclear.

Neutrophils

Neutrophils are derived for the $CD34^+$ hematopoietic stem cells. Neutrophils are characterized by a multilobed nucleus and are normally found in the bloodstream and tissues. Neutrophils are terminally differentiated cells that are notable morphologically for their granules, whose synthesis and assembly occur only during early stages of neutrophil development. Primary (azurophilic) and secondary (specific) granules contain various antimicrobial enzymes, neutral proteases, and acid hydrolases. Neutrophils, in contrast to eosinophils, are natural residents of the lung, particularly the lung parenchyma. Airway neutrophilia can be observed in response to viral infections, during nocturnal exacerbations of asthma, and in the BAL fluid of allergic asthmatics 4 hours, but not 24 hours, after inhaled allergen challenge. Neutrophils contain or synthesize a number of molecules with the potential to damage airway tissue and, perhaps more importantly, to act as chemotactic factors or mediators for other inflammatory cells.

T Cells

T cells are thought to be a prominent source of cytokines in the asthmatic inflammatory response. In asthma, an increase in activated T cells is observed in the airway. Furthermore, increased numbers of activated BAL T cells have been correlated with increased bronchial responsiveness and numbers of eosinophils. These observations suggest that T cells may play a critical role is the pathogenesis of asthma by regulating or orchestrating the inflammatory response.

The study of T cells and their relationship to inflammation led to the discovery of "helper" $CD4^+$ T cell subsets called T helper-1 (Th1) and T helper-2 (Th2) cells. These subsets are distinguishable on the basis of their patterns of cytokine production. In addition, a Th0 has been defined which are naïve T cells that have not encountered antigen. Th1 cells are noted for the secretion of IL-12 and IFN-γ, whereas Th2 cells secrete IL-4, IL-5, and IL-13.

It follows that Th2 cells, by virtue of their associated cytokines, can specifically enhance allergic inflammation with promotion of IgE synthesis and eosinophil activation and accumulation. It has been proposed that allergic inflammation represents the predominant activation of Th2 cells and release of their proinflammatory cytokines. In accord with this notion, cells in the BAL fluid from patients with asthma have shown increased mRNA expression for both IL-4 and IL-5. This and other observations suggest that Th2 cells and their associated cytokines play a major role in orchestrating the inflammatory response in the asthmatic airway, in particular its IgE production (IL-4, IL-13), eosinophilia (IL-5), mucus secretion (IL-13), and airway hyperresponsiveness (IL-13).

Although in vitro experiments indicate that Th1 and Th2 cells inhibit the activity of the other, the analyses of animal models of airway inflammation and BAL fluid from human asthma subjects suggests that both Th1 and Th2 cells and their respective cytokines are present, although Th2 does appear to predominate. Given the role of IFN-γ in increasing the expression of adhesion molecules and antigen presentation molecules, it is likely that a coordinated Th1 and Th2 response coexists in asthmatic airway inflammation.

Recently, another subset of $CD4^+$ T cells has been identified: the T regulatory cell. T regulatory cells are characterized by high levels of CD25 cell surface expression, expression of

the FOXP3 transcription factor, and secretion of IL-10 and TGF-β. These cells are noted to have an immunosuppressive function for both Th1 and Th2 cells and are thought to be important in generating and maintaining tolerance to antigen. Furthermore, glucocorticoids or cytokines such as IL-6 are thought to increase or decrease, respectively, the activity of T regulatory cells. Thus, T regulatory cells may represent another critical component in the regulation of airway inflammation.

Macrophage and Dendritic Cells

Macrophage and dendritic cells are phagocytic cells capable of presenting antigen to T cells. Alveolar macrophages are present in abundance within the airway of normal and asthmatic patients and are known to play a critical role in the clearing of microbes from the airway. There are also suggestions that alveolar macrophages can suppress allergic inflammation in the airway by the secretion of Th1 cytokines, including IL-12, IL-18, and IFN-γ. In a rat model, the airway hyperresponsiveness of one strain could be suppressed with the adoptive transfer alveolar macrophage from another non-hyperresponsive strain. This supports a role for alveolar macrophage to modulate airway responses in asthma.

In contrast to the alveolar macrophage, dendritic cells can play either a proinflammatory or tolerogenic role in allergic inflammation. These functions correspond with two distinct subsets of dendritic cells, myeloid and plasmacytoid, respectively. The dendritic cells are present in the lung in an immature form, either adjacent to epithelial cells or in the interstitium. These immature dendritic cells encounter antigen and migrate to a local lymph node, where they mature, characterized by increased expression of MHC class II molecules and B7 costimulatory molecules. The plasmacytoid dendritic cells can then induce tolerance, possibly by inducing T regulatory cells or by providing inhibitory costimulatory signaling via PDL-1 (programmed death ligand-1). In contrast, myeloid dendritic cells are thought to be important both for the initial sensitization with allergen as well as for enhancing the inflammation upon repeat exposure to allergen. Interestingly, repeated exposure to antigen may bypass the requirement for dendritic cells to migrate to a lymph node. In mice, it has been observed that following repeat antigen challenge, the myeloid dendritic cell population increases in numbers significantly within the airway in a mature form. This suggests that these cells may be maturing and interacting with the influx of T cells (predominantly Th2) within the airway itself rather than migrating to a lymph node.

Airway Smooth Muscle Cells

Bronchospasm remains an important component of asthma, particularly acute asthma. Despite this long-standing recognition, the details of airway smooth muscle function, both in normal and asthmatic persons, are still under investigation. It is recognized that the airway smooth muscle contraction is a component of airway hyperresponsiveness. Relaxation of this smooth muscle contraction has been the predominant target of beta-agonist therapy for asthma. However, additional findings of airway smooth muscle cell proliferation and hypertrophy along with subepithelial fibrosis are observed. These changes are thought to be a consequence, in part, of smooth muscle effector functions triggered by inflammatory mediator signaling. Some of the airway smooth muscle immunoregulatory and effector functions are mediated by the secretion of cytokines, chemokines, and extracellular matrix components, including GM-CSF, TGF-β, RANTES, eotaxin, IL-8, MCP-1 (monocyte chemotactic protein-1), fibronectin, collagen, and laminin.

Epithelial Cells and Goblet Cells

Airway epithelium functions as much more than a simple anatomic barrier. These cells actively regulate fluid and ion transport in the airway as well as mucus production. One of the most important activities of the airway epithelium is mucociliary clearance of secretions in conjunction with foreign particles. In addition, epithelial cells also participate in inflammation with the release of several molecular mediators, including cytokines, chemokines, and lipid mediators. Furthermore, epithelial cells are capable of producing endothelins, which are a family of three related peptides with potent bronchoconstrictor activity. Some of the stimuli for endothelin secretion include IL-1, IL-6, IL-8, TNF-α, TGF-β and LPS (lipopolysaccharide). Endothelin secretion is inhibited by IFN-γ and glucocorticoid treatment.

Goblet cells are a component of the bronchial epithelium and comprise up to 25 percent of the epithelial surface. The primary function of goblet cells is to secrete mucin into the airway, which along with other proteins and lipids, produces a thin layer of lubrication in the airway (mucus). The epithelial cells and submucosal glands assist in the production of mucus components. The mucus traps particulate matter and debris within the airway and, in conjunction with the mucociliary clearance apparatus, is able to clear these products from the airway. In asthma, goblet cell hyperplasia and increased mucus production are typically observed. The increased numbers of goblet cells are derived from the proliferation and differentiation of epithelial cells. In asthma, several cytokine signaling pathways, including IL-9 and IL-13, induce goblet cell hyperplasia and increased secretion of mucin into the airway. The clinical sequelae are mucus plugging and obstruction.

MOLECULAR MEDIATORS

The above-mentioned cells are able to coordinate and regulate the inflammatory process with the synthesis and secretion of several different classes of molecular mediators. These mediators have a variety of functions as discussed below.

Cytokines

Cytokines are small-molecular-weight glycosylated signaling molecules secreted by a number of different cell types with

autocrine, paracrine, or endocrine signaling activities. The over 30 cytokines identified thus far are categorized as interleukins, interferons, and growth factors. Cytokine secretion is usually a brief, self-limited event. It may, however, require new mRNA and protein synthesis, which takes place over a matter of hours rather than seconds or minutes. A variety of cytokines have been implicated in the regulation of airway inflammation and thus in the pathogenesis of asthma (Table 45-1). Support for cytokine involvement in inflammation was obtained by the detection of these mediators in the airways of patients with asthma, particularly in bronchoalveolar lavage fluid after allergen challenge and in situ hybridization of retrieved cells or biopsy materials.

The overall effect of the complex cytokine network in the airway depends on a number of factors, including the relative abundance of the various cytokines, their ability to recruit and perpetuate the actions of inflammatory cells such as eosinophils and lymphocytes, and their ability to amplify inflammation by interacting with structural cells such as fibroblasts, endothelial cells, and epithelial cells. There is no question, however, that cytokines are key mediators in the pathogenesis of the chronic inflammation characteristic of asthma.

The recognition that cytokines may have key immunoregulatory activities in the pathogenesis of asthma has led to the development of specific therapeutics to inhibit their function. Currently, humanized monoclonal antibodies, anti-IL-5 and anti-TNF-α, have been used for the treatment of asthma. Neither has yet emerged as the "magic bullet" for the treatment of asthma, although each, in preliminary studies, has been shown to have some clinical efficacy, anti-IL-5 for the prevention of airway modeling and anti–TNF-α or improvement in lung function.

Chemokines

The chemokines are small-molecular-weight proteins, 8-12 kD, that are classified in four categories based on the organization of specific cysteine residues in their protein sequence: C, CC, CXC, CX3C. The predominant function of chemokines is the recruitment or chemotaxis of inflammatory cells. Some chemokines also have additional signaling function. There are corresponding families of chemokine receptors for each class of chemokines. Notably, there is considerable overlap and redundancy in the chemokines and their target receptors.

Since the localization of inflammatory cells into the airway is dependent to a large extent on chemotaxis via chemokine signaling, the chemokine receptors have become an attractive target for asthma therapy. There are currently chemokine receptor inhibitors for CCR5 as well as others in development as potential therapy for asthma.

IgE

Allergic inflammation plays a prominent role in the pathogenesis of asthma. The initial association of IgE with asthma was based on several epidemiological studies. With the increased understanding of the role of mast cell mediators in the pathogenesis of asthma, the importance of IgE in triggering mast cell activation and the resulting airway inflammation was underscored. This relationship between IgE levels and asthma led to the development of a humanized monoclonal antibody directed to IgE for asthma therapy. This antibody (omalizumab, Xolair) has been shown to be effective in the treatment of severe asthma, specifically allowing a significant reduction in dosage of corticosteroids.

Leukotrienes

The leukotrienes are a family of lipid compounds generated from the metabolism of arachidonic acid via the lipoxygenase pathway (Fig. 45-2). These compounds are typically not preformed; rather, they are rapidly synthesized within minutes following activation of the source cell. LTC_4, LTD_4, and LTE_4 are potent bronchoconstrictors that are produced by several cell types, including eosinophils and mast cells. The leukotrienes are also able to increase mucus secretion in the airway and facilitate a plasma leak generating edema in the airway. The use of leukotriene receptor antagonists (e.g., montelukast, Singulair) is currently recommended as a second-line agent in the treatment of asthma (behind inhaled corticosteroids).

Prostanoids

The prostanoids are a family of lipid compounds generated from the metabolism of arachidonic acid via the cyclooxygenase pathway (Fig. 45-2). Most of the prostanoids, i.e., PGD_2, PGF_2, and TxA_2, are potent bronchoconstrictors and can be produced by several cell types including eosinophils and mast cells. However, another prostanoid, PGE_2, has bronchodilatory and anti-inflammatory activity. The use of nonsteroidal anti-inflammatory medications to inhibit cyclooxygenase activity has not been shown to have an appreciable effect on airway inflammation. It has been observed that PGD_2 is the predominant prostanoid involved in asthma. Therefore, specific PGD_2 receptor antagonists are currently being developed to ameliorate some of the bronchoconstriction in asthma.

Nitric Oxide

The role of nitric oxide (NO) in the pathogenesis of asthma is unclear. NO is continually synthesized at low levels in the airways of normal subjects. Cell sources of NO in the respiratory tract include airway epithelial cells, smooth muscle cells, sensory nerves, endothelial cells, and macrophages. At low levels, NO is a bronchodilator and vasodilator that antagonizes endothelin and has protective effects in the airway. Higher levels of NO are found in asthma, secondary to increased inducible NO synthase expression. Higher levels of NO production may be detrimental to airway epithelium. This may be mediated by the ability of NO to react with superoxide anion in inflamed tissue to produce biologic oxidants that could contribute to ongoing tissue damage and chronic asthmatic inflammation. The production of NO is thought to reflect the level or severity

Table 45-1

Cytokines

Cytokine	Primary Source(s)	Primary Target(s)	Effects or Function
bFGF (basic fibroblast growth factor)	Endothelial cells	Fibroblasts	Proliferation of fibroblasts and extracellular matrix formation
G-CSF (granulocyte colony stimulating factor	Monocytes, fibroblasts, epithelial cells	Neutrophils	Proliferation and differentiation
GM-CSF (granulocyte-monocyte colony stimulating factor)	Macrophage, T cells	Eosinophils, neutrophils, macrophage	Proliferation, differentiation, activation, prolonged cell survival, and enhanced cytokine production Degranulation (eosinophils)
IFN-α (interferon)	Monocytes, macrophage	Virus-infected cells	Inhibition of viral replication
IFN-β	Monocytes, macrophage	Virus-infected cells	Inhibition of viral replication
IFN-γ	Th1 cells, CD8+ T cells, natural killer cells	Macrophage CD4+ T cells CD8+ T cells	Differentiation, activation, and expression of Fcγ receptor, MHC molecules, and cytokines Shift in cytokine profile to Th1 phenotype and expression of IL-2 receptor Increased cytotoxicity
IL-1	Monocytes, macrophage	Th2 cells CD8+ T cells B cells	Production of cytokines Production of cytokines and increased cell cytotoxicity Proliferation, differentiation, and Ig production
IL-2	CD4+ T cells	T cells	Proliferation, differentiation, production of cytokines
IL-3	T-cells	Hematopoietic stem cells	Proliferation and differentiation
IL-4	Th2 cells	B cells Th1 cells Th2 cells CD8+ T-cells Natural killer cells	Proliferation, activation, and production of MHC class II, IL-6, TNF, and CD23; class switching to IgE; enhanced production of IgE, IgG1, and IgG4; diminished production of IgM, IgG2, and IgG3 Inhibition of differentiation and IFN-γ production Differentiation Differentiation Inhibition of proliferation
IL-5	T cells	Eosinophils	Proliferation, chemoattraction, adhesion, activation, and degranulation

Table 45-1

(*Continued*)

Cytokine	Primary Source(s)	Primary Target(s)	Effects or Function
IL-6	Monocytes, macrophage	B cells	Maturation to plasma cells, class switching to IgA
		Monocytes, macrophage	Production of IL-1 and TNF-α
IL-7	Bone marrow stromal cells	Pre-B cells	Proliferation
		T cells	Proliferation
IL-8	Macrophage	Neutrophils	Chemoattraction and inhibition of adhesion
IL-9	Th2 cells	B cells	Enhanced response to IL-4
IL-10	T cells	Monocytes	Differentiation to macrophage
		Macrophage	Inhibition of MHC class II and adhesion molecule expression; inhibition of IFN-γ, TNF-α, and IL-4
IL-11	Bone marrow stromal cells	B cells	Similar to IL-6
IL-12	Monocytes, macrophage	Natural killer cells	Activation
		Th0 cells	Proliferation and production of IL-2
		Th1 cells	Production of IFN-γ and TNF-α
		Th2 cells	Inhibition of IL-4, IL-5 and IL-10 expression
IL-13	Th2 cells	B cells	Similar to IL-4
		Monocytes	Enhanced expression of MHC class II molecules and integrins; inhibition of IL-1 and TNF expression
IL-14	Activated T cells	Activated B cells	Proliferation of B cells and suppression of Ig secretion
IL-15	Monocytes, macrophage	T cells, natural killer cells	Proliferation and increased cytotoxicity; expression of ICAM-3
IL-16	CD8+ T cells	CD4+ T cells	Proliferation, chemoattraction
IL-17	CD4+ T cells	CD4+ T cells	Proliferation and expression of autocrine factors
IL-18	Macrophage	Activated B cells	Similar to IL-12
IL-19	T cells, B cells, Monocytes		Increased expression of IL-4 and IL-13
IL-20	T-cells	Keratinocytes	Proliferation

Table 45-1

(*Continued*)

Cytokine	Primary Source(s)	Primary Target(s)	Effects or Function
IL-21	CD4+ T cells	?	?
IL-22	Th1 cells, NK cells	Hepatocytes	Increased expression of acute phase reactants
IL-23	Macrophage, dendritic cells	T cells, NK cells	?
IL-24	Monocytes, T cells	?	?
IL-25	CD4+ T cells	T cells, epithelial cells	Increased expression of Th2 cytokines
IL-26	Th1 cells, NK cells	?	?
IL-27	Antigen presenting cell	Naïve CD4 + T cells	Proliferation
IL-28	Mononuclear cells	?	Antiviral activity
IL-29	Mononuclear cells	?	Antiviral activity
M-CSF (macrophage colony stimulating factor)	Monocytes, fibroblasts, epithelial cells	Hematopoietic stem cells	Differentiation of monocytes
PDGF (platelet derived growth factor)	Platelets, monocytes, macrophage	Fibroblasts, smooth muscle	Proliferation and chemoattractant for fibroblasts; active in wound healing, atherogenesis, and airway remodeling
SCF (stem cell factor)	Bone marrow stromal cells, fibroblasts	Mast cells	Chemoattraction, induction of histamine release, differentiation and proliferation
TGF-β (transforming growth factor)	Platelets, mononuclear cells	T cells B cells NK cells Fibroblasts Macrophage	Inhibits proliferation Ig class switch for IgA Inhibits cytotoxicity Proliferation and fibrosis Chemotaxis
TNF-α (tumor necrosis factor)	Monocytes, macrophage, granulocytes	T cells Neutrophils, endothelial cells, epithelial cells	Proliferation, increased cytokine expression Increased phagocytosis, increased MHC class I and II expression, increased adhesion molecule expression

of airway inflammation. Thus, exhaled NO measurement has been utilized successfully as a tool to reflect the extent of airway inflammation as a measure of asthma control.

Granule Proteins

The granulocytes (mast cells, basophils, eosinophils, and neutrophils) are capable of releasing granule proteins, each of which has been proposed to play a role in the pathogenesis of asthma.

Insights into the kinetics and importance of mast cell mediators have been obtained from measurements of the levels of BAL histamine and tryptase. These studies have demonstrated that mast cell activation is an early event, with elevated BAL histamine and tryptase levels being seen 12 minutes after endobronchial antigen challenge and the levels of tryptase returning to normal by 48 hours. The levels of histamine remain elevated after 48 hours, raising the possibility that non–mast cells (e.g., basophils) are activated and produce the histamine at these later points. Furthermore, the BAL of allergic asthmatic subjects had only moderately elevated levels of tryptase at baseline but higher concentrations of tryptase following antigen challenge. Histamine is capable of inducing bronchoconstriction, increasing vascular permeability to cause edema, and increasing mucus secretion. The role of tryptase is not well established, although there are data to suggest that tryptase can activate inflammatory cells such as eosinophils, mast cells, and epithelial cells by cleaving a family of protease activated receptors (PAR) on their cell surfaces.

Major basic protein (MBP) is the principal protein constituent of eosinophil granules. It is toxic for epithelial tissues, induces airway hyperresponsiveness, and causes histamine release from basophils. Eosinophil cationic protein (ECP) is more cytotoxic to the epithelium than MBP and damages target cells by membrane pore formation. Eosinophil derived neurotoxin (EDN), as the name implies, damages myelinated neurons. Eosinophil peroxidase (EPO) differs from neutrophil and monocyte myeloperoxidases (MPOs); it decreases LTC_4 and LTD_4 degradation and causes histamine release from mast cells.

Neutrophil release of MPO and neutrophil elastase enhances their host defense function and is potentially injurious to normal tissues, including airway epithelium. The primary granules contain MPO and lysozyme as well as hydrolases and proteinases, which are important in tissue penetration by neutrophils. Secondary granules contain lysozyme and collagenases, which can also potentially damage airway tissue. Thus, the neutrophil granule proteins are considered toxic to the airway epithelium and tissue.

ROLE OF ADHESION MOLECULES IN INFLAMMATION

The recruitment of cells from the circulation and their activation in the airways, in part, involves cell-cell and cell-extracellular matrix communication, a process that is facilitated and regulated by adhesion molecules and cytokines. Adhesion molecules are cell surface proteins that have been grouped according to structural and functional similarities. Several categories have been identified, including the selectins, integrins, and members of the immunoglobulin (Ig) gene superfamily. These molecules interact with complementary binding sites (ligands) on respective cells, allowing them to adhere to epithelial or endothelial surfaces and, in some cases, enter the pulmonary interstitium.

Selectins

Three members of the selectin group have been identified: endothelial (E)-selectin, platelet (P)-selectin, and leukocyte (L)-selectin. Both E- and P-selectin are found on endothelial cells, while L-selectin is located only on leukocytes, including lymphocytes, eosinophils, monocytes, basophils, and neutrophils. L-selectin can also be shed from leukocytes and, like P-selectin, may be found in a circulating soluble form, in which it is potentially available to participate in inflammatory reactions.

Integrins

Integrins are found on the surfaces of leukocytes but not endothelial cells. They are classified according to the composition of their various subunits, including several different alpha and beta chains. One line of evidence for the importance of integrins in human disease is the finding that partial or total absence of a β_2-integrin subunit leads to a crucial defect of neutrophil recruitment to sites of inflammation and recurrent, potentially life-threatening bacterial infections in patients with leukocyte adhesion deficiency syndromes. Some integrin interactions that are

important in leukocyte–endothelial cell adhesion and signaling include very late antigen-4 (VLA-4) with lymphocyte function–associated antigen–1 (LFA-1), also known as CD11a/CD18, which also serves as a ligand for intercellular adhesion molecule–1 (ICAM-1) and ICAM-2. Not surprisingly, integrins have also been implicated in tissue repair, platelet aggregation, and tumor invasion, in addition to their other, more general roles in leukocyte binding and recruitment. Integrins are the primary mediators of cell-extracellular matrix adhesion. In asthma, integrins are also important for transendothelial migration of inflammatory cells into the airways.

Ig Gene Superfamily Members

Endothelial proteins of the immunoglobulin gene superfamily share functional as well as structural similarities with immunoglobulin domains. ICAM-1, ICAM-2, vascular cell adhesion molecule–1 (VCAM-1), platelet–endothelial cell adhesion molecule–1 (PECAM-1), and mucosal addressin cell adhesion molecule–1 (MadCAM-1) are all active in later steps of leukocyte–endothelial cell adhesion. These interactions are not final random events, but represent a coordinated effort of cells, cell surface molecules, and cytokines.

Mechanisms of Cellular Migration

There are three major interrelated steps in leukocyte recruitment from the circulation into tissues. They are categorized as adhesion, diapedesis, and chemotaxis (Fig. 45-3). Although the specific molecules and cytokines associated with these processes may vary, depending on the particular cells involved, the following general steps for leukocyte–endothelial cell and extracellular matrix interaction are thought to occur. As leukocytes move through capillary vessels, they initially contact the endothelial cell walls in a random fashion. In vascular beds in the region of inflammation, endothelial cells are "activated," with increased expression of adhesion molecules, such as E-selectin, on their cell surfaces. During flow through vessels with activated endothelial cells, leukocytes begin to "roll" along the endothelial cell luminal surfaces as a consequence of the interactions of adhesion molecules on leukocyte and endothelial cell surfaces. As leukocytes travel near sites of inflammation, locally produced cytokines up-regulate expression of cell surface proteins, including those active in cell adhesion and migration. These activated leukocytes then participate in "firm adhesion," much of which is mediated through interactions of leukocyte integrins (VLA-4, CD11a/CD18) and endothelial cell surface Ig gene superfamily members (ICAM-1, VCAM-1).

The next step is transmigration of leukocytes across endothelial cells and between endothelial cells into the surrounding tissues, i.e., diapedesis. Since there are cell-type specific differences in the expression of adhesion molecules, the pattern of adhesion molecule expression on the endothelium can confer selectivity in recruitment of specific leukocytes. For example, endothelial cell VCAM-1 binds mononuclear leukocytes and eosinophils, but not neutrophils. In contrast, both neutrophil and eosinophil migration across endothelial cells is enhanced by binding to ICAM-1. Various inflammatory mediators, including cytokines and chemokines, induce an increased expression of adhesion molecules and ligands that aid in the preferential recruitment of particular cell types into the tissues. The consequence of these interactions is the recruitment of inflammatory cells into target tissues such as the airway and, frequently, a complete or partial activation of these cells during their transit.

AIRWAY INFLAMMATION IN ASTHMA

Thus far, a description of cells, the mediators they release, and the mechanism for their recruitment into tissue have been presented, but how do they cooperate to generate asthma? It is likely that each of these components plays a role in the pathophysiology of an asthma exacerbation. However, given the heterogeneity in clinical and physiological features of asthma from patient to patient and from trigger to trigger, it is likely that the relative contributions of each cell type and/or mediator can vary. Furthermore, it is clear that multiple cells types are able to express similar sets of molecular mediators; thus, it

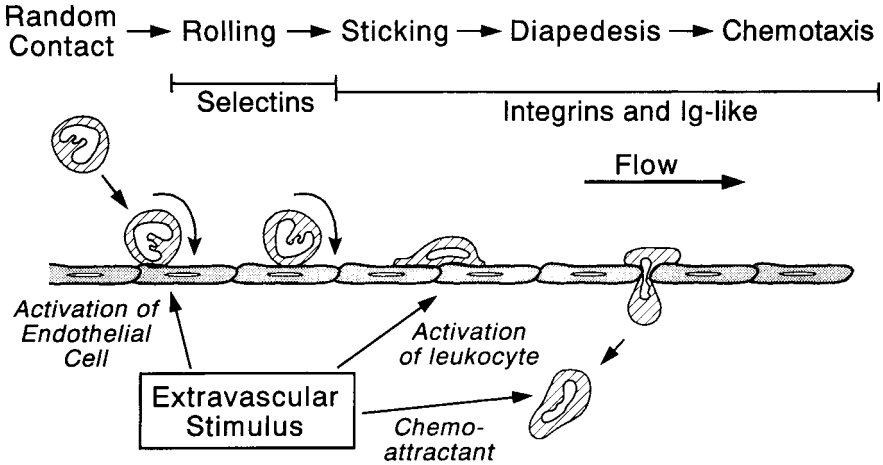

Figure 45-3 Mechanism of leukocyte vascular adhesion and migration into tissues and airways. Leukocytes ''roll" along endothelial cell layer and then selectively adhere firmly to endothelium near inflammatory sites. The adhering leukocytes then migrate into subendothelial tissue. Cell surface molecules (selectins, integrins, Ig superfamily members) facilitate the process. *(Based on data of Carlos TM, Harlan JM: Leukocyte-endothelial adhesion molecules. Blood 84:2068–2101, 1994, with permission.)*

is possible that different patterns of cell activation can result in the same effector responses.

In a quiescent state, the cells involved in the pathogenesis of asthma are resident in the airway tissue, peripheral circulation, or local lymph nodes (Fig. 45-4*A*). Following exposure to an asthma trigger, the inflammatory cascade is initiated resulting in cell activation, cell recruitment, cell hyperplasia, and release of mediators (Fig. 45-4*B*), which collectively yield the hallmark findings of asthma: airway obstruction, mucus secretion, and hyperresponsiveness.

CONCLUSION

Recent cellular and molecular advances have yielded a wealth of information regarding the biology of asthma. There is an extensive cadre of cell and molecular "players" involved in asthma. It is clear that allergic inflammation is the result of a complex interaction of numerous signaling and effector events. The orchestration of this inflammatory response comprises the participation of airway cells, mast cells, and lymphocytes; the generation of proinflammatory cytokines; the recruitment and activation of eosinophils and neutrophils; and the development of factors in the lung that sustain these events to cause persistent airway obstruction and injury. Many questions remain to be answered, including the genetic factors at work in the initiation and regulation of this process and an individual's susceptibility to this process. What is clear is the importance of airway inflammation to altered airway physiology in asthma and the relevance of this component of asthma as a principal therapeutic target. As further research begins to unravel more details regarding the inflammatory response, specific targets will be identified for the development of novel therapies to safely abrogate the inflammatory process and possibly cure asthma.

Asthma: Epidemiology

Andrea J. Apter • Scott T. Weiss

Asthma is a clinical syndrome that affects 20 million Americans and accounts for 12.7 million medical visits yearly. One-third of those afflicted with asthma are children under the age of 18 years. It is estimated that roughly half of these children received their diagnosis prior to the age of 6 years. As a result, the origins of asthma are believed to have a clear genetic component that is often manifest in early childhood. The clinical course of this illness is influenced greatly by exposures, including respiratory viruses, indoor allergens, maternal tobacco smoke, and other physical and social aspects of the environment. Thus, this clinical disease has important consequences in childhood and may have important consequences for adult obstructive lung disease.

Asthma is an extremely common clinical problem and the most common cause of hospitalization for children in the United States. The estimated annual direct and indirect cost of asthma care is rising dramatically and totaled approximately $16 billion in 2001 in the United States according to the National Heart Lung and Blood Institute (NHLBI). In 2002 14.7 million school days were missed due to childhood asthma, while adults missed 11.8 million work days in the same year. The paradox of this illness is that despite important strides in understanding etiologic environmental factors and mechanisms of airway inflammation characteristic of the syndrome, its prevalence and morbidity remain unacceptably high. Although asthma morbidity and mortality rates have been steady over the last few years, the rates are dramatically higher than past 25 years ago and continue to be very significant, particularly for urban minority groups, low-income populations, and children.

The purpose of this chapter is to describe trends in asthma epidemiology, specifically prevalence, hospitalization, and mortality. In so doing, we examine potential reasons for these trends, and the recent research on the interactions of genes and environment. We also examine the relationship of the intermediate phenotypes of airway hyperresponsiveness and allergy to the asthma syndrome and consider a variety of risk factors for asthma occurrence. We conclude with a review of asthma natural history and the implications of the current trends.

DEFINITIONS AND PREVALENCE

The NHLBI defined asthma in 2002 as:

a chronic inflammatory disorder of the airways in which many cells and cellular elements play a role. The chronic inflammation causes recurrent episodes of wheezing, breathlessness, chest tightness, and coughing, particularly at night and in the early morning. These episodes are usually associated with widespread but variable airflow obstruction that is often reversible either spontaneously or with treatment.

Because asthma is a clinical syndrome, there is no gold standard for its diagnosis. As such, physicians employ nonstandardized algorithms for making the diagnosis, such as a history of wheezing or a parental history of asthma in conjunction with a favorable response to a bronchodilator to identify the asthmatic patient. Frequently, age, gender, and other patient characteristics such as smoking status or response to allergen may influence a physician's diagnosis. Rarely are tests of airway responsiveness systematically used to investigate symptomatic patients in the clinical setting.

In general, epidemiologic surveys have tended to rely on historical or questionnaire sources to identify patients with asthma. Asthma cases have been identified, either by physicians or surveys of population groups in whom the definition of who is asthmatic has been left to the patients themselves, surrogates, or the report of the diagnosis having been made by the patient's physician. Clearly, each of these methods of identifying asthma patients has inherent weaknesses. One must, therefore, assume that some bias in the reporting of cases is present and that the biases in each method of gathering data are different.

The National Health Interview Survey (NHIS) is an annual random population household interview survey that provides information on asthma prevalence in the United States. Its data demonstrate an almost doubling of asthma prevalence over the last quarter century, from 3.2 per 100 population in 1981 to 5.5 percent per 100 in 1996 (Fig. 46-1). In 1997 the NHIS questions and methodology were modified, limiting comparisons of prevalence before and after 1997. Instead of asking whether the respondent or a family member had had asthma over the past 12 months the newer version asks, "Has a doctor or other health professional ever told you that you had asthma?" (lifetime prevalence). Information about adults can no longer be obtained from a family member or proxy. If the response is affirmative, an "attack" question is asked, "During the past 12 months have you had an episode of asthma or asthma attack?" Beginning in 2001, if the lifetime prevalence response was positive, a point prevalence or "Current" measure was added asking, "Do you still have asthma?" The data from the "Current" question, is most comparable with previous data, but not exactly the same. It indicates no rise in asthma prevalence over 2001 through 2003. The prevalence in children under 18 years is higher than adults, for example, in 2003, 8.5 per 100 compared with 6.4 (Fig. 46-1).

There is a difference in prevalence by racial/ethnic groups. Until 1997 racial groups were classified as black or white with black population having slightly higher 12-month prevalence. In 2003, with an expanded racial and ethnic classification, the current prevalence was 9.2 for black non-Hispanics, 5.5 for Hispanics, and 6.9 per 100 for white non-Hispanics. It is noteworthy that the rate for Puerto Ricans was 14 per 100.

The current data show a significant modification of prevalence by gender, in that males tend to predominate in this younger age group, whereas gender ratios equalize in the pubertal years, and females predominate throughout the rest of the adult life. For example, the current prevalence for males between 5 and 14 years in 2003 was 10.8 per 100 compared with 8.1 for females, but in adults 18 years and older female prevalence is about twice that for males. Thus, age and gender play an important role in modifying disease prevalence. There does not appear to be substantial regional variation in prevalence rates.

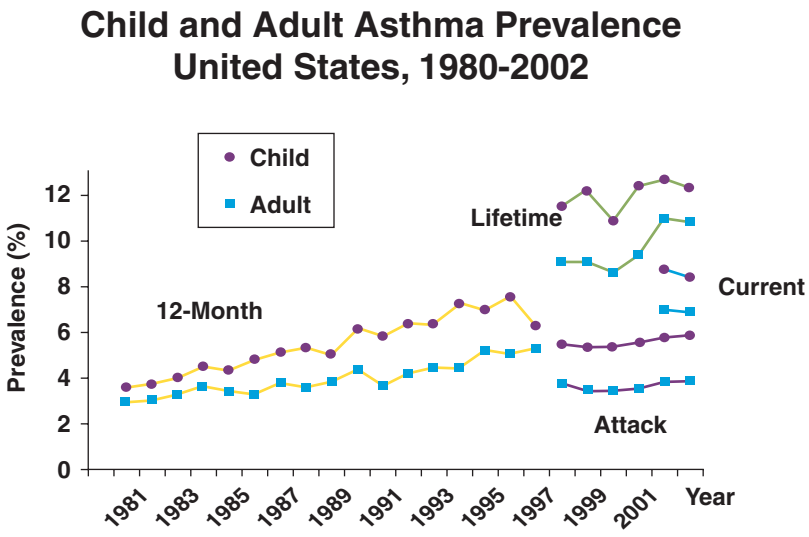

Figure 46-1 National asthma prevalence figures from the National Health Interview Survey (NHIS). This survey was redesigned in 1997. The previous measure of asthma prevalence was a 12-month period prevalence estimate; proxy responses were accepted and no doctor diagnosis was required. This measure was replaced by two others in 1997, both of which required a medical diagnosis of asthma, and proxy reporting was eliminated. One new measure was lifetime prevalence; the second measured the occurrence of an asthma episode or attack in the past 12 months (a period prevalence). In 2001, a point prevalence measure was added to assess current asthma prevalence. If the respondent answered ''yes" to the lifetime question, a second question asked, ''Do you still have asthma?" As can be seen in this graph, children have higher asthma prevalence than adults on all four measures.

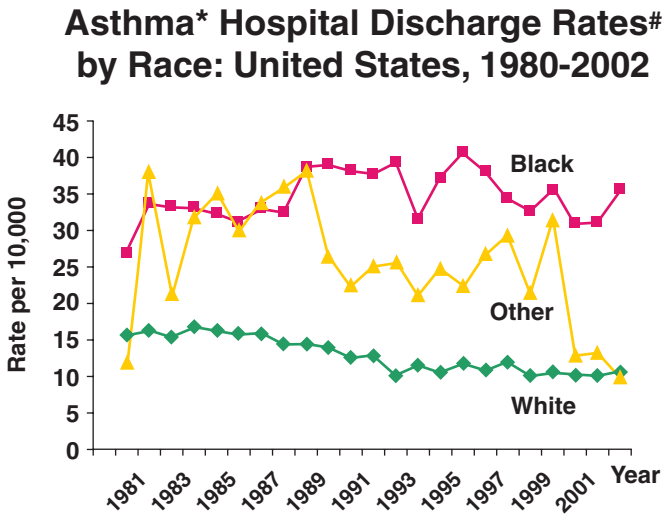

Figure 46-2 Asthma hospital discharge rates per 10,000 population from 1980 to 2002 for three racial groups; black, white, and ''other." During this period, asthma hospital discharge rates have been consistently higher for blacks than whites. Since the late 1980s, asthma *prevalence* has also been higher for blacks than whites, but not sufficiently higher to explain the higher hospitalization rates. The rates for the ''other" group (other than black or white) are more variable because of the relatively smaller size of the population. Source: National Hospital Discharge Survey, National Center for Health Statistics, Centers for Disease Control. *, first-listed diagnosis; #, age adjusted to 2000 US population.

HOSPITALIZATIONS AND EMERGENCY DEPARTMENT VISITS

Data from the National Hospitalization Discharge Survey suggest that hospitalization and emergency department (ED) visit rates for asthma have been reasonably stable from 1980 to 2002 even during a period of rising prevalence (Fig. 46-2). With respect to age, ED visits and hospitalizations are highest among children and particularly among children 0 to 4 years of age, in whom there were 59 hospitalizations and 162 per 10,000 ED visits in 2002. Females are hospitalized and make ED visits more frequently than males. What is particularly striking are racial/ethnic disparities in ED visits and hospitalizations. In 2002, the hospitalization rate for blacks was more than three times that for whites and the ED visit rate was almost five times higher than for whites. These differences are proportionally larger than the milder increase in prevalence in blacks over whites (Fig. 46-3). It is important to note that race data are frequently missing in reviewed records. Since 2000, race data have been absent from about 25 percent of hospital records.

TRENDS IN ASTHMA MORTALITY

Asthma mortality rates in the United States are quite low. Figure 46-4 describes the trends in asthma mortality in the United States between 1979 and 2001. There is an overall decline in deaths since 1998, although 11 percent of that decline can be attributed to the new coding. However, the downward trend in countrywide asthma mortality belies pockets of very high prevalence, morbidity, and mortality in inner-city minority populations.

These mortality rates do not represent a public health concern in an absolute sense, as the number of deaths is still very low. However, the rates do represent a clear public health concern because almost all asthma deaths are preventable, and certain urban and minority areas have extremely high mortality rates, suggesting inadequate care practices.

INTERMEDIATE PHENOTYPES

There are two intermediate phenotypes that contribute to the asthmatic syndrome: airway responsiveness and allergy. Both have a genetic component, and both are influenced by environmental factors. We will discuss these phenotypes and their interrelationship to each other and to asthma.

Airway Responsiveness

Airway responsiveness is measured by quantitating the decline in lung function caused by using increasing doses of a bronchoconstrictive stimulus, such as histamine or methacholine. When the patient's FEV_1 decreases by 20 percent from its initial value, or after a maximum stimulus dose has been administered, the test is terminated. The dose at which this drop occurs is called the *provocative dose* (PD_{20}). Individuals that manifest a PD_{20} at a low dose of stimulus are said to have increased airway responsiveness and are hyperresponsive to the inhaled agent.

Cross-sectional population-based surveys of children and adults conducted in many different countries and using a variety of techniques for measuring airway responsiveness have shown that the prevalence of airway hyperresponsiveness is roughly 20 percent in the general population. The prevalence of increased airway responsiveness exceeds the prevalence of asthma by from two- to fivefold.

These studies have also demonstrated that airway responsiveness is log normally distributed in the general population. An example of this is given in Fig. 46-5. In this population-based study of the distribution of histamine airway responsiveness, symptomatic or asthmatic subjects

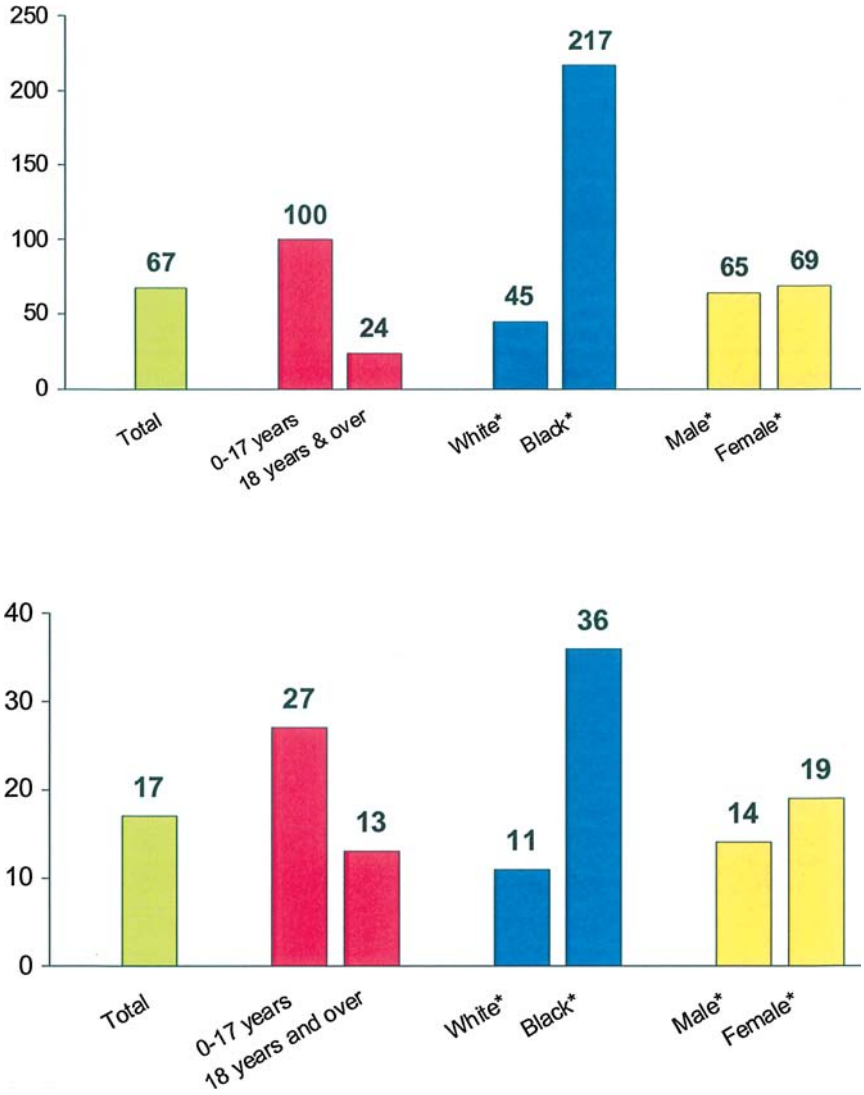

Figure 46-3 Asthma emergency department visits *(top)* and hospitalizations *(bottom)* per 10,000 populations, 2002. Hospitalizations are three times more frequent and emergency department visits almost five times more frequent among blacks. Hospitalizations are more frequent in children than adults. Source: National Hospital Ambulatory Medical Care Survey, National Center for Health Statistics, Centers for Disease Control. *, age adjusted to 2000 population.

appear at the more responsive end of the distribution, but there is considerable overlap with asymptomatic subjects. Other population-based studies have confirmed that a large number of asymptomatic subjects manifest increased airway hyperresponsiveness to this agent.

It has now been well demonstrated in studies of both children and adults that airway hyperresponsiveness antedates and predicts the development of asthma. Increased airway responsiveness carries at least twice the risk for the development of asthma in children and young adults. But increased airway responsiveness is a necessary, but not a sufficient condition for the development of asthma. In all likelihood, subjects who are genetically predisposed have increased airway responsiveness. They then encounter environmental stimuli that generate airway inflammation. The inflammation then moves them in the direction of greater responsiveness and the development of respiratory symptoms. This theoretical paradigm is graphically depicted in Fig. 46-6.

A variety of mechanical factors influence airway responsiveness. First, and most important, is the level of lung function. Individuals with lower levels of lung function are more likely to have increased airway responsiveness. In part, this is simply a mathematical phenomenon. Since airway responsiveness is expressed as a percent change from baseline, baseline value will obviously be important in determining the level at which an individual would be considered responsive (i.e., have a PD_{20}). This can be best understood with a simple mathematical example. A man with a 5-L FEV_1 would be required to drop his pre-challenge level of lung function by 1 L to achieve a PD_{20} for FEV_1. In contrast, a man with a 500-ml FEV_1 will only need to drop his FEV_1 by 100 ml to achieve a comparable PD_{20} for FEV_1. Other factors, such as the central deposition and distribution of the inhaled aerosol, the fact that airflow is inversely proportional to the fourth power of the airway radius, and baseline bronchomotor tone all contribute to the relationship of lung function to airway responsiveness. For this reason, airway responsiveness is likely to be increased at the extremes of age (i.e., in children and older adults) and reduced in young adults between the ages of 15 and 45 years.

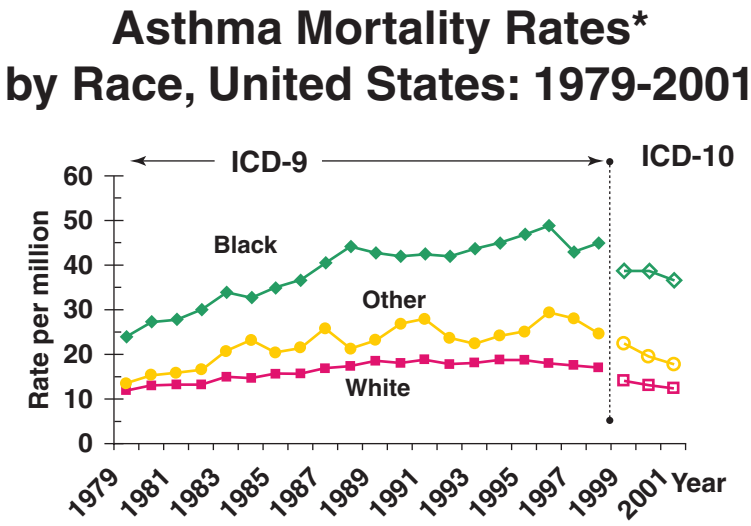

Figure 46-4 Asthma mortality trends. Since1998, both the overall number of deaths and the rate have clearly declined. However, a new mortality coding scheme was implemented in 1999. About 11 percent of the decline in asthma deaths can be attributed to the new coding scheme. This graph shows the difference in mortality rates by race. The green line is the mortality rate for blacks, the red line is for whites, and the yellow line represents all other races combined. Clearly, asthma mortality rates rose for each of these three racial groups during the period before 1995. Source: Underlying Cause of death: National Center for Health Statistics. *, age-adjusted to 2000 population.

Seminar Respir Infect 6:225–234, with permission.)*

Allergy

Allergy refers to immediate (Type 1) hypersensitivity to environmental antigens. It is characterized by wheal and flare reactions to skin testing with common environmental antigens, usually with appropriate clinical history. Atopy is the demonstration of allergy and familial aggregation of this trait.

The pathophysiology of the allergic response has been explained by a conceptualization sometimes called the TH1-TH2 paradigm of CD4+ T helper cells. This model, summarized in Fig. 46-7, is also the basis for much recent clinical research seeking to understand the development of asthma. Antigen presenting cells (APCs) display peptide antigens, either allergen or infectious, on their cell surfaces for recognition by naïve T cells (TH0). TH0 differentiate into TH1 or TH2 cells, depending on the nature of the antigen, the characteristics of the APC, local concentration of cytokines, and other factors not fully understood. TH1 cells secrete IFN-γ, while TH2 cells secrete IL-4 and IL-5. For example, activation of APC by microbial products results in production of IL-12 and TH0 cells differentiate into TH1 cells. The presence of IL-4 results in differentiation of TH0 cells into TH2 cells. TH2 cells promote allergic inflammation through the production of cytokines including IL-4, IL-5, and IL-13. IL-4 and IL-13 induce B lymphocytes to differentiate into IgE-producing plasma cells. IL-5 secreted by TH2 cells results in eosinophilopoiesis and resistance to apoptosis. In addition to IFN-γ, TH1 cells produce tumor necrosis factor-β (TNF-β) and IL-2. A TH1 response results in activation of macrophages and natural killer cells and production of IgG1, which plays a role in complement binding and opsonization.TH1 and TH2 cells cross-regulate each other. That is, IFN-γ inhibits TH2 proliferation and IL-4 inhibits IFN-γ–induced macrophage activation. T-regulatory cells are recently characterized cells that inhibit TH1 and TH2 cells.

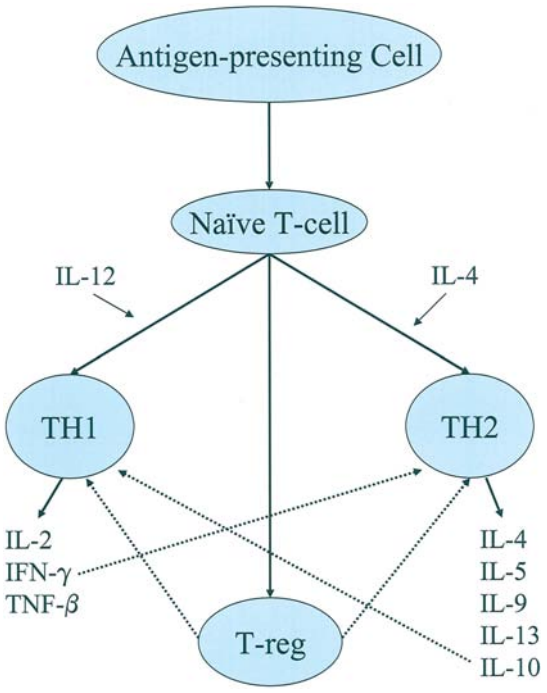

Figure 46-7 The TH1-TH2 paradigm. The figure depicts the developing immune system and the cytokines elaborated by mature CD4+ T lymphocytes in both Th1 and Th 2 cells. It also shows the central role of T-regulatory cells in controlling Th 1 and Th 2 clinical expression.

TH1 and TH2 cells also interact with cells of the innate immune system. The relationship of acute inflammation to chronic irreversible processes in targeted cells like smooth muscle, in airway remodeling, is another area of expanding interest to researchers.

Recent research suggests the TH1-TH2 paradigm is more complex than as described above. In mouse models of asthma, TH1 and TH2 cells have been observed to synergistically promote inflammation and airway hyperresponsiveness. In a birth cohort of 172 children, Heaton et al found allergic diseases and asthma associated with IL-4, IL-5, IgE production, and eosinophilia; but they also found IFN-γ production associated with airway hyperreactivity and skin-test reactivity. Additionally, the investigators found that cytokine patterns among the children were heterogeneous.

Clinical Markers of Allergy

A variety of clinical allergy markers have been utilized in epidemiologic studies of asthma based on the TH1-TH2 paradigm. Specific and total IgE, measured by skin or serologic testing, assess sensitization as well as exposure to environmental antigens and frequently are used to determine the prevalence of allergic responsiveness. Skin test reactivity depends on at least three separate factors: (1) an intact immune system; (2) the presence of IgE-sensitized mast cells that release mediators when exposed to antigen; (3) and skin that can respond to histamine with the development of an inflammatory response, including erythema and induration. Although these manifestations of an allergic response depend on prior exposure to environmental antigen, they do not measure or take into account the level of exposure in the environment.

Total serum IgE, although used in epidemiologic studies, has relatively limited value in the diagnoses of atopic diseases, with the exception allergic bronchopulmonary aspergillosis (see Chapter 49). Although total and specific IgE levels correlate with each other and with skin test results, no level of total IgE avoids misclassifying a significant proportion of those with and without allergic diseases. The limitations in clinical information imposed by these tests limit their utility when they are used epidemiologic studies.

Total and specific IgE measurements appear to be comparable in males and females. Both increase with age and peak at approximately age 15 years. After this time, there is a progressive decline, although the decline in skin test reactivity exceeds the reduction in total serum IgE, perhaps related to local factors in the skin.

Clinical Implications of the TH1-TH2 Paradigm

As indicated, processes that lead to the development of a hypothesized TH2-dominant phenotype in early life are

complex and the subject of ongoing research. It is believed that IgE responses to inhalant allergens are commonly set in early childhood. It is also believed that sensitization, i.e., production of IgE directed at environmental antigens, is not only a function of genetic susceptibility, dose, timing, and duration of allergen exposure, but also may reflect exposure to other environmental antigens, particularly microbial or viral organisms. One hypothesis of the development of atopic disease, the "hygiene hypothesis," states that the development of TH1 responses are dependent upon early exposure to infection. Since newborns are thought to have TH2-dominant immune responses, the development of TH1 responsiveness depends upon exposure to infection. That is, respiratory or gastrointestinal infections may stimulate macrophages to produce interferon-α and IL-12 that stimulate NK cells to produce IFN-γ, which would inhibit the development of a TH2-type response. The Tucson Epidemiologic Study, a birth cohort of 1246 subjects, noted that children who had a nonwheezing lower respiratory tract illness before 9 months of age had lower total IgE levels at 9 months and 6 years of age when compared with children who had no lower respiratory illnesses before 9 months of age. These children were also less likely to be atopic than those who had no lower respiratory tract illnesses. These investigators also found that children exposed to more siblings at home or to day care in the first 6 months of life, presumably exposed to more infections, were protected from the development of asthma between ages 6 and 13 years. Interestingly, investigators from Norway using a birth cohort of 2540 children followed until age 10 did not find a protective effect of early respiratory infections and the subsequent development of asthma or day care attendance. This research confirms the complexity of environmental influences on the immune system. The TH1-TH2 paradigm will need further exploration of its explanatory ability in asthma.

Relationship of Airway Responsiveness and Allergy to Asthma

Atopy and increased airway responsiveness are separate but related factors, both of which contribute to the development of the asthma phenotype. Over 80 percent of childhood asthmatics are atopic and there are many studies of exposure to allergen in sensitive individuals associated with bronchospasm. Thus, exposure and sensitization are linked to airway responsiveness.

But individuals may have airway hyperresponsiveness without atopic manifestations. The introduction of omalizumab, a recombinant, humanized anti-IgE antibody, is helping to elucidate the relationship of airway responsiveness and allergy. Omalizumab lowers total serum IgE and reduces eosinophils in sputum. In some studies it has allowed reduction of corticosteroid therapy, but in others it has failed to show reduce airway hyperresponsiveness, supporting the notion that airway hyperreactivity and allergy have other separate influences.

Current research explores the relationship between exposure to allergen and the subsequent development of asthma. A birth cohort design has been used to examine this relationship. Preventing loss of participants to follow-up makes these studies difficult to conduct. It is also difficult to measure exposure to allergen, that is, to quantify inhalation by subjects, while accounting for intermittent and varying exposure over time and place. Furthermore, there is an imperfect correlation among skin test reactivity, total serum IgE level, and peripheral blood eosinophil count, such that no single phenotypic marker completely defines the atopic state. Nevertheless, in studies of children with atopic parents, exposure is associated with the development of asthma. Sensitization, a reflection of exposure and genetics, has also been associated with the development of asthma. It is likely that where no relationship is found between exposure and the development of asthma, genetic influences are not present, i.e., the majority of the studied families are not atopic.

The Tucson Respiratory Study showed that patterns of wheezing and lung function tend to be established by age 6. Increased sensitization and higher levels of indoor allergens (exposure) may be important risk factors that have changed in the past 30 years, potentially accounting for some of the increased prevalence of asthma. Buildings with synthetic wall-to-wall carpeting, higher humidity, cloth-upholstered furniture, and bed-reduced ventilation have higher levels of house dust mites and other indoor allergens. Evidence from Scandinavian studies suggests that thermally tighter homes have been associated with higher indoor allergen levels. Other risk factors, notably maternal cigarette smoking, childhood respiratory infection, and the effects of poverty, likely contribute to the development of asthma. Such research demonstrates that environmental-gene interactions contribute to the development of asthma.

GENETIC SUSCEPTIBILITY AND GENE-ENVIRONMENT INTERACTIONS

Geneticists describe asthma as a complex disease, a disease in which many genes influence the development and phenotype of asthma, each having only a small influence. Since the human genome project was completed in 2000, remarkable advances have been made in identifying asthma genes.

There are two main types of genetic studies; linkage studies and association studies. In an association study, candidate genes are examined to determine a statistical association between polymorphism in the gene and asthma phenotypes; either cases and controls or trios can be used. These studies focus on known pathophysiology.

Linkage studies start with families with well-characterized phenotypes such as asthma. Genes within families are examined for linkage, the sharing of genes markers that may be located near or at the disease gene. Association studies are then used to follow up and "fine map" the linkage peak. These studies focus on novel genes.

To date five genes: ADAM 33, DPP10, PDH11, GPRA, and HLA-G, have been identified by linkage and fine

mapping. Fifteen other genes: IL1R, IL4, IL4RA, IL13, LTC4S, CTLA4, SCYA11, ADRB2, CD14, SPINK5, NOS1, STAT6, HLA-DRB, FCER1B, TGFB1, have been replicated in four or more genetic association studies. This is more than what has been found for many other complex traits.

ENVIRONMENTAL RISK FACTORS

Below we present some of the most important environmental risk factors for the development or exacerbation of asthma not discussed earlier.

Perinatal Factors

Prematurity carries an increased risk for the development of asthma. Prematurity also is associated with bronchopulmonary dysplasia, a disease characterized by increased airway responsiveness and asthma symptoms. Some investigators have found that low birth weight independent of prematurity has been associated with asthma risk. Note that blacks have higher rates of prematurity than whites; thus, prematurity may contribute to racial differences in asthma prevalence and morbidity. Young maternal age (i.e., less than 20 years) has not been shown to have a consistent independent association with the development of asthma. Despite much research, there is no conclusive evidence that breastfeeding influences atopic sensitization or the development of asthma.

Indoor and Outdoor Allergens

Indoor allergen sources include animals (cats, dogs, rodents); insects (mites, cockroaches); and fungi. Allergens from pets, particularly cats, are well-known precipitants of asthma exacerbations. There has been some recent investigation as to whether exposure to pets would be useful in preventing asthma, but most data indicate an increased risk of the development of asthma in homes of atopic families with pet exposure (i.e., a genetic-environmental interaction). It is noteworthy that animal allergens, particularly cat allergen, can be found in settled dust and in circulating air in homes, school classrooms, and other buildings that never housed a cat.

House dust mites are ubiquitous in all but very dry climates and sensitization to mite body and fecal allergens is associated with asthma. Mites infest fabrics, including mattresses, bedding, floor coverings, and upholstered furniture. The use of wall-to-wall carpets has increased exposure to mites. Covering mattresses and pillows with vapor-permeable fine weave materials, washing bedding in hot (greater than 130°F) water, vacuuming weekly, and removing carpets, especially from the bedroom, reduce mite levels.

Whether reducing exposure results in improvement in asthma outcome has been difficult to ascertain. Horak and coworkers randomly assigned 696 infants to receive mite-impermeable mattress encasings and their parents education about reduction of mite exposure. The control families received educational information in which avoidance of mite exposure was not presented. The investigators were unable to show a protective effect against the development of asthma. In contrast, a recent small study showed efficacy in prevention of asthma exacerbations. Adherence to the demanding protocols for control of mite exposure is difficult and whether control of exposure without other simultaneous interventions like control of environmental tobacco smoke (ETS) or pet exposure is not yet established.

Sensitization to cockroach has been shown to be associated with the development of asthma and asthma morbidity. Although the presence of this allergen is not limited to low-income homes, it has not been studied in more affluent settings. Removal of this allergen is difficult and more research is needed to evaluate the impact on asthma of allergen removal.

Although home and school dampness and the presence of fungi have been associated with reports of respiratory symptoms, it has not been determined whether mold allergens or mold-derived irritants or other factors are involved.

Some recent studies have employed multifaceted environmental interventions making assessment of individual factors impossible. None have been conclusively successful.

Day care establishments may be sources of indoor allergens, including pets, insects, fungi. They also may be sources of gram-negative bacterial endotoxin and lipopolysaccharides, which induce TH1 activity and have been hypothesized to be protective against the development of allergy and asthma. However, longitudinal studies have not consistently supported this notion. A recent study found that day care exposure was associated with increased risk of wheeze in the first 6 years of life in children with a maternal history of asthma. Day care and presumably endotoxin exposure were not protective in this study.

Outdoor allergens include trees, grass, and weed pollen constituents. Susceptible individuals may have increased asthma symptoms at times of pollination. For example, in the Northeast and Midwest grass pollinates in May and June and ragweed in late August and September. Pollens most closely linked to exacerbations of asthma in at-risk individuals are trees such as birch, oak and Western red cedar; grasses; and ragweed.

Smoking and Environmental Tobacco Smoke

Maternal cigarette smoking is a major risk factor for the development of asthma in the first year of life. The risk of developing asthma is roughly twofold in infants born to nonatopic mothers who smoke but increases to almost fourfold in infants of allergic parents with mothers who smoke. The predominant effect of maternal cigarette smoking is due to in utero exposure with decreased lung function at birth. A large population-based birth cohort study from Finland by Jaakkola and Gissler shows that infants of mothers who smoke carry increased risk of developing asthma through the first 7 years of life and only a small fraction of the effect during the first 7 years is mediated by fetal growth. It

is also clear that maternal cigarette smoke exposure is associated with a greater occurrence of lower respiratory tract infections.

ETS exacerbates asthma in children of all ages. Wilson and coworkers evaluated a cotinine-feedback behavioral intervention administered to caregivers which successfully reduced ETS exposure and health care utilization by children with asthma at one year follow-up. In adults, cigarette smoking is associated with the development of airway hyperreactivity. Whether this hyperreactivity represents asthma or COPD can be difficult to determine. Cigarette smoking in asthma produce a synergistic and accelerated decline in lung function. Additionally, the response to corticosteroid therapy used for asthma is reduced in active smokers.

Other Pollutants

Outdoor pollutants implicated in the development or exacerbations of asthma include ozone, sulfur dioxide, particulate matte, and components of motor vehicle exhaust. Measuring exposure to potential pollutants is difficult and correlating exposure with symptoms and exacerbations of disease is very expensive. Most monitoring of pollutants is from fixed external stations. Sometimes proxy measures of pollutant exposure, such as traffic counts, are used. Although potentially more accurate, monitoring of personal exposures is particularly difficult and expensive. Assessing which of the many possible simultaneous outdoor inhalants affects asthma morbidity is also a formidable task. Conclusions drawn from such data may be indirect. An example is the observation that asthma morbidity is highest among low-income individuals who tend to live in less desirable areas, which are frequently those with high traffic volumes and pollution.

There has been much interest in indoor environmental pollutants, such as nitrogen dioxide, sulfur dioxide, volatile organic compounds, and particulate matter, and their possible association with asthma, particularly in inner city homes. As with studies of outdoor pollution difficulties in measurement over time, controlling for other exposures such as allergens, infectious agents, and social determinants of health, while linking exposures to symptoms and physical findings makes research challenging.

Race/Ethnicity and Socioeconomic Status

Asthma prevalence and especially morbidity and mortality are higher in blacks than whites. Whether these racial differences in asthma prevalence, hospitalization, and mortality are solely due to inadequate treatment and access to medical care remains unclear, but there is indisputable evidence of unequal treatment of minority and low income groups by health professionals. Additionally, environmental factors that are the products of poverty, such as urban crowding, exposure to tobacco smoke or other pollutants or allergens contribute to these findings. In one recent paper, maternal exposure to community violence was related to asthma morbidity of children, even controlling for socioeconomic status, housing deterioration, and negative life events such as the death of a family member.

There is much current debate about the relative importance of social and genetic effects and/or gene-environment interactions that might account for the health disparity seen in asthma and other diseases. In most studies race and ethnicity are not well-defined and socioeconomic factors tend to be inseparably linked to ethnicity and race. Perceptions of a persons' race influence social experiences including those with the health system. In a recent survey, black and Hispanic women were more likely to report a doctor's diagnosis of asthma and less likely to report a diagnosis of hayfever or eczema. However, these women had higher mean total IgE levels and were more likely to be sensitized to aeroallergens. The investigators concluded that these findings could represent either under-diagnosis by medical personnel (e.g., fewer referrals to an allergist or other specialist) or under-reporting of symptoms by patients. They also concluded that it was unlikely that genetics alone could explain the differences in sensitization and that these differences more likely were related to differences in housing and community environmental exposures.

There are many ethnic groups within the United States for whom there is no information on asthma morbidity and access to care. It was noted earlier that minority status is missing from 25 percent of surveys of the National Hospital Discharge Survey. This survey finds Puerto Rican ethnic groups have very high morbidity from asthma, while recent studies have not shown the same effect in Mexican groups. Social effects might account for this difference among Hispanic groups. Non-Puerto Rican Hispanics are more likely to be illegal residents, making it less likely that these persons will seek medical care and, less likely that they will be counted in health statistics.

As our cultural and ethnic diversity increases, communication between patient and health care provider becomes more complicated and miscommunication more likely. Miscommunication may result in mistrust of the medical advice, or refusal of treatment and poor adherence and thus contribute to health disparities. Supporting this argument we found patients beliefs in the risks over the benefits of inhaled steroids to be associated with lower adherence. In focus groups, blacks with moderate or severe asthma reported their adherence was influenced by reliance on their own assessment of asthma control over that of the health provider. They expressed concern about adverse effects of inhaled steroid therapy and several had misperceptions of their risks. Such misperceptions can be addressed in the patient-provider encounter. Adherence was also adversely affected by the cost of the medication or its copay and insurers' approval policies and restricted formularies.

Obesity

Obesity has reached epidemic proportions in the United States and has been related to asthma in cross-sectional and longitudinal studies. A number of mechanisms for this

relationship have been proposed. A mechanical effect is postulated to be the result of decreased tidal volume and decreased functional residual capacity leading to reduced ability of the smooth muscles to stretch and thus respond to changes in respiration with exercise. Obesity enhances gastroesophageal reflux, a condition associated with asthma. Immune effects also have been postulated. For example, certain inflammatory cytokines such as tumor necrosis factor-α (TNF-α) and IL-6 are expressed by adipocytes. TNF expression is increased in asthma exacerbations and may have a role in amplifying the inflammatory response of asthma. IL-6 stimulates a Th1 response which may contribute to the inflammation of severe asthma. Leptin, a product of adipocytes, is a member of the IL-6 cytokine family. Whether or not leptin plays a role in asthma is unknown. Because asthma in adults is more common in women and because estrogen is increased in obesity, estrogen has been hypothesized to play a role in a link between asthma and obesity but no such role has been demonstrated.

Since asthma and obesity are both complex diseases, it is possible that some genetic susceptibilities are shared (pleiotropy). There is some evidence for this in that there are regions of the human genome important for both asthma and obesity, such as chromosome 6p, which contains the gene for TNF. Alternatively, it is possible that obesity is related to asthma as an epiphenomenon; that is, that there are shared lifestyle or social exposures, for example, physical exercise or diet, that influence both obesity and asthma. Obesity is more prevalent in the same socioeconomic groups in which asthma is more prevalent. No randomized interventional studies have been completed showing that weight reduction ameliorates asthma.. Clearly, more research is needed.

Respiratory Illness

There is a prominent association between lower respiratory tract viral infections and wheezing illnesses in infancy and increased risk of chronic childhood asthma. Respiratory syncytial virus (RSV) has drawn particular attention, since it is the major cause of bronchiolitis in children and RSV infection is associated with IgE production, airway inflammation, and increased airway responsiveness. Severe RSV bronchiolitis in infancy is associated with the development of chronic wheezing in later life. Respiratory tract infections by rhinoviruses, parainfluenza viruses, influenza virus, and human metapneumovirus during infancy are all associated with childhood wheezing.

It is hypothesized that susceptibility to asthma associated with viral infection in early life results from the interaction of developmental, genetic, and environmental factors. Developmentally, infancy is a time of pulmonary alveolarization and a time when the immune system has not reached full maturity. It has also been observed that most children who wheezed before 2 years of age had few if any respiratory symptoms when studied 3 to 5 years later.

Atopic status and bronchial hyperreactivity may be important genetically determined characteristics that influence whether RSV or other respiratory viral infections increase the risk of developing asthma. Most children who wheezed only during the first 2 years of life had lower levels of lung function when evaluated at age 2 and 6 years. In contrast, children who wheezed early in life and who were still wheezing at age 6 years had normal lung function, but statistically elevated serum total IgE levels when studied during the first year of life. When restudied at age 6 years, they had elevated IgE, but lung function had deteriorated and was below that of individuals who had never wheezed. This has led to the hypothesis that there are two wheezing syndromes associated with lower respiratory tract infection in young children. One occurs in children with small airway caliber who lack bronchial hyperresponsiveness, and have excellent prognosis. The other syndrome, which represents early-onset asthma, is associated with increased prevalence of allergic markers, bronchial hyperreactivity, and a significant decrease in lung function over the first 6 years of life. RSV bronchiolitis is most prominently associated with the development of asthma in patients with a concomitant family history of atopy and/or asthma.

Viral respiratory illnesses trigger asthmatic exacerbations. A number of studies have demonstrated a close temporal relationship, at the individual and population level, between virus infection and asthma exacerbations. These studies have also demonstrated that: (1) in contrast to viral, bacterial infections are not associated with asthmatic exacerbations; (2) viruses precipitate a high percentage of severe (versus mild) asthmatic exacerbations; and (3) viral infections can induce nonspecific increases in airway responsiveness and airway obstruction in children.

PROGNOSIS

The prognosis of asthma in early childhood has been clarified substantially by data from the Tucson Epidemiologic Study. These investigators followed a cohort of children through the first 6 years of life. They characterized four groups of children: "persistent wheezers," who wheezed both before and after the age of 3 years; "transient early wheezers," who wheezed before the age of 3 years and then stopped; "transient late wheezers," who wheezed after age 3 years but not before; and "never wheezers." Fully 40 percent of all children in the Tucson Epidemiologic cohort wheezed in the first year of life.

Significant predictors of persistent wheezing, and hence children at greatest risk for developing chronic asthma, were young maternal age, IgE level at 9 months, parents with asthma, maternal cigarette smoke exposure in utero, abnormal lung function at birth, and male gender. It is likely that early-life wheezing is predominantly a mechanical factor and less due to severe and chronic airway inflammation. It also seems unlikely that allergen exposure predominates as a factor in early childhood.

The characteristics of older children who wheeze are atopy, female gender, and active and passive cigarette smoking. By preadolescence, atopy and environmental allergen exposure are important risk factors for wheezing in children.

In roughly half of all childhood asthmatics, symptoms decrease or disappear by late adolescence and early adulthood. Characteristics that suggest a good prognosis include male gender, precipitation of attacks by viral respiratory illness, and children with airway parenchymal desynapsis (i.e., large lungs but small airways). These children are predominantly male, and, although often atopic, still are likely to outgrow their asthma. In a longitudinal study of children initially 5 to 9 years of age followed over a 13-year period, the effect of asthma on lung growth was different for boys than girls. Boys with asthma had larger growth in vital capacity than boys without asthma and tended to have mild disease. This was associated with fewer hospitalizations for asthma, despite somewhat greater prevalence than in girls. Asthmatic girls, however, had persistent reductions in FEV_1 and were more likely to be hospitalized for asthma, despite an initially reduced prevalence relative to the boys. These data are consistent with asthma being milder in boys in that the boys are more likely to "outgrow" their asthma. Existing data suggest that atopy per se is not a risk factor for asthma persistence. In older adults, airway responsiveness predicts the development of asthma and antedates and predicts accelerated decline in lung function. Active cigarette smoking further increases the risk of asthma in older adults. Several studies suggest that asthma in adults with or without active cigarette smoking is associated with the development of fixed airflow obstruction. The severity of adult asthma is clearly predicted by the severity of childhood asthma, and the persistence of symptoms in childhood and early adulthood is associated with reduced lung function and more severe disease in later adult life.

IMPLICATIONS OF CURRENT TRENDS IN PREVALENCE, MORBIDITY, HOSPITALIZATIONS, AND MORTALITY

Although prevalence, morbidity, and hospitalizations have remained stable recently, these absolute levels remain unacceptably high, particularly for certain minority groups and low-income populations. Risk factors such as obesity, prematurity, young maternal age, and cigarette smoking are all associated with these same patient groups, speaking to social and health care disparities. There are many vulnerable groups for which no data on asthma prevalence and morbidity yet exist. Certainly, genetic differences exist from patient to patient. These differences must be better characterized. Understanding the influence of gene-gene and gene-environment interactions is crucial. Gene-environmental interactions must be carefully studied for all exposures, and particularly for the exposure of socioeconomic status and cultural groups.

ACKNOWLEDGMENTS

We gratefully acknowledge the Air Pollution and Respiratory Health Branch, National Center for Environmental Health, CDC, for production of Figs. 48-1, 48-2, and 48-4. We particularly would like to thank Jeanne Moorman, MS, for her help with the figures and review of relevant parts of the chapter, and Anyana Banerjee for helping to guide us to relevant data. We also would like to thank Lara Akinbami, MD, National Center for Health Statistics, for her assistance and for the National Center for Health Statistics for production of Fig. 48-3. We greatly acknowledge the careful review and suggestions of Arnold I Levinson, MD.

Aspirin- and Exercise-Induced Asthma

Gregory P. Geba

Asthma is well known to be triggered by specific immune factors such as aeroallergen exposures. There are, however, several important nonallergic triggers for the development of asthmatic bronchial obstruction. Two of the most important are aspirin and related nonsteroidal anti-inflammatory drugs (NSAIDs), and exercise. Both of these can provoke airway responses in individuals with established symptomatic aeroallergen-induced asthma or, in some instances, seem to occur in isolation. These two nonspecific triggers may also share pathophysiological mechanisms, including mast cell and leukotriene mediation and appear to be, in part, related to vascular responses that may mediate the airway narrowing.

ASPIRIN-INDUCED ASTHMA

The first report of aspirin-induced asthma (AIA) was made by Hirschberg in 1902. Six decades later, the association between aspirin sensitivity, asthma, and nasal polyps was documented in a classic paper by Samter and Beer. In 1928, the clinical importance of sensitivity to aspirin was highlighted by van Leewen, who challenged 100 asthmatics with aspirin, provoking bronchoconstriction in 16. Several others have made similar observations, documenting a prevalence of aspirin sensitivity in asthmatics that ranges from 5 percent to as high as 30 percent, depending on the characteristics of the asthmatics studied (severity increases risk) and the criteria applied to make the diagnosis.

Aspirin was the first drug recognized to be capable of precipitating asthma. With the development of other analgesic and NSAIDs after 1950, these related agents were also implicated in exacerbations of asthma. In a study of 781 asthmatics observed over a period of 2 years, drugs were found to provoke asthmatic airway responses in 10.5 percent of the patients. Reactions to NSAIDs were thought to be responsible for 77 percent of the exacerbations, with aspirin accounting for two-thirds of the reactions to NSAIDs, or nearly 50 percent of all instances of drug-induced asthma. Thus, although aspirin is the most common drug to induce asthma and the most common NSAID to cause asthma, other NSAIDs are responsible for an important number of attacks of asthma.

Clinical Presentation

Reactions to aspirin can take two distinct forms: *cutaneous*, leading to urticaria and angioedema, and *respiratory*, resulting in rhinoconjunctivitis and bronchospasm. In the former, a subpopulation of patients with established urticaria experienced cutaneous flares of hives with or without angioedema after ingesting NSAIDs. Almost all of these patients were able to ingest the same NSAIDs before the development of urticaria, suggesting that the NSAIDs interact with an underlying urticarial process but do not directly and independently cause the hives. Therefore, avoiding the ingestion of NSAIDs does not eliminate the urticarial syndromes experienced by these patients. In contrast, a small subgroup of patients experienced hives exclusively *after* exposure to these

drugs, without an antecedent history of underlying chronic urticaria. It is postulated, although, not proven, that such patients manifest immunoglobulin E (IgE)-mediated immune responses to some NSAID-related antigen. NSAID avoidance therefore is an effective treatment for urticaria in these patients.

In general, the upper (nasal) and lower (asthma) respiratory manifestations of aspirin sensitivity are generally temporally linked, although sometimes upper respiratory symptoms, typically rhinitis, precede the development of lower respiratory asthmatic reactions to these agents. AIA can occur upon a background of established asthma or can appear de novo without previous symptoms of asthma. This observation has led to the use of more accurate descriptors for this condition such as: aspirin-*intolerant* asthma or aspirin-*exacerbated* respiratory disease (AERD); the latter is used to account for the full spectrum of respiratory symptoms that can be provoked by aspirin.

Clinically, patients often first present with what appears to be an upper respiratory tract illness of viral origin leading to persistent inflammation of the nasal mucosa and paranasal sinuses, which becomes chronic. Chronic nasal inflammation is characterized by impressive mucosal eosinophilic infiltration which frequently leads to the development of nasal polyps. These patients usually cannot be distinguished from asthmatics with sinusitis and nasal polyps until the relationship is established between the ingestion of aspirin or related compounds and exacerbation of asthma. Although nasal polyps were originally described by Samter as part of the classic triad, it is becoming increasingly evident that polyps are often absent. In contrast, almost all cases present with sinusitis. Opacification of one or more sinuses on plain radiographs can be seen in some 90 percent of these patients; an even higher prevalence of sinus disease may be detected by computed tomography (CT) sinus scans that typically show mucosal thickening and, sometimes, air-fluid levels.

Many patients with AIA are not atopic; aeroallergen skin testing is positive in 30 to 60 percent of these patients, but skin tests are negative. For many, IgE levels are in the normal range. The search for NSAID-specific IgEs is often unsuccessful. Furthermore, after acute challenge with aspirin, patients with AIA do not develop blood eosinophilia and fail to produce detectable increases in blood histamine or in complement activity; such increments occur following acute aeroallergen challenge of atopic asthmatics, suggesting that atopic mechanisms are not primarily responsible for the development of this syndrome.

The typical reaction after aspirin ingestion by patients with AIA is the slow development (within 30 min to 4 h, mean 50 min) of nasal congestion with profuse rhinorrhea, cutaneous flushing of the head and neck, mild conjunctivitis, and bronchial obstruction, usually manifested as wheezing. A typical reaction provoked by an oral challenge under laboratory conditions is illustrated in Fig. 47-1. In severe

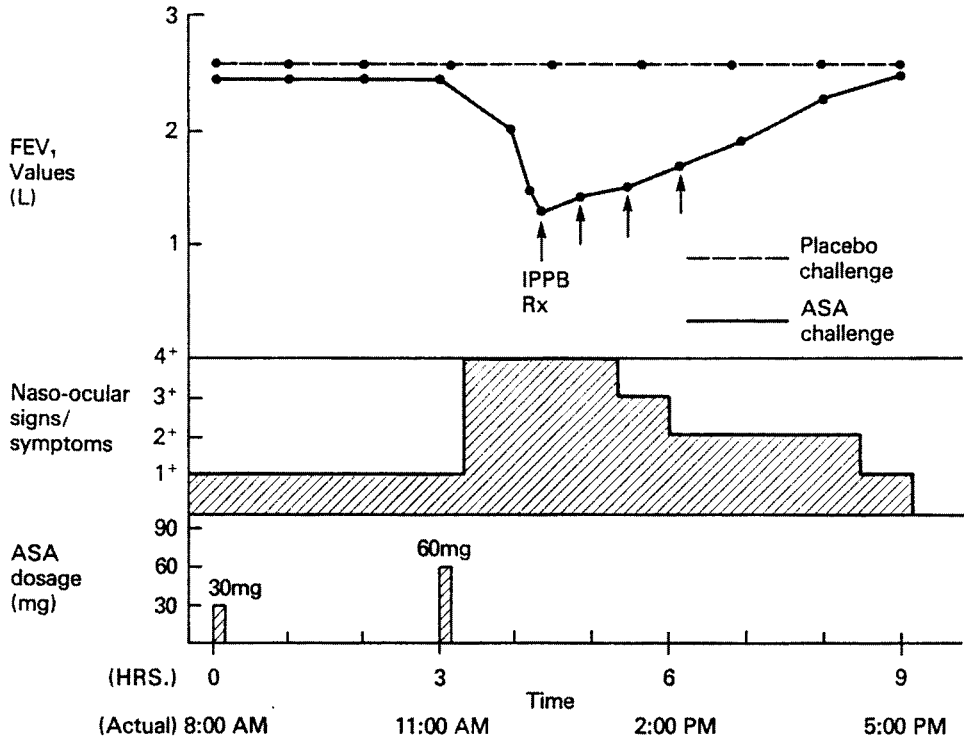

Figure 47-1 Typical reaction to aspirin in AIA. The timeline illustrates the kinetics of respiratory compromise and naso-ocular symptoms after graded aspirin or placebo challenge. IPPB = intermittent positive-pressure ventilation with β-adrenergic agonist bronchodilator. *(Based on data of Stevenson DD, Simon RA: Aspirin sensitivity: Respiratory and cutaneous manifestations, in Middleton E Jr, et al (eds),* Allergy: Principles and Practice. *St. Louis, CV Mosby, 1993, pp 1747–1767.)*

reactions, headache, nausea, and vomiting and acute hypercarbic respiratory failure can occur, culminating in death. Life-threatening responses with faster kinetics have also been reported after systemically administered NSAIDs, such as ketorolac. Combined cutaneous and respiratory reactions (i.e., true urticarial eruptions in association with asthma) occur in less than 3 percent of cases.

Genetics

In contrast to classic atopic asthma, which patients usually develop before the age of 20, AIA typically occurs in individuals in the fourth decade of life. Thus, AIA appears to be an acquired disease. In general, these patients do not have a prior history of exposure and potential sensitization to NSAIDs. Familial predisposition is also rare; in one study a positive family history was noted in only 2 of 500 patients. Men and women are affected equally. Despite the lack of familial association, one study did show an increase in the expression of HLA-DQw2 in one group of such patients. A later study in European patients showed increased expression of HLA-DPB1*0301 (odds ratios [OR]: 4.4 and 5.3) and decreased expression of DPB1*0401 (OR: 0.42 and 0.49) in AIA versus normals and nonaspirin-sensitive asthmatics, respectively. Korean investigators confirmed a higher risk of AIA in patients carrying HLA-DPB1*0301, whereas individuals who carried HLA-DRB1*1302 and/or DQB1*0609 exhibited a higher risk of aspirin-induced urticaria.

Other studies have implicated up-regulation of the expression of leukotriene C_4 (LTC_4) synthase which was found to be increased in blood eosinophils of patients with AIA. In Europeans, single nucleotide polymorphism (SNP) resulting from an A-444C transversion seemed to be associated with increased expression of the LTC_4 synthase and a higher relative risk of AIA (2.62; 95 percent CI: 1.38, 4.98). More recently, the same group showed a functional and gender association of the G-765C polymorphism in the cyclooxygenase-2 (COX-2) promoter region in AIA patients with severe disease. Another group in Japan found a functional promoter polymorphism for the TBX21 gene, the human analog for the T-bet gene in mice; absence of this gene had previously been shown to result in airway eosinophilia and hyperresponsiveness. The polymorphism –1993T-C SNP was in linkage disequilibrium with a synonymous coding 390A-G SNP in exon 1, and was significantly associated with AIA. Others have observed increased transcription or polymorphisms in the 5-lipoxygenase activating protein (ALOX5AP) gene in AIA. New insight may result from the recent observation of selective expression in AIA patients of cysteinyl leukotriene type 2 receptor, but not type 1 receptor, expressed by infiltrating inflammatory cells of the upper airway; this expression was not observed in aspirin-sensitive patients with chronic allergic rhinitis or in normals. Taken together, although much more remains to be discovered, AIA may be a disease with multiple genetic associations, a disease that depends on gene-environment interaction for its expression. A genetic predisposition in individuals who are also exposed to certain environmental factors appears to be required to produce the full manifestations of the disease.

Cross-Reactivity

Cross-reactivity of aspirin with other NSAIDs was first recognized in 1967 by Vanselow and Smith. This report was followed by others of reactions to structurally unrelated NSAIDs, which suggested that these reactions were not atopic. It was subsequently shown that the ability of these drugs to provoke asthma in susceptible patients was related to their ability to inhibit cyclooxygenase and that the degree of cross-reactivity with aspirin was related to the degree to which these agents inhibited cyclooxygenase in vitro. Subsequently the discovery of isoforms of cyclooxygenase have revealed that the dominant form that is inhibited by low doses of aspirin, and capable of eliciting airways responses in AIA, is cyclooxygenase-1 (COX-1). Drugs that are less potent inhibitors of COX-1 but are structurally related to aspirin (e.g., sodium salicylate) at clinical doses do not provoke AIA.

The association of AIA with the COX-1 isoform of the enzyme has been buttressed by studies performed with recently available specific inhibitors of COX-2, which, in clinical doses, nearly completely spare inhibition of COX-1. In two separate studies it has been shown convincingly that selective inhibitors of COX-2 (celecoxib and rofecoxib) do not provoke airway changes typical of AIA in patients known to have the disorder, or in those challenged in the laboratory de novo in the process of diagnosing the disease.

Szczeklik et al challenged 12 known AIA patients with 12.5 and 25 mg of rofecoxib (typical doses given daily for arthritis) who failed to manifest a response physiologically and did not exhibit the increase in urinary leukotriene E_4 (LTE_4) levels expected after aspirin challenge. Stevenson and Simon performed a larger study, which involved 60 patients with documented AERD who received 12.5 and 25 mg of rofecoxib; none reacted. A follow-up study, using highest single doses of rofecoxib reserved for acute pain of limited duration, found that none reacted. Similar data is available for celecoxib at the highest clinical doses. Dahlen et al challenged 27 patients with AERD with doses up to 200 mg of celecoxib without reaction. Even higher doses (400 mg) used by Gyllfors et al were also tolerated by patients with AIA without airway changes (Fig. 47-2) or increases in urinary LTE_4 levels. A list of NSAIDs reported to provoke AIA, and those not associated with AIA, is given in Table 47-1.

A number of other analgesics have long been thought to be well tolerated in patients with AIA. They are also listed in Table 47-1. However, some analgesics formerly considered to be safe for use by patients with AIA were subsequently shown to be capable of provoking bronchospasm if given in large doses. For example, acetaminophen, in doses generally greater than 1000 mg and salicylate, in doses of 2000 mg or more, can provoke significant decreases in forced expiratory volume in 1 second (FEV1) in some aspirin-sensitive asthmatics. Reactions to high doses of these drugs, when they occur, tend to be milder than the reactions seen with aspirin.

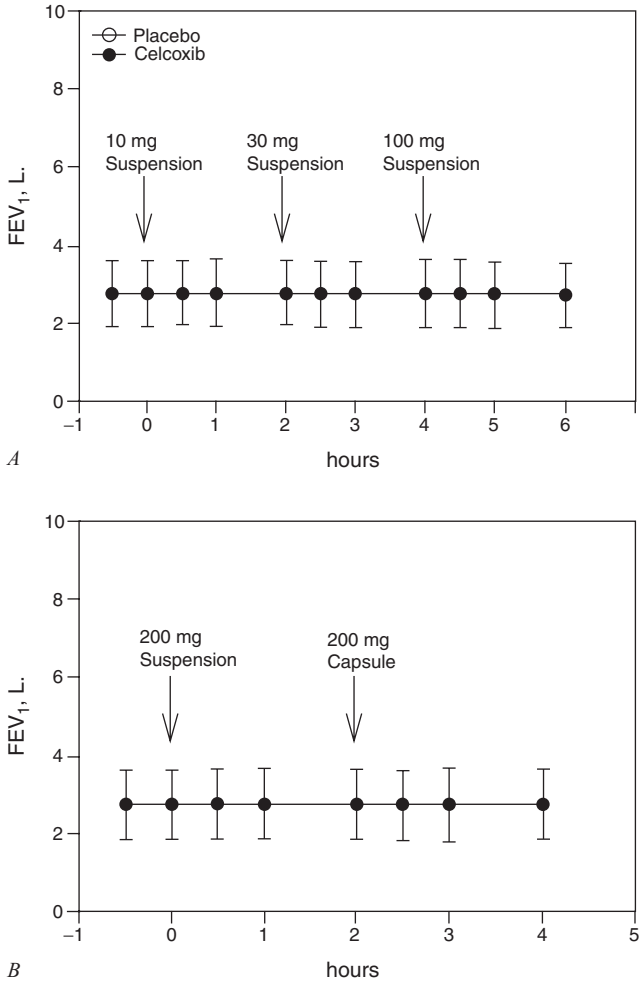

Figure 47-2 Lack of airway bronchoconstriction to increasing doses of a COX-2 inhibitor in aspirin-sensitive asthmatics. FEV_1 measured before and after oral challenge. *Panel A:* Double-blind crossover challenge. *Panel B:* Open label challenge. *(From Gyllfors P, et al: Biochemical and clinical evidence that aspirin-intolerant asthmatic subjects tolerate the cyclo-oxygenase 2-selective drug celecoxib.* J Allergy Clin Immunol *111:1116–1121, 2003.)*

A similar phenomenon has been observed with meloxicam and nimesulide, drugs that inhibit COX-2 somewhat more than COX-1. At typical low clinical doses, they appear to be well tolerated in patients with AIA, however at high doses, cross-reactions may occur.

It is important to note that reactions to NSAIDs (including aspirin, as well as COX-2 selective inhibitors) may be the result of prior sensitization to these drugs and the formation of NSAID-specific IgE antibodies. After a period of sensitization, patients may experience anaphylactic reactions to the specific NSAID; the reactions may manifest as wheezing, urticaria, angioedema, and in some instances, severe, life-threatening hypotension. Although this condition is much less common than non-IgE–mediated reactions to NSAIDs and aspirin which tend to occur after first exposure, it should be considered in the differential diagnosis in an appropriate clinical situation. Avoidance of the causative NSAID prevents relapses.

Table 47-1

NSAIDs in Aspirin-Induced Asthma (AIA)

NSAIDs that Can Provoke Airway Narrowing in AIA

- Carboxylic acids
  - Salicylates
    - Acetylsalicylic acid (aspirin, Easpirin, Zorpin)
  - Acetic acids
    - Indomethacin (Indocin)
    - Sulindac (Clinoril)
    - Tolmetin (Tolectin)
    - Diclofenac (Voltaren)
    - Ketorolac (Toradol)
    - Zomepirac (Zomax)
  - Propionic acids
    - Ibuprofen (Motrin, Advil, Nuprin)
    - Naproxen (Naprosyn)
  - Fenamates
    - Meclofenamate (Meclomen)
    - Mefenamic acid (Ponstel)
  - Enolic acids
    - Piroxicam (Feldene)

NSAIDs and Analgesics that Appear to Be Well Tolerated in AIA

- Sodium salicylate
- Choline salicylate
- Salicylamide
- Dextropropoxyphene
- Acetaminophen in low doses
- Selective COX-2 inhibitors

Although it was initially believed that tartrazine dyes were capable of provoking asthma exacerbations in patients with AIA, this has not been confirmed by further study. Tartrazine doses of 25 to 50 mg, used in a double-blind challenge of patients with proven AIA, did not provoke detectable changes in lung function. This observation supports the view that tartrazine intolerance is extremely rare and that true cross-reactivity with aspirin probably does not exist. Similar conclusions can be drawn regarding the cross-reactivity of other FD&C dyes, sodium benzoate, other benzoic acid derivatives, monosodium glutamate, and sodium and potassium sulfites. None of these agents has been associated with inhibition of COX-1, suggesting that their previous association with the syndrome may have been purely the result of serendipity.

An interesting association has been made of AIA with sensitivity to hydrocortisone. Several case reports were followed by two larger studies demonstrating that a small percentage of patients with AIA may experience acute bronchospasm (15 to 30 min) after the intravenous or intramuscular injection of hydrocortisone. The vehicles and diluents used in the hydrocortisone preparations could not

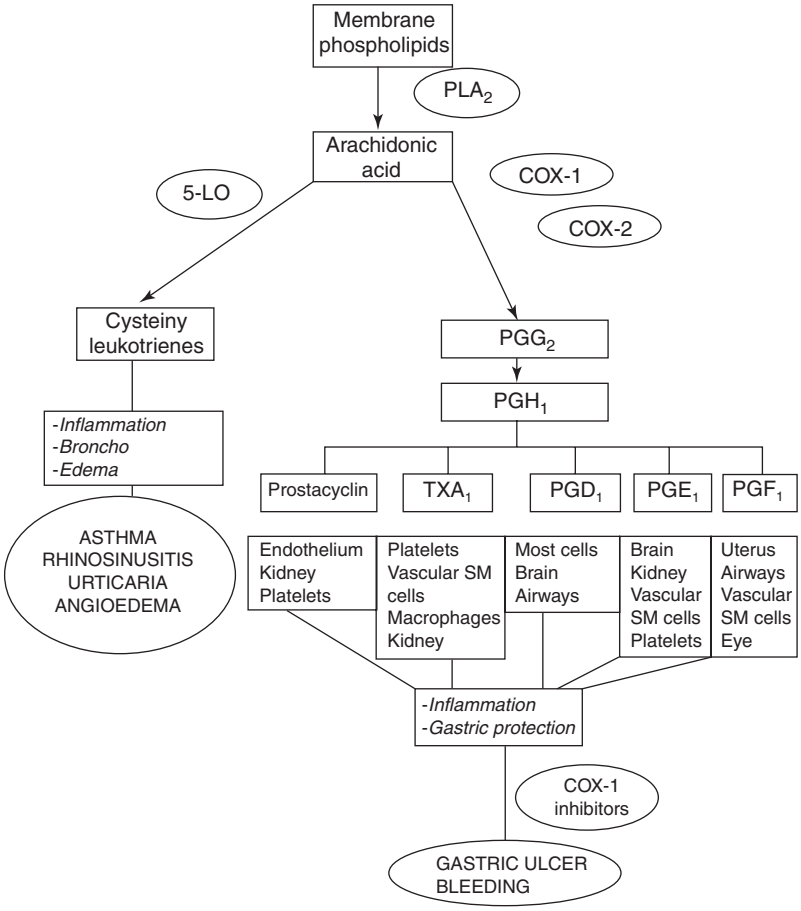

Figure 47-3 Enzymatic pathways of arachidonic acid metabolism. (*From Sanchez-Borges M, et al: Cutaneous reactions to aspirin and nonsteroidal anti-inflammatory drugs.* Clin Rev Allergy Immunol *24:125–135, 2003.)*

be linked to the reactivity. One of these studies showed no bronchoconstrictor response to methylprednisolone, dexamethasone, or betamethasone when given intravenously, demonstrating that these potent anti-inflammatory steroid preparations, related to hydrocortisone but with different chemical structure of their side chains, could be used safely. The mechanism of this reaction is not known, though corticosteroids can reduce phospholipase A_2 (PLA_2) activity (generally decreasing eicosanoid production) and broadly inhibit isoforms of cyclooxygenase, especially COX-2.

Pathogenesis

Although understanding of the genetic predisposition to AIA and identification of provoking agents has increased over the last 5 years, the pathophysiological basis of AIA continues to be a subject of considerable study and is not yet solved, so that initiating and propagating stimuli of this condition are still not known. The dominant theory points to an alteration in the balance between leukotrienes and prostaglandins generated by the lipoxygenase– and cyclooxygenase–dependent pathways of arachidonic acid metabolism. Other attempts to explain the spectrum of symptoms are based on the release of other mediators, most likely from mast cells, basophils, or platelets. These theories include up-regulation of releasability of mast cell-basophil mediators by unknown substances that affect mast cell membranes, greater production than normal of histamine by basophils of patients with AIA, decreased production of prostaglandin E_2 (PGE_2) and enhanced production of leukotriene B_4 (LTB_4) by AIA basophils, and enhanced aspirin-induced release of serotonin and other mediators by AIA platelets. It has been proposed that complement activation may play an important role in these processes. However, the role of complement activation in AIA has been questioned by data that show no significant changes in CH_{50} and C_4 levels in patients who experience an exacerbation of asthma after acute oral aspirin challenge.

Alterations in arachidonic acid metabolism appear to play a central role in AIA. The major pathways of cyclooxygenase and lipoxygenase metabolism of arachidonic acid are illustrated in Fig. 47-3. Arachidonic acid is derived from membrane phospholipid by PLA_2. It is then metabolized via the cyclooxygenase pathway to prostaglandins (COX-2 more than COX-1) and thromboxanes (COX-1 more than COX-2) or via the lipoxygenase pathway to sulfidopeptide (cysteinyl) leukotrienes. The leukotrienes have a variety of effects, including the induction of contraction of bronchial smooth muscle. In contrast, the prostaglandins, in particular PGE_2, act as bronchodilators and may inhibit T- cell–mediated inflammatory responses in the lung. Aspirin and the other NSAIDs that cause AIA inhibit COX-1 activity. A shift occurs after the administration of aspirin or appropriate doses of the other

agents, shunting approximately 90 percent of the arachidonic acid metabolism to the 5-lipoxygenase pathway, decreasing prostaglandin and thromboxane production, and increasing leukotriene generation. In comparison to normal individuals, patients with AIA generate leukotrienes in inordinate quantities after aspirin challenge. Discovery that patients with AIA produce less of the anti-inflammatory mediators lipoxin and 15-epimer lipoxin might enhance effects of this shift. Patients with AIA may also be more sensitive than normal subjects to the bronchoconstrictor properties of leukotrienes (particularly LTE_4) and more susceptible to the loss of the bronchodilating, and potentially anti-inflammatory, effects of PGE_2. The data supporting these conclusions are briefly summarized below.

Several groups have analyzed the nasal lavage fluid from aspirin-sensitive and control patients and found inducible levels of cysteinyl leukotrienes and plasma proteins when patients with AIA were challenged with oral or nasal aspirin. One study found that LTC_4 and LTD_4 levels were not significantly increased in normal subjects, but could be induced to some degree in patients with allergic rhinitis and in those with isolated nasal polyps (increasing by 93 and 69 percent, respectively, above baseline levels). Similarly, although histamine levels increased significantly in the AIA group (greater than threefold increase in total protein) the levels did not increase significantly in the control groups. Analysis of the nasal lavage fluids showed impressive increases in lactoferrin and lysozyme, suggesting that submucosal glands are stimulated by the challenges.

In a follow-up study, the cellular source of these nasal abnormalities was investigated by analysis of nasal lavage fluids induced by aspirin challenge for the presence of mast cell tryptase and eosinophil cationic protein (ECP). Significant increases in nasal tryptase, histamine, and cysteinyl leukotrienes were observed after AIA was provoked in these patients. ECP levels at baseline were variable and did not increase significantly after challenge. These results support the idea that after aspirin challenge, the leukotrienes in the nasal secretions of patients with AIA are probably of mast cell origin. They also suggest that eosinophils are not as important as mast cells in the pathogenesis of the nasal manifestations of AIA. These findings are consistent with earlier work that showed similar increases in *blood* tryptase (4 h) and *urinary* LTE_4 levels (6 h) and decreases in blood eosinophil counts ($p < 0.01$) (6 h) after aspirin challenge.

The metabolism of arachidonic acid in the lung has not been studied as extensively. The available data show both similarities and differences with findings in the nose and circulation. For example, bronchoalveolar lavage fluid (BALF) obtained 30 min after inhalation of threshold doses of lysine-aspirin contained depressed levels of cyclooxygenase-dependent mediators (PGE_2, PGD_2, thromboxane B_2 (TXB_2), and $PGF_{2\alpha}$). However, only small increases occurred in LTE_4 and 5-hydroxyeicosatetraenoic acid (HETE) levels. Lysine-aspirin inhalation also did not elicit a significant increase in tryptase levels in the BALF and led to a significant fall in ECP levels even though baseline eosinophil and ECP levels were higher in the AIA group than in the placebo-treated nonasthmatics. The authors postulated that the altered pulmonary eicosanoid production might be related to the eosinophilic inflammation in the airways of patients with AIA. In order to dissect further the mechanism of bronchospasm in AIA, a number of investigators used inhibitors of leukotriene effector function. The first administered a specific sulfidopeptide leukotriene receptor antagonist via inhalation and noted that it attenuated AIA in five of six subjects by 43 to 74 percent. This was followed by a double-blind, placebo-controlled, crossover study that showed that a specific leukotriene receptor antagonist, given in a single oral dose 1 h before provocative challenge with perithreshold lysine-aspirin inhalant, could almost completely block the development of aspirin-induced bronchospasm. This was achieved without evidence of any direct bronchodilatory effect of the drug before lysine-aspirin challenge, confirming that leukotriene receptor antagonist was effective in preventing analgesic-induced (dipyrone) bronchospasm.

Leukotriene effects in the lung can also be modulated by blocking 5-lipoxygenase activity. The efficacy of this approach was demonstrated in a randomized, double-blind, crossover study in which the 5-lypoxygenase inhibitor zileuton (600 mg orally, 4 times a day, for 6 to 8 days before aspirin challenge) led to a greater than 70 percent reduction in the baseline excretion of urinary LTE_4, a greater than 60 percent reduction in mean maximal urinary concentration of LTE_4 after aspirin challenge, and almost complete suppression of subthreshold and threshold oral aspirin-induced bronchospasm. In addition, naso-ocular, gastrointestinal, and dermal symptoms were reduced to the levels of symptoms produced by placebo challenge. Similar data have been generated with the cysteinyl leukotriene receptor antagonists montelukast and zafirlukast.

In summary, although the mechanism of AIA remains incompletely understood, there appears to be a clear role for lipoxygenase products in the pathogenesis of the disorder. The available data also suggest that mast cells, stimulated by aspirin directly or indirectly, discharge their leukotriene mediators in large amounts into nasal secretions but may not play the same role in the lung. The presence of increased numbers of eosinophils and altered eosinophil phenotype may be more relevant to the pathophysiology in the lung, linked to the airway inflammation that characterizes this disorder. The increased number of these cells probably reflects their recruitment secondary to the release of mast cell–derived mediators, including leukotrienes and cytokines.

Diagnosis

Although some promise exists for the development of in vitro tests to identify patients with AIA based on differential in vitro and platelet responses to aspirin and NSAIDs, these methods have not yet been validated for routine use. AIA is still diagnosed by in vivo testing using placebo-controlled

Table 47-2

Diagnosis of Aspirin-Induced Asthma: Aspirin (ASA) Challenge Protocols

Single-Blind Oral 3-Day Aspirin Challenge

		Test days	
Time	1	2	3
0	Placebo	ASA 30 mg	ASA 100–150 mg
3 h	Placebo	ASA 45–60 mg	ASA 150–325 mg
6 h	Placebo	ASA 60–100 mg	ASA 325–650 mg

Double-Blind Oral Aspirin Challenge

Both tester and patient are blinded to eliminate potential bias.

Bronchial Challenge with Lysine-Aspirin

Time (Min)	Challenge (Lysine-aspirin in mg/ml)
0	Placebo
45	Placebo
90	11.25
135	22.5
180	45
225	90
270	180
315	360
350	360 (10 breaths)

Patients receive four breaths of all doses of lysine-aspirin unless otherwise indicated.

oral challenges of persons suspected of having this disorder (Table 47-2). This testing can be performed according to published protocols using single-blind or double-blind approaches. These protocols generally begin with a 3-mg dose of aspirin, although higher initial doses (30 mg) have been recently advocated since, if reactions occur at this dose, they are easily treated. The dosage is then increased to a maximum of 650 mg over a 3-day period. Spirometric pulmonary function is monitored serially during the challenge to assess the degree of bronchial constriction. Airway reactivity to methacholine is not a viable surrogate for spirometry, since aspirin does not consistently alter methacholine sensitivity. Aspirin challenge should probably be reserved for use in research centers experienced with its application and adverse effects. An alternative to oral challenge, used in some centers in Europe for the diagnosis of AIA, and increasingly elsewhere, is the inhalation of stabilized lysine-aspirin, followed by serial lung function measurements, or nasal provocation with aspirin or lysine-aspirin followed by serial rhinomanometry or acoustic rhinometry. Currently, lysine-aspirin is not yet available for clinical use in the United States.

Treatment

Optimal treatment of patients with AIA requires knowledge of the proper approaches to treat acute aspirin-induced bronchial symptoms and associated nasal and sinus pathology. No specific therapy has emerged that can be recommended for the routine treatment of acute bronchospasm provoked by NSAIDs. It has been stated that corticosteroids are not effective after acute aspirin ingestion, and that theophylline and cromolyn sodium play no definite role. Treatment of symptoms after acute ingestion therefore relies mainly on β-adrenergic agonists to reverse bronchospasm, and topical vasoconstrictors for both nasal congestion and eye symptoms. Frequent applications of these agents usually are necessary to maintain nasal and airway potency over the 2- to 6-h duration of the reaction.

On a chronic basis, the treatment of AIA depends on the correct diagnosis and avoidance of aspirin and other cyclooxygenase inhibitors that could cross-react to induce acute bronchospasm. Patients should be instructed that many over-the-counter medications contain aspirin or other

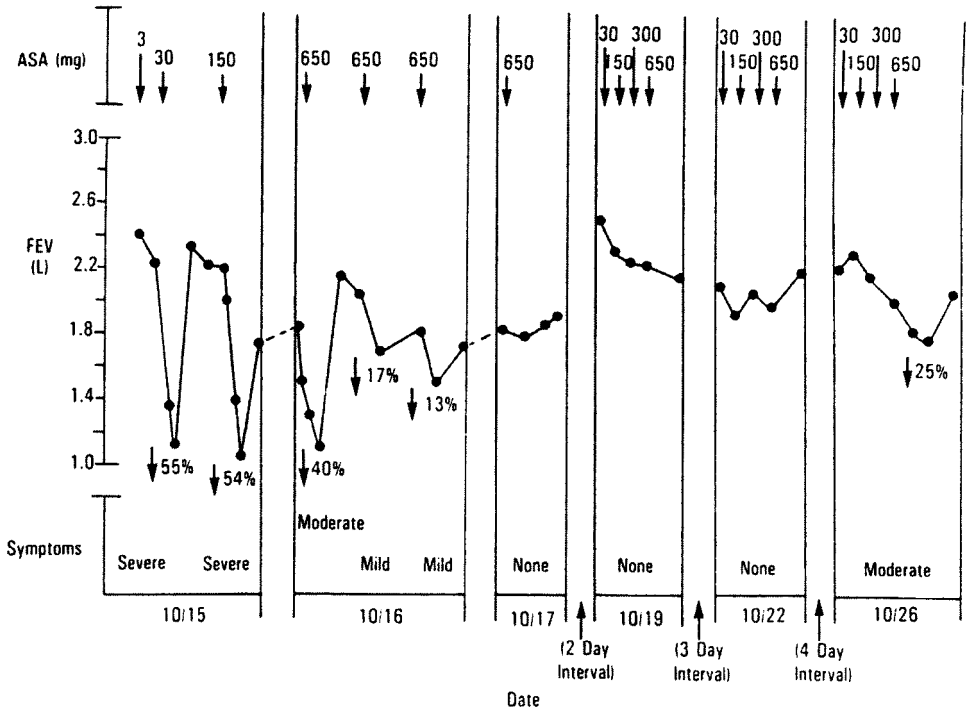

Figure 47-4 Airway desensitization to aspirin challenge in AIA. Timeline of respiratory function and overall symptoms after serial aspirin dosing. The reappearance of respiratory compromise and symptoms after 4 days without aspirin shows the need for continuous aspirin administration to maintain desensitized state. *(Based on data of Pleskow WW, et al: Aspirin desensitization in aspirin-sensitive asthmatic patients: Clinical manifestations and characterization of the refractory period.* J Allergy Clin Immunol *69:11–19, 1982.)*

NSAIDs, and they should carefully read package inserts before using any medication.

Drug treatment of AIA should focus on treating the underlying asthma and the strict avoidance of aspirin and cross-reacting NSAIDs. Currently there also appears to be no role for systemic corticosteroids or theophylline in the prevention of AIA. Some investigators have found that antihistamines, such as clemastine and mast cell stabilizers such as ketotifen, cromolyn and nedocromil, can be effective prophylactically. However, not all subjects who are taking these drugs are protected against bronchoconstriction after aspirin challenge. The 5-lipoxygenase inhibitor zileuton was not found to be effective in preventing FEV_1 decline or naso-ocular reactions to direct aspirin challenge, although it had been shown in a previous study to improve chronic asthma symptoms when added to conventional therapy. In contrast, experience with the cysteinyl leukotriene receptor antagonists has been variable, but mostly positive and may be more effective in those who carry the variant C allele of LTC_{4S} than in noncarriers. Pretreatment with inhaled or systemic steroids or long-acting β-agonist (salmeterol) was shown to at least partially attenuate decrements in aspirin-induced respiratory lung function. The failure of tacrolimus (0.1 mg/kg) (a drug that could potentially affect both T-cell–generated cytokine responses and prevent release of mast cell histamine and leukotrienes) to prevent aspirin-induced respiratory reactions in patients with AERD on aspirin challenge suggests that this agent cannot be relied upon to prevent reactions to aspirin-intolerant asthmatics and cannot be used to facilitate "silent" aspirin desensitization in the patient with AERD.

In individuals in whom aspirin (or cross-reacting NSAIDs) cannot be avoided (i.e., in the setting of cardiovascular prophylaxis) or the efficacy of prophylactic measures cannot be assured, aspirin "desensitization" can be considered. Protocols are available for selected patients (Fig. 47-4). These methods can effectively protect many from experiencing symptoms on exposure to aspirin or NSAIDs and will maintain this level of desensitization as long as aspirin, in doses of 325 to 650 mg a day, is continued. In a study of 25 aspirin-sensitive asthmatics, such therapy decreased nasal symptoms by 67 percent and the severity of asthma by 48 percent. In the largest study of its kind, 172 patients with AERD were desensitized to aspirin from 1995 to 2000; they were subsequently treated then with 1300 mg of aspirin each day and followed for 1 to 5 years. Clinical improvements occurred during the first 6 months: measures of improvement included clinical course, reduction in dose of systemic corticosteroid, and improvement in global assessments; these effects were maintained, but not further enhanced, during the remainder of the study. Approximately 67 percent (115 of 172) improved, 16 failed to improve, 24 discontinued aspirin because of aspirin-related side effects, while another 17 dropped out for other reasons.

It is interesting to note that although there are some reports of the development of increased methacholine reactivity

in patients soon after aspirin challenge, baseline methacholine responsiveness does not seem to be successfully downregulated by aspirin desensitization. Also, there is no firm evidence that aspirin desensitization leads to abatement in skin disease in those with aspirin-urticaria syndrome.

Inhaled PGE_2 was shown to prevent bronchoconstriction in a high proportion of patients challenged with inhaled L-lysine aspirin in two small studies. In two studies using misoprostol, a stable analog of PGE_1, prior to challenge with L-lysine aspirin (400 μg 1 h before) or a predetermined threshold dose of aspirin (400 μg before, followed by 200 μg with the provocative dose of aspirin), evidence was provided of some protection in 7 of 11 patients ($p = 0.024$) and in 6 of 7 patients (statistically only significant at time points 3 h after challenge), respectively. To test whether asthma symptoms might improve on treatment with misoprostol, another group performed a double blind crossover study that showed that misoprostol, given for a period of 6 weeks (at dose of 800 to 1600 μg/d) led to only a small improvement in nasal symptomatology without any effect on asthma control in 17 patients with proven AIA. Thus, evidence for a specific method to control AIA, other than the desensitization methods described above, has not proven to be reliable. Fortunately, for those who require aspirin to prevent disease, such as those on low-dose aspirin, given for cardiovascular prophylaxis, the threshold needed to provoke airway and skin reactions is above that of the dose required for cardiovascular prophylaxis.

The potential contribution of chronic sinusitis to exacerbations of asthma is well established. Aspirin sensitivity, chronic sinusitis, and nasal polyposis are well documented to coexist in AIA. Thus, the presence of these upper-airway disorders must be considered in patients with AIA and effective treatment instituted if they are identified. High-dose topical intranasal corticosteroids can shrink polyp tissue and prevent obstruction of nasal passageways. In the setting of chronic sinusitis, standard approaches—including topical vasoconstrictors, antihistamines, and antibiotics—should also be used. Surgery to drain sinuses and remove polyps has been shown to be effective in the short term; however, polyps can regrow and the sinusitis often recurs. In selected patients in whom aspirin provokes nasal symptoms predominantly, administration of intranasal lysine-aspirin at increasing weekly doses has been used successfully to desensitize such patients and prevent regrowth of polyps in one study. A more recent and larger randomized clinical trial, although underpowered due to dropouts, used a crossover design after withdrawal of intranasal steroids. Lower doses of lysine-aspirin were administered more frequently (16 mg intranasally every 48 h). Results showed encouraging immunohistochemical changes in nasal submucosal inflammatory cells from turbinate tissue, characterized by decreased expression of CysLT1 but no clinical improvement (diary scores of nasal and chest symptoms) or improvement on rhinometry.

Despite aspirin desensitization and careful treatment of the often-associated sinusitis, an appreciable proportion of patients with AIA do not achieve complete control of asthma or nasal symptoms. It is postulated that this failure may reflect permanently remodeled airways or residual allergic triggers that require specific measures for allergy control and anti-inflammatory therapy. Evaluation of the effect of strict avoidance of allergens, specific allergen immunotherapy, more intensive local management of the inflamed nasal mucosa and anti-IgE treatment may help to clarify the role of atopy in the persistence of symptoms after aspirin desensitization.

EXERCISE AND ASTHMA

The first report of exercise-induced asthma (EIA) is attributed to John Floyer in 1698. Nearly 300 years later, interest in this subject grew when it was recognized that exercise or hyperventilation could provoke asthma attacks. EIA can be defined as a condition in which vigorous physical activity triggers acute airway narrowing in persons with heightened airway reactivity. It appears that EIA is always associated with the asthmatic diathesis, although EIA can be seen before other characteristic features of asthma emerge. Various reports indicate that EIA is common, affecting between 50 and 90 percent of all asthmatics and 40 percent of patients with allergic rhinitis without known asthma. Some have suggested that all asthmatics can be shown to manifest airway narrowing in response to thermal provocations of sufficient intensity, whether induced by exercise or hyperventilation. Other individuals susceptible to exercise-induced asthma are first-degree relatives of asthmatics, atopic "nonasthmatics," and patients with cystic fibrosis. Approximately 10 percent of pediatric patients have been found to have EIA, a prevalence higher than that of clinical asthma.

Recent evidence suggests that elite athletes may be predisposed to develop EIA. Surveys conducted of athletes at the Atlanta (summer) and Nagano (winter) Olympic Games showed a prevalence of 16 to 17 percent. The prevalence may actually be higher in those who are regularly exposed to high minute ventilation of the cold, dry air which is typical of winter sports. The prevalence of EIA in figure skating (35 percent) and ice hockey (35 percent) may be responsible for increasing the overall frequency of EIA in winter sports; this high incidence has been documented by Wilber (referenced in Storms, 2005) to be as high as 23 percent.

Clinical Presentation

Patients with EIA generally manifest a series of fairly predictable symptoms and alterations in pulmonary function (Fig. 47-5). Normal individuals and asthmatics generally respond at first to exercise by bronchodilation, probably mediated by the release of catecholamines. This response is short-lived, peaking at midexercise, and is followed by return of normal baseline airway tone at the end of exercise. In patients with EIA, the transient bronchodilation and reversal are followed by bronchoconstriction coincident with symptoms of cough, wheezing, dyspnea, and chest tightness typical of asthmatic attacks. Typically, when provoked by a brief, intense

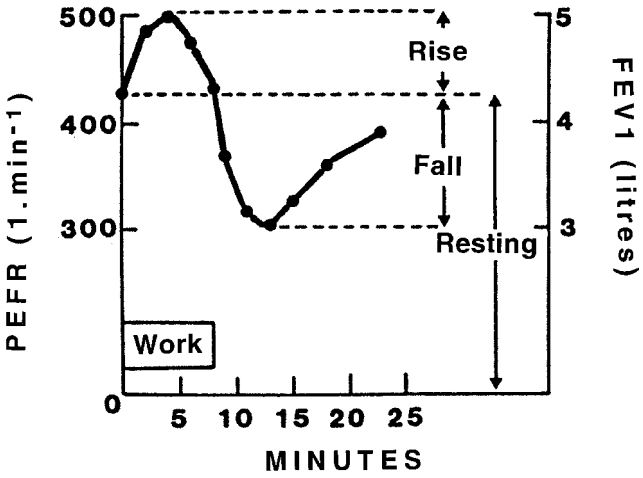

Figure 47-5 Typical pulmonary function changes induced by exercise in EIA. Transient bronchodilation during exercise and bronchospasm after exercise are noted. *(Based on data of Anderson SD: Is there a unifying hypothesis for exercise-induced asthma?* J Allergy Clin Immunol *73:660–665, 1984.)*

exercise period in the laboratory, maximal bronchoconstriction occurs 5 to 10 min after the cessation of exercise and lasts for 30 to 60 min (Fig. 47-5). Rarely, although it can limit the performance of trained athletes, does this form of bronchoconstriction result in ventilatory failure.

In addition to asthma after exercise, many athletes describe dyspnea during exercise. If these athletes are able to continue to exercise despite the initial airway constriction, especially if they can increase their level of activity, relief of bronchoconstriction often occurs. This relief is associated with symptomatic improvement with time that is described as "running through the attack." The development of dyspnea during exercise is related to the development of bronchoconstriction at lower work intensities (simulating a postexercise state), which is avoided by interval training at higher intensities (simulating an exercise state). This has been taken as evidence that airway function during exercise reflects a balance between bronchoconstrictor and protective bronchodilator influences, and that this balance can be influenced by rapid changes in exercise intensity.

The reproducibility of EIA is highly dependent on the specific characteristics of the stimulus and patient-related factors. The net influence of exercise intensity, the temperature and humidity of the inspired air, and the patient's baseline airway reactivity are fundamental in determining whether exercise will lead to bronchoconstriction. The better the asthma is controlled at baseline, EIA may be more difficult to provoke. If climatic conditions vary, even though asthma is not well controlled, EIA may fail to develop. Classic work has shown that for a fixed minute ventilation, cold, dry air inspired during exercise is more likely to provoke EIA than warm, humid air. Thus, EIA is more likely to occur while jogging during the winter than while swimming indoors.

It is interesting that about 50 percent of patients with EIA will not manifest a bronchoconstrictor response after exercise if rechallenged with the same stimulus within 60 min, and thus appear to establish a refractory state. Neither baseline airway obstruction nor the degree of obstruction provoked by exercise can be used to determine who will be refractory to repeated exercise challenges. After 3 h, even patients who are refractory to repeated challenge will again respond to exercise with bronchoconstriction.

Pathophysiology

The mechanisms associated with exercise-induced bronchoconstriction have been studied intensively for more than two decades. Despite this intense scrutiny, and recent application of genetic and molecular techniques, the pathophysiology of this response is still a subject of debate. The theories now appear to have coalesced to two pathogenic schemas that may, or may not, be mutually exclusive. The two theories of pathogenesis focus on the roles of heat exchange, water loss and subsequent airway rewarming, and airway inflammation. The role of inflammation as a reaction to these stimuli or as an enhancer of the effects of these two principles' pathophysiological pathways is probably tied to leukotrienes and related lipoxygenase products.

Heat Exchange and Water Loss

During tidal breathing, heat (via conduction and evaporation) and water (via evaporation) are transferred from the mucosa of the upper airways to the entering air. Since exercise requires marked increases in minute ventilation, exceeding the volume of air that can be inspired through nasal structures, air enters directly through the mouth, bypassing the normal warming and conditioning function of the nose. The lower respiratory mucosa attempts to compensate for the function of the bypassed nose. Heat and water fluxes occur first. The lower airways are cooled and dried and then subject to rewarming by warm blood carried by the bronchial circulation.

In the late 1970s, a number of investigators postulated that EIA was the result of increased heat loss in the airway. This was based on the observation that cold, dry air caused a greater fall in FEV_1 than did hot, dry air and on correlations between heat exchange and the degree of bronchoconstriction. Others, however, showed that the temperature of the inspired air was not crucial for inducing bronchoconstriction and that temperatures of dry inspired air varying as much as 60° could still provoke airway narrowing. This suggested that airway evaporative water loss might be more important than airway cooling. The water loss was predicted to change the osmolarity of the cellular and extracellular components of the airway wall, stimulating increased bronchial blood flow in order to increase the delivery of water. In addition, it was hypothesized that bronchial wall hyperosmolarity increased the release of proinflammatory mediators from resident airway inflammatory cells such as mast cells. This concept was supported by work that demonstrated that changes in the humidity of inspired air, and not temperature, determine the magnitude of EIA. Further support for this construct came

from studies using cold gas mixtures with different water-carrying capacities, which showed a significant correlation between the airway response and the evaporative heat loss, but not the total heat loss or temperature gradient.

In apparent contrast to these data is the considerable body of work that does not support the concept that osmolar changes precipitate EIA. The most important of these showed that increasing minute ventilation at constant humidity increases the severity of EIA.

Airway Rewarming

An important theory that also remains to be proven was offered by McFadden, who proposed that the process of airway rewarming is involved in the pathogenesis of the airway narrowing that occurs in EIA. This theory postulates that loss of heat during exercise leads transiently to a decrease in bronchial blood flow. At the end of exercise, the bronchi undergo reactive hyperemia characterized by vascular engorgement, which leads to compromise of airway caliber and edema of the walls of the airway. The strongest support for this theory is provided by studies that show that the severity of EIA can be controlled by regulation of the thermal gradient during exercise and the rate of rewarming after exercise.

In summary, there is evidence that associates exercise-induced bronchoconstriction with a sequence of events that includes heat loss, water loss, and airway rewarming. However, the degree to which these alterations in temperature and water exchange contribute to the pathogenesis of EIA is still a topic of debate and investigation.

Inflammation and EIA

Theories that postulate a role for inflammatory mediators in the pathogenesis of EIA have recently received new support and are being harmonized with the already considerable evidence that supports a role for inflammation in the pathogenesis of other forms of asthma. New information about exercise suggests that individuals predisposed to EIA, specifically elite athletes, may manifest a degree of airway inflammation that had not been previously recognized. Instead of demonstrating a lower rate of EIA, which would potentially enable a higher level of exercise performance, and which might be expected in those best equipped to excel in sports, elite athletes appear to exhibit a paradoxically higher incidence of EIA and a higher degree of airway inflammation without necessarily manifesting a higher prevalence of underlying clinical asthma.

Older data on the role of inflammation in EIA did not necessarily support this link. One study analyzing the characteristics of BALF from patients with EIA 12 min after exercise failed to find evidence for mast cell mediator release since levels of BAL histamine, tryptase, LTC_4, and PGD_2 were not altered. Similarly, studies performed 1 h and 25 h after exercise did not reveal significant differences in the cellularity of BAL or in the levels of histamine or tryptase.

In contrast, one group studying elite cross-country skiers, found elevated airway T lymphocytes and eosinophils compared to controls. Several others have demonstrated changes in exhaled nitric oxide, which generally decreased with exercise, suggesting a high basal level and ventilatory clearance of this gas associated with airway inflammation. A second group found increases in plasma adenosine after exercise. A third group documented the presence of a late phase airway response after exercise that was demonstrable in 50 percent of competitive athletes studied. Most importantly, the new concept that these changes might be provoked by exercise, rather than be a reflection of underlying inflammation in those who manifest EIA, is supported by studies of Helenius et al, who showed that athletes who stopped high-level training and modulated the amount of exercise they subsequently pursued, experienced reduced asthma symptoms and diminished bronchial responsiveness to histamine.

Leukotrienes in EIA

To determine whether leukotrienes play a role in the pathogenesis of EIA, LTD_4 receptor antagonists and 5-lipoxygenase inhibitors have been used. Studies using an intravenous LTD_4 receptor antagonist administered 20 min before exercise demonstrated significant attenuation of the maximal provoked bronchoconstriction and a decrease in the mean time to recover from bronchoconstriction (8 min for the treatment group versus 33 min for placebo). Similar results were noted by others using oral or inhaled leukotriene antagonists. In general, although the protection was relatively small, it was significant and equivalent in potency to inhaled cromolyn.

The results obtained with peptido-leukotriene antagonists are consistent with those obtained with the effects of a 5-lipoxygenase inhibitor on bronchoconstriction induced by cold, dry air. In the most important study of this kind, a 5-lipoxygenase antagonist was as effective as cromolyn or terbutaline in augmenting respiratory heat exchange. Thus, leukotrienes may mediate the airway inflammation and contribute to the pathogenesis of EIA.

Genetics

Little information is available on the potential genetic underpinnings of EIA. However, this topic has recently received some attention. Using microarray analysis, one group demonstrated enhanced transcription of 5-lipoxygenase (ALOX5) and 5-lipoxygenase activating protein (ALOX5AP) genes. More recently, in studies conducted in a large cohort of Korean children with asthma, others have provided evidence of LTC_4 synthase (A-444C) promoter polymorphisms in association with greater severity of EIA. These observations suggest the potential existence of disease-modifying genes in exercise-induced bronchospasm.

Differential Diagnosis

The diagnosis of EIA is most accurately established by employing validated exercise protocols coupled with pulmonary function testing. However, patients are commonly given a presumptive diagnosis based on their history and physical examination. Important points in the clinical history include the

Table 47-3

Differential Diagnosis of Exercise-Induced Asthma

Cardiac Disease	Functional abnormalities
Coronary ischemia	Vocal cord dysfunction
Mitral valve prolapse	Panic disorders
Atrial myxoma	General
Cardiomyopathy	Deconditioning
Arrythmias	Anemia
Lung disease	
Fixed airway obstruction	
Interstitial lung disease	
Exercise-induced cough	

level and type of exercise that provokes asthma, the timing of symptom onset, the situation that modifies the onset of symptoms, and the precise symptoms experienced. Many of the symptoms of EIA can mimic other conditions that would require an entirely different therapeutic approach (Table 47-3). For example, chest tightness with exercise should be unequivocally distinguished from coronary ischemia. Other cardiac disorders that can mimic EIA are arrhythmias, cardiomyopathies, atrial myxoma, and mitral valve prolapse, all of which can manifest with dyspnea and wheezing. The presence of a murmur, click, or other findings on physical examination should help to identify patients with these conditions. Exercise-induced anaphylaxis can also mimic EIA but will generally exhibit skin manifestations (urticaria), and respiratory symptoms will be less prominent. Two other conditions that have been reported to mimic EIA are fixed glottal and tracheal obstruction, which become noticeable during the increased ventilation of exercise and exercise-induced vocal cord/arytenoids dysfunction but are not present at rest. Some observers have also suggested that panic disorders and the excessive tachypnea associated with deconditioning can be confused with EIA. Symptoms due to these other conditions generally are greatest *during* exercise provocation rather than afterward, when airflow limitation due to EIA usually reaches its peak.

Exercise-induced cough is another phenomenon that can mimic EIA. Both may be induced by changes in the osmolarity of the airways reflecting water loss from the respiratory tract during exercise. The inhalation of humid air also prevents both phenomena. However, EIA and exercise-induced cough respond differently to β-adrenergic agonists, suggesting that they are mediated by different underlying mechanisms. It is postulated that exercise-induced cough is the direct result of changes in osmolarity provoked by airway drying, whereas EIA is due to the release of mediators that results from the process of airway drying. Therefore, although nearly all patients with EIA cough when provoked by exercise, there are patients who have exercise-induced cough without bronchospasm, and thus do not have EIA.

Physiological Documentation

Because a simple history of cough or wheezing may not reliably predict EIA, especially in those in whom a trial of preventive measures has not been successful, formal exercise testing may be required. The clinician needs to document airflow obstruction that reaches a peak during the recovery period, immediately after provocation. Two basic methods of provocation have been used, exercise and the inhalation of dry air (isocapnic hyperventilation, ISH). The latter is an acceptable surrogate for exercise, since the bronchoconstriction it induces is similar to that induced by exercise in terms of magnitude, time course, and refractory period. However, significant differences exist between the two provocation techniques. Exercise provocation, whether performed on an ergometer or a treadmill, leads to significantly greater increases in heart rate, metabolic rate, and oxygen consumption. Exercise, but not ISH, is accompanied by increased numbers of circulating basophils and increased circulating catecholamines and cyclic adenosine monophosphate. The differences in the last two parameters probably explain why the bronchodilatory response that characterizes exercise is not provoked by ISH. ISH does, however, have a number of advantages over exercise. The first relates to the ease with which the ISH protocol can be standardized; the other relates to the finding that oxygen consumption and heart rate are not increased with ISH. As a result, ISH is useful in differentiating EIA from occult cardiac disease and is especially valuable when elderly or cardiac patients are being evaluated.

The most commonly used protocol for the diagnosis of EIA in the United States is that published by O'Byrne et al and modified by Phillips et al (Fig. 47-6). This protocol registers changes in pulmonary function in response to varying rates of ventilation using dry air which contains a fixed CO_2 content of 4.9 percent to maintain isocapnia. Each ventilatory challenge is performed for 3 min; spirometry is performed at intervals thereafter (usually 2, 5, and 10 min after the end of hyperventilation). Serial increase in hyperventilation is continued until maximal voluntary ventilation is reached. If the FEV_1 falls 10 to 20 percent after provocation, the test is considered positive, confirming the diagnosis of EIA. Although some have pointed out that it is not necessary to condition air to subfreezing temperatures in order to perform the test, Scandinavian investigators have shown that assessing bronchoconstrictor responses to whole-body exposure to very cold air resulted in a significant increase in the number of asthmatic patients who experienced bronchoconstriction. Others have pointed out the need to assess athletes in the sport in which they compete, since they may not realize that a significant drop in FEV_1 has occurred due to their conditioning; manifestations of disease during challenge may be needed to document the decrease in lung function.

In order to optimize the validity, repeatability, and practicality of exercise testing for the diagnosis of EIA, a variety of

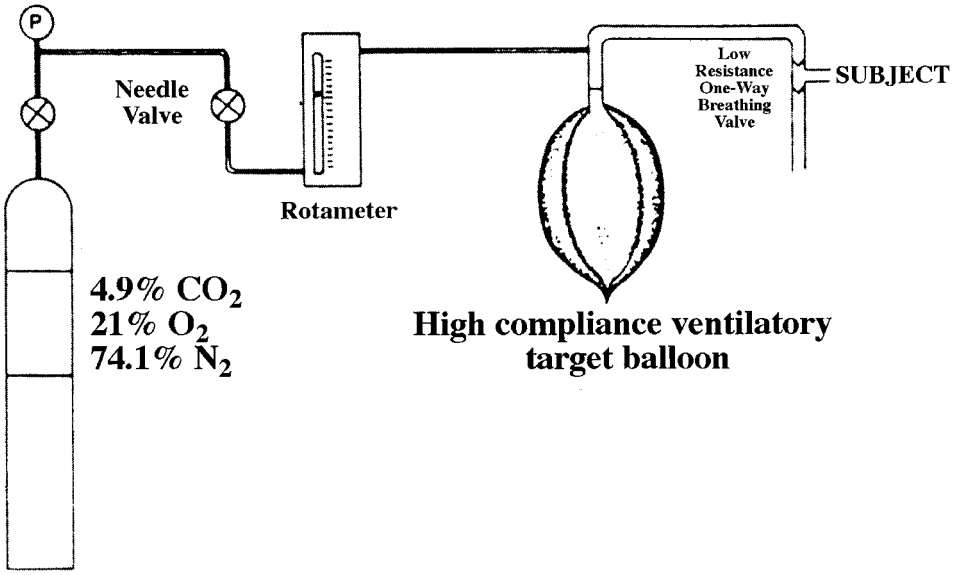

Figure 47-6 Apparatus for isocapnic hyperventilation challenge to diagnose EIA. *(Based on data of Phillips YY, et al: Eucapnic voluntary hyperventilation of compressed gas mixture: A simple method for bronchial challenge by respiratory heat loss.* Am Rev Respir Dis *131:31–35, 1985.)*

testing protocols have been used. Unfortunately, at times the criteria used to define a positive test in these different studies have been arbitrary. Although the optimal diagnostic algorithm for the assessment of EIA is still lacking, recent data reported on athletes from the 2002 Olympic Winter Games, compared eucapnic voluntary hyperventilation (EVH) with exercise testing outdoors in the cold (2°C and 45 percent humidity). The EVH test for 6 min with cold, dry air proved to be best in assessing the presence of EIA.

In addition to the difficulties inherent in the standardization of the challenge protocol, the clinician must be aware of situations that can lead to false-negative evaluations. Specifically, it is important that all drugs that can attenuate bronchoconstrictor responses—such as calcium channel blockers, methylxanthines, cromolyn, and β-adrenergic agonists—be discontinued for a sufficient period before the evaluation.

Treatment

The treatment of EIA depends, in part, on the treatment of the underlying asthma since in general, patients with more severe baseline asthma are most inconvenienced by EIA (Table 47-4). It has been shown that inhaled steroids attenuate the development of EIA during provocation in the laboratory and increase the clinical threshold for developing EIA. Prophylactic measures to prevent EIA include avoiding exercises that expose the patient to cold, dry air and favoring those that expose the patient to humid air during exercise. Patients can reduce the severity of their EIA by breathing through the nose rather than through the mouth during exercise. Face masks (e.g., 3M Cold Weather Mask) can be used by the many people who find it impossible to breathe through the nose during intense exercise. It is still unclear whether physical training and improvement in work capacity can relieve symptoms of EIA. These methods should be useful, at least in theory, since a better-trained athlete may require a lower mandatory minute volume—which may lead to less water loss from the airways and less severe EIA. Two studies—one in Los Angeles and the other in Toronto—showed that exposure of patients with EIA to air high in ozone did not minimize EIA. This suggests that choosing a day to exercise on the basis of ozone will not help prevent EIA. A series of repeated short sprints has been shown to be effective in inducing the refractory state, which might then allow the athlete to exercise maximally without developing EIA. A warm-up period to induce the refractory period has been advocated to improve performance in the competitive athlete. However, this effect may not last for longer than 40 min.

Several classes of drugs have been shown to prevent EIA if administered just before (10 to 15 min) exercise. The

Table 47-4

Treatment of Exercise-Induced Asthma (EIA)

Treatment Immediately Before Exercise (10–20 min before)	Treatment of Underlying Disease (days before)
β-adrenergic agonists	Goal: Improved asthma control
Cromolyn sodium	Inhaled corticosteroids
Nedocromil	Systemic corticosteroids
? Anticholinergics	? Theophylline
? Inhaled furosemide	
? Leukotriene receptor antagonists	

list includes β-adrenergic agonists, cromolyn sodium, anticholinergics, and possibly rapid-release theophylline (see Table 47-4). The β-adrenergic agonists are the most effective drugs for use against EIA. They are 90 percent effective in preventing EIA when used just before exercise. They are especially useful if the patient has some reversible airway obstruction, since they also improve lung function before exercise. Longer-acting β-adrenergic agonists, have also been found to be effective in preventing EIA. The duration of protection they confer may approach 10 h or more. This may be important in preventing EIA in patients who do not have immediate access to an inhaler and anticipate the need for prophylaxis due to exercise scheduled for later in the day (i.e., students). It is interesting that the cough so often associated with EIA, appears to occur independently of the bronchospasm provoked by exercise. Although exercise-induced airway narrowing is prevented by the inhalation of β-adrenergic agonists before exercise, the cough is not.

Cromolyn sodium also has been shown to attenuate bronchoconstriction in most patients with EIA. Since it is not a direct bronchodilator, this medication will not be effective in those who seek reversal of pre-exercise bronchoconstriction. Cromolyn does, however, have two advantages over other agents. First, it does not contribute to tachycardia and is therefore useful in elderly patients or patients with cardiac problems. In addition, cromolyn has been shown to prevent the late bronchoconstrictor response to exercise. Related drugs (including nedocromil, minocromil, and oxatomide, but not ketotifen) have similarly been shown to be effective against EIA.

Anticholinergics, such as ipratropium bromide, prevent airway narrowing after exercise in a high percentage of patients with EIA. They are especially useful in those who experience a rapid bronchodilating response to the drug. However, for most patients, the slow onset of action limits the effectiveness of these agents after bronchodilation has occurred.

Theophylline with its weak bronchodilatory effects, high side-effect profile, and slow onset of action, is not recommended for routine use as pretreatment for EIA. However, it has been shown to confer protection against EIA if 100 to 200 mg is taken 2 h before exercise. Other orally administered drugs that are not commonly used, but have the potential to be helpful in preventing EIA, are terbutaline, albuterol (2 h before exercise), some α-adrenergic agonists, verapamil, and sublingual nifedipine (the last two if taken 30 min before exercise), as well as the inhaled antihistamine clemastine. In addition, terfenadine was shown by one group to prevent EIA. For the elite athlete, only a few of the above drugs are approved for use in competition by the International Olympic Committee. They include inhaled albuterol, terbutaline, cromolyn, and nedocromil and oral theophylline. Long-acting β-agonists and all oral sympathomimetics are not approved.

Other directions in drug therapy for EIA hold promise for the future. Diuretics are known to be of some use in the prevention of EIA in adults. The most recent use of these agents indicates that inhaled furosemide (20 to 30 mg by inhalation 20 min before exercise) also attenuates EIA in children and can be combined with nedocromil to increase the protective effects of the drug. Leukotriene antagonists have been advocated by some, if protection of short-acting β-agonists alone is insufficient. Because of their low side-effect profile, leukotriene antagonists would appear to be well suited as single agents for use against EIA. However, additional head-to-head studies showing efficacy during exercise would be required before these agents can be favored over inhaled β-adrenergic agonists in routine prophylaxis against EIA. Increasingly, the use of performance-enhancing drugs has made it mandatory that competitive athletes with EIA specifically consult such organizations as the World Anti-Doping Agency (WADA; www.wada-ama.org), the U.S. Anti-Doping Agency (www.usantidoping.org), and other agencies such as the National Collegiate Athletic Association to assure that the treatments being used for the prevention of EIA are not prohibited for use in competition.

Asthma: Clinical Presentation and Management

Rodolfo M. Pascual • JeRay J. Johnson • Stephen P. Peters

Asthma can be defined as an inflammatory disorder characterized by variable airflow obstruction; airway hyperresponsiveness to specific and nonspecific stimuli; and symptoms of wheezing, chest tightness, cough, and, occasionally, dyspnea. Heightened airway responsiveness is a pathognomic feature of asthma. Clinically, increased airway responsiveness manifests as intolerance to air pollution, smoke, strong odors or fumes, and particulate matter such as dust. Exposure to these agents typically results in transient symptoms of cough and chest tightness. Emotional factors such as laughing or crying may exacerbate symptoms in a large number of patients.

Although asthma is frequently referred to as a disease, as if it were a single nosologic entity with a unique pathogenesis, experienced clinicians recognize that this is not the case. Asthma is more likely a syndrome, one that comprises multiple disorders manifesting common symptoms but having distinct and probably different pathogenetic and etiologic mechanisms. Phenotypic heterogeneity is evident not only in terms of the etiologic factors involved but also in terms of the severity and natural history of the disorder among different patients. Asthma has been classified as *extrinsic* or *intrinsic*, depending on the suspected role of allergens as etiologic factors. Atopic subjects are considered to have extrinsic asthma, while nonatopic subjects have intrinsic asthma. However, this nomenclature has been used with diminishing frequency, because it does not aid in establishing an etiologic diagnosis nor does it help in defining treatment strategies. The presence of atopy, often defined by the presence of skin test sensitivity to aeroallergens, does not, by itself, indicate that allergens are important triggers of asthma, since a large percentage of skin-sensitive persons report no allergic symptoms. Moreover, exercise and viral respiratory infections may play a more prominent role than allergens as triggers of symptoms in some atopic subjects. Classifying patients as having intrinsic asthma is problematic also, since it implies that all possible allergens in the environment have been excluded as etiologic factors—a task that is nearly impossible to achieve.

Although allergens are often triggers of acute asthma, there is a growing appreciation of their role as inducers of subclinical inflammation that may lead to enhanced airway responsiveness and greater susceptibility to the provocative effects of exercise and viral infections. In this regard, it is important to understand the distinction between triggers and etiologic factors. Whereas triggers may lead to symptoms, they do so only in susceptible persons who already possess the underlying asthmatic diathesis. In cases of occupational asthma, the disease can often be classified according to its etiology. In these circumstances, not only is the specific agent that triggers symptoms known, but the same agent is usually the underlying cause of asthma. Another category of asthma is that which is exercise induced. The term *exercise-induced asthma* is somewhat misleading, suggesting that exercise is the cause of the asthma. In fact, exercise is not a cause of asthma. Rather, it is one of many nonimmunologic triggers that produce symptoms in patients who already have the disease.

Perhaps the most useful classification of asthma is that based on levels of severity. This approach has facilitated the

development of rational treatment guidelines that have been endorsed by expert physicians throughout the world. This classification, as well as management strategies based on it, is discussed later in this chapter. However, patients move among different severity classes so these schemes have limited usefulness. Future guidelines should place increased emphasis on the burden that asthma places on patients as well as the risks that it poses for them.

CLINICAL PRESENTATION AND DIAGNOSIS

The diagnosis of asthma is made clinically, usually on the basis of a history of typical symptoms and confirmatory, objective evidence of variable airflow obstruction. The diagnosis of asthma is usually made accurately, although the degree of diagnostic accuracy is probably patient-age dependent. For example, asthma diagnosis in young adults is usually not difficult, since there are few other conditions that mimic asthma or confound its clinical presentation. With increasing age, cardiovascular disease and other forms of chronic lung disease are more common, and the differential diagnosis of episodic chest symptoms is more extensive. Finding an irreversible component of airway obstruction in asthmatics adds to the challenge of distinguishing between asthma and tobacco-related chronic obstructive pulmonary disease (COPD), in current and exsmokers. Because the predictive value of clinical and laboratory findings in establishing the diagnosis of asthma appears to decline with advancing age, the probability of misdiagnosis is highest in the elderly, who have the same high asthma prevalence (4 to 7 percent) as younger adults. The following clinical and laboratory manifestations are important in consideration of the diagnosis of asthma.

History

The history of symptoms, their pattern of occurrence, precipitating or aggravating factors, and the profile of a typical exacerbation are important elements of the clinical evaluation. During an acute episode, usual complaints include wheeze and a sensation of chest tightness. Breathlessness may also occur, although this symptom is often interpreted as a sensation of having difficulty inspiring, or "getting air in." This sensation is probably due to dynamic lung hyperinflation that accompanies acute asthma episodes. When there is hyperinflation, further inspiratory efforts are made against a higher respiratory system recoil pressure. Cough may also be present; on occasion, it may be the sole presenting manifestation of an episode of asthma. Symptoms may occur abruptly or evolve slowly over days or weeks. The frequency and severity with which symptoms occur vary considerably within the asthmatic population. Although no single symptom is specific for asthma, wheezing is a useful sign, since most asthmatics complain of more than just rare episodes of wheezing, and nonasthmatics rarely report frequent wheezing. Especially in younger patients, the symptom of chest tightness is also helpful, since it occurs more often in association with asthma than with other pulmonary or cardiac disorders. Chest symptoms that vary by season and are accompanied by symptoms of irritation of other mucous membranes, such as conjunctivitis and rhinitis, are typical of allergic asthma. Whereas pollens and some mold spores are likely to provoke seasonal symptoms, indoor allergens, such as house dust mites, cockroaches, and animal dander proteins are more apt to result in perennial symptoms.

Early-morning symptoms or nocturnal episodes are very common in adult asthmatics. It is important to distinguish whether nocturnal symptoms are due to asthma, gastroesophageal reflux, or angina. Typically, nocturnal asthma symptoms occur between 4:00 and 6:00 A.M.; usually they are relieved with administration of inhaled bronchodilators. This contrasts with gastroesophageal reflux, which causes similar symptoms soon after the patient reclines at night, or cardiovascular symptoms, which can occur at any time.

Viral respiratory infections are a common cause of exacerbations of asthma in adults. The viruses most commonly implicated are rhinovirus, respiratory syncytial virus, influenza virus, and parainfluenza virus. *Mycoplasma* and *Chlamydia* are also associated with exacerbations of asthma; other bacterial infections are not. It should be noted that viral respiratory infections can evoke an increase in airway responsiveness in otherwise healthy persons, causing self-limited episodes of chest tightness, cough, and wheezing that may last for as long as 8 to 12 weeks. Although these episodes are frequently diagnosed as asthma, the disappearance of symptoms after 8 to 12 weeks suggests that the illness was due to a temporary, postviral increase in airway responsiveness.

Exercise-induced Asthma

A history of symptoms after heavy exertion, especially in cold air, is highly suggestive of exercise-induced asthma. Typically, the patient experiences symptoms at the end of exercise, rather than during its performance. Excessive coughing after exercise, sometimes in the absence of wheezing, may also be a sign of asthma. Patients with COPD or heart failure may experience exertional dyspnea, but, as a rule, these patients do not develop symptoms of chest tightness, cough, and wheeze.

Asthma and Aspirin Sensitivity

The association of asthma and sensitivity to aspirin and other nonsteroidal anti-inflammatory drugs (NSAIDs) is well established. Of particular note is the triad of asthma, nasal polyps, and aspirin intolerance. This condition is thought to affect 2 to 3 percent of all asthmatic patients and up to 20 percent of patients with severe asthma. In this syndrome, the first symptom is usually rhinitis. This is followed several years later by the development of aspirin intolerance and asthma symptoms and finally, usually much later, nasal polyps. Nasal polyps are usually bilateral and originate from the turbinates, as well as the paranasal sinuses. Aspirin-induced asthma has been associated with enhanced leukotriene production and

mast cell activation, but mechanisms responsible for these events remain unclear.

Although aspirin-induced asthmatic episodes often resemble allergic reactions, there is no evidence that IgE-related immunologic mechanisms are at work. As a rule, aspirin intolerance is associated with severe asthma that is often resistant to therapy, including glucocorticoid therapy. The diagnosis of aspirin intolerance and asthma is made on the basis of the history and clinical findings of sinusitis and nasal polyps; it can be confirmed by aspirin challenge procedures. β-Adrenergic receptor–blocking drugs, including those contained in topical ophthalmic preparations, can also precipitate severe, acute, and sometimes fatal asthmatic episodes. Accordingly, beta blockers are contraindicated during acute asthma exacerbations and the risk-benefit ratio should be considered before they are used in stable outpatients with asthma.

Occupational Asthma

Asthma related to occupational exposure can often be identified on the basis of a typical history of symptoms during the work week and improvement over the weekend. Symptoms may occur during exposure to the etiologic substance, or they may be delayed until the evening or night after the work day. It is important to distinguish between occupational asthma that is triggered by nonspecific irritants in patients with preexisting or concurrent asthma and asthma that arises de novo as a consequence of exposure to a specific etiologic agent. A number of natural and synthetic chemicals are known to cause asthma by IgE-mediated mechanisms, as well as by nonallergic mechanisms of unknown origin. The diagnosis of occupational asthma is based on a history of typical symptoms, the presence of variable airflow obstruction, and a demonstrable link between asthma and workplace exposure.

Physical Examination

Wheezing, the most characteristic physical finding in asthma, is caused by turbulent airflow through narrowed airways. In asthma, wheezing is usually present during expiration, although it may be present during inspiration as well. The quality of wheezing should not be considered predictive of the degree of obstruction in an individual patient. Patients who are asymptomatic, or who complain only of cough, may demonstrate end-expiratory wheezing, although this is a nonspecific and insensitive sign of asthma. It is important to note that wheezing of any character is not specific for asthma; notably, in cases of very mild or very severe airway obstruction, wheezing may be absent.

Clinical signs of rhinitis, sinusitis, and nasal polyps are seen more commonly in patients with asthma than in those with other chronic lower respiratory tract disorders or congestive heart failure. Chronic sinus disease may be difficult to diagnose on clinical grounds; imaging studies may be required. Marked weight loss or severe wasting is not seen in asthma but is commonly seen in severe emphysema. Signs of hyperinflation and diminished breath and heart sounds are usually observed during an acute exacerbation. Use of accessory muscles of respiration and the presence of pulsus paradoxus are signs of severe airway obstruction and are usually observed during acute episodes. Because ventilatory effort can be diminished with respiratory muscle fatigue, the absence of pulsus paradoxus does not preclude severe airway obstruction. Stridor, a high-pitched inspiratory sound, heard best with auscultation over the upper airways, should prompt a further search for causes of upper-airway obstruction, including vocal cord dysfunction, tracheal or bronchial stenosis, vocal cord paralysis, upper-airway tumors, and airway narrowing due to thyroid enlargement.

Laboratory Studies

The use of laboratory studies in the diagnosis of asthma is largely restricted to spirometry. Skin testing and serologic studies may also be useful in defining allergic triggers of asthma in some patients, although the clinical history often provides more clinically relevant information regarding the relation between symptoms and exposure. Radiographic studies, blood tests, and more extensive lung function studies are used to exclude other conditions that may mimic asthma or complicate its clinical presentation.

Pulmonary Function Tests

Pulmonary function tests are important for confirming the diagnosis of asthma, establishing the severity of the disease, and monitoring the response to therapy. The diagnosis of asthma is usually confirmed by objective demonstration of airflow obstruction by spirometry. In addition, there should be evidence of significant improvement in the 1-s forced expired volume (FEV_1) acutely after bronchodilator administration, or with repeated measurement over time. Unfortunately, there are no standard criteria for judging the degree of reversibility after bronchodilator administration for diagnostic purposes. Although a postbronchodilator increase in FEV_1 of greater than 12 percent is often considered evidence of reversible airway obstruction, this level is arbitrary and lacks sensitivity or specificity for detecting asthma. Clinical experience has shown that there is substantial overlap in the degree of bronchodilator reversibility when one compares patients with asthma to those with COPD. Thus, while a marked spirometric response to inhaled bronchodilator confirms reversibility of airway obstruction and is strongly indicative of asthma, this finding does not rule out COPD, nor does the lack of an acute bronchodilator response rule out asthma.

Since office spirometry is inexpensive and easy to perform, there seems to be little justification for sacrificing diagnostic sensitivity and specificity by using peak expiratory flow (PEF) measurements made in the office for the initial diagnosis of asthma. However, home monitoring of variability in PEF may be of diagnostic use, especially in patients with mild, intermittent symptoms who often demonstrate normal spirometry during physician visits.

Measurement of lung volumes is useful for excluding restrictive lung disease. In asthma, an increase in residual volume is typically seen, reflecting airway closure at a lung

volume that is higher than normal. During acute asthmatic episodes, functional residual capacity and total lung capacity may also be increased.

Measurement of diffusing capacity of the lung (D_{LCO}) deserves mention because of its value in differentiating patients with emphysema from those with asthma. Emphysema, characterized by alveolar septal destruction and loss of pulmonary capillary volume, is associated with a reduced D_{LCO}; by contrast, the D_{LCO} is usually normal or supranormal in asthma.

Bronchial Challenge Testing

Abnormal airway responsiveness, a sine qua non for asthma, is detected in the laboratory by an exaggerated response to inhaled pharmacologic agents, such as histamine, adenosine, or methacholine; or physical stimuli, such as exercise and hyperventilation. The correlation between different airway challenge tests is remarkably good, especially between histamine and methacholine and, to a lesser extent, among other pharmacologic agents, and the physical measures exercise and cold air hyperventilation.

The largest experience with pharmacologic challenge testing is with intermittent and continuous aerosol generation techniques using methacholine or histamine. The two techniques give remarkably similar results when airway responsiveness is expressed as the concentration of drug causing a 20 percent fall in FEV_1 (PC_{20}), as determined from dose-response curves. Some studies have shown that 100 percent of patients with current asthma symptoms demonstrate a PC_{20} at histamine concentrations less than or equal to 8 mg/ml, while others, using methacholine, have reported a sensitivity of approximately 85 percent at the same PC_{20} threshold. False-negative results can be obtained in patients who experience only intermittent symptoms and are tested when they are asymptomatic. Indeed, atopic patients with seasonal asthma symptoms may demonstrate PC_{20} greater than 8 mg/ml when tested "out of season." False-negative challenge responses may also occur in patients with occupational asthma if tests are performed remote in time from exposure to the etiologic agent. Whereas diagnostic tests are more likely to be performed in patients who have had recent symptoms, pharmacologic challenges are generally conceded to have a low false-negative rate. Thus, when a diagnostic threshold PC_{20} of less than or equal to 8 mg/ml is used, pharmacologic challenges are sensitive tests with a high negative predictive value (i.e., a PC_{20} greater than 8 mg/ml excludes a diagnosis of asthma with a high degree of accuracy). Most surveys indicate that the specificity of pharmacologic challenge testing is approximately 90 percent when a PC_{20} of less than or equal to 8 mg/ml is used as the diagnostic threshold. The prevalence of abnormal responsiveness in nonatopic, nonasthmatic subjects who have no history of prior respiratory problems ranges from 5 to 10 percent; in such patients, the term "false-positive" should be used with caution. The significance of abnormal responsiveness in this population is uncertain. For example, it is not known whether the retention of abnormal responsiveness in former asthmatics predisposes to relapse later in life. Likewise, it is not known whether abnormal airway responsiveness predisposes to the subsequent development of asthma or COPD.

Physical measures to assess airway responsiveness include exercise and isocapnic hyperventilation. Both stimuli induce airway obstruction as a consequence of cooling or drying of the airway mucosa. The requirement for strenuous physical work limits the use of such challenges to persons who are physically capable of performing them.

Clinical Application of Bronchial Challenge Tests

The specificity of bronchial challenge tests in the diagnosis of asthma is compromised further by the finding that abnormal airway responsiveness is associated with a number of other disorders, including cystic fibrosis, COPD, and heart failure. Moreover, conditions associated with airway injury or inflammation—such as viral respiratory infections, exposure to pollutants, and exposure to aeroallergens—can induce a temporary state of abnormal responsiveness. Accordingly, pharmacologic challenges are not useful for discriminating between asthma and COPD in patients with abnormal spirometry. Hence, airway challenge testing is used, perhaps most usefully, in evaluating patients who have unexplained chest symptoms and normal spirometry results.

Since the clinical history, by itself, has little value in establishing a diagnosis of asthma in patients with atypical symptoms, bronchial provocation testing may be especially useful for excluding a diagnosis of asthma because of the low false-negative rate and high negative predictive value. Conversely, the finding of abnormal responsiveness in such patients may not be diagnostic of asthma because of the test's poor positive predictive value and the possibility that hyperresponsiveness may also reflect self-limited pathology that occurs with transient airway inflammation secondary to viral infections. In any event, the demonstration of abnormal airway responsiveness may be taken as presumptive evidence of an association between symptoms and abnormal responsiveness, thus providing an objective basis for asthma therapy.

Blood Tests

Arterial blood gases are typically normal in patients with chronic, stable asthma. During an acute, severe episode, hypoxia is often present. Arterial P_{CO_2} is typically reduced owing to hyperventilation. With severe obstruction, arterial P_{CO_2} may rise because of respiratory muscle fatigue and an inability to maintain the required alveolar ventilation.

Peripheral blood eosinophilia (greater than 4 percent or 300 to 400 per mm^3) may be seen in both allergic and nonallergic asthmatics. When present, eosinophilia may be used to support a diagnosis of asthma; however, its absence is of no value in excluding asthma. Unusually high eosinophil counts (greater than 800 per mm^3) suggest the presence of other disorders, such as allergic bronchopulmonary aspergillosis, Churg-Strauss syndrome, tropical eosinophilia, and Loeffler's

syndrome. It should be noted that eosinophilia may not be present if the patient is taking corticosteroids.

Epidemiologic studies have demonstrated an association between asthma and total serum immunoglobulin E (IgE) levels, standardized for age and sex. Whether this association signifies that aeroallergens are prominent etiologic factors, or that immunologic processes in the pathogenesis of asthma are capable of stimulating IgE production as an unrelated phenomenon needs further definition. Studies have also shown a relationship between total serum IgE and asthma in patients with negative skin tests. In addition, other studies have reported that elevations in total IgE are strongly associated with asthma, whereas skin test reactivity is more closely related to allergic rhinitis. Importantly, IgE levels are used to calculate the dose of the anti-IgE antibody omalizumab, when it is used for asthma treatment as discussed below.

Other blood tests may be useful for ruling out vasculitis or allergic bronchopulmonary fungal disease. However, these tests should be employed only when clinical suspicion warrants pursuit of uncommon causes of asthma symptoms.

Sputum Examination

In research studies sputum eosinophil counts have been shown to predict clinical outcomes, particularly exacerbations when corticosteroids are withdrawn, but more research needs to be done before sputum examination can be used as a clinical tool.

Allergy Tests

Tests to determine whether the patient is allergic and to investigate the role of specific allergens as a cause of asthma are of value in some patients, particularly when the clinical history suggests that specific aeroallergens are important triggers in a particular patient, and when asthma symptoms are accompanied by other symptoms typical of allergic disease, such as rhinitis and conjunctivitis. In selected populations, evaluations for perennial or indoor allergens, such as dust mite, cockroach, or animal dander have become increasingly important.

The components of an allergic evaluation include a detailed history of the patient's environment and possible triggers, followed by tests of allergic sensitivity. Sensitivity to a particular allergen (or the presence of specific IgE antibody) can be verified by skin tests or in vitro serum antibody studies. Allergy evaluation is useful for developing avoidance treatment strategies or, in selected cases, for developing immunotherapy regimens.

Radiography

Because the chest radiograph is generally unremarkable in patients with uncomplicated asthma, it is used primarily to exclude other causes of respiratory symptoms. Nonspecific radiographic findings, such as overinflation, prominent hilar vessels, and bronchial wall thickening may be seen. Computed tomography may demonstrate atelectasis, bronchial wall thickening, or mucus impaction.

Exhaled Nitric Oxide

In research studies low eNO values have demonstrated reasonable sensitivity and specificity in discriminating between subjects with asthma and normal subjects, but more research needs to be done before eNO can be used as a diagnostic tool.

Differential Diagnosis

There are a number of conditions to consider in the differential diagnosis of asthma and these are listed in Table 48-1.

Table 48-1

The Differential Diagnosis of Asthma

Condition	Comment
Other airway diseases	
COPD	Significant smoking history Airflow obstruction less reversible Reduced D_{LCO}
Bronchiectasis	Maybe secondary to numerous disorders Patients usually produce purulent sputum Computed tomography usually diagnostic
Reactive airways viral syndrome	Transient, usually resolves after several weeks
Rhinosinusitis	Usually report nasal congestion and post nasal drip Common co-morbid illness accompanying asthma
Gastroesophageal reflux disease	Usually have other complaints but may be silent Common co-morbid illness accompanying asthma
Congestive heart failure	Usually have exertional dyspnea but not at rest Echocardiography helpful
Laryngeal dysfunction	Stridor Diagnosis challenging, laryngoscopy helpful May co-exist with asthma
Upper airway obstruction	May or may not exhibit stridor Flow-volume loop may be helpful Endoscopy diagnostic

MANAGEMENT OF ASTHMA

Successful management of the asthmatic patient requires an appreciation of two basic principles. First, asthma exhibits considerable heterogeneity with respect to etiology, clinical presentation, severity, natural history, and response to therapy. Because of this heterogeneity, it is unlikely that a single management approach will work for all patients. Thus, therapy must be tailored to the individual patient. The second principle recognizes that in each patient, symptom severity may vary considerably over time. For example, some patients may experience a remission of symptoms during adolescence, only to have them recur with even greater severity later in life. Even when the disease remains relatively stable over long intervals, intercurrent flares that arise as a result of seasonal allergies or infection are the rule in asthma. Thus, the patient should be monitored regularly, and treatment should be modified on an ongoing basis to meet the patient's current needs.

Chronic Stable Asthma

A number of comprehensive treatment guidelines drafted by multidisciplinary expert committees have been published. In the following discussion, no attempt is made to recapitulate published guidelines; rather, there is an effort to summarize the recommended general approaches, point out gaps in information, and highlight areas where controversy exists. The management of persistent asthma in adults is highlighted in Table 48-2.

Nonpharmacologic Therapy

Recent studies suggest that patient education and environmental control programs are effective in reducing asthma morbidity, although additional research is needed to better determine which methods are the most effective and which patients benefit the most.

Education

The goal of asthma education is to improve patient understanding of the disease and its management and, consequently, to improve adherence to treatment recommendations. Another aim is to engage the patient in self-management practices, especially in terms of identifying and avoiding asthma triggers and recognizing and treating exacerbations of asthma in their earliest stages.

Controlled trials evaluating structured education and self-management programs for adult asthmatics generally show that such programs result in better asthma control and decreased emergency room visits and hospitalizations. The success of patient education programs is, to a large extent, dependent on their format. For example, individual one-on-one educational sessions and sessions with small groups of patients have been shown to be of comparable efficacy; both are more effective than provision of written materials alone in terms of symptom control, use of proper inhaler technique, application of environmental control practices, and encouragement of physical activity. However, the provision of written materials alone may be sufficient to decrease hospital and emergency room use. Personal contact with a knowledgeable professional is considered superior to provision of either audiovisual or written materials. Like drug therapy, the educational program, as well as the method and frequency of reinforcement, should be tailored to the individual.

The educational program should impart to the patient an understanding of the disease, including the knowledge that symptoms are a product of airflow obstruction and therapy is designed to both prevent and relieve the obstruction. The patient should understand that asthma is a chronic disorder, unlikely ever to go into complete remission, and appreciate that symptoms will fluctuate and occasional exacerbations are to be expected. In addition, reassurance should be provided that, with proper treatment, these events can be minimized; in most cases, a normal lifestyle and life expectancy can be anticipated.

Since educational programs that include self-management strategies are superior, they should also encompass a discussion of the patient's individual treatment plan, including the purpose of different drugs, as well as their side effects. Distinguishing between drugs that control or prevent symptoms and those that relieve symptoms is necessary to reinforcing the importance of "controller" medications that offer no immediate relief of symptoms. Instruction in the proper use of inhaled medications is of obvious importance; so, too, is a description of likely triggers of episodes of asthma and ways to avoid such triggers. Finally, teaching the patient to recognize and intervene in exacerbations during their earliest stages can be helpful in avoiding more serious morbidity and, in some cases, mortality. Educating the patient in self-administration of oral glucocorticoids and providing a telephone number where professional assistance is available around the clock are, in our experience, crucial elements of a management program designed to reduce morbidity and hospitalizations.

Environmental Control

An important, often overlooked part of the management plan for all asthmatics, especially those with severe asthma who remain symptomatic despite intensive drug therapy, consists of measures to control environmental triggers. Avoidance of aeroallergens, viral respiratory pathogens, air pollution, and certain drugs can prevent exacerbations, reduce the need for drug treatment, and decrease utilization of emergency facilities. Of perhaps greater importance is avoidance of factors that may contribute to longer-term, airway inflammation responsible for abnormal airway responsiveness. Allergens from house dust mites, cockroaches, molds, and pets, particularly cats and dogs, have been associated with asthma. While the house dust mite is recognized as a significant cause of asthma throughout the developed world, the relative importance of different indoor allergens may vary among populations. For example, cockroach allergen may play a more prominent role in asthma in inner-city populations. Complete removal from exposure to house dust mites has been shown to reduce

Table 48-2

Management of Persistent Asthma in Adults

Asthma Severity*	**Mild***	**Moderate***	**Severe***
Daytime symptoms	2–6 days/week Usually no reduction in activity	Daily Exacerbations reduce activity	Continual Significant reduction in activity
Nocturnal awakenings	More than two monthly	More than once weekly	Most nights
Relief medication use	Less than daily	Daily	Several times daily
Lung function FEV_1	>80% Predicted	60–80% Predicted	<60% Predicted
PEE variability	<30%	>30%	>30%
Controller medications	Low-dose ICS (highly preferred) OR Leukotriene receptor antagonist OR Theophylline SR	Low–moderate dose ICS + long acting β-agonist OR Low–moderate dose ICS + Leukotriene receptor antagonist OR Low–moderate dose ICS + theophylline SR	Moderate–high dose ICS + long acting β-agonist AND Oral steroids Anti-IgE therapy
Relief medications	Short-acting MDI	Short-acting MDI	Short acting MDI Consider HFN
Diagnose and treat other conditions	Manage environment	Manage environment	Manage environment
	Treat rhinosinusitis	Treat rhinosinusitis Assess for GERD with esophageal pH study	Treat rhinosinusitis Assess for GERD with esophageal pH study
Written action plans	Consider	Recommended, base on PEF/FEV_1	Recommended, base on PEF/FEV_1
Immunotherapy	Consider	Consider	Contraindicated
Monitoring	Annual spirometry	Annual office spirometry Monitor PEF Consider home spirometry	Annual office spirometry Monitor PEF Consider home spirometry
Office visits	Annual	2–3/year	At least every 3 months

ICS = inhaled corticosteroid; PEF = peak expiratory flow; FEV_1 = one second forced expiratory volume; SR = sustained release. Usual or initial outpatient status.

asthma severity and airway hyperresponsiveness. However, incomplete or partial reductions of dust mite counts are of questionable benefit in improving asthma control. Occupational asthma due to low-molecular-weight chemicals is also more likely to abate if patients are completely removed from exposure to the offending agent early in the course of their disease. Most patients with chronic asthma have numerous triggers. Therefore, the impact of avoidance of any single trigger is likely to vary considerably from patient to patient.

Vaccination

Inactivated influenza vaccine may be safely administered to patients with asthma. It seems likely that influenza vaccination would decrease the incidence of exacerbations of asthma; however, this has not conclusively been shown. Patients with

asthma should receive inactivated influenza vaccine if there are no other contraindications and especially if they are elderly or have other co-morbid conditions that increase the risk of death from influenza infection.

Immunotherapy

Allergen immunotherapy also appears to be of benefit in highly selected patients with defined allergic triggers. As a rule, patients who have many allergic triggers tend to benefit less from immunotherapy than those with a single trigger. Patients who have mild- or moderate- persistent asthma not adequately controlled with inhaled medications may be considered for immunotherapy, but those with concomitant nasal symptoms appear to benefit the most. Although serious complications from immunotherapy are rare, they occur more frequently in patients with asthma. Furthermore, because of a high incidence of adverse systemic reactions, persons whose FEV_1 is less than 70 percent of predicted should be considered at high risk of complications from immunotherapy.

Pharmacologic Management

Current guidelines advocate classifying asthma according to clinical severity using symptoms, lung function, and drug use as variables. Disease stratification guides the rational use of controller agents, as discussed below. Drugs currently available to treat asthma (listed in Tables 48-3 and 48-4) are classified as long-term control medications or "controllers" and quick-relief medications or "relievers" on the basis of their principal pharmacodynamic and clinical effect. Thus, short-acting bronchodilators such as inhaled beta agonists or anticholinergics are considered quick-relief medications. Corticosteroids, long-acting beta agonists, leukotriene pathway inhibitors, cromolyn sodium, nedocromil sodium, sustained-release theophylline, and omalizumab are considered long-term control medications, since they are used to achieve and maintain control of symptoms and are usually used daily on a long-term basis. Former nomenclature that classified drugs according to whether or not they had bronchodilator or anti-inflammatory properties is discouraged, since some medications have anti-inflammatory as well as bronchodilator properties.

β-Adrenergic Agonists

Inhaled β_2-adrenergic agonists are the drugs of choice for relief of symptoms due to acute airway obstruction. Short-acting beta agonists have a rapid onset of action and 3- to 6-hour duration of activity. At recommended doses, inhaled beta agonists have few adverse effects. Since regular use of short-acting beta agonists has not been shown to be superior to as needed use of these agents, we recommend that these agents be used as needed.

Long-acting inhaled beta agonists have at least 12 hours duration of action and are not generally recommended for the short-term relief of acute symptoms, although formoterol has an onset of action as rapid as albuterol and can be used as a reliever. *Importantly, whereas long-acting beta agonists are generally the preferred agents to be used with inhaled steroids in combination therapy, they should not be used as monotherapy for the control of asthma of any severity.* The combination of formoterol and budesonide has been demonstrated to be effective when used as both a controller and relief agent and thus provides the advantage of a single device used for both purposes.

Theophylline

Theophylline now is primarily used as an adjunctive therapy, and for its steroid sparing effects, due to its narrow therapeutic index and the availability of safer and more effective alternatives. The steroid sparing effects of theophylline seem to occur at levels below the traditional therapeutic range of 10 to 20 mg/L. Thus, we recommend that the drug be titrated to steady-state serum concentrations of 5 to 10 mg/L or peak concentrations of no higher than 15 mg/L.

Anticholinergic Agents

These agents induce airway smooth-muscle relaxation by blocking muscarinic receptors on airway smooth muscle, inhibiting vagally mediated cholinergic tone. In general, the short-acting anticholinergic agent ipratropium is not as effective as beta agonists as bronchodilators in asthma. It remains to be seen whether the long-acting anticholinergic drug tiotropium will prove to be useful as an asthma treatment.

Glucocorticoids

Glucocorticoid steroids are the most effective agents available for treating persistent asthma. Inhaled steroids improve lung function when compared with placebo and reduce exacerbation rates. Patients with persistent asthma stabilized on inhaled steroids experience increased exacerbations when the steroids are withdrawn. Importantly, retrospective data suggest that the consistent use of inhaled steroids reduces asthma mortality. Finally, although the efficacy of inhaled glucocorticoids is clear, they suffer from important limitations. For example, the dose-response curve of inhaled steroids is relatively flat, meaning that higher doses are only incrementally better than low to medium doses. When there are persistent symptoms, rather than increasing the inhaled steroid dose the addition of long-acting beta agonists, leukotriene receptor antagonists, or theophylline provide superior bronchodilation and improve other outcomes, so that combination therapy is preferred.

Cromolyn Sodium and Nedocromil Sodium

Cromolyn sodium and nedocromil sodium are classified as controller agents, and because they are remarkably safe, these drugs are considered first-line agents in the treatment of children with asthma, although they are inferior to inhaled steroids with respect to most relevant outcomes. In adults, however, the drugs are most often prescribed for patients with mild disease, since responses are unpredictable.

Table 48-3

Asthma Medications

Type	Class	Drugs	Indication/Comment
Quick-relief	Short-acting β-adrenergic agonists	Albuterol: PO, MDI, HFN Levalbuterol: HFN, MDI Pirbuterol: MDI Metaproterenol: PO, MDI, HFN Terbutaline: PO, MDI, SC Isoproterenol: MDI, HFN, IV, SL Bitolterol: MDI, HFN	First-line agents for fast relief of bronchospasm, used for all severity classes MDI β_2-selective adrenergic agonists are preferred
	Adrenergic agonist	Epinephrine: MDI, SC	
	Anti-cholinergic	Ipratropium bromide: MDI, HFN	Also useful for patients intolerant of β-adrenergic agonists
Long-term controllers	Inhaled Corticosteroids	Beclamethasone dipropionate: MDI Budesonide: MDI, HFN Flunisolide: MDI Fluticasone: MDI Mometasone furoate Triamcinolone acetonide: MDI Ciclesonide*	Persistent asthma of any severity, may be used in combination with systemic steroids
	Systemic Corticosteroids	Methylprednisolone: IV, PO Prednisolone: PO Prednisone: PO	Severe persistent asthma not controlled with high dose inhaled steroids or for asthma exacerbations
	Cromones	Cromolyn sodium: MDI, HFN Nedocromil: MDI	Mild persistent asthma
	Long acting β-adrenergic agonists	Salmeterol: MDI Formoterol: MDI Sustained release albuterol: PO	Moderate–severe persistent asthma
	Anticholinergic	Tiotropium	FDA approved for COPD only
	Methylxanthines	Theophylline: PO	Alternate therapy for mild persistent asthma, add on to steroids for moderate–severe persistent asthma
	Leukotriene pathway inhibitors	Montelukast: PO Zafirlukast: PO Zileuton: PO	Alternate therapy for mild persistent asthma, add on to steroids for moderate–severe persistent asthma
	Combinations	Fluticasone/Salmeterol: MDI Budesonide/Formoterol: MDI*	Moderate–severe persistent asthma
	Monoclonal anti-IgE antibody	Omalizumab: SC	Moderate–servere allergic asthma, has steroid sparing properties

PO = oral; MDI = inhaler; HFN = liquid for high flow nebulizer; IV = parenteral; SC = subcutaneous; SL = sublingual.
** Not FDA approved.*

Table 48-4

Detailed Asthma Medications

Type	Class	Mechanism(s)	Indication	Name/route(s)	Dose	Side Effects	Comments
Symptom reliever	Short-acting β_2-adrenergic agonist	β-adrenergic agonist selective for type 2 beta receptor, increases cAMP, activates protein kinase A, and induces bronchodilation by multiple mechanisms	First-line agents for fast relief of bronchospasm	Albuterol: oral, inhaled, and nebulized	Oral: 1 tab every 3–4 h, slow release form available Inhaled: 2 puffs every 4 h, or 30 min prior to exercise for prevention of bronchoconstriction Nebulized: every 3–4 h	Tachycardia, palpitations, nervousness, hypokalemia, tremor	First choice for bronchodilation. Inhaled route is preferred over oral route for faster onset of action and fewer side effects. Increased use or decreased effectiveness may be sign or worsened control. Not recommended for long-term treatment. Chlorofluorocarbon (CFC) propellent in MDI being phased out. HFA formulation has no CFCs. Nebulized solution may be mixed with ipratropium.
				Levalbuterol: Nebulized	Nebulized every 6 to 8 h	Fewer side effects than racemic albuterol	Levo enantomer of albuterol, nebulized combination with ipratropium not studied for compatability. Not been shown to be significantly superior to albuterol.
				Pirbuterol: Inhaled	Inhaled: 1 to 2 puffs every 4 to 6 h		
				Metaproterenol: oral, inhaled, and nebulized	Oral: 1 tab 3–4 times per day Inhaled: 2 puffs every 4 h inhaled Nebulized: every 4 to 6 h		Rare adverse cardiac events have been reported. Not recommended as first-line drug.

	Terbutaline: oral, inhaled, subcutaneous	Oral: 1 tab every 6 h (max 15 mg/d) Inhaled: 2 puffs every 4–6 h Subcutaneous: 0.25 mg, may repeat after 30 min, max 0.5 mg in 4 h		Not recommended as first-line drug as beta agonist side effects more commonly encountered. Intravenous solution available for tocolysis.
	Bitolterol: inhaled, nebulized	Inhaled: 2 puffs every 8 h Nebulized: every 6–8 h		Cannot be mixed with other medications in nebulized solution.
Nonselective beta (β_1,β_2,)-adrenergic agonist	Isoproterenol: inhaled, nebulized, sublingual, intravenous	Inhaled: 1–2 puffs every 4 h Nebulized: 5–15 breaths every 5–10 min, max of 5 times per day Sublingual: 10–20 mg every 3–4 h, max 60 mg per day Intravenous: 2–10 μg per min.	Tachycardia, palpitations, nervousness, hypokalemia, tremor, headache, seizure, paradoxical bronchospasm	Used for anesthesia-induced bronchospasm.
Nonselective (β_1,β_2,α) adrenergic agonist	Epinephrine: Inhaled, subcutaneous	Inhaled: 1–2 puffs every 3 h Subcutaneous: 0.2–0.5 mg every 2 h needed	As for isoproterenol plus convulsions, chills, fever, hallucinations	Not recommended as first-line medication

(*Continued*)

Table 48-4

(*Continued*)

Type	Class	Mechanism(s)	Indication	Name/route(s)	Dose	Side Effects	Comments
	Anticholinergic	Muscarinic receptor antagonist, (subtypes M_3 and M_2), blocks action of acetylcholine on airway smooth muscle resulting in bronchodilation, reduction in mucus secretion	Quick relief of symptoms	Ipratropium bromide: inhaled, nebulized	Inhaled: 2 puffs every 4–6 h Nebulized: every 6 h	Dry mouth, bitter taste, nasal congestion	Alternative for patients intolerant of beta agonists. May be mixed with albuterol in nebulized solution. Slower onset of action than beta agonists.
Long-term controllers	Combination inhalers	Combine the anti-inflammatory properties of glucocorticoids and the bronchodilation of long-acting beta-agonists	First line controller agents for moderate–severe persistent asthma	Fluticasone/ salmeterol Budesonide/ formoterol	Inhaled: 1 puff twice daily Not available in the U.S.	Same as for individual components	
	Inhaled corticosteroids	Anti-inflammatory: effects are broad, bind to glucocorticoid receptors and mediate transcriptional repression of a variety of inflammatory mediators, decreases infiltration of	Mild persistent–severe persistent asthma	Beclomethasone dipropionate Budesonide Flunisolide Fluticasone Mometasone furoate Triamcinolone acetonide	1–3 puffs twice daily One puff twice daily 2–4 puffs per day 1–3 puffs per day 2–3 puffs four times daily or 4–6 puffs twice daily	Skin thinning, easy bruising, adrenal suppression, cataracts, osteoporosis, oral candidiasis, mild growth retardation in children, hoarseness	Mouth washing after use reduces risk of oral candidiasis.

		airways by several inflammatory cell types, reduces cytokine and chemokine secretion by several cell types					
	Systemic corticosteroids	Anti-inflammatory	Severe persistent asthma not controlled with high-dose inhaled corticosteroids or used in taper dosing for asthma exacerbations	Methylprednisolone: intravenous Prednisolone: oral Prednisone: oral	60–500 mg daily in divided doses 5–60 mg daily or every other day	Skin thinning, easy bruising, adrenal suppression, cataracts, osteoporosis, oral candidiasis, psychosis, hyperglycemi a fluid retention	Dose should be titrated to minimum required for desired asthma control
	Cromones	Anti-inflammatory	Mild persistent asthma	Cromolyn sodium: inhaled, nebulized Nedocromil: inhaled	2–4 puffs 4 times per day 2 puffs 4 times per day	Cough Cough, bitter taste	Favorable safety profile, maximum benefit may take 4 to 6 wk.
	Long-acting beta agonists	β adrenergic agonist selective for type 2 beta receptor, increases cAMP, activates protein kinase A, and induces bronchodilation by multiple mechanisms	Moderate–severe persistent asthma	Salmeterol: inhaled Formoterol: inhaled Sustained release albuterol	1 puff every 12 h 1 puff every 12 h 1 tab every 12 h	Tachycardia, anxiety, headache, hypokalemia	Inhaled form has fewer side effects than oral. Salmeterol has both CFC and dry powder forms. Long-acting beta agonists should not be used to treat acute attacks. LABAs should always be used in combination with anti-inflammatory medications for asthma.

(*Continued*)

Table 48-4

(*Continued*)

Type	Class	Mechanism(s)	Indication	Name/route(s)	Dose	Side Effects	Comments
	Methylxanthines	Phosphodiesterae inhibitor, increases cAMP, activates protein kinase A, and induces bronchodilation by multiple mechanisms	Alternate therapy for mild persistent asthma Add-on to steroids for moderate–severe asthma	Theophylline: sustained release: oral	Variable dosing schedules	Nause/vomiting. Toxic level—seizures, tachycardia, arrhythmia	Absorption and dosing dependent on several factors including brand, comorbidities, and medication interactions. Monitoring of drug levels required.
	Leukotriene pathway inhibitors	Cysteinyl-leukotriene receptor type 1 antagonists, blocks action of leukotrienes LTC_4 and LTD_4, reduces inflammation, and causes bronchodilation	Alternate therapy for mild persistent asthma	Montelukast: oral Zafirlukast	1 tab once daily 1 tab twice daily	Rare—neurologic/hepatic complications reported	Association with Churg-Strauss syndrome initially reported but likely due to steroid withdraw and not leukotriene inhibitor.
		5-lipoxygenase inhibitor, reduces production of LTB_4, LTC_4, and LTD_4 by a variety of cell types, reduces inflammation, and is a modest bronchodilator	Add-on to steroids for moderate–severe asthma	Zileuton	1 tab 4 times daily		

	Anti-IgE monoclonal antibody	Binds IgE antibodies	Add-on to steroids for moderate–severe persistent allergic asthma	Omalizumab	150–375 mg subcutaneously every 2 or 4 wks; dosage determined by IgE level before first treatment and body weight	Injection site reaction, rash, headache, anaphylaxis	Not indicated if atopy not present as determined by RAST or skin testing
	Long-acting anti-cholinergic	Muscarinic receptor antagonist, M_3 type selective	Not FDA approved for asthma Consider as add-on controller for severe persistent asthma	Tiotropium	1 puff daily	Dry mouth, urinary retention	Should not be used with ipratropium because of excessive anticholinergic side effects

Lipoxygenase Inhibitors and Leukotriene Receptor Antagonists

Leukotriene pathway inhibitors are a group of compounds that alter the pathophysiologic effects of leukotrienes derived from the 5-lipoxygenation of arachidonic acid. Two classes of agents are available: inhibitors of the 5-lipoxygenase (5-LO) enzyme and cysteinyl-leukotriene receptor type 1 antagonists. Although inhaled corticosteroids are superior asthma controllers, leukotriene pathway inhibitors may be substituted for ICS in selected patients with mild disease and are especially useful when steroids are poorly tolerated, steroid use is not desired by the patient, or there is significant, concomitant rhinosinusitis. Furthermore, leukotriene pathway inhibitors are useful as add-on therapy to inhaled steroids in selected patients with moderate to severe asthma and have steroid sparing effects.

Anti-IgE Monoclonal Antibodies

A monoclonal antibody to IgE (omalizumab) rapidly reduces serum IgE and is an adjunctive agent for atopic asthmatic patients dependent on corticosteroids. Several studies of its use in patients with moderate to severe corticosteroid dependent asthma have shown a significant steroid-sparing effect and a reduction in exacerbation frequency. We recommend that omalizumab be considered for moderate to severe atopic asthmatics, especially when high doses of inhaled steroids or oral steroids are required for disease control. It is most likely to be useful when patients require more than 800 μg of inhaled steroids, take daily oral steroids, have an FEV_1 less than 65 percent predicted, or have required emergency room treatment within the prior year.

Treatment Regimens Based on Severity Classification

The classification of asthma as mild intermittent, mild persistent, moderate persistent, or severe persistent, as presented in published treatment guidelines, allows for a stepwise approach to controller drug therapy (Table 48-2). Current guidelines suffer from significant limitations because patients may frequently move amongst severity groups. Future guidelines will probably more precisely stratify patients based on estimates of asthma burden that account for usual disease severity and the risk posed by individual patient's asthma. This approach recognizes that severity may vary with time and facilitates treatment as a dynamic process, with increments and decrements in drug dosages dictated by changes in severity of illness. Importantly, rigorous adherence to guideline-based therapy will lead to improved asthma control in the majority of patients no matter what the baseline disease severity; this has been demonstrated in a large multinational randomized controlled trial. Although errors in management are most often related to undertreatment with drugs, overtreatment can also be a problem, especially in patients with moderate to severe asthma. In such patients there is a tendency to maintain a static treatment regimen, even after symptoms are controlled and clinical stability is achieved. Treatment goals established in these guidelines include no limitations in activities or missed school or work, no chronic nighttime or daytime symptoms, minimal to no exacerbations, near-normal spirometry, minimal use of quick-relief medications, and minimal to no medication side effects. For all asthma patients, short-acting beta agonists used in recommended doses and delivered by metered dose inhaler are the preferred agents for the relief of acute symptoms though short acting anticholinergic agents are a reasonable alternative. Escalating need for relief medications is an important marker of poorly controlled disease or an exacerbation and should prompt consideration of a step-up in controller therapy or for more severe exacerbations, the initiation of a protocol for acute exacerbations as described later in the chapter.

Mild Intermittent Asthma

Some asthmatic patients experience only mild, intermittent symptoms that are of brief duration. In fact, in a review of drug utilization records from a large health maintenance organization with a pharmacy benefit plan, it was found that approximately 70 percent of patients with asthma use fewer than four canisters of a short- or intermediate-acting beta agonist per year (Fish JE and Peters SP, unpublished observations). The use of inhaled beta agonists on an as-needed basis as sole therapy is usually recommended and is likely to provide satisfactory results with no major side effects for most of these asthmatics.

Patients whose symptoms occur under predictable circumstances (e.g., with exercise or exposure to airborne allergens such as dander and occupational agents) benefit from preventive treatment with an inhaled beta agonist, leukotriene inhibitor, or cromolyn sodium. The treatment of choice is, of course, avoidance of the offending agent, although that is not always possible.

Mild Persistent Asthma

Current treatment guidelines recommend the addition of a long-term control medication on a scheduled, daily basis when mild symptoms are no longer intermittent. Long-term control medications are those that are assumed to alleviate the underlying inflammatory basis of asthma. The low-dose inhaled glucocorticoids are the preferred medications in this group, although alternatives include leukotriene inhibitors, cromolyn, or nedocromil. Although as-needed inhaled steroids have been compared with scheduled inhaled steroids for mild persistent asthma in one randomized trial with promising results, insufficient evidence exists at this time to recommend this approach.

Moderate Persistent Asthma

Current guidelines recommend low-dose inhaled steroids combined with a long acting beta agonist or medium-dose inhaled steroids as preferred therapy. Alternatively, lower-dose inhaled steroids may be combined with a leukotriene receptor antagonist or theophylline based on data from studies demonstrating the steroid-sparing properties of these agents. The anti-IgE antibody omalizumab may be useful, and immunotherapy may be considered in carefully selected

patients. Allergen specific immunotherapy should be utilized only when strict environmental avoidance and medications, including inhaled steroids, have failed to control a patient's asthma and only after careful consideration of the risks. Immunotherapy should only be administered by physicians expert in its use.

Severe Persistent Asthma

For purposes of discussion, severe asthma can be defined as asthma in which symptoms persist despite treatment with high-dose inhaled glucocorticoids and additional therapy in the form of long-acting beta agonists, leukotriene pathway inhibitors, or theophylline. Since severe asthma is frequently caused by poor adherence to drug regimens or exposure to environmental factors or drugs such as aspirin or beta blockers, a thorough investigation of these factors is indicated before the start of additional drug therapy.

For the patient with severe asthma, chemotherapeutic options are quite limited. Although doses of inhaled glucocorticoids can be increased, dosages of theophylline and long-acting beta agonists are limited because of the risk of toxicity. Options include increasing the dose of inhaled glucocorticoids, adding sustained-release theophylline or a leukotriene modifier in patients already taking inhaled glucocorticoids and long-acting beta agonists, and adding a long-acting beta agonist to the regimen for patients already taking inhaled glucocorticoids and theophylline or a leukotriene modifier. As for moderate persistent asthma, the addition of the monoclonal anti IgE antibody omalizumab has been shown to be useful in severe persistent disease. Multiple, well-designed studies have shown benefits in this population including a significant reduction in IgE levels, asthma exacerbations, beta agonist use, and glucocorticoids as well as incremental improvements in lung function.

Leukotriene inhibitors have been studied in patients requiring moderate to high doses of inhaled corticosteroids to maintain control and have been found to have a steroid-sparing effect. In one study, inhaled steroid doses were able to be reduced by nearly 50 percent in those patients taking montelukast. However, further studies are needed to determine the role of leukotriene inhibitors in patients with severe persistent asthma already taking maximal pharmacologic therapy, including high-dose inhaled corticosteroids and long-acting beta agonists. Allergen-specific immunotherapy may be considered in this group; however, the risk of severe events including death is highest in patients with severe asthma.

Patients who fail to achieve symptom control, despite treatment with high-dose inhaled glucocorticoids and one or more long-acting bronchodilators are considered candidates for systemic glucocorticoid therapy. When chronic systemic steroids are needed, oral glucocorticoids are favored over parenteral formulations and, in principle, should be given in the lowest dose possible daily or every other day. For exacerbations or to achieve initial control, oral glucocorticoids may be given in moderate to high doses (0.25 to 1.0 mg/kg/d) for 8 to 21 days, followed by a tapering course to the lowest dose that maintains control. This approach is often sufficient to modify the underlying disease process and to permit better control at lower doses. Although a "threshold dose" of glucocorticoids is required to maintain stability in some patients, this approach may achieve results that are good enough to permit complete discontinuation of oral glucocorticoids.

Whereas potent and higher-dose formulations of inhaled glucocorticoids are now available, it is reasonable to ask whether the administration of increasing doses of inhaled glucocorticoids is more appropriate than prescribing oral steroids. For equivalent therapeutic effects, inhaled glucocorticoids have been shown to produce fewer steroid-related side effects than oral glucocorticoids. Moreover, comparisons of oral prednisolone (40 mg/d) with budesonide (3.2 mg/d) have demonstrated greater systemic toxicity with prednisolone, despite greater efficacy with budesonide. Patients who require high doses of oral glucocorticoids to maintain control of symptoms are referred to as *steroid-dependent* asthmatics. This is in contrast to *steroid-resistant* patients, who fail to demonstrate an improvement in lung function on reasonably high doses of systemic steroids, despite demonstrable improvement with inhaled beta agonists. Steroid resistance may be a primary defect due to an unknown intrinsic abnormality, or it may be a secondary defect related to increased steroid metabolism or the effects of drugs that alter steroid activity. Steroid dependence, on the other hand, is thought to be a reflection of severe disease with intense airway inflammation. In fact, these may simply be semantic differences, since intense airway inflammation itself may alter steroid responsiveness, and steroid dependence may be nothing more than an intermediate form of true resistance. Glucocorticoid resistance in asthma and its potential mechanisms have been reviewed. In patients with severe asthma manifesting steroid dependence or resistance, consideration should be given to the use of alternative anti-inflammatory agents.

Alternative Anti-inflammatory Therapies

Because of the complex array of inflammatory mechanisms putatively at work in asthma, there has been hope that agents such as macrolide antibiotics, gold salts, methotrexate, cyclosporine, colchicine, and others might prove effective in management.

Studies of the steroid-sparing effects of macrolide antibiotics in asthma management have yielded discordant results. Macrolides may alter steroid metabolism, treat chronic, subclinical airway infection from *mycoplasma* and *chlamydia bacteria,* or have other anti-inflammatory effects. In one controlled study, the administration of clarithromycin to subjects with asthma resulted in improvements in lung function, but only in those with demonstrable evidence of *mycoplasma* or *chlamydia* infection.

Because of the lack of long-term efficacy or safety data, the usefulness of gold salts in asthma should be considered unproved.

Several controlled studies of the efficacy of methotrexate in the management of severe asthma have been carried out

with mixed results. In general, the discordant results obtained from these trials suggest that the benefits of methotrexate are not universal and are, perhaps, of questionable significance, particularly in light of the potential for significant adverse reactions to the drug.

In the only controlled trial of cyclosporine (5 mg/kg/d) in steroid-dependent asthmatics, peak flow improved and fewer exacerbations occurred in the treated group during the 12-week trial. However, the treated group experienced frequent side effects, including headache, hypertension, hypertrichosis, paresthesias, and infections with herpes zoster while significant reduction in oral prednisone dose was achieved. More evidence is needed before the use of cyclosporine as a steroid-sparing agent can be recommended.

Colchicine has been shown to relieve symptoms and reduce rescue bronchodilator usage in patients with allergic asthma. Colchicine was compared with placebo as an alternative agent to inhaled steroids in one large study of moderate asthmatics. The main study finding was that colchicine was not superior to placebo as an alternative agent to inhaled steroids. We therefore do not recommend that colchicine be used in lieu of inhaled steroids.

Agents designed to inhibit the effects of cytokine products, such as IL-4 and IL-5, have been studied in clinical trials with disappointing results. Because of the specificity of newer agents, it is likely that some agents will prove more effective in certain patients than others, and the variability in response will reflect differences in the relative importance of different pathogenetic pathways.

Treatment of Associated Conditions

Successful management of asthma often requires treatment of conditions that are thought to aggravate asthmatic symptoms. Asthma may coexist with a number of disorders that affect lung function. Gastroesophageal reflux disease, obesity, and chronic sinusitis are the most common of these disorders associated with poorly controlled asthma.

Gastroesophageal Reflux Disease

Respiratory symptoms including cough, breathlessness, and wheeze have been associated with gastroesophageal reflux disease for more than 40 years. The widely accepted notion that gastroesophageal reflux disease (GERD) can aggravate asthma is based, to a large extent, on empiric observations that antireflux therapy often improves asthma control. In general, most studies, whether they have examined the effect of medical or surgical therapy for GERD on asthma-related outcomes, have employed small numbers of subjects and have suffered from poor study design. A recent meta-analysis in which only data from controlled trials was included, failed to show a consistent effect of anti-reflux therapy on asthma outcomes, including asthma symptoms, medication use, lung function, or nocturnal asthma.

In spite of the lack of data from rigorous clinical trials (or meta-analyses for that matter), many clinicians will assess the possibility that GERD may be aggravating asthma. Ambulatory intraesophageal pH monitoring is a sensitive and specific diagnostic test to verify the diagnosis of GERD. While a negative study is valuable in excluding GERD as a cause of asthma symptoms, a positive study does not indicate that GERD is the cause of asthma symptoms. As a rule, an empiric course of antireflux therapy is necessary to establish a causal relationship.

The diagnosis of GERD should be considered in patients with worsening asthma symptoms after meals or with reclining, patients with intractable nocturnal asthma, patients whose disease is poorly controlled on antiasthma medications, those who require either systemic or high-dose inhaled glucocorticoid therapy, and elderly patients with new-onset asthma. Because of the costs and potential side effects of long-term anti-reflux treatment and the growing appreciation that chronic GERD may have serious consequences, we recommend specialty consultation or ambulatory intraesophageal pH monitoring prior to the initiation of treatment. Empiric treatment should especially be avoided when patients do not have classic reflux complaints. Antireflux therapy should be offered to patients with confirmed GERD who complain of reflux symptoms (heartburn, water brash, regurgitation, dysphagia, hoarseness, and choking) in association with wheezing or other asthma symptoms.

Medical management of GERD consists of weight loss when appropriate, elevation of the head of the bed, avoidance of large meals or recumbency after meals, and medications that raise gastric pH like histamine$_2$-receptor antagonists or proton-pump inhibitors. Usually high doses of medications are needed for adequate acid suppression. Alternatively, studies have demonstrated the efficacy of surgical approaches to GERD, although the effect of anti-reflux surgery on asthma outcomes is not clear.

Chronic Rhinosinusitis

The relationship between asthma and chronic sinusitis is well established, although the underlying mechanisms are not clear. In general, the association between asthma and chronic sinusitis is limited to patients with extensive disease, as determined by patency of the nasal passages and ostiomeatal complex and thickening of the sinus mucosa. Although aggressive treatment of chronic sinusitis is generally believed to result in improved asthma control, there is little published supportive evidence. The treatment of choice for sinusitis includes antibiotics, decongestants, and intranasal topical glucocorticoids. Patients who fail to respond to medical therapy may benefit from endoscopic sphenoethmoidectomy. It should be noted, however, that the results of endoscopic sinus surgery are poorest in patients with asthma, especially those with aspirin sensitivity and polyposis. Specific allergen immunotherapy is particularly useful in asthmatics with concomitant allergic rhinosinusitis and considered after careful consideration of risks and benefits.

Obesity

It has long been felt that obesity contributes to the morbidity of asthma. There is growing epidemiologic evidence that

obesity is associated with asthma. Most prospective studies show an association between body mass index (BMI) and the subsequent development of asthma, however nearly all the studies relied on patient-reported asthma. Indeed in one important study (NHANES III) obese patients reported having more asthma, wheezing, and bronchodilator use but they were less likely to demonstrate airflow obstruction than non-obese patients. Thus, it appears that obese patients are more likely to be misdiagnosed with asthma and to be incorrectly treated. Importantly in one prospective study where the asthma was physician diagnosed, a BMI greater than or equal to 28 was associated with asthma, and this effect appeared to be driven by obese female subjects. The reasons for these associations are not known but are an area of active research. Finally, since intervention studies have shown that weight loss can favorably affect asthma outcomes, it seems prudent to aggressively treat obesity in the asthmatic patient.

Patient Monitoring

In an individual patient, asthma severity may fluctuate with time, owing to changes in environmental exposure or improved disease management, or because of the natural history of the disease. Ongoing treatment should remain consistent with the current disease severity. Hence, just as therapy is "stepped-up" to gain control in symptomatic patients, a gradual reduction in medications, starting with the medication with the greatest toxicity, should be attempted once stability is achieved and sustained for several months. Long-term monitoring of the asthmatic patient is essential for proper adjustment of the management plan. Published guidelines have emphasized the importance of objective measurements over symptoms because of poor patient perception of airway obstruction, especially in patients with long-standing asthma. On the other hand, for some patients, symptoms may be a more sensitive indicator of deterioration than are peak expiratory flow measurements. Clearly, the best strategy for monitoring asthma on a long-term basis is to use both objective and subjective measures. The amount of rescue beta agonist used on a daily basis is also a useful barometer of asthma control.

Peak Expiratory Flow, Spirometry, and Action Plans

Whereas spirometry is recommended to diagnose airway obstruction in the initial assessment of the asthmatic patient, we believe that spirometry and peak flow measurements provide comparable information for monitoring patients on a long-term basis. The historical advantage of peak flow measurements has been their relative ease of performance and lack of expense with self-monitoring on a daily basis. The recent development of hand-held, automated spirometers providing digital output of FEV_1 and data storage capability offers an alternative for home monitoring. Studies have demonstrated that patients can perform home spirometry skillfully after adequate training; however, built-in software that assesses the quality of the forced vital capacity maneuver oftentimes does not perform well. Asthma treatment guidelines have included an enthusiastic recommendation that patients use peak expiratory flow measurements not only to monitor their course but also to dictate self-administered treatment regimens. This recommendation is based on studies showing improvement in subjective, as well as objective, measures of asthma control when patients used peak flow measurements related to their personal best peak flow to adjust medication usage. Moreover, one retrospective study suggested that the usage of action plans was related to reduced mortality. The combination of home monitoring and a comprehensive education and self-management program has been shown to increase pulmonary function, reduce physician visits and emergency room admissions, and reduce use of inhaled beta agonists and prednisone when compared with a program of minimal education and no self-management.

Given the variable nature of asthma and the people it afflicts, it seems unlikely that either peak flow- or symptom-guided self-management would benefit all patients at all times. Clearly, no single treatment algorithm is apt to be the best therapeutic plan for all patients with the same change in peak flow. Likewise, not all patients are capable of executing, or even comprehending, complicated treatment plans. Future studies should focus on whether the benefits of peak flow–guided self-management, if any, outweigh the risks of over treatment that might result from its use. Severely asthmatic patients using home peak flow monitoring tend to use more oral glucocorticoids. Although this may be viewed as a potential benefit of peak flow monitoring, it is unclear whether the increased use is always appropriate or medically warranted. Although the correspondence between peak expiratory flow and its variability and symptoms or other measures of asthma severity is quite good, it is not absolute. It is the authors' opinion that if used, action plans should be written using clear, simple language and should be individualized based on patients' understanding of their asthma, its severity, and their demonstrated ability to comply with instructions. Adherence may be assessed during an initial 2-week assessment period in which patients chart their daily symptoms and lung function measurements. An example of a written action plan is provided in the online supplement.

Markers of Airway Inflammation

The importance of using markers of airway inflammation to monitor disease activity is uncertain. While asthma symptoms, airway responsiveness, and numbers of airway inflammatory cells correlate, the correlations are primarily of statistical interest and are not predictive of one another in an individual patient. For example, there is considerable overlap in airway responsiveness between patients who require only occasional therapy and those who are steroid dependent. That asymptomatic asthmatics with normal lung function have evidence of ongoing airway inflammation is also well established. Defining the marker that best reflects the inflammatory diathesis of asthma is an important scientific challenge.

As discussed above the measurement of bronchial hyperresponsiveness (BHR) is a sensitive tool used for the initial

diagnosis of asthma. Measuring BHR may also have additional utility in the subsequent management of asthma. For example, in one study it was shown that a treatment strategy aimed at specifically reducing BHR was superior to a strategy based on symptoms, medication usage, and PEF measurements (i.e., that suggested by most published guidelines) with regard to reducing exacerbations and improving lung function.

Because of their poor sensitivity and specificity, blood eosinophil counts are not recommended in routine monitoring of asthma severity or as a barometer of airway inflammation. In contrast, sputum eosinophils counts have been shown to predict exacerbations when steroids are withdrawn; however, further study will be needed before measurement of sputum eosinophils can be widely used to monitor patients.

Levels of nitric oxide (NO) in mixed expired gas have been found to be elevated in asthmatics as compared with normal subjects. The level may reflect the degree of underlying airway inflammation. Mixed expired concentrations of NO have been shown to fall during glucocorticoid therapy in patients with severe exacerbations of asthma, suggesting a possible role for NO as an index of disease severity or treatment efficacy. Exhaled NO measurements have been used successfully to titrate inhaled steroids without any loss of asthma control; thus, eNO may be used as a tool in conjunction with other clinical measures to optimize asthma management as recommended by guidelines (i.e., achieving disease control using the lowest doses of medications possible).

Managing Asthma Exacerbations

Asthma especially in its severe forms is characterized by disease exacerbations, and such exacerbations result in substantial morbidity, occasional mortality, and considerable medical and economic costs. The majority of randomized controlled trials of asthma therapies and most studies performed in humans examining asthma pathogenesis have been done in patients with milder asthma. Clinical experience has shown that the majority of exacerbations occur in a minority of asthma patients. Exacerbation-prone patients seem to be at increased risk for attacks of near-fatal asthma. Importantly, when deaths from asthma have been analyzed, most decedents had experienced worsening symptoms of a period of several hours to several days—highlighting the importance of identifying and educating the at-risk patient. It must be recognized that life-threatening episodes can develop in patients whose asthma appears to be mild at baseline. Patients who have baseline severe, poorly controlled disease, those who frequently access the ER, or are frequently hospitalized—essentially those with prior life-threatening episodes—seem to be at the highest risk. These patients should be identified and targeted for intensive disease management including patient education, pharmacologic therapy, and close disease monitoring.

Nonpharmacologic Therapy

Fortunately, the need for mechanical ventilation for acute, severe asthma is an uncommon event because barotrauma occurs frequently in this group. These patients suffer from lung hyperinflation and are difficult to ventilate, but more recently the appreciation that avoidance of barotrauma reduces mortality in acute, severe asthma has resulted in the utilization of lung protective strategies. High transpulmonary pressures can be ameliorated by hypoventilation with resultant permissive hypercapnia, and the use of high inspiratory flow rates that increase expiratory flow time and facilitate lung emptying. Noninvasive positive pressure ventilation may be used safely in carefully selected patients; however, clinical trial data are lacking.

Pharmacologic Management

The cornerstone of therapy for an exacerbation of asthma involves the escalation of both glucocorticoids and quick-relief medications, usually inhaled β_2-adrenergic agonists, with frequent reassessment of the degree of airflow obstruction.

Glucocorticoids

Surprising little is known with regards to the optimal dosing of systemic glucocorticoids in acute asthma, although it is generally felt, for reasons that are poorly understood, that inflammation in acute asthma is relatively resistant to glucocorticoids, hence systemic steroids are often used. For those exacerbations requiring hospitalization typically parenteral steroids in doses ranging from 1 to 10 mg/kg/d of prednisolone or the equivalent in divided doses are used and the steroids tapered at a rate determined by the patient's response. Oftentimes a few days of therapy are required before a noticeable improvement in lung function occurs. Important side effects with parenteral steroids include delirium, hyperglycemia, and fluid retention. Steroids may be tapered once there is a response but it is the authors' opinion that systemic steroids should be tapered over a 2-week period in cases of severe asthma exacerbation. In instances in which there is a prompt response to therapy in the emergency department and the patient is not admitted, lower doses of steroids may be used but systemic therapy is still advised for at least several days and tapering should be done with close outpatient follow-up. In instances in which outpatient oral glucocorticoids are used for less severe exacerbations, we recommend doses in the range of 0.25 to 1 mg/kg/d tapered over a 7- to 14-day period, the initial dose and tapering regimen determined by prior history (i.e., previously successful regimens), severity of the exacerbation, and response. Very mild or subacute exacerbations in asthmatics with mild persistent disease may be managed in some cases by escalating the dose of or initiating inhaled steroids in cases in which patients are taking low-dose steroids or no steroids, respectively.

Bronchodilators

Exacerbations of asthma should never be treated by escalating bronchodilators alone. Fatalities from asthma usually result when patients fail to promptly seek medical attention and commonly patients who died from asthma had self-medicated with escalating doses of quick-relief

medications or long-acting bronchodilators. Although systemic β_2-adrenergic agonists are available it is clear that inhaled β_2-adrenergic agonists are safer and equally efficacious. Inhaled β_2-adrenergic agonists may be used safely in quite high doses with close monitoring. For example, continuous administration of albuterol at doses of 10 mg per hour is a commonly used protocol for acute severe asthma in hospital emergency departments. Intravenous aminophylline, terbutaline, or epinephrine may be used, but the risks of toxicity are much greater than when inhaled β_2-adrenergic agonists are used. Inhaled ipratropium appears to provide further bronchodilation in acute severe asthma.

Other Considerations

Antibiotics are not indicated for acute asthma exacerbations unless there is objective evidence of bacterial pneumonia or co-existing bacterial sinusitis. Oxygen therapy should be used to avoid hypoxia (i.e., oxygen saturation greater than or equal to 92 percent). Oxygen should be titrated to the lowest dose needed since the use of excessive oxygen concentrations can lead to CO_2 retention and a respiratory acidosis in some patients. Prophylaxis for deep venous thrombosis is indicated for the hospitalized asthma patient. Stress ulcer prophylaxis is also indicated given the increased risks imparted by the use of systemic steroids, and this is especially true in the rare patient requiring mechanical ventilation.

Patient Monitoring

Most patients that present to the emergency department with acute severe asthma require intensive bronchodilator therapy and supplemental oxygen. Hypoxia is to be avoided at all costs, so continuous monitoring of oxygen saturation is needed until there is a meaningful response to treatment. High-dose bronchodilator therapy, while generally well tolerated, occasionally causes arrhythmia; therefore, continuous EKG monitoring is also required. Patients who continue to manifest severe airflow obstruction after initial intensive treatment should be admitted to an intensive care unit. When there is clinical improvement but significant obstruction remains, hospitalization is required. In less severe exacerbations patients who promptly respond to treatment in the emergency department may be discharged but close outpatient follow-up is essential.

Allergic Bronchopulmonary Aspergillosis (Mycosis)

Geoffrey Chupp • Carolyn L. Rochester

Allergic bronchopulmonary aspergillosis (ABPA) is an idiopathic inflammatory lung disease characterized by an allergic inflammatory response to the colonization of *Aspergillus* or other fungi in the lung. It was first described in 1952 by Hinson and coworkers and then again in 1967, when Scadding recognized an association of this disease with proximal bronchiectasis in areas previously affected by infiltrates (predominantly in the upper lobes). The first adult case of ABPA in the United States was described in 1968. Although most cases entail hypersensitivity to *Aspergillus* spp. (especially *A. fumigatus)* the finding of a virtually identical clinical syndrome associated with immune sensitivity to *Candida albicans, Helminthosporium* spp., *Curvularia lunata, Drechslera hawaiiensis, Stemphylium languinosum, Saccharomyces cerevisiae,* and *Pseudallescheria boydii* has led to the term *allergic bronchopulmonary mycosis* to describe this syndrome. The precise prevalence of ABPA is unknown, owing in part to variability in diagnostic criteria used in various studies, the lack of distinction between ABPA and mold-sensitive asthma, and to delays in the diagnosis of patients with long-standing disease. Given this consideration it is estimated that ABPA complicates approximately 7 to 14 percent of cases of chronic steroid–dependent asthma and 7 to 15 percent of cases of cystic fibrosis. Most cases of ABPA are recognized in the third to fifth decade of life, but may also present during childhood. In some patients it is likely that ABPA started early in life and continued, unrecognized, until adulthood. Interestingly, familial cases have been reported. The spectrum of disease is broad and can be severe and debilitating, requiring lung transplantation; however, if recognized early and managed aggressively, ABPA is treatable, can remit indefinitely, and progressive lung damage can be avoided. For the purposes of this review, ABPA will be discussed; however, clinicians should be cognizant that diagnostic testing for other fungi needs to be pursued when organisms other than *Aspergillus* spp. are suspected culprits.

PATHOGENESIS

Although the pathogenesis of ABPA is incompletely understood, it is believed to result from a complex immunological reaction to chronic airway colonization by *Aspergillus* (or other relevant fungal) species. *Aspergillus* spp. are ubiquitous, thermotolerant organisms that reside in decaying organic matter. Inhaled spores colonize the airway, proliferate, and result in chronic antigenic stimulation of the airway, tissue injury, and the clinical features of ABPA. While the pathogenesis of ABPA remains poorly understood, it does appear that susceptibility to ABPA, the presence and magnitude of tissue response to *Aspergillus* and the development of clinical disease depend on host factors such as genetic background and T-cell responsiveness to *Aspergillus* antigens.

Investigations into the genetic links to ABPA have produced some interesting results. Best characterized is the

possible link between gene mutations in the cystic fibrosis transmembrane conductance regulator (CFTR) and the pathogenesis of ABPA. CFTR mutations are more common among patients with ABPA compared to the general population and asthmatics without sensitivity to *Aspergillus fumigatus*. Another genetic link to ABPA is that Th2-type T-cell reactivity to selected *Aspergillus* antigens is determined by the presence of MHC Class II DR2 or DR5 alleles, which may predispose patients to the disease, whereas the MHC DQ2 allele may be protective.

At the microscopic level ABPA is characterized by an intense eosinophilic and mononuclear cell inflammatory response that leads to airway injury and bronchiectasis. A role for type I hypersensitivity reactions is strongly suggested by the elevated serum levels of total and *Aspergillus*-specific IgE. Type III hypersensitivity is suggested by the presence of *Aspergillus* precipitins and circulating immune complexes during disease exacerbations. A type IV cell-mediated immune reaction may also be at work, based on the finding of dual (immediate and delayed) cutaneous reactions and in vitro lymphocyte transformation to *Aspergillus* antigen stimulation in some patients.

There has been a substantial amount of work done on the immune response in ABPA. A pathogenetic role for helper T lymphocytes is suggested by a number of findings, including: the presence of increased numbers of airway Th2 cells and levels of soluble interleukin 2 receptors (suggesting T-cell activation) in the circulation of persons with active ABPA; the derivation of *Aspergillus*-specific T-cell clones with T helper–2 (Th2) patterns of cytokine production from the blood of patients with ABPA; the correlations between activated T-cell number, the levels of the T cell–derived cytokines IL-4 and IL-5, and the number of airway eosinophils in the disease; the critical role IL-5 plays in murine models of ABPA; and the increased reactivity of Th2 cells to *Aspergillus* antigens among patients with ABPA as compared with patients with asthma and skin reactivity to *Aspergillus*. In addition to lymphocytes, eosinophils and basophils may contribute to local airway injury and neutrophils likely play a role in airway inflammation and destruction in ABPA as evidenced by the fact that sputum IL-8 levels correlate with sputum neutrophilia, matrix metalloproteinase levels, and FEV_1 among patients with ABPA.

It is also clear that the fungus itself is of substantial pathogenetic importance. *Aspergillus*-derived proteases likely cause epithelial cell injury and protective barrier disruption, which triggers immune hypersensitivity by inducing inflammation or by allowing increased penetration of fungal antigens into the airway wall. *Aspergillus*-derived proteases may also stimulate proinflammatory cytokines such as IL-8, release of growth factors, and may cause tissue damage leading to bronchiectasis. In addition, a variety of other *Aspergillus*-derived antigens (including cytotoxins and heat shock proteins) with demonstrated ability to bind IgE and IgG derived from the blood of patients with ABPA each initiate and drive both the IgE (hypersensitivity) and IgG immune response. *Aspergillus*-derived proteases with antibody-binding capacity can also amplify the inflammatory response. *Aspergillus* antigens such as Aspf1 (a cytotoxic protein), Aspf2 (a fibrinogen binding protein), Aspf5 (a metalloprotease), Aspf6 (manganese superoxide dismutase), Aspf8 (a ribosomal protein), Aspf13 and Aspf18 (serine proteases), as well as Aspf3 and Aspf4 have all been implicated in these processes. Lastly, host response to *Aspergillus fumigatus* antigens includes surfactant proteins (SP) A and D that may play a protective role against ABPA by interfering with binding between *Aspergillus fumigatus* antigens and IgE, although SPD levels do not correlate with acute exacerbations of ABPA in humans.

CLINICAL FEATURES

Although ABPA typically presents in patients with a history of difficult to control asthma, the spectrum of presentation is highly variable and needs to be considered in any patient with moderate to severe asthma and hypersensitivity to *Aspergillus fumigatus*. Typical presenting complaints are nonspecific and include dyspnea, wheezing, poor asthma control, cough (commonly productive of thick, brown mucus plugs), malaise, low-grade fever, and occasionally, hemoptysis. There may be an antecedent history of recurrent asthma exacerbations in conjunction with pneumonias without a culture-identified bacterial source. In addition, a history of atopy with rhinitis, drug allergy, and/or allergic conjunctivitis are common. It is often not until a patient has been repeatedly ill over weeks to months and unresponsive to standard treatments that the diagnosis is considered.

Diagnostic Guidelines

In general, the diagnosis of ABPA is based on appropriate clinical features in combination with supporting radiological and serological findings. While there are no absolutely specific diagnostic criteria (along with the lack of specific clinical findings on presentation and overlap with other common diseases such as asthma, allergy, and bronchiectasis) guidelines have been proposed to aid clinicians in the diagnosis of ABPA (Table 49-1). These guidelines have evolved over time and may be somewhat confusing; however, they can allow for the early detection of ABPA before lung damage occurs and take into account the effect corticosteroids can have on suppressing some clinical features of the disease. ABPA is generally considered to present in two different forms; ABPA-seropositive and ABPA-central bronchiectasis (CB). Patients with ABPA-S may display the following diagnostic criteria proposed by Greenberger and Patterson: (1) history of asthma; (2) total IgE >1000 IU/ml; (3) elevated serum anti-AF IgE and IgG; (4) positive immediate hypersensitivity skin test to *Aspergillus*; and (5) serum precipitins to *Aspergillus fumigatus* or other relevant fungus. (This criterion is considered positive by the presence of an anti-*Aspergillus fumigatus* IgG titer.) These patients may have normal radiographic studies. Patients with ABPA-CB have all of the criteria of ABPA-S and also have

Table 49-1

Criteria for the Diagnosis of ABPA

Seropositive ABPA (ABPA-S)
- History of Asthma (often difficult to control)
- Elevated total serum IgE (usually >1000 IU/ml)
- Immediate skin test reactivity to *Aspergillus fumigatus*
- Elevated specific serum IgE to *Aspergillus fumigatus*
- Presence of serum precipitins or elevared specific serum IgG to *Aspergillus fumigatus*

ABPA central bronchiectasis (ABPA-CB)
- Above criteria are positive
- Central bronchiectasis by high resolution CT scan

Other supportive clinical findings
- Peripheral blood eosinophilia (often absent especially if patient is on oral corticosteroids)
- Patchy, fleeting infiltrates (often absent especially if patient is on oral corticosteroids)
- Expectoration of brown mucuc plugs
- Mucoid-impacted bronchi evident on radiographic studies
- Sputum culture positive for *Aspergillus fumigatus*

central bronchiectasis on high-resolution CT scan or chest x-ray. Patients with ABPA-S tend to have fewer symptoms, lower IgE levels, less severe airflow obstruction, and fewer exacerbations than persons with ABPA-CB. IgE levels fluctuate with disease activity, and a normal IgE level in a symptomatic untreated person virtually excludes the diagnosis. It remains unclear whether ABPA-S is a milder form of the disease (e.g., representing a different host response) or an earlier stage of illness. In addition, patients may have a history of current or previous pulmonary infiltrates, peripheral blood eosinophils (~10,000 cells/m) or expectoration of brown mucus plugs. Identification of *Aspergillus* (or other relevant fungus) in the sputum and dual (immediate and delayed) cutaneous reactions to challenge with *Aspergillus* are also common clinical features of ABPA. Rare cases lacking a history of asthma but meeting the other major diagnostic criteria have been reported.

The differential diagnosis of ABPA includes corticosteroid-dependent asthma without ABPA, tuberculosis, parasitic infections, hypersensitivity pneumonitis, Churg-Strauss syndrome, acute eosinophilic pneumonia (including drug-induced pneumonitis), chronic eosinophilic pneumonia, lymphoma, idiopathic hypereosinophilic syndrome, autoimmune disease, crack/cocaine use, CF, and other causes of bronchiectasis. In addition, the diagnosis of ABPA in patients with mold-sensitive asthma and CF poses particular diagnostic difficulty. This is especially true in asthmatics in the absence of bronchiectasis. Serum precipitins to *Aspergillus* spp. may be present in up to 10 percent and positive immediate skin tests to *Aspergillus* in up to 25 percent of asthmatics. Persons with mold-sensitive asthma or ABPA can have peripheral blood eosinophilia and/or elevated serum total IgE levels. However, most persons with ABPA have 2- to 20-fold higher serum levels of *Aspergillus*-specific IgE and total IgE than do mold-sensitive asthmatics without ABPA. In addition, as mentioned, proximal bronchiectasis is not seen in mold-sensitive asthma but is common in ABPA. A more confusing diagnostic conundrum occurs when considering the diagnosis of ABPA in patients with CF, because patients with CF alone can manifest chronic airflow obstruction, recurrent exacerbations with infections and/or bronchoconstriction, underlying bronchiectasis, pulmonary infiltrates, chronic sputum production, *Aspergillus* colonization of the airways, and positive serum precipitins. Distinguishing ABPA in CF patients is critical because infectious CF exacerbations and the presence of ABPA require different treatments. The steroid treatment required for ABPA may be detrimental in the setting of infection, yet antibiotics alone given for infection may be inadequate to control the inflammation associated with ABPA. Among patients with CF factors associated with the risk of ABPA include: adolescent age, atopy, severe lung disease, and colonization with *Pseudomonas aeruginosa.* ABPA should be suspected in patients with CF who develop clinical deterioration, exhibit a greater than fourfold increase in total serum IgE (especially >1000 IU/ml), have immediate cutaneous reactivity to *Aspergillus* or increase in *Aspergillus*-specific IgE or IgG, and show change in baseline CXR. Annual screening of total serum IgE is recommended—if the level rises >500 IU/ml, immediate cutaneous hypersensitivity testing for reactivity to *Aspergillus fumigatus* or testing for serum anti-*Aspergillus fumigatus* IgE is recommended. One study suggests that the presence of IgE reactive against the purified *Aspergillus* allergens Aspf3 and Aspf4 are useful to distinguish patients with ABPA and CF or *Aspergillus*-sensitive asthma from patients without ABPA.

Clinical Staging of ABPA

Five clinical stages of ABPA have been recognized based on clinical, serological, and radiographic characteristics (Table 49-2). Stage I, the *acute* stage, is characterized by symptoms of moderate to severe asthma, elevated total IgE (typically >1000 IU/ml), an elevated anti-*Aspergillus fumigatus* IgE or hypersensitivity skin test to *Aspergillus fumigatus,* infiltrates on chest radiograph (with or without proximal bronchiectasis), peripheral blood eosinophilia (frequently >2000/mm^3), and positive precipitating or anti-IgG antibodies to *A. fumigatus* (up to fivefold concentration of serum may be required for detection of the precipitating antibodies). Patients with stage II ABPA have disease that is in *remission.* This is characterized by the resolution of symptoms, radiographic clearing, and decreased stabilization of total IgE levels. Remissions are of varying length, can last several months to years or may be permanent, allowing corticosteroid treatment to be tapered or discontinued. Patients with stage III ABPA have *recurrent*

Table 49-2

Client Stages of ABPA

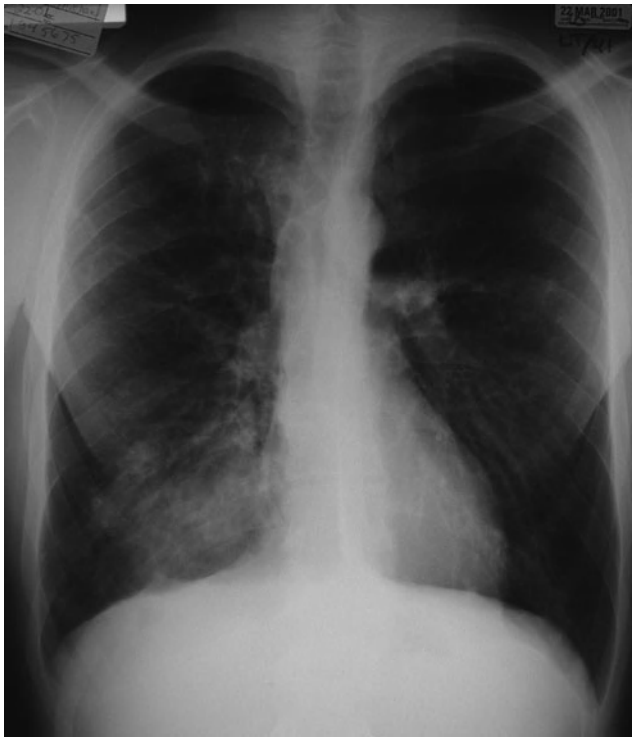
Stage I: Acute
- Acute asthma symptoms
- Elevated serum IgE (>1000 IU/ml)
- Peripheral blood eosinophilia (may be absent in patients treated with oral coricosteroids)
- Fleeting infiltrates on chest x-ray (may be absent in patients treated with oral coricosteroids)
- Positive specific IgE, IgG, skin test reactivity, and precipitins to *A. fumigatus*
- Responds to steroids/antifungal therapy

Stage II: Remission
- Resolution of symptoms
- Resolution of pulmonary infiltrates
- Improvement in eosinophilia and *A. fumigatus* specific blood abnormalities

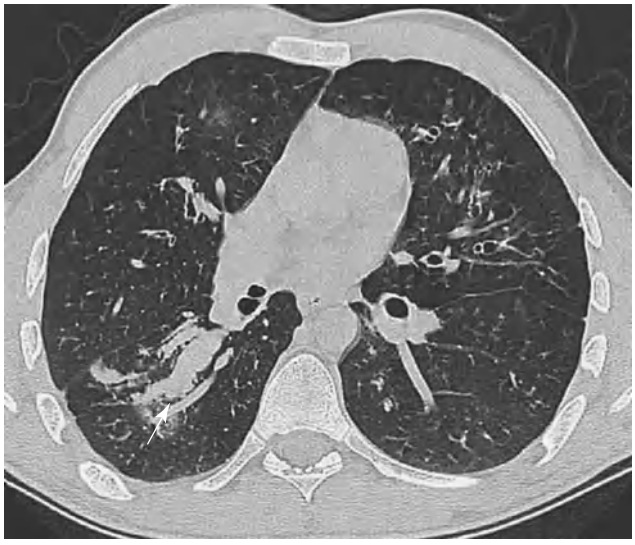
Stage III: Exacerbation/recurrence
- Recurrence/worsenning of clinical symptoms
- Recurrent pulmonary infiltrates
- Rising IgE levels

Stage IV: Steroid-dependent-asthma
- Refractory steriod-dependent asthma
- Persistently elevated serum IgE levels
- Persistently elevated *A. fumigatus*–specific blood abnormalities

Stage V: Fibrotic lung disease
- Refractory steriod-dependent asthma
- Fibrotic lung disease (irreversible obstructive and restrictive defects with impaired diffusing capacity)
- Chronic bronchiectasis symptoms (sputrum production, frequent infections)



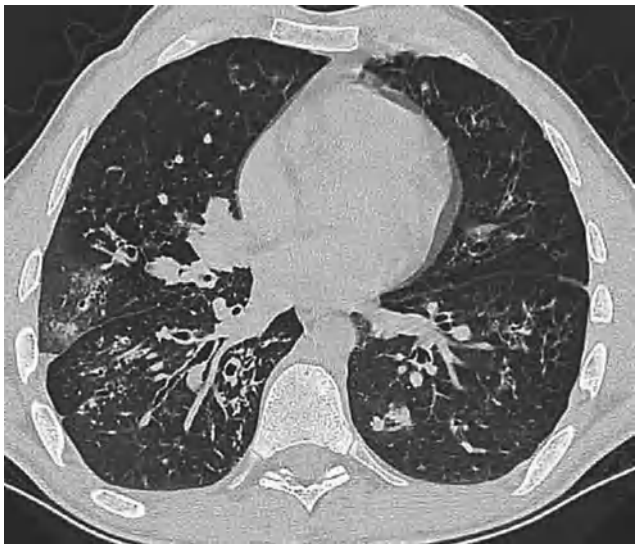
A



B

Figure 49-1 A 27-year-old man with a history of moderate asthma, recurrent bronchitis, and mild hemoptysis. Serological studies were consistent with ABPA (IgE 9,490 IU/ml) and radiographic studies are consistent with bronchiectasis. *A*. PA chest x-ray shows hyperinflated lungs, bronchial dilatation, and right lower lobe opacity consistent with mucoid impaction. *B*. High-resolution CT scan image of impacted bronchus (arrow) and chronic inflammatory changes. *C*. Dilated central bronchus consistent with cylindrical/central bronchiectasis.

disease or disease *exacerbations* (Fig. 49-1). Their disease is characterized by the development of new pulmonary infiltrates or by a >100 percent increase in total IgE. Elevation of IgE may precede clinical or radiological worsening during this stage, and an isolated increase in severity of bronchospasm does not constitute an exacerbation. Although a majority of disease exacerbations are associated with a concomitant increase in symptoms, exacerbations may occur in the absence of any increase in symptoms. Indeed, since up to one-third of patients with radiographic infiltrates may be asymptomatic, evolving progressive lung damage may remain unrecognized. Total serum IgE levels should be monitored every 1 to 2 months for at least a year after diagnosis, and chest radiographs should be performed intermittently. *Aspergillus*-specific IgA levels may also be elevated in the acute or exacerbation stages of disease. Exacerbations are more likely to occur during seasons or environments when mold counts are high. Stage IV ABPA is defined as *steroid-dependent asthma.* In stage IV disease, total IgE, *Aspergillus* precipitins, and *Aspergillus*-specific IgE and IgG typically remain elevated



C

Figure 49-1 (*Continued*)

despite chronic steroid therapy. The frequency of exacerbations may increase. Stage V is defined as *pulmonary fibrosis.* Stage V patients have prominent symptoms of dyspnea; are often steroid dependent because of persistent bronchospasm; frequently have chronic sputum production, recurrent respiratory infections, and irreversible pulmonary function abnormalities (obstruction, restriction, and/or gas exchange abnormalities), and may have cyanosis or clubbing. The serological profile of patients with stage IV disease persists during stage V. Stage V disease is generally thought to be the consequence of longstanding, often unrecognized disease, but may occur occasionally among patients with little prior clinical evidence to suggest the diagnosis (Fig. 49-2).

Figure 49-2 Representative CT image of the lungs of a 41-year-old woman who presented with stage V ABPA (IgE 1500 IU/ml). Pulmonary function studies demonstrated severe combined obstructive and restrictive defects. CT shows bilateral upper lobe scarring and emphysematous changes.

DIAGNOSTIC STUDIES

In addition to the blood abnormalities described in the preceding, analysis of BAL fluid from patients with ABPA reveals a moderate eosinophilia and increased levels of *Aspergillus*-specific IgE and IgA but not IgG. On bronchoscopy mucoid impaction may be evident, and bronchial brushings may reveal mucus containing aggregates of eosinophils, fungal hyphae, and eosinophil-derived Charcot-Leyden crystals. Pulmonary function tests typically reveal an obstructive ventilatory defect (due to bronchospasm or mucus impaction of the bronchi) during stages I, III, IV, and often V and may not correlate with the duration of ABPA or asthma. Persons with stage V disease typically also have a restrictive ventilatory defect with a reduced DLCO (Fig. 49-2).

The typical radiographic manifestations of ABPA include parenchymal infiltrates and bronchiectasis (Figs. 49-1 to 49-3). The infiltrates are often irregular and transient (1 to 6 weeks). They have a predilection for upper lobes, although all lobes may be affected. The bronchiectasis is classically cylindric and proximal (central), occurring within the proximal two-thirds of the lung (Fig. 49-1*B*). Mucoid impaction in dilated bronchi leads to a characteristic (but nonspecific) radiographic appearance of ABPA termed the "finger in glove" opacity. "Tramline shadows" (parallel linear shadows extending from the hilum in bronchial distribution and reflecting longitudinal views of inflamed, edematous bronchi), "toothpaste shadows" (representing mucoid impaction of the bronchi), "ring shadows" (dilated bronchi with inflamed bronchial walls seen on end), local consolidation, or lobar collapse are also common features. Involvement of the small airways may lead to centrilobular nodules and branching tree-in bud opacities (Fig. 49-1). Less common radiographic findings include bullous changes, pneumothorax, pleural effusion, cavitating nodular lesions, aspergilloma (Figs. 49-2 and 49-3) and migratory parenchymal opacities, some of which have a ground-glass appearance.

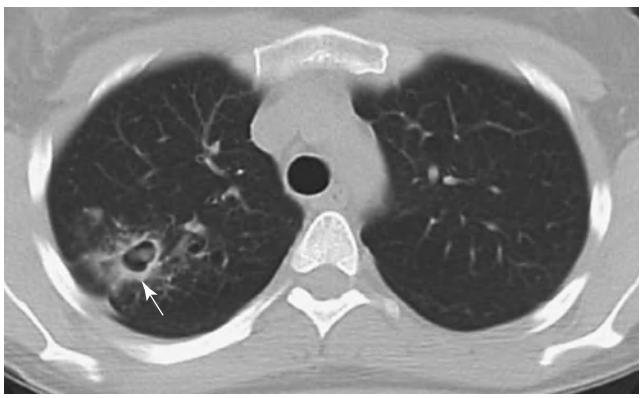


Figure 49-3 A 21-year-old woman with ABPA who responded to treatment with oral corticosteroids and chronic antifungal therapy developed an aspergilloma and hemoptysis (arrow). Amphotericin paste injection failed and the patient ultimately underwent a right upper lobe lobectomy.

High-resolution CT scanning is the most reliable noninvasive means of detecting proximal bronchiectasis.

Open lung biopsy is usually not required to establish the diagnosis of ABPA. Histopathological findings in this disease include intense bronchocentric inflammation with prominent eosinophilia as well as lymphocytes, plasma cells, and monocytes. Bronchi may be filled and/or impacted with copious mucus plugs containing fibrin, Charcot-Leyden crystals, Curschmann spirals, and fungal hyphae. Bronchiectasis of segmental and subsegmental bronchi may be evident. Regions of bronchocentric granulomatosis, eosinophilic pneumonia, eosinophilic microabscess, lymphocytic or desquamative interstitial pneumonitis, proliferative or obliterative bronchiolitis, lipoid pneumonia, or interstitial fibrosis may also be seen.

TREATMENT

Goals in treating ABPA consist of controlling symptoms, preventing exacerbations, and preserving normal lung function. Systemic corticosteroids are the mainstay of therapy for ABPA. Since without treatment ABPA can cause marked chronic lung impairment due to bronchiectasis or pulmonary fibrosis, initiation of appropriate treatment early in the course of disease is essential. Although most data are derived from small uncontrolled trials and there is no definitive proof that corticosteroid therapy prevents the development of central bronchiectasis, retrospective studies have suggested that early therapeutic intervention with corticosteroids may prevent progression to lung fibrosis. Therapy for stage I or III disease should include prednisone, 0.5 to 1 mg/kg a day for 2 weeks, followed by 0.5 mg/kg every other day for 6 to 8 weeks. A subsequent taper (by 5 to 10 mg every 2 weeks) over the ensuing 3 months can then be tried. The duration of treatment must be guided by stage and severity of disease. A low maintenance dose (e.g., 7.5 mg/day) may be required long term to control the disease and prevent recurrence in some patients. Corticosteroid therapy leads to relief of symptoms and decreased airflow obstruction, decreased (>35 percent decrease) serum IgE, reduction in peripheral blood eosinophils, and resolution of pulmonary inflammation and infiltrates. IgE levels should be monitored within 1 to 2 months of an acute episode or exacerbation and should be followed every 2 months thereafter since levels may rise, reflecting disease activity prior to or in the absence of clinical symptoms. Escalation of steroid therapy should be considered if IgE levels rise more than 100 percent. CXR should be monitored every 3 months within the first year of an acute episode or exacerbation, and may be followed yearly thereafter if the disease is quiescent. Pulmonary function testing should be followed up yearly as well. Although treatment of acute exacerbations is believed to be helpful to prevent fibrotic lung disease, it is not clear that early detection and treatment of disease flares that are asymptomatic affect disease progression. Patients with CF and ABPA may derive some symptomatic or functional improvement from steroid treatment. However, patients with CF who are on steroids should be followed closely for development of invasive aspergillosis. It is unclear whether the development of ABPA alters the course of CF disease progression.

Although not advocated as primary treatment, inhaled corticosteroids are useful for control of bronchospasm and can help minimize the dose of systemic steroid necessary to control wheezing. They have been used occasionally as a steroid-sparing agent for the treatment of symptomatic exacerbations and pulmonary infiltrates, and may help maintain stability of lung function. In addition, adjuvant treatment with bronchodilators and antibiotics also helps control bronchospasm and secondary respiratory infection.

In the last decade, the development of oral antifungal agents has brought new hope to patients with ABPA. Even though the current concept is that ABPA is not an "infection," evidence is mounting to support the use of the antifungal agent itraconazole in patients with ABPA. In one randomized controlled study, itraconazole (200 mg bid for 16 weeks) led to significant reductions in corticosteroid dose, decreased IgE levels, greater resolution of pulmonary infiltrates, as well as gains in exercise tolerance or pulmonary function. Among several clinical studies, itraconazole treatment also reduces *Aspergillus* antibody titers, and reduces eosinophilia as compared with placebo. Itraconazole treatment (200 mg/day or every other day) is generally recommended for patients with ABPA who are steroid dependent, have frequent relapses, and in whom the cost and risks are not felt to outweigh the potential benefits. Itraconazole also has demonstrated utility in ABPA associated with CF. If itraconazole is used, steady-state levels should be checked after 1 to 2 weeks, 4 hours after the dose is given, to assess drug absorption, since itraconazole interferes with the hepatic metabolism of several medicines, including cyclosporine, oral hypoglycemics, tacrolimus, terfenadine, cisapride, and midazolam. Particular caution should be exercised in its use among patients taking any of these medications. In addition, physicians must be mindful of adrenal insufficiency associated with itraconazole treatment among patients with ABPA taking inhaled corticosteroids, as itraconazole may cause reduced steroid clearance and/or possible direct suppression of adrenal steroid production. Interval screening for adrenal insufficiency should be considered among such persons. In contrast, the efficacy of itraconazole in ABPA may be less among persons taking agents that raise gastric pH, as this can dramatically reduce drug absorption.

Other antifungal agents, including nystatin, amphotericin B, miconazole, clotrimazole, and natamycin, are generally ineffective in controlling ABPA. Ketoconazole may be effective, but its utility is limited by hepatotoxicity. Efficacy of voriconazole has not yet been studied in ABPA, but anecdotal reports from our center and others suggest similar results to itraconazole. Last, the new biologically engineered antibody omalizumab, directed against IgE, is an intriguing consideration but has not been extensively studied. Given the pharmacokinetics of this agent

omalizumab may be most useful in patients with relatively low IgE levels.

In addition to medical therapy, patients with ABPA should avoid areas and environmental conditions associated with high mold count, such as decomposing organic materials and moldy indoor environments. One should consider the use of HEPA filter devices if such exposures are unavoidable.

PROGNOSIS

With appropriate treatment long-term control of ABPA is feasible, and durable remissions are common. Treatment of stage I disease with corticosteroids typically results in decreased sputum production, improved control of bronchospasm, >35 percent reduction in total IgE within 8 weeks, clearing of precipitating antibodies, and resolution of radiographic infiltrates. IgE levels typically do not completely normalize but rather decrease by approximately one-half of peak levels seen in the acute stage. Progression of stage IV disease to pulmonary fibrosis can be prevented if patients are maintained on low-dose steroids, and most patients with stage V disease have a stable course over several years. Persons with an FEV_1 persistently <0.8 L have a worse prognosis. In addition to severe airflow obstruction and pulmonary fibrosis, long-term complications of ABPA occasionally include the development of an aspergilloma (Fig. 49-3), chronic or recurrent lobar atelectasis, allergic *Aspergillus* sinusitis, or *Aspergillus* tissue invasion and semi-invasive *Aspergillosis.* Transplantation has been undertaken successfully among patients with ABPA, however, post-transplant recurrence of ABPA has been reported.

CHAPTER

Upper Airway Obstruction in Adults

Sidney S. Braman • Muhanned A. Abu-Hijleh

The upper airway is the segment of the conducting airways that extends between the nose (during nasopharyngeal breathing) or the mouth (during oropharyngeal breathing) and the main carina, located at the distal end of the trachea. Air passes through five conducting compartments on its way to the lung: oral cavity, nose, pharynx, larynx, and trachea. Physiological points of narrowing are the nostrils, the velopharyngeal valve (at the passage between the nasopharynx and oropharynx), and the glottis. Clinically significant obstruction in adults may occur within any compartment (see Chapter 2 for detailed anatomic description). The incidence and prevalence of upper airway obstruction in adults is not known. Malignant etiologies and benign strictures related to airway interventions are becoming more prevalent. Other common etiologies of upper airway obstruction in adults include infection, inflammatory disorders, trauma, and extrinsic compression related to pathology of adjacent structures. Initial management focuses on securing the airway and stabilizing the patient. Some conditions require bypassing the obstruction using translaryngeal intubation or tracheostomy. Definitive management depends on the underlying etiology and may include both medical and surgical interventions. The field of interventional pulmonology offers various new management modalities. This chapter provides a brief overview of upper airway obstruction in adults and focuses on clinical features, assessment, etiology, and management.

HISTORICAL PERSPECTIVE

Obstruction of the upper airway and its management concerned physicians for centuries. In the first century B.C., Asclepiades described tracheostomy to improve upper airway obstruction. In the mid-sixteenth century, the first successful tracheostomy was performed to relieve upper airway obstruction caused by a pharyngeal abscess. In the early nineteenth century, the procedure was used to treat croup, and, subsequently, diphtheria. Reports from the same period indicated that 25 percent of children in Paris who were dying from diphtheria were saved by the procedure. By the turn of the twentieth century, rigid bronchoscopy was used to remove a foreign body from the trachea. Finally, Ikeda introduced the flexible bronchoscope in 1967.

New causes of upper airway obstruction, radiologic techniques to detect upper airway obstruction, and treatment strategies have evolved in recent decades. Malignancy and related obstruction of the upper airway have become more prevalent with increasing tobacco use and exposure to modern environmental toxins. Complications of endotracheal intubation and tracheostomy have become well recognized causes of benign upper airway stenosis. Improvement in pharmacologic agents to treat infectious, inflammatory, and malignant etiologies, as well as developments in radiation oncology, have had significant effects on management of upper airway obstruction. More recently, advances involving anesthetic agents and anesthesia techniques, along with development of sophisticated surgical procedures for reconstruction of the larynx, trachea, and bronchi, have had a considerable impact on the management of this condition. Development of new endoscopic and imaging techniques and introduction of interventional pulmonology also have proved useful in the management of upper airway obstruction.

CLINICAL FEATURES

Upper and Lower Airway Obstruction

The causes of upper airway obstruction are considerably less common than diseases of the lower airways, such as chronic obstructive pulmonary disease (COPD) and asthma. However, symptoms (e.g., dyspnea, noisy breathing,) and clinical signs (e.g., wheezing, diminished breath sounds) may be identical, leading to diagnostic confusion. Since COPD and asthma are much more common, they are often assumed to be the cause of the patient's symptoms.

Significant upper airway obstruction may be obscured for a considerable period of time, resulting in delayed diagnosis and possible catastrophic outcome. When the obstruction develops acutely, asphyxia and death may result within minutes to hours. Therapy for acute asthma or an exacerbation of COPD is ineffective in this setting. When upper airway obstruction develops slowly, a delay in diagnosis may predispose patients to unnecessary complications, including bleeding or respiratory failure, and, in the case of an upper airway malignancy, to advanced and incurable disease.

Symptoms and Signs of Upper Airway Obstruction

The main symptoms of upper airway obstruction are dyspnea and noisy breathing. These symptoms are especially prominent during exercise and also may be aggravated by a change in body position. The patient may complain that breathing is labored in the recumbent position and may have a severely disrupted sleep pattern. Upper airway obstruction in such patients causes sleep apnea syndrome (see Chapter 97), which may resolve completely when the obstruction is relieved. Therefore, daytime somnolence may be a prominent feature of upper airway obstruction. In severely affected patients, cor pulmonale may occur as a result of chronic hypoxemia and hypercarbia.

Typically, significant anatomic obstruction precedes overt symptoms. For example, by the time exertional dyspnea occurs, the airway diameter is likely to be reduced to about 8 mm. Dyspnea at rest develops when the airway diameter reaches 5 mm, coinciding with the onset of stridor. Stridor is a loud, musical sound of constant pitch that usually connotes obstruction of the larynx or upper trachea. Although it should be easy to distinguish stridor from wheezing, which emanates from lower airways, sound recordings from the neck and chest have shown that the sound signals from the asthmatic wheeze and stridor are of similar frequency. This explains why errors in diagnosis can be made and an upper airway obstruction due to a tumor or foreign body may be mistakenly treated as asthma.

Unlike wheezing, which is characteristic of diffuse lower airway narrowing and occurs predominantly during expiration, the musical sounds of stridor usually occur during inspiration and are heard loudest in the neck. Maneuvers that increase air flow, such as voluntary hyperventilation, accentuate stridor. Neck flexion may change the intensity of stridor, suggesting a thoracic outlet obstruction. When the obstructing lesion is below the thoracic inlet, both inspiratory and expiratory stridor may be heard. At times, the character of a patient's voice may be a clue to an upper airway obstruction. Hoarseness may be a sign of a laryngeal abnormality. Muffling of the voice without hoarseness may represent a supraglottic process.

Physiological Assessment

Just as upper airway obstruction must be quite advanced before development of symptoms, physiological abnormalities do not become apparent on lung function testing until severe obstruction occurs. Studies of subjects breathing through tubes of varying diameters suggest that upper airway obstruction must narrow the airway lumen to less than 8 mm in diameter in order to produce abnormalities on a flow-volume loop (see below). This corresponds to an obstruction of more than 80 percent of the tracheal lumen. The forced expiratory volume in 1 s (FEV_1) remains above 90 percent of control until a 6-mm orifice is created. Therefore, spirometry, which is often the first screening test for pulmonary symptoms, may not be an effective way to detect upper airway abnormalities. The peak expiratory flow rate (PEFR) and maximal voluntary

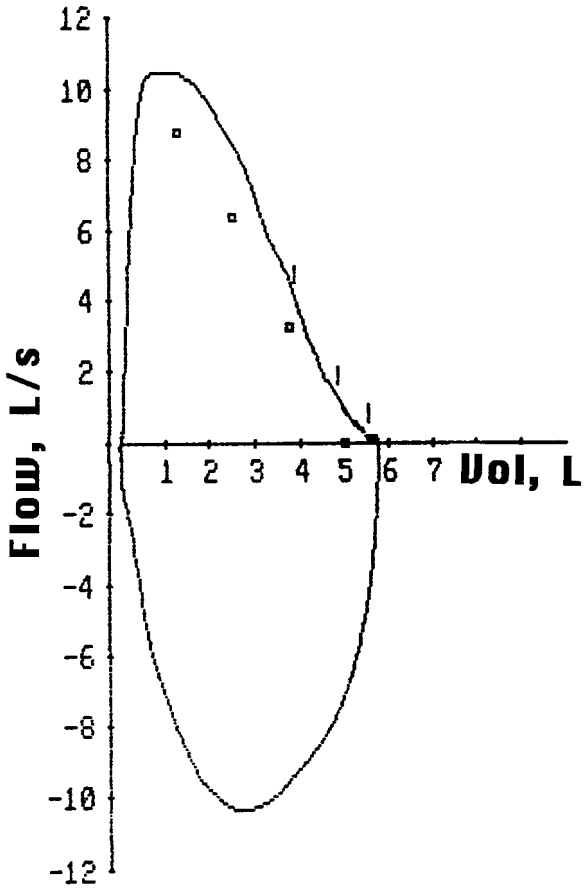

Figure 50-1 Normal flow-volume loop following maximal expiratory *(above)* and inspiratory *(below)* effort. Small vertical lines denote seconds.

ventilation (MVV) are more sensitive than the FEV_1 in detecting upper airway obstruction.

The flow-volume loop, which is a recording of maximal inspiratory and expiratory flow at various lung volumes, is an important tool for the diagnosis of upper airway obstruction. The configuration of the normal flow-volume loop is shown in Fig. 50-1. During a forced expiratory maneuver from total lung capacity (TLC), the maximal flow achieved during the first 25 percent of the forced vital capacity is dependent on effort, i.e., an increase in driving pressure (effort) may result in increased flow. During the remaining 75 percent of the forced vital capacity maneuver, flow is determined by the mechanical properties of the lungs and is not effort dependent. During this portion of forced exhalation, a linear deceleration of flow is caused by dynamic compression of the intrathoracic airways (Fig. 50-2 *A*). An increase in effort and therefore pleural pressure causes further compression of the intrathoracic airways and a further limitation of airflow. At higher lung volumes, flow may be limited by an upper airway obstruction. At low lung volumes, flow may not be affected by an upper airway obstruction, since measurement of flow in this effort-independent portion of the curve represents the function of the peripheral airways. Since the FEV_1 reflects a large portion of flow at these lower lung volumes, it is not a sensitive test for upper airway obstruction.

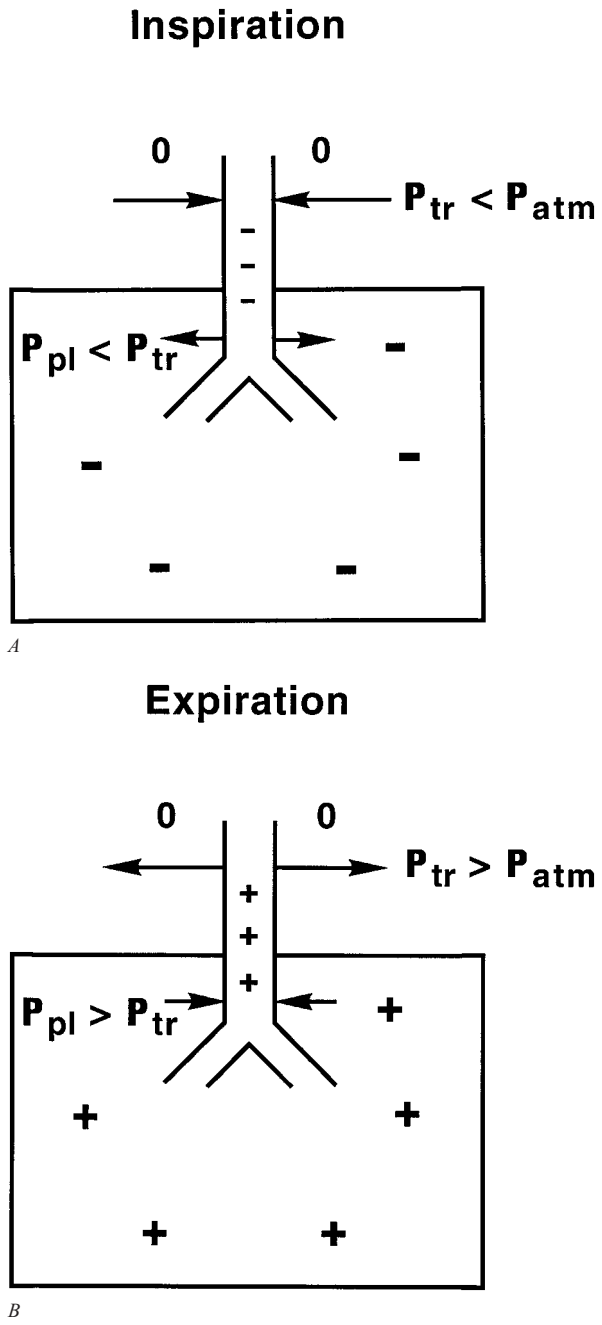

Figure 50-2 Forces acting on intra- and extrathoracic airway walls during inspiration and expiration. 0 = atmospheric pressure; + = positive pressure; − = negative pressure. *A*. During inspiration, extrathoracic tracheal pressure (P_{TR}) falls below atmospheric pressure (P_{ATM}), favoring narrowing of the lumen *(arrows)*. Intrapleural pressure (P_{PL}) becomes negative, favoring airway enlargement *(arrows)*. *B*. During expiration, the extrathoracic tracheal pressure (P_{TR}) becomes positive and, therefore, greater than P_{ATM}, favoring enlargement of the lumen *(arrows)*. Intrapleural pressure (P_{PL}) is positive, causing dynamic compression of the intrathoracic trachea *(arrows)*.

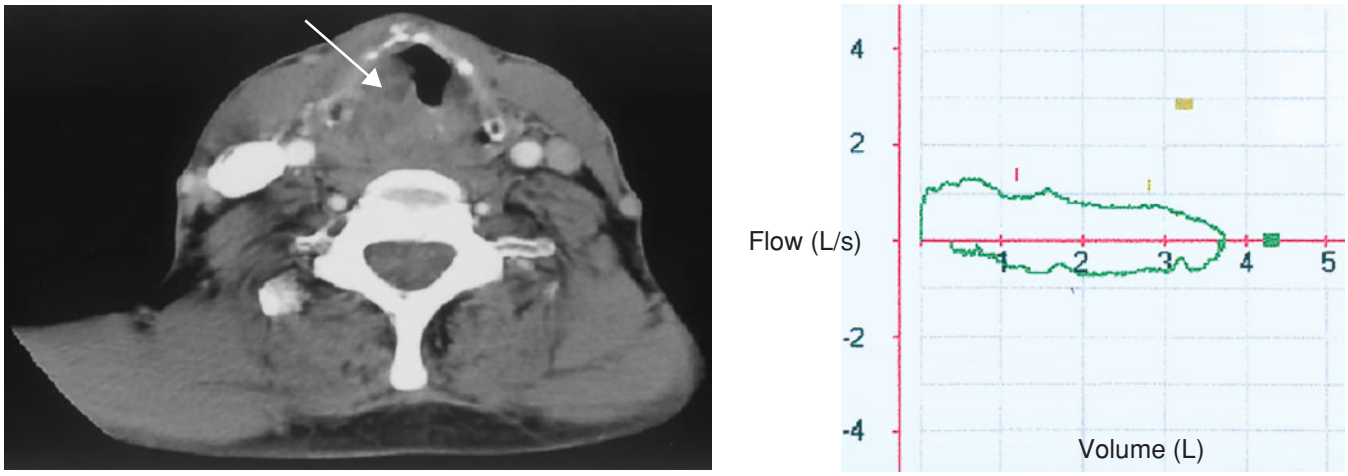
Because the PEFR reflects flow at higher lung volumes, it may be abnormal when the FEV_1 is not.

In generating the flow-volume loop, forced inspiratory flow is limited by effort during the entire inspiratory maneuver. Flow increases from residual volume to near the



A *B*

Figure 50-3 *A*, *B*. Flow-volume loop in fixed upper-airway obstruction due to laryngeal abscess in a 56-year-old man who developed persistent wheezing, hoarseness of voice, and intermittent stridor for 3 months after a brief intubation for asthma exacerbation. Computed tomography scan of the neck shows a laryngeal abscess with significant impingement on the laryngeal inlet. The flow-volume loop demonstrates a plateau of flow during inspiration and expiration; the $FEF_{50\%}/FIF_{50\%}$ ratio is near 1.

midportion of the curve, where it becomes maximal at the peak inspiratory flow rate. Flow then declines until TLC is reached. The pressure surrounding the extrathoracic portion of the upper airway is atmospheric. The turbulent nonlaminar airflow, which occurs during forced inspiration and causes airway pressure to fall in this portion of the airway, favors slight narrowing of the extrathoracic airway (Fig. 50-2*B*). Peak inspiratory flow, therefore, is less than peak expiratory flow in normal subjects. Because of the dynamic compression of the intrathoracic airways that occurs during exhalation, flow during the middle of inspiration, i.e., the forced inspiratory flow at 50 percent of the forced vital capacity ($FIF_{50\%}$), is usually greater than flow during the middle of forced expiration, i.e., the forced expiratory flow at 50 percent of the forced vital capacity ($FEF_{50\%}$). Typical patterns of the flow-volume loop may be seen, depending on whether the obstruction to flow is "fixed" or "variable," and whether the site of the obstruction is above or below the thoracic outlet or suprasternal notch.

Fixed obstructions of the upper airway are those whose cross-sectional area does not change in response to transmural pressure differences during inspiration or expiration. A fixed obstruction may occur in either the intrathoracic or extrathoracic airways. Irrespective of the site of the obstruction, a fixed lesion results in the flattening of the flow-volume loop. A *variable obstruction* is one that responds to transmural pressure changes, eliciting varying degrees of obstruction during the respiratory cycle. Since the stresses on the intrathoracic and extrathoracic airways are different, changes seen in the flow-volume loop vary according to the site of the obstruction.

A number of conditions have been associated with nondistensible narrowing of the upper airway and fixed airway obstruction. Benign strictures and malignancy are common examples. Maximal inspiratory and expiratory flow-volume loops with fixed obstruction show constant flow, represented by a plateau during both inspiration and expiration (Fig. 50-3*A*, *B*). On the expiratory curve, the plateau effect is seen in the effort-dependent portion of the curve near TLC; very little change is noted in the effort-dependent portion near residual volume. Since the inspiratory curve is similar in appearance, the ratio of $FEF_{50\%}$ to $FIF_{50\%}$ is normal (close to 1). The forced inspiratory volume in 1 s (FIV_1) and FEV_1 are nearly the same in fixed upper airway obstruction.

Vocal cord paralysis is a common cause of variable extrathoracic obstruction. A variable extrathoracic airway obstruction increases the turbulence of inspiratory flow, and intraluminal pressure falls markedly below atmospheric pressure. This leads to partial collapse of an already narrowed airway and a plateau in the inspiratory flow loop (Fig. 50-4*A*, *B*). Expiratory flow is not significantly affected, since the markedly positive pressure in the airway tends to decrease the obstruction. The ratio of $FEF_{50\%}$ to $FIF_{50\%}$ is high (usually greater than 2). Similarly, the FEV_1 is greater than the FIV_1.

A variable obstruction in the intrathoracic airways reverses the situation. A predominant reduction in maximal expiratory flow is associated with a relative preservation of maximal inspiratory flow. This association occurs because intrapleural pressure becomes markedly positive during forced expiration and causes dynamic compression of the intrathoracic airways. The obstruction caused by an intrathoracic lesion is accentuated and a plateau in expiratory flow occurs on the flow-volume loop (Fig. 50-5*A*, *B*). A plateau of flow suggests that the lesion has caused the airway lumen to reach its minimal size. A flow peak may precede the plateau, suggesting that the obstruction may not affect flow until a certain lung volume is reached. During inspiration, intrapleural

B

Figure 50-5 Variable intrathoracic obstruction due to squamous cell carcinoma of the trachea. *A*. Computed tomography of the chest shows a tracheal lesion *(arrow)*, which was not readily apparent on plain chest radiograph. *B*. Superimposed flow-volume loops show a plateau of expiratory flow preceded by a peak of flow at higher lung volumes. The forced inspiratory flow is preserved in comparison to expiratory flow, but it is also reduced. $FEF_{50\%}/FIF_{50\%}$ is 0.4.

pressure is markedly negative; therefore, the obstruction is decreased. The ratio of $FEF_{50\%}$ to $FIF_{50\%}$ is very low and may approach 0.3. Similarly, the FEV_1 is considerably lower than the FIV_1. Although the flow ratios are similar to those seen in patients with COPD and chronic asthma, these disorders often can be distinguished by the appearance of the flow-volume loop. Thus, the expiratory curve in patients with COPD and asthma is primarily altered in the effort-independent portion of the curve, leading to a characteristic shape unlike the plateau configuration of an upper airway obstruction (Fig. 50-6).

When a hospital laboratory or physician's office is not equipped to perform flow-volume loops, results of other tests, such as routine spirometry, may be helpful. If the forced spirogram shows that the PEFR is reduced disproportionately to the reduction in FEV_1, an upper airway obstruction should be suspected. Other findings that suggest the diagnosis include a ratio of less than 1.0 for the inspiratory flow between 25 percent and 75 percent of the inspired vital capacity ($FIF_{25–75\%}$) and a value of less than 1.0 for the expiratory flow between 25 percent and 75 percent of the expired vital capacity ($FEF_{25–75\%}$). Another indication is an FEV_1 that is decreased to the same degree as the $FEF_{25–75\%}$. The MVV may also be a useful test, since it measures both inspiratory and expiratory flows. A ratio of MVV to FEV_1 of less than 25 percent is often found with upper airway obstruction. Whenever the MVV is reduced in association with a normal FEV_1, a diagnosis of upper airway obstruction should be considered.

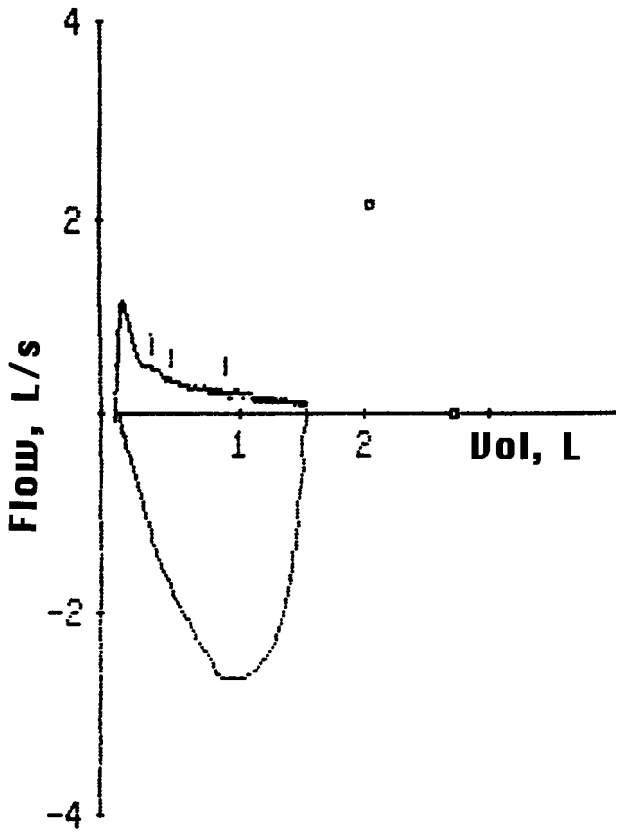

Figure 50-6 Flow-volume loop typical of chronic obstructive lung disease. Very low $FEF_{50\%}/FIF_{50\%}$ and typical curvilinear shape are noted.

Figure 50-7 Acute epiglottitis. Lateral soft-tissue radiograph of the neck of a patient with stridor shows swelling of the epiglottis *(large arrow)* and loss of normal convexity of the edematous aryepiglottic folds *(small arrow)*.

In contrast to the situation in patients with diffuse obstructive disease of the lower airways (e.g., COPD, asthma), the distribution of ventilation in the lungs is normal, and ventilation-perfusion mismatch does not occur. Hypercarbia is not seen unless the degree of obstruction is very severe, although nocturnal hypercarbia may occur while daytime levels of P_{CO_2} are normal. Hypoxemia is also not present except during exercise and with severe airflow limitation, when it may accompany increases in the level of P_{CO_2}. In contrast to asthma and many instances of COPD, the airflow obstruction caused by an upper airway lesion does not resolve following the inhalation of a bronchodilator.

Radiographic Assessment

When acute airflow obstruction occurs as a result of an abnormality of the extrathoracic airway, roentgenographic studies of the soft tissues of the neck in the emergency setting may be helpful (Fig. 50-7). However, computed tomography (CT) has afforded the most important approach to imaging of the extrathoracic airways (Fig. 50-8). The standard chest roentgenogram is often not helpful in detecting the presence, or the cause, of upper airway obstruction. Occasionally, in patients with chronic airway obstruction, generalized hyperinflation of the lungs may occur; in the absence of asthma or COPD this finding may raise suspicion of occult disease in the central airways. The trachea is usually well visualized on the posteroanterior (PA) and lateral views in chest roentgenograms of good quality. It is located in the midline and is moderately deviated at the level of the aortic arch. However, many standard roentgenograms are underpenetrated so that the trachea may become a "blind spot." In one study, only 13 of 53 tracheal tumors were evident to the radiologist on the standard PA roentgenogram. The use of digital imaging techniques may avoid such pitfalls. However, thoracic CT studies have become the procedure of choice for imaging the upper airway.

The sensitivity of CT scanning for detecting upper airway disease surpasses that of the routine chest roentgenogram (97 percent versus 66 percent, respectively). Helical CT scanning (HCT) minimizes artifacts due to respiratory motion and provides imaging of the whole thoracic volume during a single breath hold. The technique represents an improvement over conventional CT scanning in that it allows detection of intraluminal, submucosal, and extraluminal lesions (Fig. 50-9*A*, *B*) and (Fig. 50-10). Since the early 1990s, HCT has become the preferred noninvasive modality for evaluation of the central airways. The use of HCT using multidetector technology and thin collimation provides high-resolution images of

Figure 50-8 Computed tomography scan of the neck demonstrating a large laryngocele compressing the lateral wall of the larynx *(arrow)* causing positional air flow obstruction.

the entire thorax, improved special resolution, greater speed of image acquisition, and excellent contrast enhancement. HCT techniques using multiplanar and three-dimensional reconstruction can provide virtual images of the thorax that enhance the perception of local and diffuse anatomic lesions of the upper airways (Fig. 50-11). The images may demonstrate the degree of tracheal widening or narrowing, show the location and longitudinal extent of abnormalities, assess tracheal wall thickness, and demonstrate associated extratracheal diseases.

The use of paired inspiratory-dynamic and expiratory multislice HCT has proved helpful for the diagnosis of tracheomalacia. Because the maximal degree of collapse in tracheomalacia usually occurs during exhalation rather than at end-expiration, dynamic expiratory imaging is preferable to end-expiratory imaging. If complete collapse is not demonstrated during expiration, then one should confirm the diagnosis by quantitatively measuring the degree of airway luminal narrowing during expiration. Tracheomalacia is generally defined as a reduction in cross-sectional area of greater than 50 percent on expiratory images. The degree of dynamic airway collapse correlates well with findings on bronchoscopy.

Another novel CT-based imaging technique is virtual bronchoscopy. The use of volumetric imaging allows for an intraluminal three-dimensional reconstruction of the airways and surrounding tissues. The technique has been used with a high degree of accuracy in assessing the width, length, and contour of fixed airway lesions, but it has not been effective in defining dynamic airway lesions, such as laryngotracheomalacia.

Computed tomography scan of the chest demonstrating marked narrowing of the trachea with intraluminal calcified nodular projections in a patient with tracheopathia osteoplastica. *B*. Computed tomography scan of the chest demonstrating multiplanner reformation of the trachea in the sagittal plane of the same patient.

Magnetic resonance imaging (MRI) is another modality that may be used to assess the central airways and surrounding mediastinal structures. MRI provides a multiplane image of the chest without the need for contrast material.

However, the technique is best used to investigate vascular structures surrounding central airways, such as vascular rings or aneurysms that may compress the trachea, rather than the airways themselves, which are better visualized using CT scanning.

CAUSES OF UPPER AIRWAY OBSTRUCTION

Infection

Deep Cervical Space Infections

Deep cervical space infections occur in potential spaces bounded by the deep cervical fascia. The cervical fascia is divided into a superficial and, a more complex, deep layer. This configuration and complexity divides the neck into functional units. Infection can spread along the planes formed by the cervical fascia. Infections affecting the deep neck tissues may result in life-threatening upper airway obstruction.

Patients with deep cervical space infections may present with sore throat, odynophagia, neck swelling, pain, fever, and dyspnea. Stridor and profound respiratory difficulty are signs of significant upper airway obstruction. Parapharyngeal, peritonsillar, submandibular, and retropharyngeal abscesses appear to be common locations in adults. The bacteriology and initiating event of deep cervical infections appear to have changed over time.

Mixed infections caused by aerobic and anaerobic infections are common and have been reported in up to two-thirds of cases. *Streptococcus viridans* and *Klebsiella pneumonia* are common pathogens. *Staphylococcus aureus, Staphylococcus epidermidis, Streptococcus pneumoniae, Escherichia coli,* and *Haemophilus influenzae* are other agents that are commonly reported. Alpha and beta hemolytic *streptococci* appear to have significantly declined in frequency. Overall, an odontogenic origin is probably most common, with upper respiratory tract infections as an important etiology in children. Intravenous drug abuse, mandibular fractures, iatrogenic and non-iatrogenic traumatic injury to the upper airway, underlying malignancy, and poor underlying immune status are associated conditions. Ludwig's angina—an infection of the submandibular space and the floor of the mouth—is potentially lethal and is commonly associated with significant upper airway obstruction. This entity is usually a cellulitic process and can affect the submandibular spaces bilaterally. In one report, 75 percent of the cases with true Ludwig's angina required tracheostomy.

Treatment of deep cervical infections involves maintenance of oxygenation and ventilation by securing an adequate airway, administration of appropriate antibiotics, and when indicated, use of surgical drainage. Complications of deep cervical infections include upper airway obstruction, Lemierre's syndrome (see below), distant infection, septic embolization, carotid artery rupture, pulmonary embolism, direct extension of infection resulting in mediastinitis and empyema, and rupture of the abscess during intubation or other interventions.

One particularly virulent cervical infection, known as Lemierre's syndrome, arises from a nasopharyngitis or peritonsillar abscess. This lateral pharyngeal space infection results in suppurative thrombophlebitis of the internal jugular vein, septicemia, and metastatic abscess formation, particularly in the lungs and joints. *Fusobacterium necrophorum* is usually the causative agent and has been cultured from blood in over 80 percent of cases. Symptoms begin with a sore throat, fever and painful swelling in the neck, followed by tender lymphadenopathy and tenderness along the sternocleidomastoid muscle (representing thrombophlebitis of the internal jugular vein). Dysphagia, trismus, and upper airway obstruction may occur as a result of swelling of the lateral pharyngeal space. Contrast-enhanced CT scan of the neck is most useful in establishing the diagnosis of thrombosis of the internal jugular vein and may demonstrate soft-tissue abscesses, fasciitis, and myositis, which may require extensive surgical debridement. Without the use of early and appropriate antibiotics, such as high-dose penicillin with metronidazole, or monotherapy with clindamycin, the mortality rate approaches 100 percent.

Epiglottitis

Epiglottitis is an infectious process that causes variable degrees of inflammation and edema of the epiglottis and supraglottic structures. Supraglottitis may be more appropriate term in adults, since the supraglottic structures usually are involved with variable involvement of the epiglottis. This condition can be life threatening. Its prevalence is 0.18 to 9.7 cases per million adults; the mortality rate may be as high as 7.1 percent. Clinical presentation includes odynophagia, with inability to swallow secretions, sore throat, dyspnea, hoarseness, fever, tachycardia, and stridor. In one review, 44 percent of the patients had a normal routine oropharyngeal examination.

Fiberoptic laryngoscopy is necessary to make the diagnosis. The procedure is safe in adults with suspected epiglottitis and should be done without delay. Radiographic studies can be helpful in ruling out other etiologies with similar presentations and in evaluating potential complications. However, the airway must be secured, and radiographic studies should not delay diagnosis or management.

Supraglottitis may involve the base of the tongue, uvula, pharynx, and false vocal cords. The disease may be increasing in prevalence among adults and declining in children, perhaps, reflecting introduction of *haemophilus*-b conjugate vaccines. Young adult males are commonly affected. The disorder appears to be more prevalent in colder, winter months and in smokers. Blood cultures are positive in less than one-third of cases. Although *Haemophilus influenzae* is the most common organism isolated in children, adult supraglottitis may be caused by a variety of organisms, including *Haemophilus influenzae, pneumococci,* group A *streptococci, Staphylococcus aureus, Streptococcus viridans*, a variety of anaerobic organisms, mycobacteria, fungi, and viruses. Throat cultures can be helpful in diagnosis and management; however, treatment should not be delayed while awaiting culture results.

Illicit drug use may be associated with epiglottitis, with inhalation of heated objects (e.g., metal pieces from a crack cocaine pipe or the tip of a marijuana cigarette) causing thermal injury to supraglottic structures. Signs, symptoms, and roentgenographic and laryngoscopic findings are similar to infectious epiglottitis.

Initial antibiotic therapy using a third-generation cephalosporin or extended-spectrum penicillin is reasonable. The prevalence of resistant organisms should be taken into account when choosing empiric antibiotic coverage. Corticosteroids often are used in management of acute epiglottitis despite lack of evidence to support their use. Based on anecdotal case reports, epinephrine is also used.

Patients should be observed closely and experienced staff should be available immediately to secure the airway by intubation or surgical approach, if needed. Securing the airway is extremely important in patients who develop stridor and other signs of significant airway obstruction. Mortality in this group has been reported to be as high as 17.6 percent.

Laryngotracheobronchitis and Bacterial Tracheitis

Laryngotracheobronchitis (croup), an acute viral respiratory illness commonly seen in children, is characterized by narrowing of the subglottic area, causing symptoms of stridor, barking cough, and hoarseness. Adult croup is a rare condition. Rare instances of diphtheric croup have been described in adults; noninfectious membranous tracheitis related to trauma also has been reported.

Acute bacterial tracheitis refers to involvement of the subglottic trachea by bacterial infection and usually follows an episode of viral laryngotracheobronchitis. Thick, purulent exudates and mucosal edema may cause symptoms of upper airway obstruction. *Staphylococcus aureus* appears to be the predominant organism. Prompt antibiotic therapy, close observation with attention to airway compromise, and frequent suctioning are important. Data to suggest effectiveness of steroids or epinephrine in adults are lacking.

Rhinoscleroma is a chronic, progressive granulomatous infection of the upper airway that may cause airflow obstruction. This disorder affects primarily the nose and paranasal sinuses, but also may involve the nasopharynx, larynx, trachea, and bronchi. The causative organism is *Klebsiella rhinoscleromatis.* Rhinoscleroma is endemic in Africa, Asia, and South America and is rare in North America. About 5 percent of patients have diffuse narrowing of the trachea. Prolonged antibiotic therapy with trimethoprim-sulfamethoxazole is effective.

Tuberculosis

The incidence of laryngeal tuberculosis may be on the rise due to the epidemic caused by the human immune deficiency virus. This form of the infection is relatively uncommon, accounting for less than 1 percent of tuberculosis cases. Laryngeal tuberculosis may present as progressive hoarseness and ulceration or a laryngeal mass. In the appropriate clinical context, a positive purified protein derivative (PPD) skin test and acid-fast bacilli in sputum may suggest the diagnosis. However, a biopsy from the laryngeal abnormality usually is required. Biopsy features include granulomatous inflammation, caseating granulomas, and acid-fast bacilli. The true vocal cords and epiglottis are the areas most likely affected. Treatment with antituberculous medications is usually adequate and should be instituted promptly, since the disease is highly contagious. Surgical interventions, including tracheostomy, are reserved for airway obstruction and long-term complications and, in one report, were required in 12 percent of the cases.

Endobronchial tuberculosis may result in significant airflow limitation that is related to the initial lesion or subsequent stricture formation. A barking cough and sputum production are common findings. The diagnosis of tuberculosis can be delayed while the diagnosis of malignancy is being entertained. Early diagnosis and treatment with antituberculous medications should decrease the development of fibrostenosis and resultant airflow limitation. The role of steroids in reducing the incidence of fibrostenotic complications remains unclear and controversial. Management may require endoscopic or surgical approaches.

Upper Airway Malignancy

Head and Neck Cancer

Head and neck cancers, which represent the fifth most common cancer worldwide, develop in the upper aerodigestive tract, including the oral cavity, pharynx, larynx, and related structures. The great majority are squamous cell carcinomas. These cancers share common risk factors, prognosis, treatment, and epidemiology. A 23 percent decline in head and neck cancers has been observed in the United States over the last two decades. The reported annual incidence was 11.2 cases per 100,000 per year from 1992 to 1999, as compared with 14.6 cases per 100,000 per year from 1976 to 1983.

The clinical presentation of head and neck cancer depends on the location and stage. Symptoms include hoarseness, hemoptysis, sore throat, and otalgia; life-threatening upper airway obstruction may be seen. Five percent of newly undiagnosed laryngeal cancers (a subcategory of head and neck cancers) present with severe dyspnea or stridor and may require emergency laryngectomy or tracheostomy.

Tracheal Malignancy

Tumors of the trachea and carina may produce a gradual decrease in airway diameter. Primary malignancies of the trachea are rare in comparison with other upper airway and bronchogenic tumors. In one study, lung cancer was 140 times more common than primary tracheal cancer.

Adenoid cystic carcinoma and squamous cell carcinoma comprise the majority of primary malignant tracheal tumors. Adenoid cystic carcinoma appears to be slightly more common. Dyspnea, cough, hemoptysis, wheeze, and stridor are frequent presenting symptoms. Surgery remains the most effective management. Emergency treatment with procedures to recanalize the airway, including airway stenting, may be necessary pending definitive surgery. Postoperative radiation therapy appears useful for primary tracheal malignancies, particularly when surgical margins are positive. Palliative radiation is used for local control when surgery is contraindicated. Five-year survivals for adenoid cystic and squamous cell carcinomas are reported at 52 percent and 39 percent, respectively. Favorable prognostic factors include negative airway margins at the time of resection and adenoid cystic histology.

Tumor metastases to the tracheal mucosa or direct tracheal extension of lung cancer from parenchymal lesions or lymph nodes are manifestations of locally advanced or metastatic disease, perhaps the most common cause of malignant tracheal obstruction. Metastases to central airways from nonpulmonary malignancy also may occur. Endobronchial metastases from breast, colorectal, renal, ovarian, thyroid, uterine, testicular, nasopharyngeal, and adrenal carcinomas, as well as sarcomas, melanomas, and plasmacytomas, have been described. In an autopsy series of over 1300 patients with solid tumors, metastatic disease to central airways occurred in 2 percent; other series report a higher incidence.

Laryngeal and Tracheal Stenosis

Postintubation and Post-tracheotomy

Concentric scar formation in the larynx or trachea may lead to narrowing and obstruction to airflow. Significant stenosis, defined as obstruction exceeding 50 percent of the lumen, can lead to serious symptoms and functional limitations.

Endotracheal intubation, tracheostomy, and prior laryngotracheal instrumentation account for most cases of laryngotracheal stenosis. The reported frequencies of tracheal stenosis following tracheostomy or laryngotracheal intubation vary widely (0.6 percent to 65 percent). Although injury to the laryngotracheal airway is common following intubation or tracheostomy, the incidence of symptomatic stenosis, demonstrated by radiographs or bronchoscopy, appears to be much lower (less than 2 percent).

Tracheal stenosis in the region of the tube cuff is related to pressure-induced ischemic injury of the mucosa and cartilage and its risk can be minimized by use of large-volume, low-pressure cuffs. The duration of translaryngeal intubation also affects the frequency and severity of laryngotracheal stenosis.

Stenosis following tracheostomy may be above the stoma, at the level of the stoma, at the cuff site, or at the tip of the cannula. Damage to the cartilage above the stoma is a common cause of tracheal stenosis after tracheostomy.

In addition to ischemic mucosal injury and ischemic chondritis, anterior and lateral tracheal wall damage, with "buckling in" fractures of the cartilage, is an important factor. The fractures can be minimized by avoiding excessive pressure on the cartilage during the procedure, selecting the appropriate size and length of the tracheostomy tube, avoiding infection, and using the lowest possible cuff pressure.

Percutaneous tracheostomy is growing in popularity as an alternative to the standard procedure. The ideal anatomic site for percutaneous tracheostomy is between the second and third, or first and second, tracheal rings (not the subglottic space). The incidence of symptomatic tracheal stenosis following percutaneous tracheostomy is comparable to the incidence that occurs after open techniques. When symptomatic tracheal stenosis and tracheomalacia are included as long-term complications, the incidence has been reported to be less than 2.5 percent.

Other Causes of Tracheal Stenosis

Other causes of laryngeal and tracheal stenosis are uncommon. They include airway trauma, including external injury; inhalational burns, irradiation; tracheal infections, including bacterial tracheitis, tuberculosis, and diphtheria; Wegener's granulomatosis; sarcoidosis; amyloidosis; collagen vascular diseases, including relapsing polychondritis, polyarteritis; inflammatory bowel disease; and congenital disorders.

Wegener's granulomatosis may present with significant subglottic stenosis, a complication reported in 16 to 23 percent of patients. Subglottic stenosis may be the only manifestation of Wegener's granulomatosis and have a clinical course distinct from other manifestations of the disease. Endoscopic biopsy of suspected sites of involvement is positive in only 5 percent to 15 percent of cases.

Sarcoidosis may be associated with granulomatous infiltration and obstruction of the upper airways. Laryngeal involvement is more common, but tracheostenosis has been described. Radiographs may show diffuse tracheostenosis, which progresses despite corticosteroid therapy. Bronchoscopy may reveal extensive tracheal narrowing.

Pulmonary amyloidosis includes tracheobronchial manifestations. The chest roentgenogram may show diffuse narrowing and wall thickening involving a long tracheal segment. Involvement is diffuse and circumferential, often with ossification of the amyloid deposits. Bronchoscopy demonstrates multiple plaques on tracheal walls or localized tumor-like masses.

Relapsing polychondritis is a rare systemic disease characterized by recurrent episodes of inflammation of cartilaginous structures. Respiratory manifestations are often severe and may be life threatening. Inflammation occurs in all cartilage types, including the elastic cartilage of the ears and nose, hyaline cartilage of all peripheral joints, and axial fibrocartilage. The most common presenting symptom is pain in the external ear due to auricular chondritis. Respiratory tract involvement may develop years after the first occurrence of auricular chondritis. Symptoms include hoarseness, aphonia, and choking. Tenderness over the thyroid and laryngeal cartilages may be present. When the trachea is involved, endoscopic examination shows inflammation and stenosis. CT demonstrates major airway collapse caused by destruction of cartilaginous rings or airway narrowing due to inflammatory edema and fibrosis. CT findings also include diffuse, smooth thickening of the trachea and proximal bronchi; thickened, densely calcified cartilaginous rings; tracheal wall nodularity; and diffuse narrowing of the tracheobronchial lumen. The posterior tracheal membrane is spared.

Tracheopathia osteoplastica is a rare, benign disease of the trachea and major bronchi in which cartilaginous or osseous nodules project into the airway lumen, often causing considerable airway deformity. The posterior membranous portion of the tracheal wall is spared. The disorder may begin just below the larynx, but most often it affects the lower two-thirds of the trachea. Extension into the proximal portions of the major bronchi may be noted. The condition usually occurs over the age of 50 years and may cause severe airflow obstruction. Its etiology is unknown.

On rare occasion, inflammatory bowel disease produces tracheobronchial stenosis and severe airflow obstruction. The associated airway mucosal inflammation may be steroid responsive early in the course of illness. If fibrosis ensues, medical management has limited success.

Laryngopharyngeal reflux may contribute to subglottic stenosis and, when documented, merits treatment.

Idiopathic progressive subglottic stenosis may be diagnosed in the absence of a clear, underlying etiology. Since most affected patients are female, a hormonal etiology has been proposed. However, estrogen receptors have not been demonstrated in specimens studied.

In addition to medical management, repeated rigid and flexible bronchoscopy-based interventions aimed at reestablishing airway patency may be necessary, particularly in those who are not considered to be surgical candidates or in whom the area of stenosis is complex or extensive. Some experts propose laser-based bronchoscopy as initial management in patients with benign laryngotracheal stenosis, reserving surgery for bronchoscopic failures (see Chapter 36). Others advocate primary surgical intervention, when possible. A multidisciplinary approach incorporating medical and surgical specialists is utilized in many centers.

Tracheomalacia

Tracheomalacia refers to loss of tracheal rigidity and resulting susceptibility to collapse. Tracheomalacia may be diffuse or localized to a tracheal segment. The affected portion may be intrathoracic, in which airway obstruction is accentuated during expiration. Less common is extrathoracic obstruction, in which airway obstruction is most marked during inspiration. Tracheobronchomalacia is the term used to describe the condition when the mainstem bronchi are involved.

Tracheomalacia in adults may be classified as congenital or acquired. The congenital form, described more extensively in children, is related to a variety of congenital

disorders and associated syndromes. The disorder may persist into adult life and is referred to as "idiopathic giant trachea," "tracheomegaly," or the "Mounier-Kuhn syndrome." Bronchiectasis and recurrent respiratory infections are common. Tracheal diverticuli have been reported in more advanced disease. Although atrophy of the longitudinal elastic fibers and muscularis layer has been described, the etiology of these changes is unclear. The diagnosis is made when the diameters of the trachea or right or left mainstem bronchi exceed the upper limits of normal by 3 or more standard deviations.

Acquired or secondary tracheomalacia in adults may be related to a variety of conditions. Tracheostomy and endotracheal intubation are probably the most common etiologies. Usually, limited, focal weakness of the trachea and dynamic airway obstruction are present. Tracheomalacia may be caused by conditions that are associated with chronic pressure on the tracheal wall, inflammation of the cartilaginous support or mucosa, interference with tracheal blood flow, or chronic infection. Traumatic injury to the central airways or surgical interventions also may lead to tracheomalacia.

Symptoms of tracheomalacia include dyspnea, cough, sputum production, and hemoptysis. Wheezing and stridor may be present in patients with significant airway obstruction.

Tracheomalacia is diagnosed by using direct bronchoscopic visualization to confirm significant narrowing of the tracheal lumen during regular, forced expiration. Assessment of the central airways using end-expiratory, dynamic, three-dimensional CT images is useful. Application of continuous positive airway pressure (CPAP) has been reported as beneficial. Surgical intervention may be useful in selected patients. Optimal medical management includes treatment of associated infections.

Extrinsic Compression of the Central Airway

The upper airway is subject to extrinsic compression by a variety abnormalities that involve adjacent structures. The compression may affect the intrathoracic trachea or extrathoracic trachea and upper airway.

Mediastinal Masses and Lymphadenopathy

Rarely, mediastinal masses present with serious limitation to airflow that develop either acutely or indolently. Common symptoms include chest pain, fever, dyspnea, and cough. Based on one large series, approximately 40 percent of mediastinal masses are malignant; 25 percent are cystic. The anterosuperior compartment is the most common site of mediastinal malignancies. Thymic neoplasms and lymphoma are the most common malignancies, followed by neurogenic tumors and teratomas. Both Hodgkin's and non-Hodgkin's lymphomas may be manifested by severe respiratory compromise due to airway compression. A similar syndrome may be due to a metastatic tumor to the mediastinal lymph nodes arising from bronchogenic or other carcinomas.

Patients with large mediastinal masses present a challenge during the perioperative period because of the potential for development of acute upper airway obstruction and other respiratory complications. In adults, complete airway obstruction during induction of anesthesia is rare. Serious pulmonary complications develop intra- and postoperatively in about 4 and 7 percent of patients, respectively. Complications may occur while the patient is placed in the supine position, during induction, or following extubation. Patients with severe symptoms, including stridor, and those with greater than 50 percent airway obstruction appear at high risk for respiratory complications; asymptomatic patients are at significantly less risk. Patients with reduced peak expiratory flow and mixed obstructive-restrictive patterns on pulmonary function testing also appear to be at increased risk for postoperative complications.

Middle mediastinal masses include benign cysts that are bronchogenic, enterogenous (duplication), pericardial, pleural, and thymic in origin. Most bronchogenic cysts are asymptomatic. However, some evoke cough, chest pain, and dyspnea. Severe respiratory distress and compressive symptoms can occur. Usually, cyst contents appear to have the density of water on CT or MRI. However, mucoid contents may give the impression of solid appearance on CT. Surgical resection and transthoracic or transbronchial drainage are options for management. Surgical intervention appears to be the preferred treatment in patients who are symptomatic. The role of interventions, including surgery, in asymptomatic patients is controversial. Enterogenous cysts are usually removed surgically.

Enlarged mediastinal lymph nodes which compress the airway may arise from infectious and noninfectious benign etiologies. One notable example is fibrosing mediastinitis, defined as the presence of excessive mediastinal fibrous tissue that tends to invade and destroy normal structures. The entity is thought to represent a reaction to an infectious granulomatous disease, especially histoplasmosis. The incidence in populations exposed to histoplasmosis remains low. Constriction of the central airways and vessels and the resulting cardiopulmonary limitations may develop several years after the initial infection. Hemoptysis is common, as are cough, dyspnea, and chest pain. CT imaging shows mediastinal fibrosis, calcification, and compression of mediastinal structures. Bronchoscopic findings include concentric airway narrowing and mucosal edema with hyperemia. Unfortunately, hemoptysis tends to be recurrent, and the disease does not respond to corticosteroids or antifungal agents. Surgical intervention is generally ineffective and may be hazardous.

Neck and Thyroid Causes

Retrosternal extension of a diffuse goiter may cause extrathoracic or intrathoracic airway obstruction. Up to 90 percent of patients with substernal goiter report respiratory symptoms. A choking sensation occurs in about one-third of patients with diffuse thyroid enlargement and 14 percent in patients with solitary thyroid nodules. Orthopnea is prevalent when the goiter is intrathoracic and may be enhanced by obesity. Flow-volume loops show evidence of upper airway

obstruction in one-third of patients. Lack of correlation has been reported between symptomatic obstruction and CT findings.

Laryngoceles and saccular cysts, which are abnormal dilatations of the laryngeal saccule (ventricle), are rare. Saccular cysts usually are filled with mucous. Laryngoceles communicate with the laryngeal lumen, resulting in air-filled structures noted on radiographic studies. Laryngoceles may be internal (i.e., confined to the larynx), external (i.e., extending into the thyrohyoid membrane superiorly), or combined. Most are asymptomatic. Hoarseness, dysphagia, pain, or signs of airway obstruction or infection may occur. A neck mass during the Valsalva maneuver may be detectable. Pyocele formation (i.e., infection in the laryngocele) may result in airway obstruction, aspiration pneumonia, or infection of the lateral pharyngeal space. The incidence of laryngeal carcinoma in association with laryngoceles makes close evaluation necessary. Endoscopic and surgical approaches may be employed in management.

Parathyroid cysts may be located in the neck or mediastinum. Fifty percent are accompanied by clinical hyperparathyroidism. Paroxysmal symptoms of airway obstruction can develop. Surgical excision is the treatment of choice; results are generally good.

Cervical osteophytes, common in the elderly, related to either degenerative spinal arthritis or more generalized idiopathic skeletal hyperostosis; the osteophytes may be associated with dysphagia. In addition, airway narrowing and ulcerations due to osteophytes have been reported. The airway compression may make even elective endotracheal intubation difficult, despite adequate preoperative evaluation.

Finally, significant upper airway compression may arise from cervical lymph node involvement with infectious or malignant disorders, hematomas or pseudoaneurysms (related to trauma, surgical interventions, central line placement, or coagulation abnormalities), abscess formation, or other expanding lesions in the soft tissue of the neck.

Esophagus

Involvement of the trachea, glottis, or vocal cords by advanced esophageal cancer is common and associated with a poor prognosis; estimated 1-year survival is less than 10 percent. Airway obstruction requiring stent placement is associated a median survival of 1 to 4 months after the placement. Tracheal obstruction may develop if an esophageal stent is placed in the setting of significant tracheal compromise. Development of tracheoesophageal fistula represents a devastating complication.

Placement of stents simultaneously in the trachea and esophagus is effective palliation for a tracheoesophageal fistula. If such double stenting is anticipated for a fistula or for simultaneous esophageal and tracheal obstructions, the tracheal stent is placed first to ensure patency of the airway, followed by the esophageal stent. Palliative external or local radiation therapy, chemotherapy, or other treatment modalities (e.g., photodynamic therapy) may be effective with or without accompanying airway interventions. The risk of esophageal disruption and rupture should be considered if stenting is performed after these local measures are employed.

Achalasia may cause a variety of pulmonary complications, including cough, aspiration with pneumonia or abscess formation, and rarely upper airway obstruction. Tracheal compression by a dilated megaesophagus is the usual etiology. Ensuring patency of the airway and decompressing the esophagus are necessary in urgent management.

Vascular Causes

Vascular rings, defined as anomalies of the aortic arch or its branches that compress the trachea or esophagus, are rare in adults (incidence less than 0.2 percent). Respiratory symptoms are common.

Right-sided aortic arch occurs in less than 0.1 percent in adults and may be associated with complete vascular rings, while double aortic arch and right-sided aortic arch with aberrant left subclavian artery appear to be the most common etiologies of vascular rings in adults.

The right-sided aortic arch usually crosses over the right mainstem bronchus and descends on either the right or the left side. The vascular ring usually is completed by the ligamentum arteriosum arising from the descending aorta, an aberrant left subclavian artery, or an aortic diverticulum. With a double aortic arch, the left arch crosses over the left mainstem bronchus and joins the descending aorta to complete the ring; the ligamentum arteriosum does not contribute to the vascular ring. Symptoms, resulting from malacia of the compressed airway and resultant dynamic airway obstruction, may be misdiagnosed as exercise-induced asthma. An increase in aortic diameter due to rising blood pressure during exercise, intravenous fluid administration, or anatomic changes with aging may contribute to symptoms. Surgical intervention is indicated in symptomatic patients.

Pulmonary artery sling with anomalous origin of the left pulmonary artery from the right pulmonary artery is very rare in adults. In neonates, the condition is symptomatic and can be fatal without surgical intervention. However, in adults the condition is usually diagnosed incidentally on imaging a patient who has no significant symptoms. This disorder may be associated with a complete tracheal ring, forming the "sling-ring" complex. This condition may present with a right paratracheal mass noted on the chest radiograph.

Compression of the trachea by large aortic or innominate artery aneurysms or pseudoaneurysms may occur and complicate management in the perioperative period. Surgical repair is indicated to relieve symptoms.

Foreign Body Aspiration

Foreign body aspiration, more common in children than adults (in whom the peak incidence is in the sixth decade), is usually recognized from the patient's history. Foreign bodies commonly lodge in the bronchi after migrating through the trachea. In adults, food products are the most commonly aspirated material. The penetration syndrome, defined as the

sudden onset of choking and intractable cough after aspirating a foreign body, with or without vomiting, is often followed by persistent cough, fever, chest pain, dyspnea, and wheezing. Impairment of the normal protective airway mechanisms is common; among the frequent associations are neurologic disorders, trauma with loss of consciousness, sedative or alcohol use, poor dentition, and advanced age. Emergency measures, entailing a food extractor or the Heimlich maneuver, can be life saving. Flexible bronchoscopy is usually successful in removing foreign bodies, although back-up rigid bronchoscopy should be available and is preferred as the primary procedure at some centers. A complicating chemical bronchitis from aspiration of vegetables or nuts may affect visualization and management of the foreign body.

Trauma

Facial Trauma

Emergency access to the airway is necessary in up to 6 percent of cases of facial trauma complicating motor vehicle accidents and other causes of crush injuries. If intubation is difficult or impossible due to the injury or related airway obstruction, emergency cricothyroidotomy or tracheostomy must be considered.

Laryngotracheal Injuries

Blunt and penetrating injuries to the laryngotracheal airway are rare. Without a high index of suspicion, clinicians may miss the diagnosis. The incidence of penetrating injuries appears to be increasing.

Stridor, wheezing, dysphonia, hemoptysis, and general neurological deficits are common. Cervical crepitus and subcutaneous emphysema also may be present. Cervical ecchymoses and hematomas, pneumomediastinum, and pneumothorax should prompt consideration of a laryngotracheal injury.

Management includes prompt securing of the airway, but blind endotracheal intubation should be avoided, since it carries the risk of complete airway obstruction. Some experts recommend tracheostomy as the primary airway management strategy. Awake fiberoptic intubation can be useful. Flexible fiberoptic laryngoscopy, rigid or flexible bronchoscopy, and CT imaging may be helpful in assessing the degree of injury. Unfortunately, the mortality of laryngotracheal injuries remains high (20 to 40 percent). Thoracic injuries and closed head injuries are commonly associated pathologies that can influence management and prognosis.

Inhalation Injuries

Thermal and chemical injuries to the upper respiratory tract may lead to serious consequences, including airway obstruction. Unfortunately, the mortality rate increases significantly when burns are accompanied by inhalational injury. Symptoms can be delayed in becoming manifest, making early recognition and intervention vital in the management of patients with inhalational injuries. The presence of cough, dyspnea, hoarseness, or loss of consciousness; or the findings of singed nasal hairs, carbonaceous sputum, or burns involving the face indicate a high likelihood of inhalation injury.

Early fiberoptic bronchoscopy remains important in evaluation and management of patients with inhalation injuries, enabling the assessment of the extent and severity of the injury, procurement of samples for bacteriologic studies, and fiberoptic intubation, as necessary. Translaryngeal intubation is the standard method of securing the airway in inhalation injury; early tracheostomy is used in some centers. A role for prophylactic corticosteroids or antibiotics is currently not supported by published reports. Significant tracheal stenosis may develop in patients who survive the initial insult, especially when translaryngeal intubation or tracheostomy is necessary.

Endotracheal Tube—Related Trauma

Postextubation stridor, due to glottic edema, laryngospasm, or laryngotracheal stenosis is a serious event. Reintubation rates for upper airway obstruction due to endotracheal tube–related trauma in critically ill patients have been reported to range from 4 percent to 33 percent. An "acceptable" rate is considered to be 5 percent to 15 percent. The cuff leak test does not accurately predict success or failure of extubation. Although the efficacy of corticosteroids or racemic epinephrine in the management of postextubation stridor is not substantiated, both are used extensively in clinical practice.

Translaryngeal intubation may also produce vocal cord paralysis, accounting for 10 to 15 percent of all cases. Paralysis may be unilateral or bilateral. Affected patients present with hoarseness or airway obstruction. Findings may occur immediately after extubation or be delayed. Prolonged intubation, use of a large endotracheal tube (number 8 or larger), placement of the tube cuff close to the vocal cords, or use of excessive cuff pressure are risk factors. The condition usually resolves spontaneously within 10 weeks.

Vocal cord (contact) granuloma may develop 4 to 6 weeks after intubation. Symptoms include prolonged hoarseness, exertional dyspnea, and stridor. Management, using antireflux medications, inhaled and systemic corticosteroids, antibiotics, botulinum toxin injection, speech therapy, smoking cessation, and rest of the voice are usually successful. Surgical intervention is reserved for cases that fail conservative management.

On occasion, dislocation of the arytenoid cartilages occurs during intubation. Rheumatoid arthritis that affects the cricoarytenoid cartilage is a risk factor for this condition. Rigid bronchoscopy or surgical interventions may be needed to reduce the dislocation.

Other disorders that may cause complications during intubation include hyperostosis of the cervical spine due to ankylosing spondylitis and cricoarytenoid joint disease due to systemic lupus erythematosus.

Neuromuscular Disorders

Neuromuscular disorders may affect the bulbar muscles, many of which surround the upper airway. When this occurs, resistance to airflow is increased, and the flow-volume loop

often shows an inspiratory flow plateau typical of variable extrathoracic upper airway obstruction. In addition, a pattern of flow oscillations during inspiration ("sawtooth pattern") may be seen. The abnormal flow pattern, first noted in patients with sleep apnea, is commonly seen in extrapyramidal disorders, myasthenia gravis, and motoneuron disease; it may also be seen in patients who have functional stridor and wheezing (see below). In extrapyramidal disorders, the flow oscillations correspond to vocal cord tremor. In motoneuron diseases, muscle denervation causes irregular muscle fasciculations, resulting in tremor of upper airway muscles.

Upper airway symptoms may be seen in Shy-Drager syndrome with extrapyramidal involvement and in Parkinson's disease. Patients may present with symptoms of chronic dyspnea or with stridor and respiratory failure relieved by endotracheal intubation. Bilateral vocal cord paralysis also results in abnormalities of inspiratory flow and a distinctive flow-volume loop. Bilateral vocal cord paralysis may be a cause of nocturnal stridor, oxygen desaturation, and sleep disruption or, in extreme cases, acute respiratory failure. In adults, causes include familial bulbar spinal muscle atrophy, postpoliomyelitis syndrome, Parkinson's disease, multiple sclerosis, acute poliomyelitis, amyotrophic lateral sclerosis, Guillain-Barré syndrome, brain stem stroke, and large cerebral hemisphere stroke. Non-neurologic causes include laryngeal nerve injury following neck surgery, endotracheal intubation injury, laryngeal trauma, infection, trauma, and thoracic aortic aneurysm. Dystonic extrapyramidal reactions due to neuroleptic medications (e.g., haloperidol) may cause significant upper airway obstruction. The usual reactions to these medications are akathisia, dyskinesia, dysarthria, and dystonic reactions, such as torticollis. Laryngeal-pharyngeal dystonia may cause severe upper airway dysfunction. If not reversed, symptoms can last for days or lead to respiratory arrest.

Vocal Cord Dysfunction

The glottis plays an active role in adjusting airflow, both voluntarily and through reflex control from laryngeal and pulmonary receptors. Normally, the glottic opening widens during inspiration and narrows during expiration. Occasionally, the glottis can become dysfunctional in the absence of organic disease. The disorder, called vocal cord dysfunction, laryngeal wheezing, or laryngeal asthma is characterized by paradoxical closure of the vocal cords intermittently during inspiration. The mechanism is unknown, but psychogenic factors appear to be more likely than a disordered processing of neural input to the larynx.

Signs and symptoms of vocal cord dysfunction resemble those of laryngeal edema, laryngospasm, vocal cord paralysis, or asthma. Wheezing or stridor and shortness of breath are typical and are often so dramatic that they suggest acute asphyxia and respiratory failure. Intubation and other emergency measures are used frequently. Slightly more than half of patients also have asthma. Patients without asthma are predominantly women who have been misdiagnosed as having asthma for an average of 5 years previously. Typically, patients have been treated with large doses of oral corticosteroids; frequent emergency room visits, hospitalizations, and endotracheal intubations characterize the clinical course of many patients.

Psychiatric disorders are common in these patients. Major psychiatric disorders, personality disorders, and sexual and physical abuse are commonly uncovered. Whereas many patients are unaware of their self-induced wheeze or stridor, others appear to derive secondary gain from their symptoms and manifest factitious illness. A high index of suspicion is warranted when the adventitious sounds are loudest over the neck in a patient who presents with wheezing, stridor, or both. Despite their respiratory distress, patients often have little difficulty completing full sentences and can hold their breath; the laryngeal-induced sounds disappear during a panting maneuver.

On pulmonary function testing, patients with vocal cord dysfunction demonstrate a pattern of variable extrathoracic airway obstruction, resulting in an increase in the ratio of $FEF_{50\%}$ to $FIF_{50\%}$. Some patients show a pattern of "sawtoothing," or fluttering of the inspiratory limb of the flow-volume loop, representing fluctuations in the abnormal cord motion (Fig. 50-12). Often, attempts to perform the flow-volume loop maneuver generate variable results from

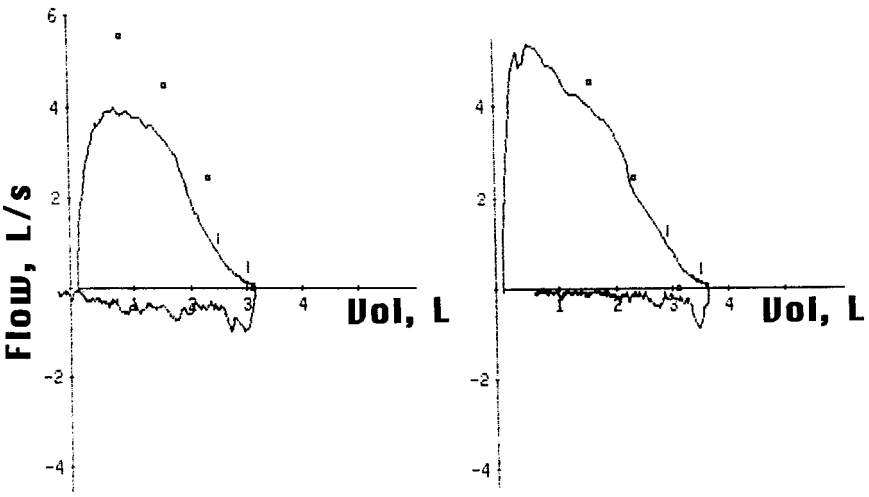

Figure 50-12 Variable extrathoracic obstruction due to vocal cord dysfunction. Two consecutive flow-volume loops from a young woman with inspiratory stridor. Variable effort accounts for the differences in configuration. $FEF_{50\%}/FIF_{50\%}$ in each is very high. The inspiratory loop is flat and demonstrates a sawtooth pattern. This pattern has also been associated with sleep apnea syndrome and various neuromuscular disorders.

test to test. A normal alveolar-arterial oxygen gradient and absence of bronchial hyperresponsiveness are other clues to the diagnosis.

The diagnosis of vocal cord dysfunction is made during direct visualization of the vocal cords during an attack. Inspiratory, anterior vocal cord closure with a posterior glottic chink is seen.

Treatment includes discussion of the diagnosis with the patient, discontinuation of unnecessary medications, and referral to a speech therapist or psychotherapist. The response to bronchodilator therapy is usually poor. Administration of an inhaled helium-oxygen mixture may alleviate symptoms during an acute attack.

Angioedema

Angioedema is characterized by well-demarcated swelling of the face, lips, tongue, and mucous membranes of the nose, mouth, and throat. When the larynx is involved, upper airway obstruction may occur and is fatal in as many as 25 percent of patients. In most instances, the cause of angioedema is unclear; prior exposure to common allergens, such as drugs, chemical additives, and insect bites should be suspected.

Contrary to what might be thought, the most common causes of angioedema are not IgE initiated. They include reactions to histamine-releasing drugs, such as narcotics and radiocontrast materials, to aspirin and other nonsteroidal anti-inflammatory drugs, and to angiotensin-converting enzyme inhibitors. Hereditary angioedema, a rare cause of upper airway obstruction, is an autosomal-dominant trait that occurs in all races. The underlying mechanism is a deficiency in production or function of C1 esterase inhibitor, a serum protease inhibitor that regulates the complement, fibrinolytic, and kinin pathways. Hereditary angioedema is characterized by painless nonpitting edema of the face and upper airway. The disorder usually begins in childhood and becomes more prominent in adolescence. Swelling progresses over many hours and then resolves spontaneously over 1 to 3 days. Despite the slow progression, death may occur from laryngeal obstruction. Physical stimuli (cold, heat, stress) and circulating immune complex diseases (e.g., due to serum sickness or systemic lupus erythematosus) are also known to cause angioedema.

Emergency management includes securing the airway, administration of corticosteroids, and use of antihistamines and epinephrine.

Miscellaneous Etiologies

A variety of uncommon etiologies also may produce upper airway obstruction.

Postpneumonectomy syndrome refers to compression of the left main bronchus between the aortic arch and left pulmonary artery following a right pneumonectomy. The syndrome also may be seen following a left pneumonectomy, sometimes in the setting of a right-sided aortic arch. Mediastinal repositioning prostheses, with or without additional fixation methods, may be useful in selected patients.

Mucus ball formation related to transtracheal oxygen catheters has been well described. Although transtracheal oxygen delivery decreases supplemental oxygen flow requirements by approximately 50 percent during rest and 30 percent during activity, development of symptomatic mucus balls (occurring in up to one-third of patients) remains a major disadvantage of the technique. Death and life-threatening events secondary to airway obstruction have been reported.

Recurrent respiratory papillomatosis in adults, caused by human papilloma virus types 6 or 11 (or, much less commonly, types 16 or 18) may result in upper airway obstruction and death. Although the larynx is most commonly affected, the tracheobronchial tree may be involved, with a predilection toward areas with prior mucosal injury, including tracheostomy sites and tracheal injuries. Lesions tend to progress down through the tracheobronchial tree. Pulmonary parenchymal involvement is rare, but it may be severe, and bronchiectasis, pulmonary nodules, and abscess formation may occur. Malignant transformation is also possible. The course of the disease is difficult to predict. Recurrent endoscopic interventions (debulking), with attendant risk of airway stenosis, are usually required. No controlled trials on the role of antiviral therapy have been conducted. Available data suggest beneficial effects of intralesional cidofovir. Favorable effects also have been reported with the use of interferon-a. Chemotherapy, radiation therapy, and targeted surgical resection are utilized for confirmed malignant transformation.

MANAGEMENT OF UPPER AIRWAY OBSTRUCTION

General Management

The primary goals in management of any patient with upper airway obstruction are assurance of adequate oxygenation and ventilation and management of the underlying condition. If airway obstruction is partial, and the patient's condition is stable, close monitoring and diagnostic studies are appropriate. Depending upon the underlying etiology, temporary measures may include close observation in an intensive care unit, elevation of the head of bed, administration of humidified oxygen, use of a helium-oxygen inhalation mixture (see below), systemic corticosteroids, and inhaled racemic epinephrine, pending definitive medical or surgical management.

A helium–oxygen gas mixture (Heliox) may be useful in management of upper airway obstruction when the obstruction is temporary and reversible. The physiologic rationale for Heliox is based upon a reduction in work of breathing achieved through administration of a low-density gas. In particular, Heliox has a lower density than does oxygen, room air, or a mixture of the two, resulting in conversion of the predominantly turbulent flow at the site of obstruction to a more laminar pattern. Furthermore, since laminar flow requires a

smaller pressure gradient than turbulent flow to achieve the same flow rate, the accompanying work of breathing is less (see Chapter 9). The major limitation of the modality is an inability to deliver gas with an FI_{O_2} of more than 40 percent. Despite physiological evidence and clinical reports of efficacy, prospective, randomized studies demonstrating improved outcome in patients receiving Heliox are lacking, as are data supporting use of corticosteroids or inhaled epinephrine in airway obstruction from a variety of causes.

Securing the Airway

Although under controlled circumstances, a significant portion of so-called difficult airways and intubations may be identified in the course of a thorough preoperative assessment, the patient with impending airway obstruction presents a challenge. Under such circumstances, a critical first concern is deciding whether an artificial airway is needed emergently. Regardless of the airway utilized, emphasis is placed on ensuring adequate oxygenation and ventilation.

Airways judged unsafe for routine management may be addressed according to the "difficult airway algorithm" recommended by the American Society of Anesthesiologists (see also Chapter 163). A difficult airway is defined as a clinical circumstance in which a conventionally trained anesthesiologist experiences difficulty using face mask ventilation, endotracheal intubation, or both.

Airway access in emergency situations may be challenging because the patient frequently is critically ill and can deteriorate quickly. The likelihood of a difficult intubation can be estimated by using the Mallampati score or a modification of the score to assess potential laryngeal exposure and prospects for adequate airway visualization.

A number of parameters, such as mouth opening distance, jaw size, thyromental distance, and cervical range of motion, have been incorporated into airway assessment scoring systems; each parameter has limited sensitivity and specificity. Combining scoring systems provides better accuracy of prediction. The "rule of threes," which is a useful, simple bedside tool, predicts successful direct laryngoscopy if the examiner can place three finger breadths (approximately 6 to 7 cm) between the upper and lower teeth, the mandible and hyoid bone, and the thyroid cartilage and sternal notch. In the emergency setting of upper airway obstruction, the most experienced physician available should secure the airway. Appropriate equipment and monitoring, along with back-up resources for alternative and invasive airway management, should be available.

A variety of invasive and noninvasive techniques are available as alternatives to standard, laryngoscopy-guided orotracheal intubation. Invasive methods include surgical and percutaneous tracheostomy, surgical and percutaneous transtracheal (needle) cricothyrotomy, translaryngeal guided or "retrograde" intubation, fiberoptic endotracheal intubation, and use of a rigid ventilating bronchoscope. Noninvasive techniques include use of specialized laryngoscope blades, guiding and lighted stylets, directional tip control tubes, and esophageal-tracheal (Combitube) or laryngeal mask airways. In selected circumstances, tactile intubation, nasotracheal intubation, or blind orotracheal intubation may be employed.

Cricothyroidotomy

Cricothyroidotomy (either surgical or based on Seldinger technique) has a long history of use in emergency access to the airway when more conservative approaches fail or are contraindicated. Currently, surgical cricothyroidotomy is performed by surgeons, anesthesiologists, and intensive care specialists. In early reports, a high incidence of laryngeal stenosis during intermediate and long-term follow-up was noted, perhaps related to the presence of infectious laryngeal disease or the use of large-bore tubes. In addition, the risk of subglottic stenosis also appears high in patients with prolonged prior intubation. Hence, although the procedure is useful for short-term airway control, tracheostomy should be considered if prolonged airway access is required.

Tracheostomy

Most tracheostomies are performed on intubated patients in the intensive care unit. Percutaneous tracheostomy is rapidly becoming the method of choice in the intensive care unit and is associated with acceptable intraoperative and postoperative complication rates. Advantages of the technique over the traditional procedure include low cost, short procedure time, low complication rate, and elimination of the need to transport critically ill patients to the operating room. Adaptation of percutaneous techniques for emergency situations also has been described.

In a review of over 1100 patients who underwent tracheostomy, 76 percent were performed in patients who required prolonged ventilation, 6 percent for upper airway obstruction, 7 percent for extensive maxillofacial trauma, and 11 percent as an adjunct for head and neck or chest surgeries; only 0.26 percent were performed as emergency procedures. Overall mortality was 0.7 percent.

Bronchoscopy and Interventional Pulmonology

Bronchoscopy, including interventional bronchoscopic techniques, is discussed in Chapter 36. Use of these techniques for managing upper airway obstruction is well established and is briefly summarized below.

Rigid bronchoscopy allows oxygenation, ventilation, and application of various therapeutic interventions, including "coring out" of obstructing lesions, control of bleeding, and removal of foreign bodies. Complications include airway rupture, bleeding, and granulation tissue formation related to mucosal injury.

Electrocautery can be applied through rigid or flexible bronchoscopy. Side effects include bleeding, perforation, and airway fire. Laser therapy, including use of Nd:YAG, argon, and CO_2 lasers, may be useful as well.

Photodynamic therapy, based on creation of a phototoxic cell reaction achieved after activating a drug trapped in target cells by nonthermal laser light, has been employed in treatment of upper airway obstruction. Disadvantages include delay in effect compared with laser therapy and electrocautery and need for follow-up debridement. Bleeding and obstruction from necrotic tumor and edema are potential complications.

Cryotherapy, based on repeated freeze-thaw cycles to achieve cell necrosis and tissue damage is used in benign and malignant disorders of the upper airway. Cryotherapy has excellent hemostatic effects; the incidence of perforation or bleeding is low. Due to the delayed beneficial effect, cryotherapy is not usually used under emergent conditions.

Finally, external beam radiation and brachytherapy are useful modalities for palliative management of airway obstruction and hemoptysis. For external beam radiation, unwanted exposure of adjacent structures is a limiting factor, while hemorrhage, radiation bronchitis, and fistulae with surrounding structures are complications of brachytherapy.

Airway Stents

Airway stents are used in the palliative management of both benign and malignant airway obstruction. Available tracheal stents include expandable metal and silicone prostheses. Major complications include stent migration, granulation tissue formation, and stent interference with mucociliary clearance. In a series of over 1500 patients who had stents placed for upper airway obstruction due to benign or malignant disorders, stent migration was reported in 9.5 percent, granulation tissue formation in 7.9 percent, and obstruction in 3.6 percent.

Cystic Fibrosis

Judith Voynow • Thomas F. Scanlin

Cystic fibrosis (CF) is a common inherited disease that has a high frequency in Caucasians. The disorder affects all exocrine glands, with symptoms involving the lungs and pancreas usually dominating the clinical picture. Two aspects of the disease make CF particularly difficult to both diagnose and manage: tremendous variability in the degree and pattern of involvement of organs in different persons and lack of information about the precise details of the molecular and cellular pathogenesis of the disease, even though the gene responsible for CF and its gene product, an integral membrane glycoprotein, have been identified. This chapter focuses on the pathophysiology and management of CF. Our current understanding of the genetics and underlying molecular biology are highlighted. Complications of the disorder are addressed, and a brief discussion of relevant psychosocial and reproductive issues is provided. Finally, potential future directions in treatment are described, including gene therapy.

GENETICS

CF demonstrates an autosomal-recessive pattern of inheritance. In the United States, the incidence of the disease is approximately 1 in 3000 in Caucasians, 1 in 6000 in Hispanics, and 1 in 10,000 in African Americans. The frequency of unaffected heterozygote carriers of a CF mutation is estimated to be 1 in 26 in persons of Northern European ancestry.

CF is caused by mutations in a single gene named the *cystic fibrosis transmembrane conductance regulator* (CFTR). This gene was identified with an approach known as positional cloning, which permitted mapping of the gene without prior knowledge of the biochemical defect through use of polymorphic DNA markers. The first genetic marker that was found to be linked to CF was paraoxonase. In 1985, the demonstration of the linkage of CF to two DNA markers, D7S15 and D7S8, and to the *met* oncogene established the localization of the CF gene to the long arm of chromosome 7. Following a series of molecular cloning experiments, which included "chromosome walking" and "jumping," a candidate gene was identified. This was proved to be the CF gene in 1989, largely through the discovery of a frequent mutation. Formal proof that this was the CF gene came in 1990 with correction of the chloride secretory defect in CF cells in vitro following transfection of the CFTR gene.

The CF gene spans approximately 230 kb of DNA and contains 27 exons. The mRNA is 6.5 kb and is detected in a variety of tissues, including lungs, pancreas, and sweat glands, which are predominantly affected in pathogenesis of the disease. The deduced polypeptide was predicted to be an integral membrane glycoprotein containing 1480 amino acids (Fig. 51-1; see "Pathogenesis"). Several major and minor splicing variants in the transcripts have been described in individuals with and without CF. In most cases, however, the significance of the alternative splicings is not clear.

The most common CF mutation, and the first to be described, is a three-base deletion in exon 10 that causes a deletion of phenylalanine from position 508 (ΔF508) of the CFTR glycoprotein. This mutation accounts for 66 percent of CF mutations. However, more than 1000 CF mutations have now been reported, and the list continues to grow. In addition, a number of benign sequence variations have been described. A listing of the most common mutations and their relative frequency is included in Table 51-1. The large

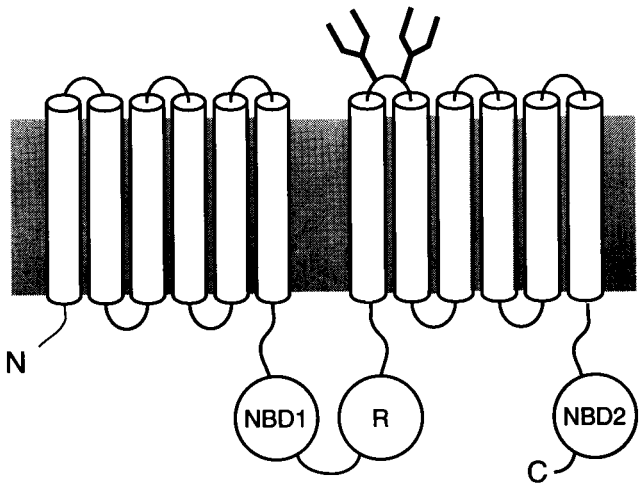

Figure 51-1 Domain model of the cystic fibrosis transmembrane conductance regulator (CFTR). Based on hydrophobicity plots, CFTR has twelve transmembrane spanning domains, two nucleotide (N) binding domains (NBD 1 and NBD 2), and a regulatory (R) domain. The twelve transmembrane domains form the ion channel "pore." In the closed state, the "R" domain is believed to obstruct the channel. Channel opening requires binding of two adenosine triphosphates (ATPs) to the nucleotide binding domains. This model is similar to other ATP-binding cassette transporter proteins that bind ATP and transport ions or micronutrients. *(Modified from Riordan J, Rommens JM, Kerem B, et al: Identification of the cystic fibrosis gene: Cloning and characterization of complementary DNA.* Science *245:1066–1073; erratum 1437, 1989.)*

number of mutations makes accurate detection of a satisfactory percentage of carriers extremely difficult, and carrier screening for the general population has not been recommended or implemented. Testing for 32 of the most common mutations is widely available; such testing will detect approximately 90 percent of the carriers in Caucasians of Northern European descent. In families with an affected individual and known mutations, prenatal diagnosis and carrier testing using direct detection of mutations is accurate and available. In families with a member diagnosed as having CF, but with undetected mutations, sequencing of the complete CFTR coding region and critical intronic regions is now also available to detect rare mutations.

PATHOGENESIS

Discovery of the gene responsible for CF and description of its product, CFTR, have provided the necessary foundation for understanding the pathogenesis of the disorder at the molecular and cellular levels. CFTR is an integral membrane glycoprotein of approximately 170 kD that is expressed in epithelial cells of affected organs. CFTR contains 1480 amino acids, which are arranged in twelve transmembrane domains, two nucleotide binding domains, and a putative regulatory domain (Fig. 51-1). The most common mutation, ΔF508, is a three-base deletion that causes deletion of phenylalanine from position 508, located in the proposed first nucleotide-binding domain. The original structural model, which was based on hydrophobicity plots, has proved to be essentially correct in its main features. CFTR shares many structural features with the "adenosine triphosphate (ATP)-binding cassette" transporter family, which includes P glycoproteins, as well as a number of bacterial transporters. CFTR has been clearly shown to function as an apical chloride channel in airway epithelial cells.

The localization of CFTR to the apical aspect of airway epithelial cells, to the ciliated duct of submucosal gland cells, and to submucosal serous cells, and the role of CFTR as an apical chloride channel fits nicely with the simplest hypothesis to account for the pathogenesis of pulmonary disease in CF: Decreased secretion of chloride and water by airway epithelial cells results in dehydrated mucus (Fig. 51-2). However, CFTR may have other functions, such as regulation of other ion channels, including the epithelial sodium channel. Loss of CFTR causes increased reabsorption of sodium; increased epithelium sodium channel activity alone alters regulation of ions and water, resulting in mucus obstruction of airways. CFTR transports bicarbonate; loss of CFTR function may result in acidification of the small intestinal lumen and, possibly, the airway lining fluid. Alternatively, CFTR may also function in *intracellular* membranes (e.g., endoplasmic reticulum, endosomes, and clathrin-coated vesicles). A consequence of the altered function of CFTR in intracellular membranes may be the mislocalization of glycosyltransferases. Together, these observations may explain abnormalities of

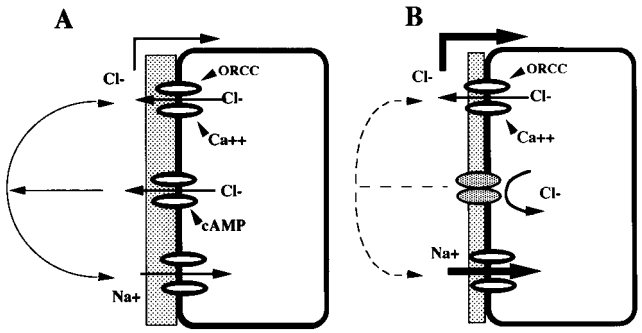

Figure 51-2 Simplified model of ion transport in airway epithelium. *A*. Normal airway cell with multiple apical ion channels. At the top, two different chloride channels are represented, the outwardly rectifying chloride channel (ORCC) and the Ca^{++}-gated chloride channel. In the center, cyclic adenosine monophosphate (cAMP)-gated cystic fibrosis transmembrane conductance regulator (CFTR) is shown. The apical sodium channel is depicted at the bottom. Experimental data suggest that CFTR interacts with the other channels, although the type of interaction is not clear (solid arcs). *B*. CF cell with nonfunctioning cAMP-gated apical chloride transport. The function of the other channels is affected in an unknown manner (dashed arcs). The net result of ion channel activity on the pericellular fluid composition (hatched area) is under investigation. Many questions remain concerning the function of CFTR and ion transport in the airway.

CF glycoproteins: increased sulfation of respiratory mucins, with decreased sialylation and increased fucosylation of both secreted and membrane glycoproteins. Altered glycosylation of airway glycoproteins may significantly impact bacterial-epithelial interactions and innate immune functions in the lung.

In addition to the effect of CFTR on epithelial ion channels and glycoprotein processing, loss of CFTR function negatively impacts innate immunity and accentuates inflammation. Absence of CFTR function is associated with impaired bacterial killing in vitro and defective function of antimicrobials including human beta-defensin 1 and lysozyme. Absence of CFTR is also associated with increased interleukin-8 (IL-8) production and decreased IL-10 in vitro. Furthermore, the presence of excessive, unopposed neutrophil elastase in the airway cleaves complement and immunoglobulins, potentially interfering with bacterial opsonization. CF airways have increased oxidant stress due to neutrophilic inflammation and reduced antioxidants such as glutathione. Finally, tissues in CF have an increased ratio of arachidonic acid metabolites to docosahexaenoic acid metabolites when compared to healthy controls, reflecting an increase in inflammatory lipids in affected tissues, and decreased levels of lipoxin, an anti-inflammatory lipid mediator in airway surface fluid. Together, these factors synergistically increase the inflammatory milieu in the airways in CF.

CFTR mutations have been grouped into four or five classes, depending on the effect of the mutation on the expression, processing, and function of the protein (Fig. 51-3). The most common mutation, ΔF508, is a processing mutation in which very little of the mutant protein reaches the apical

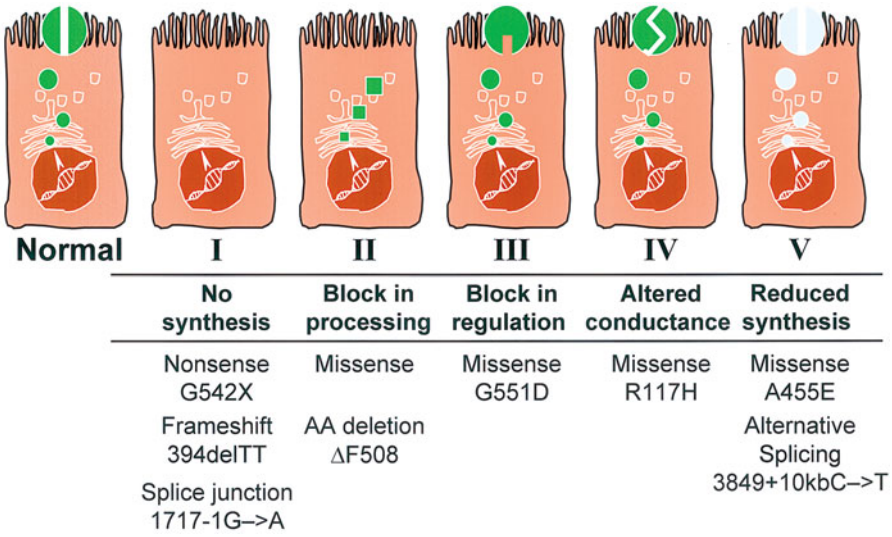

Figure 51-3 Classification of cystic fibrosis transmembrane conductance regulator (CFTR) mutations by molecular and biochemical abnormalities. This schematic depicts the effect of different classes of CFTR mutations on expression and function in the cell. Class I mutations block mRNA transcription. Class II mutations prevent normal CFTR protein processing and localization. Class III mutations permit CFTR localization at the apical membrane but inhibit chloride channel conductance. Class IV mutations result in partial chloride channel conductance. Class V mutations affect transcription, translation, or protein processing resulting in reduced CFTR expression at the apical membrane. Examples of mutations in each class are depicted below the cell models. Epithelial cell models with fingerlike projections depict cilia at the apical surface. Fully processed CFTR protein is depicted by the gray circles embedded among the cilia at the apical surface of the cells. (*From Welsh MJ and Smith AE: Molecular Mechanisms of CFTR Chloride Channel Dysfunction in Cystic Fibrosis.* Cell *73:1251–1254, 1993, with permission.*)

surface. If the mutant protein escapes normal intracellular processing, however, ΔF508 protein functions normally in the apical membrane. Furthermore, only 25 percent of normal CFTR transcripts are properly processed and transported to the cell surface. The remaining 75 percent are degraded before being processed. These data suggest that one therapeutic strategy to overcome the defect in CF is to disrupt normal intracellular processing mechanisms.

PATHOPHYSIOLOGY

In CF, all exocrine glands appear to be affected primarily, albeit to varying degrees. Because exocrine glands perform highly specialized functions in a variety of organs—e.g., in the skin, respiratory tract, gastrointestinal tract, and reproductive system—the number of possible symptoms and complications in CF is large. Table 51-2 highlights the complications and symptoms of CF according to the age groups in which they most often occur. Obstruction of exocrine ducts by viscous secretions appears to play a cardinal role in the pathogenesis of almost all manifestations of the disease. In 10 to 20 percent of patients, the initial manifestation is often *meconium ileus*—i.e., obstruction of the intestine by thick, viscous meconium stool. Chronic pulmonary disease, pancreatic insufficiency, and focal biliary cirrhosis progress gradually throughout the course of the disease, albeit at different rates in different patients. Progressive obstruction of exocrine ducts is a regular feature of the disease except in sweat glands, where obstruction of ducts has not been implicated in pathogenesis.

Respiratory Tract

In the lungs, hypersecretion of viscid mucus and chronic bacterial infection combine to produce a progressive and distinctive type of chronic obstructive airway disease that eventually leads to diffuse, severe bronchiectasis. The earliest pathological lesions are found in the distal bronchioles. Whether the viscid secretions are primary or are secondary to chronic bacterial infections remains unsettled. In favor of a primary disturbance is the demonstration of mucus obstructing submucosal gland ducts in the airways of neonates with CF, who have not yet developed any evidence of bacterial infection or chronic colonization of the airways. With the use of sophisticated culture methods, bacterial pathogens can almost invariably be isolated from the respiratory tract of patients with CF. The most common pathogens isolated from sputum cultures are *Staphylococcus aureus* and *Pseudomonas aeruginosa.* Less commonly found are *Escherichia coli, Klebsiella,* and *Haemophilus influenzae.* In later stages of the disease, *Pseudomonas* usually predominates. By adulthood, more than 80 percent of patients are colonized with *P. aeruginosa.*

Neutrophil-dominated lower-airway inflammation also plays a primary role in the pathogenesis of the characteristic central bronchiectasis of CF. Bronchoalveolar lavage fluid (BALF) demonstrates increased neutrophils and various cytokines, especially IL-8, even in infants whose BALF is sterile.

Table 51-2

Complications and Presenting Symptoms of Cystic Fibrosis by Age Group

Infancy	Childhood	Adolescence/Adulthood
Meconium ileus	Pulmonary infections with *Staphylococcus* and *Pseudomonas*	Chronic bronchitis
Obstructive jaundice	Malnutrition with steatorrhea and pancreatic insufficiency	Pansinusitis
Edema with hypoproteinemia, anemia, and hypoprothrombinemia	Heat prostration with hypoelectrolytemia and metabolic alkalosis	Hemoptysis
Failure to thrive	"Atypical asthma" with clubbing and/or bronchiectasis	Chronic abdominal pain
Intussusception	Esophageal varices	Delayed sexual development
Volvulus	Hypersplenism	Obstructive aspermia
Rectal prolapse	Nasal polyps	
Recurrent pneumonia/bronchiolitis		

Typically, respiratory secretions increase when a patient with CF, already chronically colonized with *Pseudomonas,* develops a viral respiratory tract infection. In turn, the increase in secretions leads to a gradual increase in cough and sputum production and then to an exacerbation of the pulmonary disease, usually manifested by increase in respiratory rate; retraction of the chest during inspiration; and diffuse, coarse inspiratory crackles. Fever and leukocytosis are common. The chest radiograph demonstrates worsening hyperinflation. Both peribronchial thickening and nodular or cystic densities are more marked than usual. Pulmonary function tests show a worsening over baseline. Usually, residual volume (RV) increases; forced vital capacity (FVC) and forced expiratory volume in 1 s (FEV_1) decrease; the forced expiratory flow between 25 and 75 percent of the exhaled vital capacity ($FEF_{25–75\%}$) also decreases. Treatment using antibiotics and chest physiotherapy generally succeeds in restoring most indices of pulmonary function to, or almost to, baseline. However, *Pseudomonas* and *Staphylococcus* persist in sputum cultures.

The most attractive hypothesis to account for the pattern of response to treatment is that therapy reduces the number and, probably, virulence of organisms. Despite the virtual return to baseline after an exacerbation, however, the cumulative effect of repeated episodes is progressive bronchiectasis or atelectasis, or a combination of the two, accompanied by a gradual and irreversible decrease in pulmonary function. The striking degree of airway destruction and relative sparing of the pulmonary parenchyma at autopsy are shown in Fig. 51-4. A simplified scheme illustrating the evolution of the process is shown in Fig. 51-5.

Gastrointestinal Tract

Although pancreatic function may be either normal or abnormal at birth, it gradually becomes increasingly abnormal in most patients with CF as the pancreatic ducts become progressively obstructed by thick, viscous secretions from the exocrine portion of the organ; pancreatic enzymes that are trapped within the ducts lead to autodestruction of the pancreas. A cycle of destruction and obliteration of the ducts is set into motion, leading to cystic dilatation of ducts proximal to sites of obstruction and fibrosis of the body of the pancreas. In advanced stages of the disease, pancreatic fibrosis sometimes causes obliteration of the islets of Langerhans and, consequently, diabetes mellitus.

The liver and biliary tract are also affected in CF. Here too, the primary mechanism appears to be obstruction of ducts by abnormally viscid secretions. The earliest pathological change is focal biliary cirrhosis that may be present in early infancy. In some patients, focal cirrhosis progresses to diffuse cirrhosis and portal hypertension. Some newborn infants with CF develop the *inspissated bile syndrome,* characterized by prolonged obstructive jaundice starting at 2 to 8 weeks of age. The jaundice often clears without therapy. In approximately 20 to 30 percent of patients, the gallbladder is small, presumably because of underdevelopment due to obstruction by viscid secretions. Compared with age-matched controls, the risk of cholelithiasis and cholecystitis is increased in adults with CF.

Figure 51-4 Section of lung from autopsy of a patient with CF, demonstrating remarkable dilation of large airways and preservation of intervening pulmonary parenchyma. *(Courtesy of Dr. S. Moolten.)*

The most striking pathological change in the intestines is hyperplasia of the mucous glands and goblet cells. Biochemical abnormalities in intestinal mucins may contribute to malabsorption of specific nutrients and bile acids. Much of the malabsorption in CF can be corrected by administration of pancreatic enzymes. However, the abnormal mucins may lead to slowing of intestinal transit time; the slowing, combined with maldigestion of food substances, sometimes causes fecal impaction in the terminal ileum and ileocecal area, a condition referred to as *meconium ileus equivalent* or distal intestinal obstruction syndrome. The fecal impaction, in turn, occasionally causes volvulus or intussusception of the bowel (Fig. 51-6).

Reproductive Organs

Except for an increase in viscosity and an abnormal midcycle fern pattern in cervical mucus, no consistent pathological changes occur in the female reproductive tract in patients with CF. In the male reproductive tract, however, the vas deferens is either atretic or absent at birth. Although the pathogenesis of this lesion is not certain, viscous secretions may contribute to obstruction in utero, followed by failure of development of the vas deferens. Spermatogenesis and testicular development are otherwise normal. Because of either partial or complete obstruction of the vas deferens, approximately 98 percent of males with CF are aspermic.

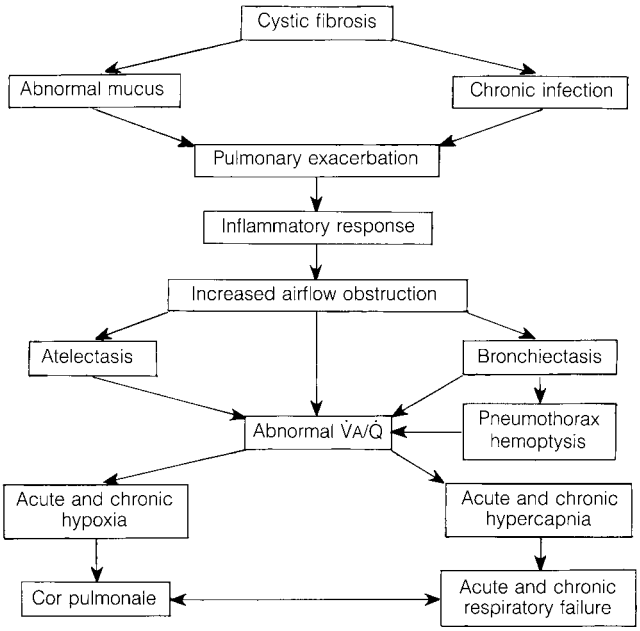

Figure 51-5 Simplified scheme for pathogenesis and progression of pulmonary disease in CF.

Sweat Glands

The sweat glands of patients with CF manifest no distinctive histological changes. Nonetheless, their function is abnormal. Micropuncture experiments have shown that the precursor solution secreted by the sweat glands is isotonic to plasma, both in CF patients and in normal subjects. In normal persons, as the sweat flows along the duct of the gland, sodium and chloride are reabsorbed, so that by the time that the opening at the skin surface is reached, sweat is hypotonic to plasma with respect to both sodium and chloride concentrations. In CF, the relative impermeability to chloride ions is thought to be responsible for the elevated chloride and sodium concentrations which are the basis for the diagnostic test, the quantitative pilocarpine iontophoresis sweat test, and are also responsible for the characteristic increase in potential differences across isolated, perfused sweat glands from CF patients.

DIAGNOSIS

The diagnosis of CF requires the demonstration of abnormally high concentrations of sodium and chloride in the sweat

A

B

C

Figure 51-6 Distal intestinal obstruction syndrome (DIOS). *A*. Presenting Gastrografin enema of a child who had crampy abdominal pain and a right lower-quadrant mass. Fecal impaction with intussception is demonstrated. *B*. Partial resolution of the obstruction following Gastrografin administration. *C*. Complete resolution of the intussception and fecal impaction.

of a person who has the characteristic history and symptoms of CF. The most prominent clinical features are chronic pulmonary disease and pancreatic insufficiency. The most compelling family history for the diagnosis is CF in a sibling. If the clinical picture and/or the family history support the diagnosis, and if two sweat tests using the quantitative pilocarpine iontophoresis method are clearly positive, the diagnosis of CF can be made with assurance. Identification of two pathological mutations, in addition to the characteristic clinical picture, is accepted as a criterion for the diagnosis. However, CF is a complex syndrome (Table 51-2) whose clinical manifestations are sometimes subtle. In addition, the family history is not always straightforward. Therefore, a high index of suspicion, coupled with a battery of clinical tests, is sometimes required to establish the diagnosis, especially in adolescents or young adults.

Since CF occurs with a high frequency in the general population, the diagnosis should be considered routinely in a broad array of differential diagnoses. Although Table 51-2 categorizes symptoms according to the age at which they most often occur, symptoms at any age should prompt consideration of the diagnosis of CF.

The most consistent feature of CF is an abnormally high concentration of sodium and chloride in sweat. Measurement of the chloride concentration is recommended for clinical testing. The only reliable sweat test is based on iontophoresis of pilocarpine, followed by quantitative determination of the concentration of chloride in an adequate, measured volume of sweat. Seventy-five milligrams of sweat is the minimum acceptable amount. When a preweighed, measured pad is used, this amount ensures that an adequate sweat flow rate (1 g/m^2 per min) has been achieved and that the sample is large enough for the determination of chloride by titration. In children, concentrations of chloride of less than 40 mEq/L are usually regarded as normal. However, the average of values for sodium and chloride concentrations are about 20 mEq/L for normal subjects and 95 mEq/L for those with CF. In children, values between 40 and 60 mEq/L are borderline elevated; such values call for further evaluation. As a result of recent experience with CF newborn screening, it has been suggested that sweat chloride values above 40 mEq/L may be diagnostic in the first few months of life.

The concentration of sodium and chloride in sweat increases gradually with age. An age-corrected scale of normal, abnormal, and borderline values of sodium concentration in sweat is available (Fig. 51-7). Conditions other than CF in which the concentrations of sodium and chloride in sweat are abnormally high include malnutrition, adrenal insufficiency, hereditary nephrogenic diabetes insipidus, ectodermal dysplasia, and fucosidosis. Except in some instances of malnutrition, these conditions are readily distinguished from CF. The finding of abnormal concentrations of sodium and chloride in sweat should automatically prompt evaluation of the patient to determine if, and to what extent, other organs are affected.

Genetic analysis can be used to confirm the diagnosis of CF. In patients with minimal symptoms, the diagnosis of CF can be made with certainty if two CF-associated alleles are present. As mentioned previously, screening for 32 of the most common alleles yields an overall sensitivity of 90 percent due to undetected alleles. Therefore, a negative mutation analysis does not rule out a diagnosis of CF, and atypical patients should be followed carefully.

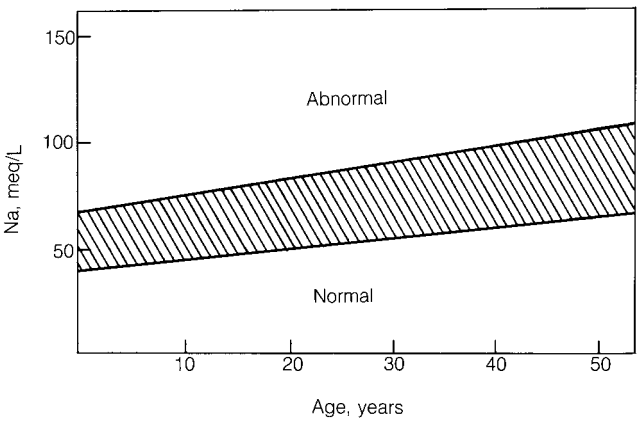

Figure 51-7 Graph of sweat test results vs. age: normal, elevated, and borderline (stippled).

Prenatal screening is standard practice for 11 states. The initial stage of screening uses the neonatal blood spot to determine the concentration of immunoreactive trypsinogen. If this is elevated, secondary screens vary from repeat immunotrypsinogen determination to ΔF508 or 25-32 mutation screen. The screening programs have a sensitivity ranging from 87 to 99 percent. Risks vs. benefits and the relative costs of the screening programs are being evaluated to determine the best approach.

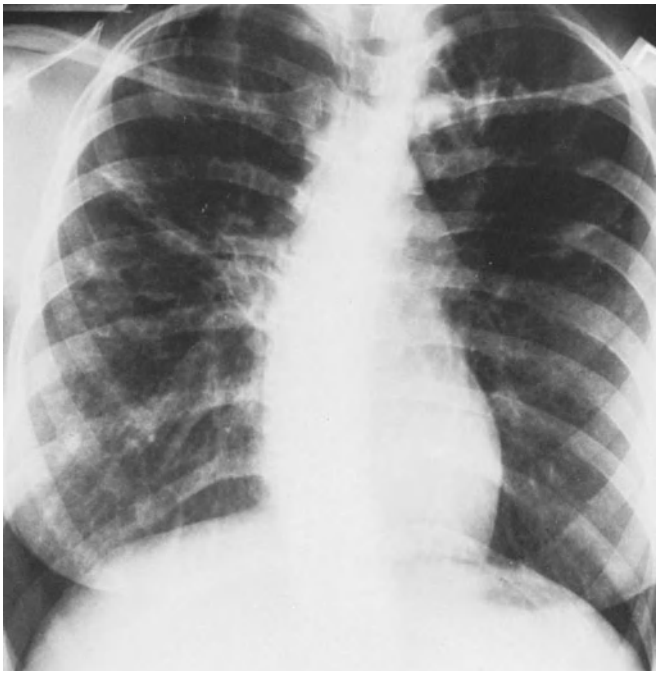
CLINICAL EVALUATION

The evaluation of patients with CF includes chest radiography, tests of pulmonary performance, sputum culture, and assessment of pancreatic, hepatic, and reproductive functions. Each is described below.

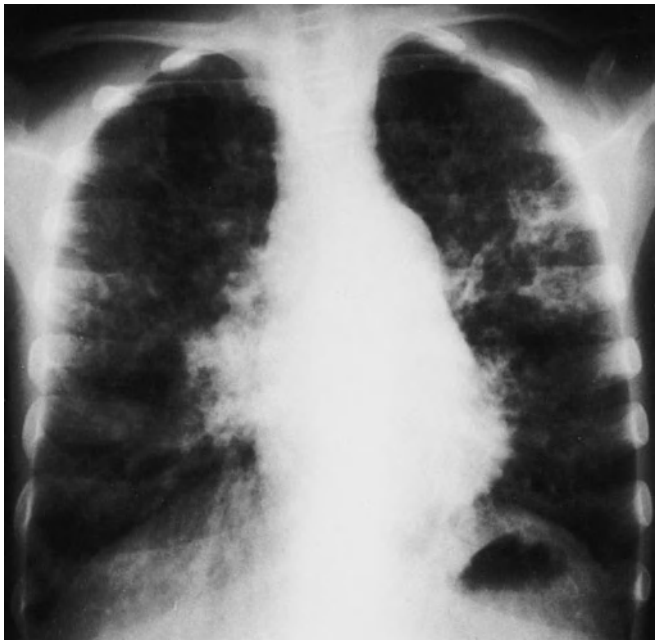
Chest Radiography

Rarely is the chest radiograph completely normal in CF. In the person with minor pulmonary symptoms, the manifestations may be questionable (e.g., mild hyperinflation and minimal peribronchial thickening). However, the radiographic findings become more distinctly abnormal as the disease increases in severity. Peribronchial thickening, which is often most prominent in the upper lobes of the lungs early in the course of the disease, usually progresses to affect all lobes. In the advanced stage of pulmonary involvement, ring shadows, cystic lesions, and nodular densities are increasingly apparent, as are areas of bronchiectasis and atelectasis. The central pulmonary artery often enlarges in the middle stages of the disease, but the cardiac silhouette remains within normal

A



B



C

Figure 51-8 Chest radiographs of three siblings with CF taken when the patients were 17 years of age. *A*. Mild hyperinflation; otherwise normal. Patient is now 32 years old and has been hospitalized once for treatment of electrolyte depletion. *B*. Diffuse peribronchial thickening, mild hyperinflation, and cystic changes in both upper lobes. The patient was hospitalized seven times for pulmonary exacerbations, once for diabetes, and once for hemoptysis. She died at age 34 following complications from lung transplantation. *C*. Severe hyperinflation, diffuse peribronchial thickening, multiple infiltrates, and increased pulmonary vascular markings and heart size. The patient died 1 month later from respiratory failure complicated by congestive heart failure.

limits until the disease is far advanced. The variability in the chest radiograph is illustrated in Fig. 51-8 for three siblings with CF when each was 17 years old.

High-resolution computed tomography (HRCT) scans are more sensitive than plain radiographs. The most common abnormalities described are "ground glass opacities." Early bronchiectasis is easily detected on the CT scan, even when routine chest radiographs are normal, as seen in Fig. 51-9.

Pulmonary Performance

The lungs of patients with CF are usually morphologically and functionally normal at birth. Over time, accumulation of tracheobronchial secretions and recurrent infections progressively impair pulmonary function in almost all patients. In the fully developed clinical syndrome, all the pulmonary function abnormalities seen in chronic bronchitis, emphysema, and asthma may occur. However, one complicating regular feature of CF—bronchiectasis—modifies pulmonary performance. Chronic, local infection and airway damage increase the compliance of bronchiectatic airways, resulting in airway collapse during rapid expirations or cough. The usefulness of pulmonary function testing in CF is twofold: tracing the natural history of the disease and assessing the value of therapeutic interventions.

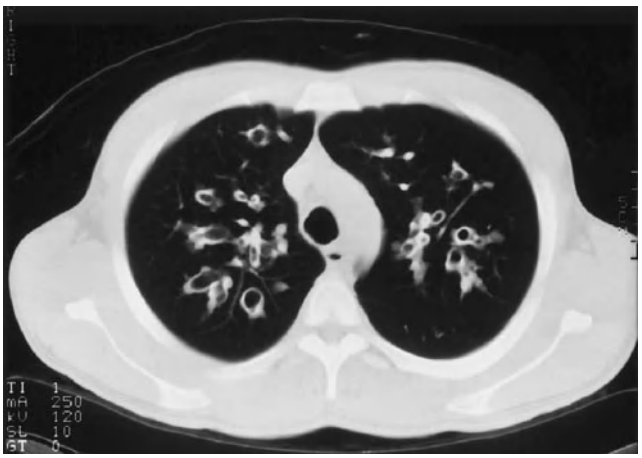


Figure 51-9 High-resolution chest computed tomography scan from a patient with CF. Marked bronchiectasis with peribronchial thickening is shown in the upper lobes.

The earliest stages of the pulmonary disorder are the most difficult to quantify. In infants, tests are limited almost entirely to those that do not depend on the patient's understanding and cooperation. A variety of methods to measure infant pulmonary function have been devised; one method, the raised volume rapid thoracoabdominal compression technique, requires sedation of infants but provides values most similar to standard spirometric values, and has detected reduced pulmonary function in infants with CF. After age 6 years, pulmonary function tests originally designed for adults may be performed quite readily on children. Changes in pulmonary performance throughout the natural history of CF can be described with confidence.

Obstruction in Small Airways

The small airways—i.e., the bronchioles—are vulnerable to obstruction early in the course of CF. At this stage, as in cigarette smokers, results of tests for small-airway disease are apt to be abnormal, while those of tests for obstruction of large airways are still normal. Three factors interact in causing the obstruction: (1) intrinsic disease of the smaller airways, often in association with bronchiectasis in the proximal, larger airways; (2) viscid secretions, impaired ciliary action, and impaired cough; and (3) progressive decrease in lung elastic recoil.

The progressive reduction in lung elastic recoil in CF is predominantly a function of overinflation due to intrinsic airway disease, rather than loss of pulmonary parenchyma. This mechanism differs from that in chronic bronchitis and emphysema, in which the combined effects of parenchymal destruction and overinflation are responsible for the decrease in elastic recoil. Emphysema is not a regular feature of CF. In some patients, emphysema occurs only late in the course of the disease (Fig. 51-4).

Airway smooth-muscle tone increases only slightly in CF. Exercise elicits bronchodilation, followed shortly thereafter by bronchoconstriction. Both the bronchodilation and bronchoconstriction are far less impressive in CF than in asthma. Indeed, exaggerated bronchomotor responses in CF raise the possibility of superimposed asthma. In distinguishing between contributions to airway obstruction by intrinsic airway disease caused by CF and asthma, maximal expiratory flow-volume curves are sometimes helpful.

Because of the bronchiolar locus of the early lesions in CF, abnormalities in breathing frequency–dependent tests (e.g., dynamic lung compliance), in volume-dependent tests (e.g., closing volume), and in maximal expiratory flow ($V_{E_{max}}$) at low lung volumes are demonstrable, even though results of tests of large-airway function (e.g., FEV_1 and airway resistance) are still normal.

Change in Lung Volumes

As with chronic bronchitis, emphysema, and asthma, RV in CF increases. Thereafter, an increase in functional residual capacity and, sometimes, in total lung capacity is seen. Later during the course of the disease, air-trapping occurs, manifest as an elevated ratio of RV to total lung capacity. This change decreases the compliance of the lung and increases the work of breathing.

Abnormalities in Gas Exchange

Early in the evolution of the pulmonary abnormalities in CF—i.e., when tests of small-airway function alone are abnormal—ventilation-perfusion abnormalities usually result in widening of the alveolar-arterial oxygen gradient and an increase in the ratio of dead space to tidal volume (V_D/V_T). These abnormalities portend increasing inhomogeneities in alveolar ventilation and blood flow as the affected child grows to adulthood. The diffusing capacity for carbon monoxide (D_{LCO}) is low at rest and does not increase normally during exercise. This observation is difficult to reconcile with the preservation of the gas-exchanging surface of the lungs (in the absence of emphysema) until late in the course of the disease (Fig. 51-4).

As obstructive disease of the airways progresses and exaggerates the imbalances between alveolar ventilation and blood flow, arterial hypoxemia develops; pulmonary hypertension, cor pulmonale, and right ventricular failure follow, in turn. Late in the course of the disease, hypercapnia and respiratory acidosis contribute to the final picture of respiratory failure. At this juncture, the ventilatory response to inhaled CO_2 is depressed. Bouts of infection punctuate the course of the illness; during each episode, pulmonary function deteriorates, but it usually returns toward baseline, except in the preterminal stages of the disorder.

Sputum Culture

The unique respiratory flora isolated from sputum cultures from patients with CF are helpful in establishing the diagnosis and in guiding the antimicrobial therapy for acute exacerbations. In many patients with CF, *P. aeruginosa* and *S. aureus* are found alone, or in combination with other organisms, in the sputum. Once present, the organisms, especially *Pseudomonas,* are rarely eradicated, despite use of intermittent or

continuous antibiotics administered intravenously, orally, or by nebulization. Although these organisms are sometimes found in sputum cultures from patients with pulmonary diseases other than CF, their association with the disorder is so consistent that a dedicated attempt to obtain a sputum culture is an integral part of the evaluation of all patients, including infants and young children, suspected of having CF. Conversely, isolation of *S. aureus* or *P. aeruginosa* in sputum in a child or young adult should raise the suspicion of CF.

Pancreatic Function

The evaluation of pancreatic function is an important part of establishing the diagnosis of CF, since almost 90 percent of patients have pancreatic insufficiency. In infants with pancreatic insufficiency due to CF, the most striking feature of the history and physical examination is often failure to thrive; the record of bowel movements may disclose only loose or frequent stools. In the older child, whose diet includes more fat and protein, a history of bulky, foul, malodorous stools is often easier to elicit. Documentation of malabsorption is best accomplished by collection of stools for 72 h while the patient is ingesting a known quantity of fat (approximately 100 g per day) and measurement of the stool fat content. A malabsorption coefficient of greater than 7 percent is usually considered abnormal; in patients with CF, the malabsorption coefficient often is around 20 to 30 percent.

In infants and young children, the determination of trypsin or chymotrypsin activity in a properly collected stool specimen is an accurate way to determine the content of pancreatic enzymes. In older patients, however, trypsin or chymotrypsin activity in a stool sample may be artificially low because of a delayed transit time that causes partial inactivation of the enzyme. In some instances, a secretin stimulation test may be helpful in demonstrating pancreatic insufficiency. For this purpose, a triple-lumen tube is introduced into the duodenum. The response to secretin is usually abnormal: the volume of secretion is small, the fluid is viscid, and the bicarbonate ion concentration is low. This test is not often used in children because it is cumbersome to perform. More recently, determination of fecal elastase-1 in a stool sample has been described as an accurate, easily obtained screening test to classify patients with CF as pancreatic insufficient or pancreatic sufficient.

For infants, the serum immunoreactive assay for trypsin is used in some centers as a screening test for pancreatic insufficiency. As a rule, serum levels of trypsin are abnormally high in CF, usually reflecting ongoing destruction of the pancreas. However, the assay does not provide an accurate measure of pancreatic function. Endocrine function of the pancreas is usually preserved in children, but approximately 50 percent of all adult patients are overtly diabetic by age 30 years.

Liver Function

Evaluation of liver function is an important part of the evaluation of CF. In infants and children, the concentrations of bilirubin and transaminases in serum sometimes increase transiently. However, concentrations of these substances are usually normal, even in patients with mild or moderate focal biliary cirrhosis. The prothrombin time is sometimes prolonged, owing to a combination of malabsorption and decreased synthesis of clotting factors by the liver. Occasionally, patients present with bleeding esophageal varices from advanced cirrhosis; endoscopy and upper gastrointestinal contrast studies are often helpful in demonstrating the varices.

Semen Analysis

Occasionally, a man who is found to have aspermia during the course of an evaluation for infertility is found to have CF. In men with CF, a complete semen analysis is part of the evaluation. Azoospermia is found in more than 98 percent of men with the disorder.

Mutation Analysis

Numerous attempts have been made, with limited success, to characterize phenotype on the basis of genotype. In general, homozygotes for ΔF508 have pancreatic insufficiency; patients with CF who have pancreatic insufficiency tend to have a worse prognosis. Several mutations, including R117H, are associated with pancreatic sufficiency and a mild phenotype. However, a direct association of a particular genotype with progression of the pulmonary disease has not been found.

An interesting genotype-phenotype correlation is the increased frequency of genotype R117H in males with congenital bilateral absence of the vas deferens (CBAVD). Males affected with this recessive disorder lack a vas deferens, but they are otherwise completely healthy and have normal sweat test results. Approximately 35 percent of chromosomes of patients with CBAVD carry a CF-associated mutation. To complicate this phenotype-genotype correlation further, 8 percent of patients with CBAVD without clinical CF have two CF-associated mutations. Genetic testing is not required to establish or confirm the diagnosis of CF when a compatible history and physical examination and abnormal sweat test results are found. Genetic testing is useful in identifying patients who have a compatible history and physical examination but whose sweat test results are negative. Certain alleles associated with CF (e.g., 3849 + 10kbC → T) are associated with nasal polyposis and bronchiectasis but normal sweat test results. The diagnosis of CF can be made with confidence in these patients. More problematic are persons with atypical presentations, normal sweat test results, and at least one CF-associated mutation. For example, mutations in at least one CFTR allele are associated with idiopathic chronic pancreatitis. More extensive genotyping should be attempted for all patients with a high clinical suspicion for CF (see "Genetics") because mutation analyses may become clinically relevant if specific therapies depend on the types of mutations present (see "Genetics" and "Future Directions").

Patients with the same genotype may have dramatically different phenotypes, raising the possibility that modifier

genes play an important role in determining the CF phenotype. Several potential candidate modifier genes are being evaluated for their impact on lung disease severity, including α_1-antitrypsin, HLA antigens, nitric oxide synthase, mannose-binding lectin, transforming growth factor β (TGFβ), tumor necrosis factor α (TNFα), and β_2-adrenergic receptor. Polymorphisms of TGFβ, have been associated with severe lung disease in a large, well-characterized cohort. Modifier genes may also affect function of other organs in CF; a modifier locus on chromosome 19 is associated with meconium ileus.

ATYPICAL CLINICAL PRESENTATIONS

Atypical clinical presentations confound the diagnosis of CF in adults; a high index of suspicion is required to establish the diagnosis. Approximately 6 percent of all CF is diagnosed after age 18 years. Late presentations of CF tend to occur in persons with pancreatic sufficiency; indeed, overweight or well-nourished persons may have CF. Recovery of unusual gram-negative organisms, mucoid *Pseudomonas* species, or *S. aureus* from sputum of asthmatics with persistent sputum production, chest radiographic abnormalities, or clubbing should prompt referral for sweat testing. Recurrent sinusitis and nasal polyposis may be the only manifestations of CF in a mildly affected person. Isolation of *P. aeruginosa* from deep nasal cultures should raise the suspicion of CF. Frequently, the sinus findings on CT mimic fungal sinusitis, demonstrating concentric, inhomogeneous material. Occasionally, persistent inflammation produces bony destruction that is mistaken for previous surgical intervention. Sweat testing and referral to a CF center should be considered for men with azoospermia or CBAVD.

TREATMENT

Intensive, comprehensive CF treatment programs designed to deal with particular symptoms, correct deficiencies, and prevent progression and complications of the disease have led to a dramatic increase in the median age of survival (Fig. 51-10). Although the value of comprehensive treatment is beyond question, far less certain are the utility of each component of the treatment plan and the level of each component necessary in a given patient. At present, the best approach still appears to be determination of the type and degree of abnormality in individual patients and design of a treatment program that will improve or maintain function of the organ systems affected.

To ensure that the treatment regimen meets the needs of the individual patient, that necessary treatment is not omitted, or that side effects of prescribed treatments do not go unnoticed, it is often desirable to hospitalize the patient for diagnosis and evaluation. Hospitalization also provides an excellent opportunity for counseling the patient, parents, and

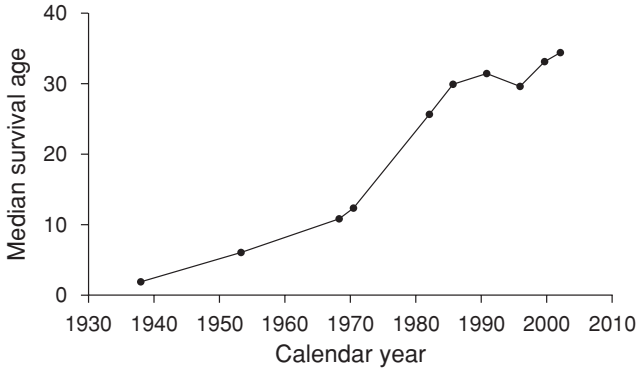

Figure 51-10 Median survival in patients with CF at various times since the first description of CF. Data before 1970 are gleaned from then-current literature. Data since 1985 are from CF Foundation Data Registry and represent projections of median survival age for a child born in that year with CF. *(From Davis PB: Cystic fibrosis since 1938.* Am J Respir Crit Care Med *173:474–482, 2006, with permission.)*

family about the diverse aspects of the diagnosis, treatment, prognosis, and inheritance pattern of CF. Hospitalization provides the opportunity to monitor the response of individual patients to each component of the therapeutic program.

An important aspect of the care of patients with CF is the network of more than 100 CF centers that exist throughout the United States and the larger network throughout the world. Most larger centers use a team approach to the care of patients. A CF care team usually includes physicians, nurses, respiratory therapists, physical therapists, nutritionists, social workers, and genetic counselors.

Management of the Pulmonary Disease

More than 90 percent of the patients with CF die from respiratory failure or pulmonary complications. The goals of treating the pulmonary disorder in CF are to prevent and treat the complications of airway obstruction and infection. Although management of the pulmonary disorder consists of many components applied in combination, the individual components of therapy are discussed separately below.

Chest Physiotherapy

Almost all treatment programs for CF include a strategy intended to clear pulmonary secretions in order to prevent complications arising from airway plugging by viscous secretions. Chest physiotherapy—i.e., "percussion and postural drainage"—performed regularly, is the most widely prescribed method. In infants and young children, chest physiotherapy is generally performed routinely, twice daily. In addition to manual chest percussion and postural drainage, there are several other effective modalities for chest physiotherapy. These alternative measures include the high-frequency chest-wall oscillatory vest; the flutter device, a small pipelike device that produces an oscillating resistance during a forced expiratory maneuver; the acapella device that produces both positive expiratory pressure and an oscillating resistance

during forced expiratory maneuver; positive expiratory pressure mask; intrapulmonary percussive ventilation; autogenic drainage and active cycle of breathing; and exercise. Some form of physiotherapy that is effective in mucus clearance is required daily because without chest physiotherapy, pulmonary function deteriorates. At present, most CF centers recommend that all patients with CF attempt to maintain clearance of pulmonary secretions with a method that is applied regularly (e.g., twice daily). An additional recommendation is that chest physiotherapy be applied more often during an exacerbation of the chronic pulmonary infection. Unfortunately, the recommendation of chest physiotherapy on a regular basis—a time-consuming and often arduous form of treatment—is difficult to implement without considerable support and encouragement from family and health professionals.

Antibiotics

During the past few decades of treatment of CF, antibiotics have proved to be the key element responsible for increased survival. A reasonable approach balances the dangers of overzealous administration of antibiotics against progressive airway damage and bronchiectasis resulting from untreated infection. The approach is based on sputum culture at the time of diagnosis and at regular intervals thereafter. When signs and symptoms herald an exacerbation of pulmonary infection (i.e., increased cough or sputum production, dyspnea, decreased exercise tolerance, decreased appetite) or new abnormalities on the physical examination (i.e., increased respiratory rate, use of accessory muscles, changes on auscultation of the chest including decreased breath sounds, new crackles or wheezes, weight loss), new abnormalities on the chest radiograph, or a decline in pulmonary function tests, chest physiotherapy is increased and appropriate antibiotics are given orally, or for severe exacerbations, intravenously.

Currently useful agents for treating staphylococcal infections include dicloxacillin, cephalexin, the newer cephalosporins, clavulanic acid combinations, and macrolides. Early in the course of the pulmonary disease, a small fraction of *Pseudomonas* strains may be sensitive to tetracycline, trimethoprim-sulfamethoxazole, or chloramphenicol. Occasionally, even *Pseudomonas* strains considered resistant according to laboratory sensitivity tests apparently respond to these antibiotics. A mechanism that has been proposed to account for this phenomenon is that even though the antibiotic is not bactericidal, it may inhibit either growth of the organism or its production of exotoxin and proteases. Ciprofloxacin, a quinolone derivative that can be given orally, is initially effective against many strains of *Pseudomonas* and has gained widespread use in the outpatient management of CF. A major disadvantage in its use is that resistance often develops after a few courses of treatment.

For treatment of a severe pulmonary exacerbation of CF caused by methicillin-resistant *Staphylococcus*, vancomycin or linezolid are indicated. For *Pseudomonas,* a combination of an aminoglycoside given intravenously and a semisynthetic penicillin is generally used. This combination is presumed to act synergistically on *Pseudomonas*, and the *Pseudomonas* is less likely to become resistant to either antibiotic.

The most popular antibiotic combination currently in use is tobramycin and ceftazidime. In order to achieve high levels of antibiotics in the airways and in secretions, the aminoglycoside is generally administered in higher doses. For example, tobramycin, 10 mg/kg per day in three divided doses, is given instead of 7.5 mg/kg per day in three divided doses. The resulting concentrations in serum are monitored. Instead of the usual therapeutic serum levels for tobramycin of 4 to 8 μg/ml, the goal in treating patients with CF is a serum level of 8 to 10 μg/ml; some centers advocate even higher levels. Serum antibiotic concentrations, renal function, and hearing acuity are monitored to avoid toxic reactions. The higher serum levels of 8 to 10 μg/ml do not seem to elicit greater toxicity than the usual levels. No advantage has been demonstrated for further increments in dosage.

Some of the newer antibiotics—e.g., piperacillin, meropenem, and ceftazidime—are also quite effective against *Pseudomonas.* Although they may be effective at first when given alone, resistance often develops quickly. Usually, these agents are used in combination with an aminoglycoside. Because the sensitivity and resistance patterns of the *Pseudomonas* often change, various combinations are tried at different times, with clinicians relying on sensitivities from recent isolates to determine which is most effective for the particular strain of *Pseudomonas.* For other resistant gram-negative organisms, such as *Burkholderia cepacia, Stenotrophomonas maltophilia,* and *Achromobacter xylosoxidans,* other antibiotic combinations are indicated, including ceftazidime, meropenem, ciprofloxacin, minocycline, aztreonam, chloramphenicol, or trimethoprim/sulfamethoxazole

Staphylococcus, Pseudomonas, and other gram-negative organisms, such as *B. cepacia, A. xylosoxidans,* and *S. maltophilia*, once found in the sputum, are rarely eradicated. However, most other manifestations of an exacerbation of pulmonary disease abate during a 2-week course of antibiotics administered intravenously; for example, the densities seen on the chest radiograph decrease, the white blood cell count decreases, fever and respiratory rate decrease, and pulmonary function test results, which often deteriorate at the start of an exacerbation, return to their previous baseline. Although many patients begin to show improvement after 5 to 7 days, most CF centers continue antibiotics intravenously for at least 2 weeks in order to decrease the relapse rate and to avoid a decrease in the interval between exacerbations. Indeed, some centers routinely recommend a 3- to 4-week course of intravenous antibiotics to treat an exacerbation of a pulmonary infection. In the occasional hospitalized patient who experiences a relapse or manifests an increase in symptoms shortly after administration of intravenous antibiotics is stopped, long-term intravenous administration of an aminoglycoside can be continued with use of a heparin lock. This technique may be helpful in allowing the patient to return home while still receiving effective doses of aminoglycosides.

Another approach that has been advocated is administration of antibiotics by inhalation—the rationale of which

is to increase antibiotic concentrations in airways infected by *Pseudomonas*. Although it has been argued that inhalation will not deliver effective concentrations to diseased portions of the lungs because of interference with ventilation by local airway obstruction, inhaled antibiotics appear to be helpful in some instances. Inhaled, preservative-free tobramycin, 300 mg twice daily for 28 days on and 28 days off (cycling therapy), improved pulmonary function (FEV_1 increased by 10 percent) at the end of the third treatment cycle (20 weeks) compared to placebo. One concern about inhaled tobramycin as a chronic therapy is the risk of bacterial resistance. In addition, questions regarding selection of patients and timing and duration of treatment remain unanswered.

Another antibiotic which has been studied as a chronic therapy in CF is azithromycin. Azithromycin, 250 mg or 500 mg thrice weekly, was evaluated in CF patients colonized with *P. aeruginosa*. After 6 months of therapy, patients on azithromycin had a modest improvement in FEV_1 (6.2 percent), increased weight gain, and decreased rates of pulmonary exacerbations. However, the same issues are raised for chronic azithromycin therapy as were raised for chronic inhaled tobramycin: the long-term issues of benefit, risk of antibiotic resistance, and cost.

Mist and Mucolytics

Mist therapy, delivered by having the patient sleep in a mist tent or through intermittent inhalation of an aerosol, was a common form of treatment of CF several decades ago. The goal was to "liquefy" respiratory secretions. However, the treatment could not be demonstrated to be helpful, and the use of mist tents has been discontinued. Intermittent aerosols are still used to deliver bronchodilators and mucolytics.

A number of mucolytic agents have been tried over the years. One that has endured is *N*-acetylcysteine. In the test tube, this agent is quite effective in dissolving mucin components and in decreasing the viscosity of sputum from patients with CF. Although some centers have found this agent to be a useful adjunct to therapy in CF, others have encountered an inordinate frequency of complicating bronchospasm or tracheitis. Some difficulties noted in the past can now be attributed to the use of a 20 percent (undiluted) solution of *N*-acetylcysteine, which can be irritating because of its extremely high osmolarity. The incidence of side effects may be decreased greatly by use of a 5 percent solution; during an exacerbation, when cough and sputum production increase, the 5 percent solution is inhaled two or three times per day, before chest physiotherapy. Should the patient develop bronchospasm, demonstrated by physical examination or by pulmonary function testing, a bronchodilator is used. If successful, the bronchodilator and the *N*-acetylcysteine are administered jointly by inhalation. However, should the bronchospasm persist despite use of the bronchodilator, *N*-acetylcysteine is not administered.

In 1994, Pulmozyme, a DNA-cleaving enzyme, was approved for use in patients with CF following a large phase III multicenter trial. More than 900 patients were enrolled for a 6-month period. Three dosing regimens were employed: placebo, 2.5 mg inhaled once daily, and 2.5 mg inhaled twice daily. The treatment groups showed a 5 percent improvement in FEV_1 over placebo, as well as a slightly lower relative risk of exacerbation of lower respiratory tract infection after 6 months. There was no difference between the once- and twice-daily treatment groups. A second study revealed that Pulmozyme, inhaled once daily over 96 weeks, maintained pulmonary function and decreased the relative risk of respiratory tract exacerbations in young CF patients with normal FEV_1 ($\geq$85 percent). Currently, this drug is in fairly widespread use for CF. However, questions regarding patient selection and timing and duration of use of this expensive drug remain unanswered.

Inhaled therapy with hypertonic saline was recently evaluated in CF. Patients inhaled 7 percent hypertonic saline twice daily following a bronchodilator for 48 weeks; results revealed only a modest improvement in FEV_1, but a significant reduction in the number of pulmonary exacerbations and days lost from school or work. It remains to be established how this therapy will fit into the maintenance therapy program for CF patients.

Bronchodilators and Anti-Inflammatory Agents

Bronchodilators are often used in treating the pulmonary manifestations of CF. Their use should be individualized. For example, in many patients, bronchospasm that is reversible with bronchodilators at one point in the course of the illness may prove refractory a short time later. Some patients undergo deterioration in pulmonary function following use of bronchodilators. In infants who are audibly wheezing, a bronchodilator can be tried. In older patients, pulmonary function testing provides a more objective and quantitative measure of bronchodilator effectiveness.

Corticosteroids have been used with good results in infants with severe obstructive airway disease that does not respond to antibiotics and bronchodilators and in patients with CF in whom the pulmonary disease is complicated by severe asthma or allergic bronchopulmonary aspergillosis. Preliminary observations initially suggested that patients with CF would benefit from long-term administration of alternate-day corticosteroids, based on the presumption that corticosteroids would decrease the airway inflammatory response. However, in a large, placebo-controlled, multicenter trial of alternate-day corticosteroids administered in two dosage regimens (1 mg/kg and 2 mg/kg), the development of many side effects precluded a general recommendation for long-term corticosteroid treatment in CF. Subgroup analysis led to the suggestion that patients with moderately severe obstructive airway disease and those with chronic *Pseudomonas* infection might benefit from treatment for periods of less than 1 year. Beneficial effects were sufficient to prompt further studies of anti-inflammatory agents in CF. A controlled 4-year trial of high doses of ibuprofen in 40 patients with CF showed improvement in the rate of decline of pulmonary function in children. Questions remain whether side effects that might

accrue with continued therapy will justify the gains. In concert, these two studies suggest that future development of a lung-specific anti-inflammatory agent with fewer systemic side effects may offer a promising approach.

Nutritional Support

Patients with CF require careful evaluation to determine if partial or complete pancreatic insufficiency is present and to design a nutritional program to correct any deficiencies. The mainstay in managing the pancreatic insufficiency of CF is use of pancreatic enzyme preparations currently available in the form of enteric-coated capsules containing coated microspheres. These pancreatic enzymes are ingested along with any food that contains protein, fat, or complex carbohydrates. The dosage is adjusted to ensure a relatively normal pattern of bowel movements, adequate weight gain or maintenance of ideal weight for height, and a decrease in bowel symptoms, such as cramping and flatulence.

The development of colonic strictures was first noted following the introduction of pancreatic enzymes with lipase contents of 25,000 units per capsule. Capsules with more than 20,000 units are no longer available. Subsequent recommendations urge caution in prescribing high total doses of lipase with any preparation; recommendations are to limit use to less than 2500 units/kg per meal. Since strictures have apparently developed in several patients using doses as low as 6000 units/kg per meal, it has been recommended that for patients who require higher doses to maintain nutritional status or to control bowel symptoms, the enzyme requirement be documented by measuring the coefficient of fat absorption and other causes pursued to account for symptoms.

As a rule, patients with CF are advised to consume a double dose of a multivitamin preparation and a vitamin E supplement each day. Infants, those in whom the prothrombin time is prolonged, and those who take antibiotics uninterruptedly require supplemental vitamin K. Vitamin A supplementation is required in children with significant fat malabsorption and failure to thrive; however, care must be taken to avoid hypervitaminosis A. Supplemental salt is needed by patients in order to prevent electrolyte depletion, metabolic alkalosis, and heat prostration. For infants, 1 to 2 g of salt per day is added to the feeding formula; children and adults are encouraged to salt their foods liberally and to take salt-containing liquids and snacks during hot weather.

Although it is true that pulmonary function is the predominant factor in determining morbidity and mortality in CF, it is becoming increasingly clear that overall patient status is closely tied to nutritional status. Importantly, achieving and maintaining normal weight for age and height for age are closely associated with maintenance of lung function in young children and adults. Data from the national 2004 CF Registry indicate that 15.7 percent of CF patients are below the fifth percentile of weight for age and that mortality is increased in this group.

Despite use of pancreatic enzyme replacement, the correction of pancreatic insufficiency is incomplete; accordingly, patients require more than 100 percent of recommended caloric intake. In some, an even greater caloric intake is necessary because of increased energy expenditure due to increased work of breathing secondary to chronic pulmonary infection. Aggressive nutritional supplementation, using either oral supplements or nocturnal nasogastric feeding of hydrolyzed formulas, has been helpful in the short term in promoting weight gain at this stage of disease. Hyperalimentation is occasionally required in infants with meconium ileus and in other special circumstances.

NATURAL HISTORY AND PROGNOSIS

A comprehensive treatment program for CF has unequivocally improved overall survival of patients. Thirty years ago, the median survival was only a few years of age; currently, it is about 35 years (Fig. 51-10). However, because CF is a complex disorder that affects different organs to different degrees, it is difficult to describe a "typical course" for a patient with CF. Some patients die in childhood or adolescence, while others survive beyond age 40 years.

An important determinant of the natural history of CF is the severity of the pulmonary disease and the rate at which it progresses. Although most patients' condition improves in response to therapy, skillful management does less to influence the course of the severely affected than that of the mildly affected patient.

A variety of scoring systems have been devised for CF. The clinical scoring system devised by Shwachman and Kulczycki and the chest radiograph scoring system devised by Brasfield and associates are widely used. However, although these and more elaborate scoring systems are useful in categorizing patients according to the severity of illness, none has proved useful in prognosticating the course of an individual patient.

Because CF is a genetic disease, the question of a familial pattern of severity is often raised. Figure 51-8 shows chest radiographs of three siblings with CF; the radiographs demonstrate mild, moderate, and severe disease in individuals in the same family. The capsule histories, which are included in the figure legend, also illustrate the variability in courses experienced.

Patients with CF can be categorized not only with respect to severity of illness, but also with regard to survival. For example, more than half of patients with CF who underwent surgery for meconium ileus before 1965 died in the first 2 months of life. Although this situation had improved markedly by 1976, the survival rate for patients with meconium ileus was still not as good as for all other patients with CF. In addition, the survival rate was much lower for females than for males, especially in adolescents. In recent years, differences between the patients in these groups have declined or disappeared. Because of improvements in the collection of mortality statistics, comparison of current data with those from previous years may be somewhat misleading, but

50 percent-survival age has not been increasing as rapidly in recent years as in the 1970s and 1980s (Fig. 51-10). Furthermore, there is a difference in outcomes among individual CF centers.

COMPLICATIONS

The course of CF is often characterized by a gradual decrease in pulmonary function, punctuated by further abrupt declines during exacerbations. Malnutrition, when present despite therapy, usually correlates best with the severity of the pulmonary disease. However, the course of CF may be suddenly altered by certain complications of the disease.

Hypoelectrolytemia and Metabolic Alkalosis

Hypoelectrolytemia and metabolic alkalosis are serious complications that are especially apt to occur during periods of hot weather, when losses of sodium and chloride increase. Electrolyte depletion may be life-threatening, especially in infants and young children (Table 51-3). Prompt fluid replacement with isotonic saline is critical.

Intestinal Obstruction

Acute or chronic crampy abdominal pain attributable to some degree of intestinal obstruction is common in patients with CF. If the obstruction is incomplete and manifested solely by a tender right lower-quadrant mass, medical therapy using oral *N*-acetylcysteine and mineral oil, GoLytely, or MiraLax is recommended. If these measures are unsuccessful, hyperosmolar enemas using an agent such as methylglucamine diatrizoate (Gastrografin) may dislodge the fecal mass. Patients with a history of crampy abdominal pain are occasionally noted to have radiographic evidence of intestinal obstruction, manifested by dilated bowel loops and air-fluid levels. After the neonatal period, intestinal obstruction is referred to as meconium ileus equivalent. An impacted fecal mass may serve as the leading edge for a volvulus or intussusception (Fig. 51-6). If either of these is present and not resolved with hyperosmolar enema, surgery is required. Careful pre- and postoperative management is essential to avoid the deterioration in pulmonary function that may follow the use of anesthesia.

Liver Disease

Cholestasis is often asymptomatic and detected by elevated serum alkaline phosphatase and transaminases on routine yearly studies. To prevent the progression to fibrosis and cirrhosis, treatment with the hydrophilic bile acid, ursodeoxycholic acid, should be initiated. Persistent hepatomegaly or splenomegaly, persistently elevated transaminases, or complications of portal hypertension establish significant liver involvement. Although cirrhosis occurs in fewer than 5 percent of people with CF, esophageal varices and portal hypertension may cause upper gastrointestinal bleeding in these patients. Once bleeding has been identified as due to varices and hemoptysis has been excluded, therapeutic endoscopy with a sclerosing agent or band ligation is undertaken. For patients with severe involvement, transjugular intrahepatic portosystemic shunting or surgical portosystemic shunts can effectively decompress esophageal varices by decreasing portal pressure.

Liver transplantation is another option for many patients with CF who have end-stage liver disease. Bleeding esophageal varices or vitamin K–resistant prolongation of the prothrombin time should prompt evaluation for liver transplantation. Criteria for priority transplantation include bleeding varices not responsive to sclerosis, severe ascites, and encephalopathy. Ideal candidates are those with an FEV_1 of at least 50 percent of predicted. Colonization with a multidrug-resistant or panresistant strain of *Pseudomonas* is a relative contraindication to transplantation. In patients in whom poor pulmonary function or drug-resistant pulmonary infection is an issue, double organ (liver and lung) transplantation may be considered. However, this surgery has been successfully accomplished only several times to date. Despite concerns about worsening airway infection during transplant-associated immunosuppression, liver transplantation in patients with CF does not worsen their pulmonary status.

Atelectasis

Atelectasis of a lung segment or lobe sometimes occurs in CF. Acute atelectasis is generally associated with few symptoms (Fig. 51-11*A*). If it is untreated, however, the end result of atelectasis is a severely bronchiectatic segment or lobe (Fig. 51-11*B*). Vigorous chest physiotherapy, in conjunction with antibiotics, is often successful in reexpanding the affected lung region. Bronchoscopy is occasionally helpful. As a rule, however, bronchoscopy is no more effective than chest physiotherapy and pulmonary pharmacotherapy. Resection of a persistently atelectatic or bronchiectatic lobe is undertaken only when the remaining areas of the lung are in relatively good condition, overall pulmonary function is good, and the evidence convincing that the affected segment is responsible for intolerable symptoms (fever, cough, or sputum production).

Figure 51-11 Chest radiographs of patients with pulmonary complications of CF. *A*. Atelectasis of the right upper lobe in a 4-month-old boy. The atelectasis resolved with antibiotics and chest physiotherapy. *B*. The same patient at 9 years of age with mild hyperinflation, central bronchiectasis, resolving right upper lobe infiltrate. The diagnosis of allergic bronchopulmonary aspergillosis was made, and the patient improved after treatment with prednisone. *C*. Pneumothorax of the right lung (arrows) in a 13-year-old boy. The pneumothorax resolved after tube thoracostomy and tetracycline sclerosis. The patient died 3 years later from respiratory failure with congestive heart failure. There were no recurrences of the pneumothorax. *D* and *E*. A 43-year-old man showing hyperinflation and diffuse peribronchial thickening. The radiograph was taken during an episode of significant hemoptysis, and no acute changes were seen on the radiograph. He works full-time and has not had another episode of hemoptysis in the last 12 years.

Pneumothorax

Recurrent pneumothorax is common in CF, particularly in older patients (Fig. 51-11*C*). Tension pneumothorax occurs in up to 30 percent of patients with CF who develop pneumothorax. Tube thoracostomy is indicated when the pneumothorax occupies more than 10 percent of the area of the hemithorax seen on the posteroanterior chest radiograph. Because the frequency of recurrence of pneumothorax is high, attempts are often made at the time of the initial event to achieve chemical or surgical pleurodesis. Surgical pleurodesis is more effective at preventing recurrence of a pneumothorax and is no longer considered a contraindication to lung transplantation.

Hemoptysis

Expectoration of a small amount of blood-streaked sputum is a fairly common occurrence in CF and is generally managed by intensifying home therapy for pulmonary infection. In contrast, hemoptysis (the expectoration of at least 30 to 60 ml of fresh blood) requires hospitalization, even with a chest radiograph that is virtually unchanged (Fig. 51-11*D*). The probable mechanism underlying most instances of hemoptysis in CF is the erosion of an area of localized infection into a bronchial vessel. Massive hemoptysis (blood loss of 300 to 2500 ml) is uncommon in CF. However, it represents a potentially life-threatening situation. Bronchoscopy, and sometimes thoracic surgery, may be required to control the hemorrhage. Bronchial artery embolization has been used successfully in patients with CF and is now the treatment of choice when a physician experienced in the procedure is available.

Infection with Unusual Organisms

CF produces central bronchiectasis, even though the disease initially is in the small bronchioles. Bronchiectatic airways are frequently colonized with unusual organisms, including *Aspergillus* and atypical mycobacteria. As is the case with pathogenic bacteria, eradication of these organisms from the airways is virtually impossible. The focus of therapy is directed toward verifying that the organisms are resulting in worsening of the disease and controlling the infection, rather than effecting a microbiologic cure.

Mycobacteria

The prevalence of infection with mycobacteria in CF is approximately 12 to 15 percent. Frequently, the sputum culture is overgrown with pathogenic bacteria; accordingly, the culture should be handled specially to enhance isolation. Patients with CF should be screened for *Mycobacterium tuberculosis* infection with yearly PPD skin tests. Prophylaxis and treatment of *M. tuberculosis* in CF are the same as for patients without CF. A decision about therapy for isolation of atypical mycobacteria is based on the likelihood that the organism is contributing to airway infection and a decline in pulmonary function. Isolation of the same organism on several occasions, positive smears, presence of progressive chest radiographic changes, further decline in pulmonary status despite vigorous antipseudomonal (or antistaphylococcal) therapy, persistent night sweats, and fever are clinical clues that the atypical mycobacteria are contributing to disease. Demonstration of tissue infection with transbronchial lung biopsy is rarely recommended. A clinical database has been established by the CF Foundation to track results of treatment for atypical mycobacterial infections in patients with CF.

Aspergillus

In an analogous fashion, molds, especially *Aspergillus,* are occasionally isolated from patients with CF. Approximately 5 to 15 percent of patients have allergic bronchopulmonary aspergillosis (ABPA). The diagnosis of ABPA in CF is difficult because of overlapping symptoms between the two disorders. Diagnostic criteria for ABPA are (1) reversible airway obstruction, (2) proximal bronchiectasis, (3) history of pulmonary infiltrates, (4) skin test positivity to aspergillus antigens, (5) precipitating serum antibodies to *A. fumigatus,* (6) elevated total serum immunoglobulin E (IgE), (7) elevated specific serum IgE and serum immunoglobin G (IgG) to *Aspergillus,* and (8) peripheral eosinophilia. A negative skin test for *Aspergillus* effectively rules out the diagnosis of ABPA. During the active phase of ABPA, elevations in total IgE and eosinophil count are seen. Rises in *Aspergillus*-specific titers (IgE and IgG) are more specific for ABPA than are serum precipitins. ABPA in patients with CF is treated with corticosteroids and itraconazole.

Gram-Negative Bacteria

In the late 1970s and early 1980s, the importance of *Burkholderia cepacia* (formerly *Pseudomonas cepacia*) was recognized. *B. cepacia* is a gram-negative, oxidase-positive rod that is uniformly resistant to polymyxin and, frequently, panresistant. Isolation of *B. cepacia* requires plating on special OFPBL (oxidative fermentive polymyxin B bacitracin lactose) or PC (*P. cepacia*) agar plates to retard growth of other gram-negative rods and enhance growth of *B. cepacia.* The plates must be maintained for a minimum of 4 days. *B. cepacia* colonization has been associated with septicemia, which is very rarely seen with *P. aeruginosa.* The clinical course after acquisition of *B. cepacia* may be fulminant, with death occurring in a matter of months. However, most patients' disease follows a more benign course. Carefully controlled epidemiologic studies are needed to better define risk factors and to establish the true virulence of *B. cepacia.* Experimental evidence exists that at least one strain of *B. cepacia* may be transmitted in an epidemic fashion. The combination of a poor clinical course after acquisition of *B. cepacia* and the evidence supporting epidemic transmission has led to cohorting or isolation of patients with CF infected with *B. cepacia,* as recommended by the CF Foundation and the Centers for Disease Control (CDC).

In addition to being colonized with *Pseudomonas* and *Burkholderia* species, patients with CF may be colonized with

other gram-negative, oxidase-positive organisms, such as *S. maltophilia, Pseudomonas oryzihabitans,* and *A. xylosoxidans.* These are pathogenic organisms, similar in importance to *P. aeruginosa.* Antibiotic therapy should be directed toward these bacteria when they are isolated from the patient with CF who is experiencing an acute exacerbation. The prolonged, prophylactic, aggressive use of antibiotics in CF has led to emergence of resistant organisms. A multiply resistant *Pseudomonas* is an organism that is resistant to all agents in at least two different classes of antibiotics. Resistance to oral fluoroquinolones occurs after about 3 weeks of therapy; if the agent is withheld, the organism occasionally becomes sensitive again.

Respiratory Failure

As the pulmonary disease of CF progresses and the degree of hypoxia increases, patients are at risk to develop pulmonary hypertension and cor pulmonale. An increase in hypoxia often occurs during exacerbations of the pulmonary disease. During the acute episode, antibiotic treatment for the underlying pulmonary disorder is intensified and supplemental oxygen is added. Expectant monitoring and aggressive treatment of nocturnal hypoxemia (maintaining $Sa_{O_2} \geq 95$ percent) prevent the onset of cor pulmonale. When respiratory failure develops in CF—i.e., hypercarbia (Pa_{CO_2} at least 55 mmHg) in addition to hypoxemia—management becomes extremely difficult. Noninvasive mechanical ventilation using bilevel positive airway pressure has been used successfully in patients with end-stage CF awaiting lung transplant; it improved oxygenation, reduced respiratory rate, and was successfully transitioned to home nocturnal use.

Mechanical ventilation is generally instituted when an acute episode, such as viral pneumonia or status asthmaticus, thrusts the patient into acute respiratory failure. This approach is particularly indicated in the patient who has had good pulmonary function before the acute episode. Mechanical ventilation is less apt to be successful if the patient has previously experienced a bout of respiratory failure. When respiratory failure marks the end of a chronic course of progressive pulmonary insufficiency despite adequate medical therapy, mechanical ventilation is usually unhelpful. None of the indications or contraindications for mechanical ventilation are absolute, however, and the clinical outcome depends, to a large extent, on the availability of a dedicated and skilled intensive care team experienced in caring for patients with CF.

Complications Related to Lung Transplantation

Lung transplantation has emerged as an option for patients with end-stage CF. Despite initial concerns about immunosuppression in patients with suppurative lung disease, the outcome for those with CF who undergo lung transplantation is among the best reported for this procedure. Two major problems prevent lung transplantation from becoming widely recommended for CF. One is the lack of suitable organs for transplantation. Forty percent of patients with CF who are awaiting transplantation die before an organ is made available. The attrition is due, in part, to the allocation of lungs on the basis of wait-list time *alone,* rather than on the basis of severity of disease; this practice has changed to permit the most severely ill patients access to transplant. The median waiting time is currently more than 12 months, but wide variability exists. The organ shortage, especially from pediatric donors, has driven the development of living related-donor transplants.

The second major problem with lung transplantation for CF is the occurrence of obliterative bronchiolitis following transplantation. Obliterative bronchiolitis is a progressive occlusion of the bronchiolar lumina by inflammatory cells and submucosal fibrosis. The cause is probably chronic allograft rejection; transient improvement in airflow is seen following augmentation of immunosuppression. About 50 percent of transplant patients develop obliterative bronchiolitis after the second year following the procedure. The disease pursues a relentless downhill course, with a median survival of about 2 years following the initial diagnosis.

The poor prognosis associated with obliterative bronchiolitis has several important implications for patient selection and timing of referral for transplantation. First, the main reason for seeking lung transplant is to improve the quality of life, rather than to improve survival. Second, the timing of referral for lung transplantation necessitates weighing the risks of dying while on the waiting list against the possibility of developing obliterative bronchiolitis.

Appropriately timed referral for transplantation includes consideration of (1) the average length of waiting time, (2) the natural history of the disease, (3) the natural history of lung transplantation, and (4) the requirement that the patient be fully ambulatory. Therefore, ideal candidates for lung transplantation are those who have less than 2 years to live and have significant functional impairment but are capable of participating in a pulmonary rehabilitation program.

Results from clinical studies may aid with proper timing of referral for lung transplantation in CF. A study of 673 patients with CF revealed that patients with an FEV_1 less than 30 percent of predicted have a 50 percent 2-year mortality. Other important clinical parameters useful in determining the timing of transplantation are the presence of hypoxemia (Pa_{O_2} under 55) and hypercarbia (Pa_{CO_2} above 50). Of interest, in both single and multivariate analyses, female gender is associated with an increased relative risk, suggesting that for female patients, referral for lung transplantation should be considered at an even earlier stage.

Because CF is a multisystem disorder, both management and proper selection of patients are more complicated than for other diseases managed with lung transplantation. Among the most difficult challenges presented by patients with CF before transplantation is the microbiology of their lower airways. As discussed previously, colonization with multidrug-resistant *B. cepacia*, specifically the genotype, genomovar III, has been associated with a poor clinical outcome. For poorly understood reasons, patients with CF

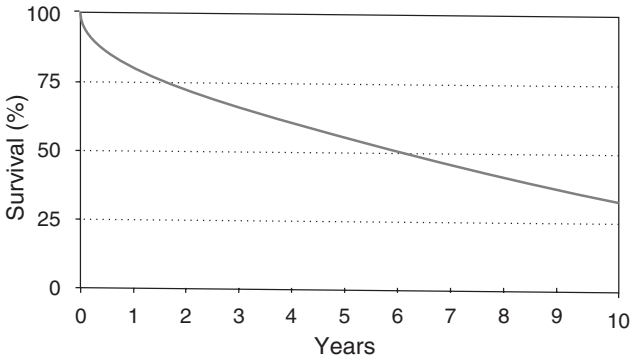

Figure 51-12 Kaplan-Meier survival for CF adult lung transplantation recipients (n = 1934) performed between January 1994 and June 2003. The CF lung transplant recipients had better survival outcomes than patients transplanted for idiopathic pulmonary fibrosis or primary pulmonary hypertension. *(From Trulock EP, Edwards LB, Taylor DO, et al: Scientific registry of the International Society for Heart and Lung transplantation: Twenty-second official adult lung and heart-lung transplant report—2005.* J Heart Lung Transplant *24:956–967, 2005.)*

metabolize drugs differently from those without CF, complicating the dosing of medications, including cyclosporine. The difficulties in achieving an optimal drug dose may be related to malabsorption or enhanced excretion of the drug. Nutritional issues also complicate the posttransplantation management of patients with CF. About 50 percent of all patients with CF over 30 years of age are overtly diabetic, and administration of corticosteroids induces diabetes in another 10 percent. Maintenance of proper nutrition is important in CF, especially for rapid postoperative recovery. Finally, gastroesophageal reflux may negatively impact pulmonary outcomes following transplantation. Despite all the special challenges to successful lung transplantation posed by patients with CF, their actuarial survival is quite good (Fig. 51-12). The 5-year survival is about 59 percent, reinforcing the tenet that lung transplantation is done principally to improve quality of life.

PSYCHOSOCIAL ISSUES

A number of psychosocial issues are important in the management of patients with CF. Special circumstances should be recognized for adults with the disorder.

General

Careful attention to the emotional, social, and financial well-being of the patient with CF and his or her family has considerable value in favorably influencing the course of the disease. At the time of diagnosis, it is important to strike an optimistic note while educating the patient about the illness and its management. As part of the early encounter with the patient, the importance of identifying and reinforcing the emotional and financial strengths of the family, as well as weaknesses that will need buttressing, should be recognized. Medical care for CF patients is costly, especially if hospital admissions are required. Many states have programs for children with disabilities that provide support for patients and families. Several states have also established special programs for adults with CF.

As the disease runs its course, counseling and feedback about disease progression are essential. As the patient and family go about setting educational, career, and family goals, they need guidance in realistic planning. It is vital that the physician develop and maintain a positive attitude. The patient who gives up hope is liable to undergo rapid deterioration. Conversely, even patients with severe pulmonary disease can continue to function well and be productive. At the stage when medical therapy is of no further avail, however, the patient and family require considerable emotional support to accept the inevitable. In recent years, many CF centers have allowed patients to die at home, rather than in the hospital. The family requires specific instructions about how to provide physical and emotional comfort for the patient in the home. Usually, home visits by some members of the CF team are required. Not all families have the strength or resources to care for the patient dying at home.

Special Considerations in Adult Patients

In 2004, the median life expectancy for patients with CF was about 35 years. Managing a chronic illness becomes more complicated when patients must also begin to manage their independence and make life decisions regarding education, marriage, children, careers, insurance, and self-care. Intense support for both patients and their families is required. Patients with a relatively mild clinical course of disease form healthy and satisfying relationships in a manner similar to that of their healthy, age-matched peers. With advanced disease, patients with CF have more difficulty in forming intimate relationships. Disturbances in body image, decreased mobility, and lack of opportunity to meet suitable partners are cited as reasons for the decreased ability to form intimate relationships in the severely affected young adult with CF.

The adult patient with CF faces unique problems with self-care. Families of patients with CF provide a tremendous amount of care that is expensive and time-consuming to replace for the independently living adult. When the disease flares, patients must "step up" their level of care at precisely the time when they are least able to do so. Judicious use of hospitalization and home care must be provided if the patient is to recover. The trend toward home management of a pulmonary exacerbation using intravenous antibiotics alone ignores the obvious contributions of nutrition, airway clearance, and rest toward resolution of the problem.

REPRODUCTIVE ISSUES

More than 98 percent of male patients with CF are sterile, secondary to bilateral absence of the vas deferens. Microsurgical

epididymal sperm aspiration (MESA), coupled with in vitro fertilization, has been successful in producing pregnancies in a few carefully selected patients. Not all males with CF are sterile, however. In addition to counseling, these men should be offered semen analysis.

Pregnancy for women with CF is increasingly common, and several important issues remain unsolved. In 2004, 191 women with CF were pregnant. This stands in marked contrast to the total of 13 pregnancies in 10 patients recorded from 1960 to 1966 (data from the 1994 CF Foundation Data Registry).

Maternal clinical status before pregnancy is the most important prognostic factor of maternal outcome. In a study of 25 women with 38 pregnancies, no significant difference was seen between pre- and postgravid gas exchange or nutritional status. A small but statistically significant decline in spirometry was noted. However, the decline was not outside the range of expected decline for the natural progression of the disease. More severely affected women suffer an irreversible decline in clinical status during pregnancy. Without an appropriately matched control group of nongravid women with CF, it is impossible to determine whether pregnancy per se is responsible for the decline or whether the decline is a reflection of the natural history of the disease.

Recommendations about pregnancy for women who are either mildly affected or severely affected is straightforward. For the woman with moderately compromised pulmonary status (i.e., FVC under 50 to 60 percent of predicted), an overall assessment of the clinical situation is recommended, although no firm guidelines can be given. Increased incidence of fetal prematurity is noted in women with a pregravid FVC below 50 percent of predicted, lending additional weight against recommending pregnancy to women with moderate to severe airflow obstruction. In any woman with CF who is contemplating pregnancy, thorough evaluation and treatment of nutritional deficiencies and pulmonary exacerbations are required. Frequent use of antibiotics is unavoidable, and the teratogenic risk of many antibiotics is unknown. Despite this theoretical risk, good maternal and fetal health depend on aggressive management of pulmonary exacerbations, including use of antibiotics. Management of the gravid patient with CF is best accomplished in a CF center that has a program in high-risk obstetrics.

For men with CF who opt for MESA and for women with CF who are contemplating pregnancy, all offspring are obligate heterozygotes for CF. These offspring need to be counseled that their risk of having a child with CF is about 1 in 50 if the genotype of the spouse is not known. Although genetic testing of children from affected parents is not recommended, they should receive genetic counseling on reaching adolescence. Parents with CF also need to consider the ethical issues of a premature parental death and its effect on the family.

Discovery of the CF gene in 1989 led to the hope that prenatal diagnosis would eventually decrease the incidence of the disease. However, affected families either are choosing not to test at-risk pregnancies or, if tested and found to be affected, are choosing to continue the pregnancy. Similarly, there has not been a large increase in the number of therapeutic abortions of fetuses with CF among women with the disorder who have a good clinical status. Obviously, the expected survival and quality of life for the child with CF must be sufficiently promising to explain these parents' decisions.

FUTURE DIRECTIONS

Concern exists that the marked improvement in survival of patients with CF noted over the past two decades is approaching a plateau. To further enhance survival in CF, physicians must look to insights gained from basic research. Although much work needs to be done, much has already been accomplished, warranting a realistic expectation that major breakthroughs will soon occur in the treatment of the disorder. Important areas for future development include new pharmacologic approaches and gene therapy.

Pharmacologic Approaches

Infection with *Pseudomonas* organisms is a critical aspect of CF that has attracted a great deal of attention. To date, *Pseudomonas* species have demonstrated a remarkable capacity to change expression of phenotype and to develop resistance to new antibiotics. One management strategy that is being employed more frequently is performance of synergy testing on isolates of *Pseudomonas* that are resistant to multiple antibiotics. Frequently, such testing directs the use of nontraditional combinations and doses of antibiotics with good therapeutic results. However, this strategy may be successful for only a limited period before panresistance develops.

Pharmacologic approaches to the basic defect in CF may offer treatment alternatives or additional benefit to the anticipated use of directed gene therapy (see below). As described earlier, many of the mutations in CF have been classified into five categories, depending on the functional consequences of the mutation on the gene product, which is an integral membrane glycoprotein. A CFTR mutation in the first category with a premature stop codon, G542X, can be activated by treating patients with intravenous gentamicin; this approach produced changes in nasal potential difference consistent with some improvement in chloride efflux. The most common mutation, ΔF508, is a class II or processing mutation in which most of the gene product remains in the endoplasmic reticulum, with only a very small amount localized to the surface membrane prior to degradation. Since CFTR has been shown to interact with several chaperones during processing, these molecules provide an attractive theoretical target for pharmacologic intervention, although, to date, there has been no functional correction with this approach. However, two agents, 4-phenylbutyric acid and glycerol, have been shown to increase cell surface localization of CFTR in vitro by an unknown mechanism. Since analogs

of 4-phenylbutyric acid have been employed clinically in treatment of sickle cell disease, a phase II clinical trial was performed. Other agents which have the property of "correcting" CFTR processing and localization to the apical membrane are being sought by the technique of high-throughput screening.

Other classes of compounds shown to "potentiate" or increase the chloride conductance of cells with the ΔF508 mutation are also being sought. Since infection and inflammation play a critical role in the pathophysiology of the lung disease of CF, efforts have been directed at decreasing airway inflammation. The approaches are both pharmacologic (e.g., use of ibuprofen and prednisone) and physiological (e.g., prevention of *Pseudomonas* binding to airway cells and immunization against *Pseudomonas*). The insufficient antioxidant capacity in CF airways is also being addressed by studies to evaluate antioxidant augmentation with nacystelyn and glutathione.

Gene Therapy

Improvements in gene transfer technology represent an important future direction in CF. Because the disease is inherited as an autosomal-recessive trait, only one normal copy of the gene needs to be provided to cells. Vectors proposed thus far for carrying the normal CFTR gene include adenovirus, adeno-associated virus, cationic liposomes, and DNA-protein complexes.

Several human clinical trials of gene therapy in CF have been initiated, based on use of adenoviral vectors, adeno-associated viral vectors, and nonviral vectors. Results have been remarkably similar among the trials. In a few patients, patchy expression of the transgene has been demonstrated in both the nose and lung using immunohistochemistry or in situ hybridization; overall efficacy has been poor. Dose-dependent inflammation has been encountered; in one study, a patient became acutely ill for several days following instillation in the lung of a high titer of replication-deficient adenovirus. Physiological correction of cyclic adenosine monophosphate (cAMP)-mediated chloride secretion in the nose has not been convincingly demonstrated after gene transfer, although a trend toward correction of the basal potential difference has been observed.

Finally, because the immune response to viral vectors constitutes a significant impediment to successful gene transfer, several approaches are currently being developed. These include production of less immunogenic viral vectors, immune suppression, development of nonimmunogenic, nonviral vectors, and using smaller molecules for gene repair inhibition of gene expression.

Progress toward cure of CF will require a multidisciplinary approach. Management of the lung disease in CF will probably be based on combined methods. However, the momentum gained from recent improvements in our understanding of basic pathogenetic mechanisms provides a basis for realistic optimism that specific therapy will result in better outcomes for patients with CF.

Bronchiolitis

Talmadge E. King, Jr. • Brent W. Kinder

Bronchiolitis is a fibrotic lung disease that primarily affects the small conducting airways, often sparing a considerable portion of the interstitium. Commonly occurring diseases with prominent involvement of the small airways (asthma, bronchitis, bronchiectasis) are described elsewhere in this book. However, several additional, uncommon small-airway diseases are important to recognize and treat. These "bronchiolar syndromes" frequently accompany infections, drug reactions, connective-tissue diseases, toxic gas or fume exposure, and organ transplantation. Bronchiolitis is an intellectual challenge to clinicians and pathologists. The "gold standard" approach is a multidisciplinary one, including clinical, radiological, and histopathological expertise, to establish the final diagnosis. This chapter reviews the clinical, radiographic, and histopathological findings of the bronchiolar syndromes.

DEFINITION AND CLASSIFICATION

Although bronchiolitis has been recognized since the 1800s, it was not until 1901 that the first detailed description of the clinicopathological syndrome appeared and the phrase *bronchiolitis obliterans* was applied. Bronchiolitis is an inflammatory reaction that follows damage to the bronchiolar epithelium of the small conducting airways. Subsequent

healing leads to excessive proliferation of granulation tissue within the airway walls, lumen, or both. Depending on disease stage, the repair process may cause narrowing and distortion of the small airways (constrictive bronchiolitis) or complete obliteration (bronchiolitis obliterans). Alveoli adjacent to the injured small airways are almost always affected, but a considerable portion of the pulmonary interstitium is often spared. Repair occurs in numerous clinical settings, with a variable clinical course and histological appearance. Consequently, a clear understanding of pathogenesis is lacking.

The nomenclature applied to the bronchiolar syndromes has been confusing. The following terms have been used: bronchiolitis obliterans, bronchiolitis fibrosa obliterans, bronchiolitis obliterans and interstitial pneumonia, bronchiolitis obliterans-organizing pneumonia (BOOP), cryptogenic-organizing pneumonia, and follicular bronchiolitis. Unfortunately, the terms are often used interchangeably to describe what are now believed to be separate and distinct clinical entities. Before the description of BOOP in 1985, most cases described as idiopathic bronchiolitis obliterans were actually cases of BOOP. Since some degree of inflammation, narrowing, and obliteration of the small airways is present in most patients, we have chosen the term *bronchiolitis* to refer to the broad spectrum of histopathological processes. Bronchiolitis obliterans refers to a histological lesion characterized by polypoid obliteration of the lumen of bronchioles, without involvement of the distal lung parenchyma by inflammation or organizing pneumonia—i.e., constrictive bronchiolitis. BOOP refers to disorders characterized histologically by intraluminal polyps in the respiratory bronchioles, alveolar ducts, and alveolar spaces, accompanied by organizing pneumonia in the more distal parenchyma. Bronchiolitis obliterans syndrome (BOS) is a clinical term that refers to the progressive airflow limitation secondary to small-airway obstruction which commonly complicates lung transplantation that is defined not by histology, but by lung function changes.

In BOOP, the alveolar walls show a mild to moderate chronic inflammatory infiltrate, type II cell hyperplasia, and foamy macrophages in the alveolar spaces; a "proliferative" bronchiolitis is present. Since only a minority of cases showing the "BOOP pattern" represent the idiopathic syndrome described in 1985, and since patients with idiopathic BOOP manifest a distinctive clinical syndrome, this group is referred to as "cryptogenic-organizing pneumonia," in order to distinguish the syndrome from other causes of the BOOP pattern.

Three classification schemes appear useful in defining cases of bronchiolitis: (1) a clinical classification based on the etiology; (2) a histopathological classification that includes two major morphologic types: proliferative bronchiolitis and constrictive bronchiolitis; and (3) a radiologic classification based on the findings of thin-section, high-resolution computed tomography (HRCT). The histopathological-radiologic classification appears most useful, since histopathological-radiologic changes correlate best with clinical manifestations.

Clinical Classification

The clinical classification of bronchiolitis is based on etiology (Table 52-1): inhalation injury, infections, drug reactions, and idiopathic causes. The first three categories are frequently recognized from their association with an acute illness or known exposure before the onset of disease. Idiopathic cases often have a more insidious onset, characterized by cough or dyspnea; initially, they may be confused with more common problems, such as chronic obstructive pulmonary disease or interstitial lung disease, depending on the predominant histopathological pattern.

Radiologic Classification

HRCT is an excellent way to examine the morphology of small-airway diseases. Consequently, it has become the method of choice for assessing these airways, often replacing the need for surgical lung biopsy. Several studies have examined the patterns found on computed tomography (CT) scans and correlated the patterns with histopathological findings. Based on radiologic features, investigators have classified bronchiolar diseases into three predominant CT patterns: (1) nodules and branching lines; (2) ground glass opacification (hazy increased attenuation, i.e., increased density of the lung with preservation of bronchial and vascular margins) and consolidation (hazy increased parenchymal attenuation in which the bronchial and vascular margins are obscured); and (3) low attenuation (i.e., decreased density of lung or "black lung") and mosaic perfusion (a patchwork of regions of varied attenuation, interpreted as secondary to regional differences in perfusion). The mosaic perfusion pattern appears to be most helpful in suggesting the presence of bronchiolitis obliterans.

Histopathological Classification

The histopathological classification (Table 52-2) of bronchiolitis includes proliferative and constrictive varieties. Each type, including the presumed pathogenesis, is described below.

Proliferative Bronchiolitis

Proliferative bronchiolitis—the "BOOP pattern"—is characterized by an organizing intraluminal exudate and is found, to some degree, in a variety of pulmonary disorders. It is particularly extensive and prominent in cryptogenic-organizing pneumonia (also called idiopathic BOOP). The intraluminal fibrotic buds (Masson bodies) are seen in respiratory bronchioles, alveolar ducts, and alveoli (Fig. 52-1). Proliferative bronchiolitis most frequently is associated with diffuse infiltrates on chest radiograph and a restrictive defect on pulmonary function testing, especially when cryptogenic organizing pneumonia is present.

Constrictive Bronchiolitis

Constrictive bronchiolitis is characterized by alterations in the walls of membranous and respiratory bronchioles which

Table 52-1

Clinical Syndromes Associated with Bronchiolitis

- *Inhalational injury*
  - Toxic gases (e.g., oxides of nitrogen)
  - Grain dusts
  - Irritant gases (e.g., chlorine)
  - Mineral dusts
  - Organic dusts (hypersensitivity pneumonitis)
  - Cigarette smoke
  - Free-base cocaine
  - Fire smoke
  - Flock worker's lung (fine nylon fiber)
  - Volatile flavoring agents
- *Postinfectious (mostly in children)*
  - Acute bronchiolitis
    - Common
      - Respiratory syncytial virus
      - Parainfluenza (types 1, 2, and 3)
      - Adenovirus (types 1, 2, 3, 5, 6, 7, and 21)
      - *Mycoplasma pneumoniae*
    - Uncommon
      - Coronavirus
      - Rubeola
- *Drug-induced reactions*
  - Penicillamine
  - Hexamethonium
  - L-Tryptophan
  - Busulfan
  - Gold
  - Cephalosporin
  - Sulfasalazine
  - Amiodarone
  - Acebutolol
  - Sulindac
  - Paraquat poisoning
- *Idiopathic*
  - No associated disease
    - Cryptogenic constrictive bronchiolitis
    - Respiratory bronchiolitis-associated interstitial lung disease
    - Cryptogenic-organizing pneumonia (also called idiopathic bronchiolitis obliterans-organizing pneumonia, BOOP)
    - Diffuse panbronchiolitis
    - Primary diffuse hyperplasia of pulmonary neuroendocrine cells
  - Associated with other disease
  - Associated with organ transplantation
    - Bone marrow
    - Heart-lung
    - Lung
  - Associated with connective-tissue diseases
    - Rheumatoid arthritis
    - Sjögren's syndrome
    - Systemic lupus erythematosus
    - Polymyositis dermatomyositis
  - Distal to bronchial obstruction ("obstructive pneumonitis")
  - Ulcerative colitis
  - Chronic eosinophilic pneumonia
  - Other rare associations
    - Radiation pneumonitis
    - Aspiration pneumonitis
    - Idiopathic pulmonary fibrosis
    - Malignant histiocytosis
    - Acute respiratory distress syndrome
    - Vasculitis, especially Wegener's granulomatosis
    - Chronic thyroiditis

cause concentric narrowing or complete obliteration of the airway lumen (Fig. 52-2). Often these lesions occur without extensive changes in alveolar ducts or alveolar walls. The changes of constrictive bronchiolitis may be extremely subtle, and frequently they are identified only after step-sectioning and special staining (e.g., use of stains to identify remnants of airway walls) of the lung biopsy. The range of histopathological changes includes: (1) subtle cellular infiltrates around the small airways; (2) extensive cellular infiltrates and smooth-muscle hyperplasia; (3) bronchiolectasia with mucus stasis, distortion, and fibrosis; and (4) total obliterative bronchiolar scarring. These lesions are seen most often in patients with progressive obstructive lung disease. A normal chest radiograph may be present. Cases of constrictive bronchiolitis are very rare.

Pathogenesis

A similar sequence of events may lead to both histopathological patterns of bronchiolitis. However, differences appear to relate to the type of insult, extent and severity of the initial insult, and predominant site of the injury (bronchioles, alveolar ducts, or both). In some diseases associated with bronchiolitis, varying degrees of both proliferative and constrictive bronchiolitis can be found on histological examination.

The initial lesion in constrictive bronchiolitis usually involves airway epithelial injury and destruction (Fig. 52-3). An inflammatory response follows, with accumulation of neutrophils at the site of injury. Neutrophils cause further injury to the airway epithelium and matrix by release of inflammatory mediators. Persistence of the injury

Table 52-2

Comparison of Key Pathological, Radiologic, and Physiological Features in Proliferative and Constrictive Bronchiolitis

Feature	Proliferative Bronchiolitis	Constrictive Bronchiolitis
Histopathological manifestations	Common finding Nonspecific reparative reaction to bronchiolar injury Organizing intraluminal exudate Most prominent in alveolar ducts Inflammatory changes in surrounding alveolar walls Foamy macrophages in alveoli	Very uncommon finding Obliterans not a constant feature Variety of histological changes: bronchiolar inflammation to progressive concentric fibrosis; smooth-muscle hyperplasia, bronchioloectasia with mucous stasis; distortion and fibrosis of small-airway walls with bronchial metaplasia extending onto peribronchiolar alveolar septa Follicular bronchitis (lymphoid hyperplasia) Cellular bronchiolitis Diffuse panbronchiolitis
Radiographic abnormalities	Bilateral patchy airspace opacities Interstitial opacities Small rounded opacities Opacities may be recurrent and migratory	May be normal Progressive increase in lung volume on serial radiographs HRCT scan may show marked heterogeneity of lung density
Pulmonary function	Restrictive defect (a mixed pattern may be seen)	Obstructive defect with hyperinflation
Clinical syndromes	Cryptogenic-organizing pneumonia (idiopathic BOOP) Collagen vascular disease (e.g., rheumatoid arthritis, dermatomyositis, SLE) Organizing acute infection (especially influenza or *Nocardia asteroides, Mycoplasma, Pneumocystis carinii, Legionella pneumophila*, cytomegalovirus, or HIV infection) Chronic eosinophilic pneumonia Hypersensitivity pneumonitis Organizing diffuse alveolar damage/(ARDS) Vasculitides, especially Wegener's granulomatosis Organ transplantation (rare) Drug-induced reactions (hexamethonium, L-tryptophan, busulfan, free-base cocaine, gold, cephalosporin, sulfasalazine, amiodarone, acebutolol, sulindac) Other uncommon associations: chronic thyroiditis, ulcerative colitis, irradiation pneumonitis, aspiration pneumonitis, distal to bronchial obstruction, "obstructive pneumonitis," chronic heart or renal failure, common variable immunodeficiency syndrome	Allograft recipients (bone marrow, heart-lung, lung) Collagen vascular disease (especially rheumatoid arthritis) Postinfectious (especially respiratory syncytial virus, adenovirus, influenza, parainfluenza, *Mycoplasma*) Inhaled toxins (e.g., nitrogen dioxide, sulfur dioxide, ammonia, chlorine, phosgene) Drugs (e.g., penicillamine, lomustine) Cigarette smoke Mineral dust airway disease (asbestosis, silica, iron oxide, aluminum oxide, talc, mica, and coal) Idiopathic Hypersensitivity reactions

Feature	Proliferative Bronchiolitis	Constrictive Bronchiolitis
Natural history	Corticosteroid responsive and usually reversible	Relatively corticosteroid unresponsive and usually progressive with the development of irreversible airflow obstruction and air trapping. May respond to macrolide antibiotics.

HRCT, high-resolution computed tomography; BOOP, bronchiolitis oblitevans-organizing pñeumonia; SLE, Systemic lupus erythematosus; HIV, human immunodeficieny virus; ARDS, acute respiratory distress syndrome.

may determine whether there is resolution and recovery or progression to a less reversible state, manifested by intramural and intraluminal fibrosis. The repair process results in the characteristic obliterative bronchiolar lesions.

In general, "proliferative" bronchiolitis appears to be a common "early" lesion that may resolve completely or partly. Intermediary steps in the development of intraluminal, extracellular matrix synthesis have been clarified. First, a florid alveolitis with edema occurs as a result of damage to the alveolar lining. The degree of alveolar lining destruction and disruption of the basal lamina, with resulting gaps on the basement membrane, appears to determine the extent of intra-alveolar fibrosis. Although the alveolar basement membrane is most frequently damaged, minor changes are also noted in the endothelial basement membrane. The alveolitis coincides with the presence of inflammatory proteins in the airspace, including immunoglobulins (IgG, IgA, and IgM), fibronectin, and procoagulant factors (fibrinogen and factors VII and X). The cellular response includes neutrophils, eosinophils, macrophages, and lymphocytes. Many mast cells are also present in the septal and intra-alveolar compartments.

After development of the alveolitis, fibroblasts migrate into the lesion, proliferate, and secrete matrix proteins. This results in the formation of Masson bodies, polypoid buds of fibroblasts, and extracellular matrix projecting into the lumina of respiratory bronchioles, alveolar ducts, and alveoli. The matrix of the Masson bodies stain positive for type III collagen and fibronectin (cell and plasma in origin). The fibroblasts in the Masson bodies also stain strongly for procollagen type I. Delicate fibrils within the matrix of some Masson bodies contain type IV collagen. Inflammatory changes in surrounding alveolar walls, including prominent foamy

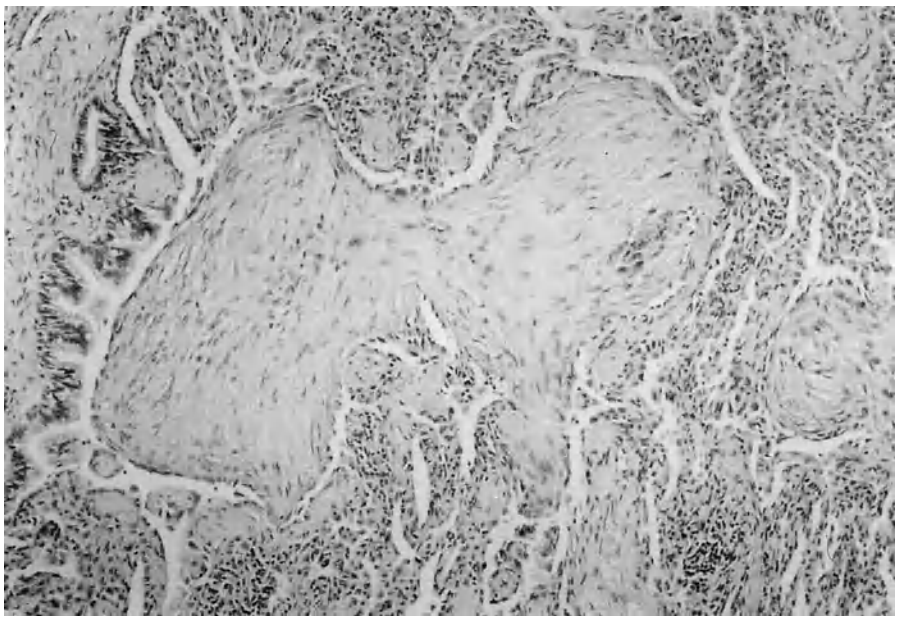

Figure 52-1 Bronchiolitis obliterans-organizing pneumonia (BOOP). Photomicrograph of open lung biopsy from a patient with cryptogenic-organizing pneumonia (COP). Polypoid masses of granulation tissue fill the lumens of a respiratory bronchiole and alveolar ducts. Adjacent alveolar interstices are broadened by a lymphoplasmacytic inflammatory infiltrate. macrophages in alveoli spaces (i.e., organizing pneumonia) are commonly present.

INHALATIONAL LUNG INJURY CAUSING BRONCHIOLITIS

The inhalation of fumes, gases, mists, mineral dusts, or organic material constitutes a significant industrial and environmental hazard in many settings (Table 52-3). Exposure can result in subtle or severe clinical illness, usually associated with immediate development of pulmonary edema and late development of constrictive bronchiolitis with airflow limitation.

Toxic Gases

The inhalation of gases or fumes (i.e., fine particulates) is a rare cause of bronchiolitis, with or without obliterans. Oxides of nitrogen are the most common and best-described agents leading to acute and chronic lung injury. Silo filler's disease is a well-studied example (Fig. 52-4). The estimated annual incidence of silo filler's disease is 5 cases per 100,000 silo-associated farm workers per year. Most cases occur during the harvest period (September and October).

Mechanism of Injury

The distribution and extent of the lung injury are determined by the concentration of the agent, duration of exposure, route

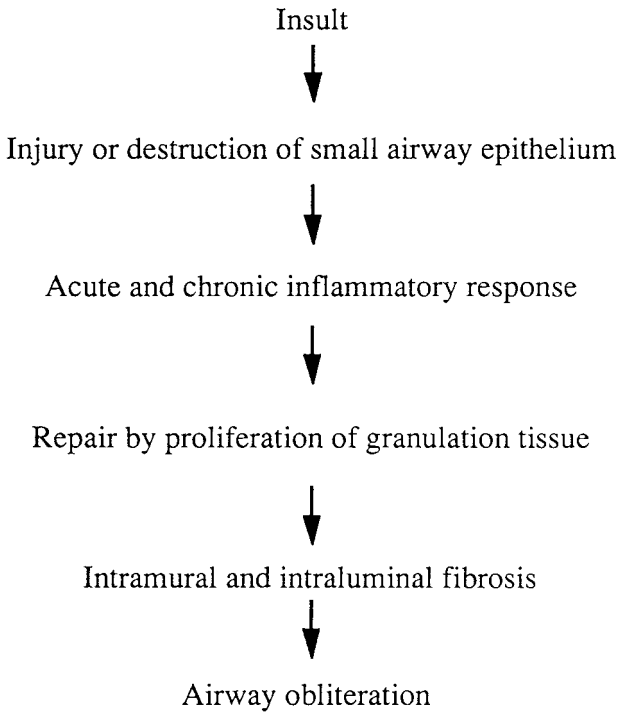

Figure 52-3 Proposed pathogenetic mechanism for airway injury in constrictive bronchiolitis. (See text for details.)

and pattern of breathing, solubility and biologic reactivity of the agent, and biologic susceptibility of the individual.

Nitrogen dioxide (NO_2) and nitrogen tetroxide are responsible for the injury. NO_2 is relatively insoluble. After inhalation, the gas reaches the periphery of the lung, where it combines with water to form nitric and nitrous acids and nitric oxide, which are powerful oxidants capable of causing severe tissue injury. Unlike highly water-soluble gases, such as chlorine, ammonia, and sulfur dioxide, NO_2 is less irritating to the mucous membranes of the nasal and upper airways. The gas produces a yellow to brown haze and an acrid, ammonia-like odor that is irritating.

Clinical Findings

Clinical manifestations of exposure to NO_2 depend on the concentration of the inhaled gas and the duration of exposure. Three clinical patterns or phases may follow exposure. All phases may not appear in an individual patient. Progression to death may be an outcome at any stage.

Acute Phase

Acutely, during milder exposures, people may develop upper-airway and visual disturbances, cough, dyspnea, fatigue, cyanosis, vomiting, hemoptysis, hypoxemia, vertigo, somnolence, headache, emotional difficulties, and loss of consciousness. These findings usually resolve within hours, but they may persist for several weeks; complete recovery without obvious sequelae is usually observed.

At higher concentrations of exposure, pulmonary edema (so-called, "chemical pneumonitis") is a frequent

complication in the early stages. Patients may be asymptomatic at the time of exposure, only to later develop (in 3 to 30 h) the clinical picture of severe acute respiratory distress syndrome. During this acute phase, patients who develop pulmonary edema and acute respiratory distress syndrome have significant pulmonary dysfunction. Hypoxemia is secondary to ventilation-perfusion mismatching as a result of altered airway dynamics and interstitial and alveolar edema, impaired diffusing capacity, and methemoglobinemia that occurs when nitrate ions react with hemoglobin. Severe metabolic acidosis occurs because of the dissolution of NO_2 in body fluids, resulting in formation of nitrous and nitric acid, as well as the lactic acidosis resulting from tissue hypoxia. Systemic hypertension may be present. Recovery without long-term sequelae is usual, but death may occur at this stage.

The radiographic manifestations during this stage include pulmonary edema (i.e., alveolar filling). In survivors, these changes clear rapidly. Physiological studies reveal the simultaneous occurrence of restrictive and obstructive ventilatory defects; the former is manifest as a shift in the static pressure-volume curve downward and to the right. These abnormalities gradually resolve in survivors. Histopathological findings, as determined from autopsy studies, include marked intra-alveolar edema and exudation, as well as thickening of the alveolar walls with lymphocytic cellular infiltrates.

Subacute Phase

In patients who progress to the second phase, physiological disturbances include hypoxemia at rest or with exercise and associated restrictive or obstructive pulmonary function abnormalities. The radiographic pattern in this late stage may be variable. A normal chest film may be seen; however, a miliary, or discretely nodular, pattern is thought to be characteristic of bronchiolitis obliterans. Occasionally, only pulmonary hyperinflation is seen, usually accompanied by a progressive and irreversible obstructive ventilatory defect noted on lung function testing.

Chronic Phase

After recovery from the acute illness, or in patients with no symptoms following exposure, recurrence or new onset of clinical illness may be seen 2 to 6 weeks later. This phase is characterized by the progressive onset of cough and dyspnea. These patients may be identified in an early, asymptomatic stage from the appearance of mild hypoxemia. Tachypnea is present, and crackles are usually heard. Widespread proliferative bronchiolitis with marked intraluminal fibrous tissue proliferation arising in the bronchiolar wall (without organizing pneumonia) is found, especially in those with preceding pulmonary edema; however, these findings may occur as the initial manifestation of previous exposure.

Management

The treatment of patients exposed to NO_2 or other toxic gases or fumes should include observation in the hospital for 48 h, followed by weekly or biweekly evaluations for 6 to 8 weeks. When dysfunction occurs, treatment with corticosteroids should be started immediately. Corticosteroid therapy has been demonstrated to be useful in the management of both the acute phase (pulmonary edema) and the late phase (bronchiolitis obliterans). Corticosteroids should be continued for a minimum of 8 weeks, since relapses have been reported with the earlier cessation of therapy. Bronchodilators are occasionally helpful, but antibiotics should be used only when clinically indicated; they should be directed at a specific pathogen. If methemoglobinemia is present, methylene blue should be administered at a dose of 2 mg/kg intravenously, followed by doses titrated according to the concentration of methemoglobin in the blood. For patients in whom this diagnosis is suspected, and for whom open lung biopsy or general anesthesia is planned, some have suggested that nitrous oxide not be used as an anesthetic because of concern that it might lead to disease progression.

Prognosis

In general, the prognosis for survivors of toxic gas or fume inhalation (fewer than one-third die acutely) is good. Some authors have suggested that lasting pulmonary disability is uncommon in silo filler's disease; others have identified a wide variety of functional derangements. What functional abnormalities result from chronic, low-level exposure to NO_2 are not clear. Education is key in preventing this disease, since simple measures to reduce the NO_2 levels and use of approved respiratory protection equipment will eliminate the risk of injury.

Other Irritant Gases

A number of irritant gases have occasionally been associated with bronchiolitis, with or without obliterans (Table 52-3). Since lung biopsies have not been performed in all cases, it is not always clear that the pulmonary injury associated with these inhalation exposures is only bronchiolitis obliterans. However, sulfur dioxide, chlorine gas, "smoke inhalation" or inhalation burns, hydrogen chloride, ammonia, phosgene,

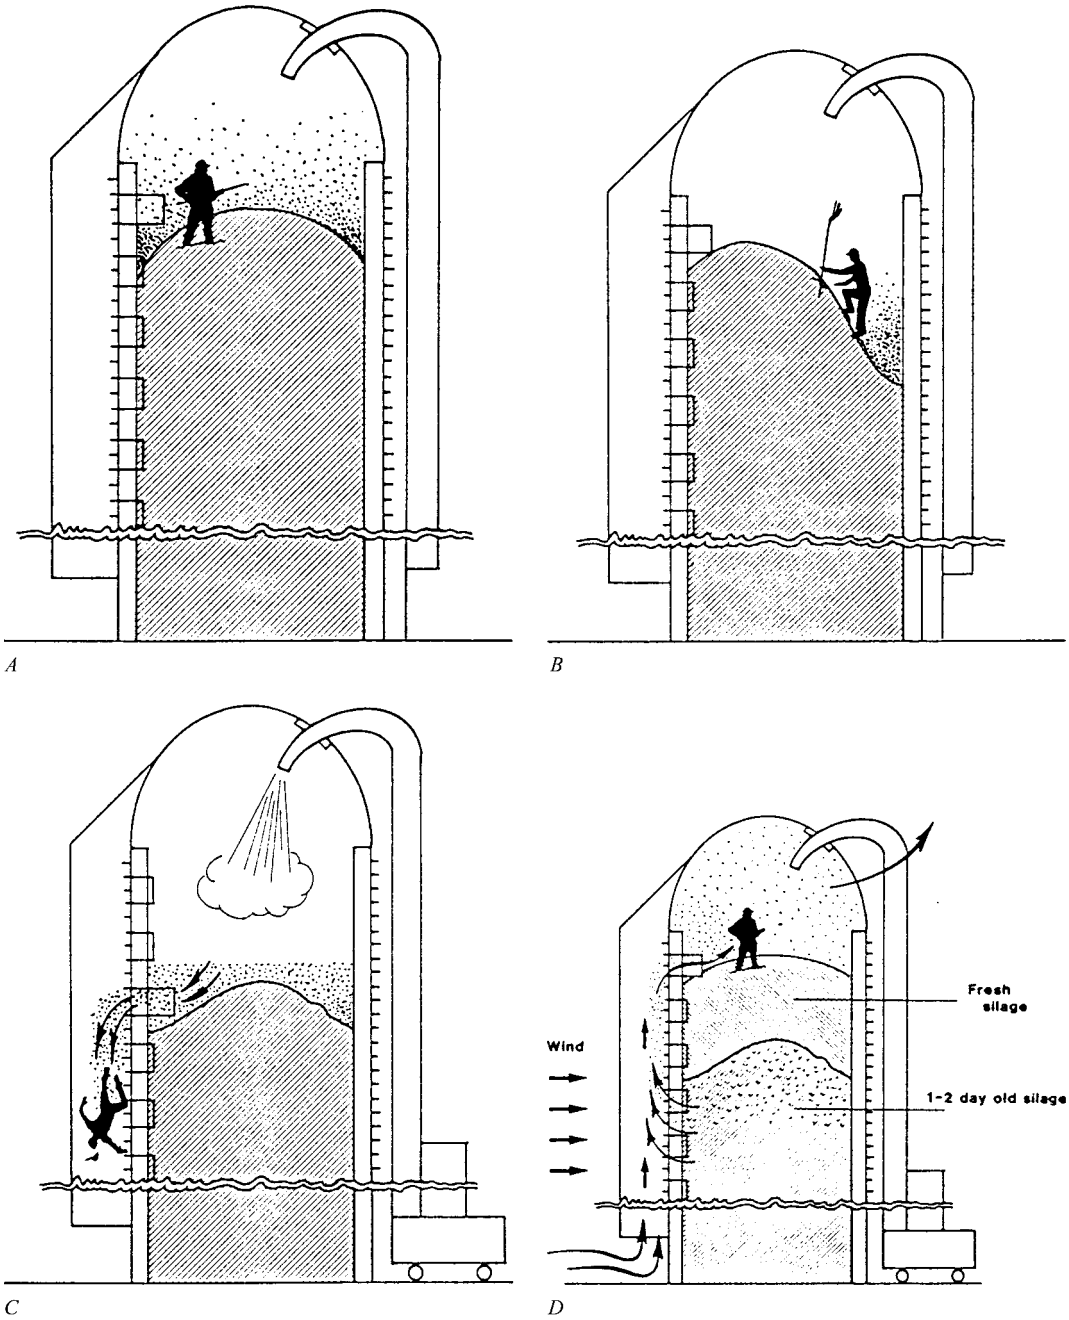

Figure 52-4 Exposure to nitrogen oxides and silo filler's disease. The upright concrete stave silo is the most common type of silo. Chopped silage is blown through the filling pipe (on right of silo) to the top of the silo and dispersed evenly. *A*. Exposure usually occurs 1 to 4 days after silo filling, when the farmer enters to level the silage, to prepare for unloading, or to spread a plastic sheet over the top. *B*. Silo gas is heavier than air and accumulates in low places within the silo. Descent into these areas may be fatal. *C*. Opening a door just above the silage may result in concentrated exposure, causing rapid loss of consciousness and a fall down the silo chute. *D*.Entry immediately after completion of silo filling may not be safe, since gas from 1- to 2-day-old silage may leak out through the silo doors and be drawn into the working spaces by a chimney-like updraft. *(Based on data from Douglas WW, Colby TV: Fume-related bronchiolitis obliterans, in Epler GR (ed)*, Diseases of the Bronchioles. *New York: Raven Press, 1994, pp 187–213, with permission.)*

and chloropicrin produce a disease with clinical, physiological, and radiographic manifestations similar to those described for NO_2 exposure. Respiratory bronchiolitis after exposure to photochemical air pollutants, ozone, and NO_2, has been reviewed.

Mineral Dusts

Pathological changes in the small airways (respiratory bronchiolitis) may be found secondary to exposure to inorganic mineral dusts, including asbestos, silica, iron oxide, aluminum oxide, several different sheet silicates, and coal.

Clinical relevance of the changes remains to be better defined. Nonetheless, development of an obstructive, rather than restrictive, pattern is increasingly recognized in subjects with inorganic mineral dust exposure.

Pathologically, these lesions are characterized by marked abnormalities in the small airways, particularly in the membranous and respiratory bronchioles. The principal finding is fibrosis in small-airway walls and, occasionally, in alveolar ducts. The lesions appear to extend down into the airway and often are accompanied by pigment deposition. Abnormalities are seen in nonsmokers, but occur most commonly in heavily exposed workers who are cigarette smokers. The pathogenesis is unclear, but a synergistic role for cigarette smoking appears likely. The injury appears to result from the inflammatory response that follows deposition of mineral particles or fibers in the walls of the small airways.

Organic Dusts

Numerous agents are associated with the development of hypersensitivity pneumonitis, a topic discussed elsewhere (see Chapter 69). Interstitial pneumonitis is seen in virtually 100 percent, and granulomas in approximately 70 percent, of patients with hypersensitivity pneumonitis; unappreciated is that bronchiolar lesions are also seen in essentially all cases. The bronchioles contain granulomas within the walls or lumina—or show tufts of granulation tissue, as seen in bronchiolitis obliterans. A reversible restrictive process is the most common physiological abnormality in hypersensitivity pneumonitis. However, small-airway dysfunction may be present in patients with early hypersensitivity pneumonitis. As the disease progresses, either obstructive or restrictive physiology may arise, depending on the predominant histopathological process present.

Volatile Flavoring Agents

A recent report described development of severe, fixed obstructive lung disease in nine former employees of a microwave popcorn factory. Four of the patients were on lung transplant lists. All had a respiratory illness resembling bronchiolitis obliterans, with symptoms of cough and dyspnea on exertion. Their median duration of employment was 2 years (range, 1 to 17 years). Each of the workers first became symptomatic between 1993 and 2000, while employed by the factory, after a median of 1.5 years of employment (range, 5 months to 9 years). Cough, shortness of breath, and wheezing were the presenting symptoms. Most patients identified had normal results on pre-placement spirometry. These values subsequently fell precipitously, with development of moderate to severe, nonreversible airway obstruction. HRCT scans showed evidence of air trapping.

The presumed inciting exposure was to a mixture of soybean oil, salt, flavorings, and coloring agents that was mixed in a large heated tank. This process produced visible dust, aerosols, and vapors with a strong buttery odor. More than 100 volatile organic compounds were identified in the air samples from the mixing room area of the plant. Diacetyl (2, 3)-butanedione, a ketone with butter-flavor characteristics, was the predominant compound isolated. The highest incidence of illness occurred in workers who worked nearest the mixing tank and who were more likely to have inhaled mixing tank substances.

Preliminary animal studies at the Division of Respiratory Disease Studies, National Institute for Occupational Safety and Health (NIOSH), suggested severe damage to airway epithelium after inhalation exposure to high air concentrations of butter-flavoring vapors (diacetyl) used at one of the worksites. After removal from exposure, patients did not recover, but they did appear to have no further loss of lung function. However, NIOSH has been investigating whether similar cases have occurred in workers at other microwave popcorn factories or who work with food-flavoring agents that might be heated and aerosolized. The general population using microwave popcorn products does not appear to be at any risk.

INFECTIOUS CAUSES OF BRONCHIOLITIS

Infection is the most common cause of acute bronchiolitis, although infectious causes are more frequent in children than adults. The usual agents include viruses and Mycoplasma pneumoniae—organisms that have a propensity to infect and injure epithelial cells of the respiratory tract. Constrictive bronchiolitis is the most common histopathological pattern observed after bronchiolar infection.

Infectious Bronchiolitis in Children

Acute bronchiolitis is a common illness in infants and young children, occurring primarily as a result of a viral infection. Pathogens include respiratory syncytial virus (approximately 34 percent of cases), parainfluenza virus types 1, 2, and 3 (approximately 30 percent of cases), adenoviruses (approximately 7 percent of cases), influenza A and B, and *Mycoplasma pneumoniae* (approximately 11 percent of cases) (Table 52-1). Males are more commonly affected with respiratory syncytial virus than are females (1.5 to 1.8:1 male-to-female ratio).

Reviews of bronchiolitis in children have been published previously. Infectious bronchiolitis obliterans is rarely seen in persons older than 2 years. Adenovirus types 3, 7, and 21 are the most common etiological agents. Other causes are measles, whooping cough due to *Bordetella pertussis*, *M. pneumoniae*, and influenza A. Severe infectious bronchiolitis obliterans leading to hospitalization and death is rare.

Clinical Findings

The usual presentation is an acute viral-like illness with mild coryza and sneezing occurring during the winter months. Several days later, cough, dyspnea, tachypnea, tachycardia, fever, chest wall retractions, sibilant and sonorous crackles,

expiratory wheezing, and, in severe cases, cyanosis, develop. Prostration and respiratory failure are unusual.

Radiographic Findings

The radiographic pattern of childhood bronchiolitis is variable. The chest radiograph may be normal or show hyperinflation with increased bronchial markings. Subsegmental consolidation and collapse may be seen. A pattern similar to that of diffuse interstitial pneumonia, often in association with hyperinflation, is seen. Some patients demonstrate a diffuse nodular or reticulonodular pattern, whereas others may show patchy alveolar or ground glass opacities. Those with a nodular pattern frequently have "pure" bronchiolitis obliterans on lung biopsy; those with a reticulonodular pattern are likely to have more interstitial inflammation and scarring. The role of HRCT has not been adequately defined, but it is thought to be important in ruling out other diagnoses, especially bronchiectasis. Ventilation-perfusion lung scans may be very helpful, since a markedly abnormal pattern of patchy, matched ventilation and perfusion defects is often seen, even when the plain chest film is unremarkable. Bronchography may reveal saccular bronchiectasis and ballooning of the airways at the blind end when the airways are distended by positive pressure; passage of contrast medium into the alveoli does not occur. Bronchography has largely been abandoned with the advent of HRCT.

Physiological Findings

Tests of lung function may be normal. However, obstructive changes with air trapping can often be documented. Pulmonary function testing has not been well studied in infants with this disease. Resting hypoxemia is frequently present.

Histopathological Findings

In this setting, open lung biopsy is the gold standard for the diagnosis of bronchiolitis obliterans. The earliest change is necrosis of the respiratory epithelium, followed by epithelial proliferation. Dense plugs of alveolar debris and strands of fibrin are seen within small bronchi and bronchioles, causing partial or complete obstruction. These findings may develop as soon as 8 days after the onset of the illness. A lymphocytic infiltrate, including collections with germinal centers, may be seen in the airway wall. Severe and widespread destruction of the respiratory epithelium may cause denudation and a pronounced inflammatory response that involves the adjacent peribronchial space and alveolar walls. Depending on the stage at which the biopsy is obtained, findings consistent with proliferative bronchiolitis ("early"), constrictive bronchiolitis ("late"), or both may be seen. The pathogenetic mechanisms in development of obliterative bronchiolitis secondary to infections and the reason for the predilection in infants are unknown.

Treatment

Treatment is symptomatic, including administration of supplemental oxygen and adequate hydration. Bronchodilators, antibiotics, antiviral agents, and corticosteroids are frequently used in management, but few controlled clinical trials on their efficacy have been performed. Mechanical ventilation is rarely required; it may be necessary if progressive respiratory failure ensues. Lung transplantation has been performed in severe cases.

Prognosis

Recovery is usual and occurs in days or weeks. Whether or not bronchiolitis in infancy predisposes to asthma or chronic obstructive pulmonary disease (COPD) in later life remains unproved.

Swyer-James (MacLeod) syndrome—unilateral hyperlucent lung—is a long-term complication of bronchiolitis in children, especially after adenoviral infection occurring in infancy. The affected child may be asymptomatic, but more often he or she has recurrent pulmonary infections and eventually develops bronchiectasis. Dyspnea on exertion, hemoptysis, and chronic productive cough are seen. Patients may have localized, unilateral, or bilateral involvement. The chest radiograph demonstrates lobar or unilateral hyperlucent lung; normal or reduced volume of the affected lung is noted on full inspiration. Severe airway obstruction occurs during expiration. The affected lung has a diminished pulmonary vascular bed, decreased pulmonary blood flow, and reduced peripheral vascular markings. Bronchography demonstrates diffuse bronchiectasis with absence of filling of the terminal bronchioles ("pruned tree" appearance). HRCT is the procedure of choice for identifying the characteristic changes in Swyer-James syndrome.

The final size of the affected lung in Swyer-James syndrome relates to the age of the patient at the time bronchiolitis occurs. If it occurs early in life, the lung fails to grow normally and appears smaller than the opposite lung. If the bronchiolitis occurs later in childhood, the lung may be of normal size. Pulmonary function tests reveal airflow obstruction and a reduced total lung capacity in cases where concomitant pulmonary fibrosis exists. The syndrome has been reported with a number of etiological agents and must be distinguished from congenital absence of the pulmonary artery, pulmonary artery occlusion, partial obstruction of a lobar or main bronchus, and congenital lobar emphysema. CT and pulmonary angiography are helpful in distinguishing among these conditions.

Infectious Bronchiolitis in Adults

Acute bronchiolitis in older children and young adults has been associated primarily with *M. pneumoniae*; however, a number of other viruses (e.g., respiratory syncytial virus, especially in the elderly) and bacterial agents have been identified (Table 52-1). Only sporadic cases of bronchiolitis obliterans secondary to infections have been reported in adults (Fig. 52-5).

The clinical presentation of infectious bronchiolitis in adults is ill defined; no systematic study has been reported. Most patients have a history of an upper respiratory tract

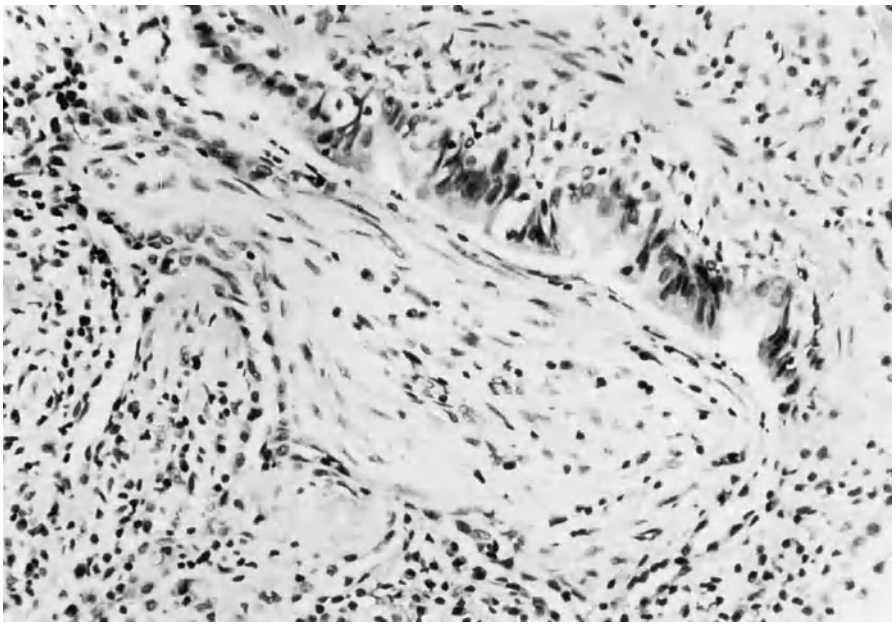

Figure 52-5 Acute infectious bronchiolitis. Photomicrograph showing acute bronchiolitis in a patient with adenovirus infection. An intraluminal infiltrate associated with epithelial necrosis (lower left) is present. In addition, a peribronchiolar infiltrate of acute and chronic inflammatory cells is demonstrated. (H&E stain, ×156.)

illness that precedes the onset of dyspnea with exertion, cough, tachypnea, fever, and wheezing. Measles, varicella-zoster, and pertussis have been reported to cause bronchiolitis obliterans in adults. A number of adults have developed an acute or subacute diffuse ventilatory obstruction that has occasionally been fatal.

IDIOPATHIC FORMS OF BRONCHIOLITIS

Several clinicopathological syndromes associated with prominent bronchiolar impairment have been reported recently. Although no specific origins have been identified, the constellation of findings in reported cases suggests that these syndromes are unique and must be distinguished from more common problems, including COPD, pneumonia, and pulmonary fibrosis. In the discussion below, three syndromes are highlighted: cryptogenic adult bronchiolitis, respiratory bronchiolitis-associated interstitial lung disease (RB-ILD), and cryptogenic-organizing pneumonia (COP) or idiopathic BOOP.

Cryptogenic ''Adult'' Bronchiolitis

Cryptogenic adult bronchiolitis is a rare clinicopathological syndrome that must be distinguished from asthma, chronic bronchitis, emphysema, cystic fibrosis, bronchiectasis, and α_1-antitrypsin deficiency. Few cases have been reported, and it is not entirely clear that all of those reported are the same entity. For example, many patients have had a significant cigarette smoking history and may have smoker's bronchiolitis. Despite these concerns, the constellation of findings in reported cases is unique and suggests that adult bronchiolitis represents a distinct, definable clinicopathological entity that is a diagnostic challenge to clinicians and pathologists.

The pathogenesis of cryptogenic adult bronchiolitis is unknown. The true incidence of the disease is also unknown, but has been estimated to be approximately 4 percent of all causes of obstructive lung diseases. The disorder is diagnosed largely by exclusion and requires a high index of suspicion, along with an awareness of its unique clinical features.

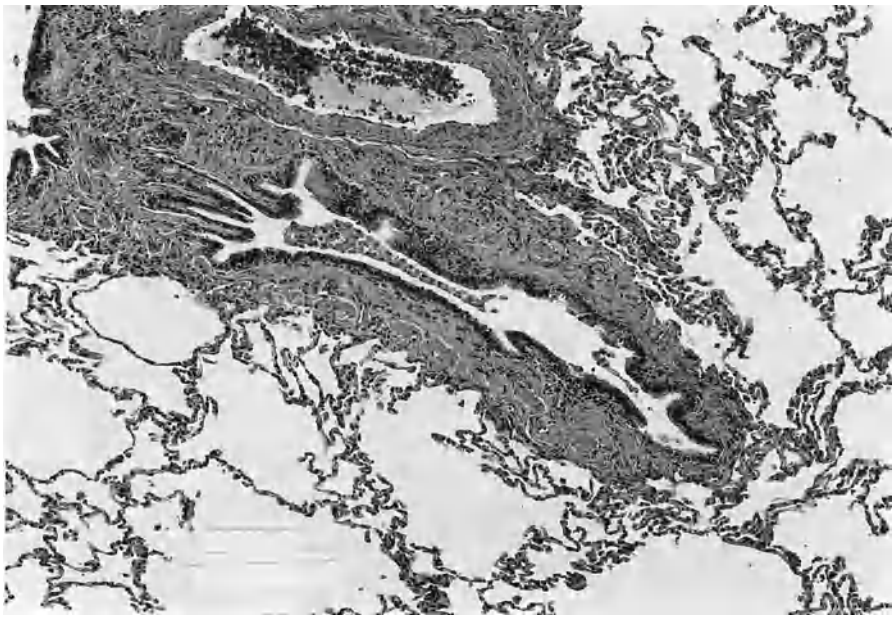
Clinical Findings

Most patients are middle-aged women who have a nonproductive cough, shortness of breath, or other nonspecific chest complaints, usually of relatively short duration (6 to 24 months). Most are identified because of an accelerated, severe obstructive respiratory disorder that is clinically distinct from the more commonly encountered obstructive disorders. A history of cigarette smoking, chronic sputum production, frequent chest infections, wheezing, known connective-tissue disorder, and immunoglobulin deficiency are absent. No association with inhalation injury or viral infection has been identified. Physical findings are unremarkable, although wheezing or crackles may be heard.

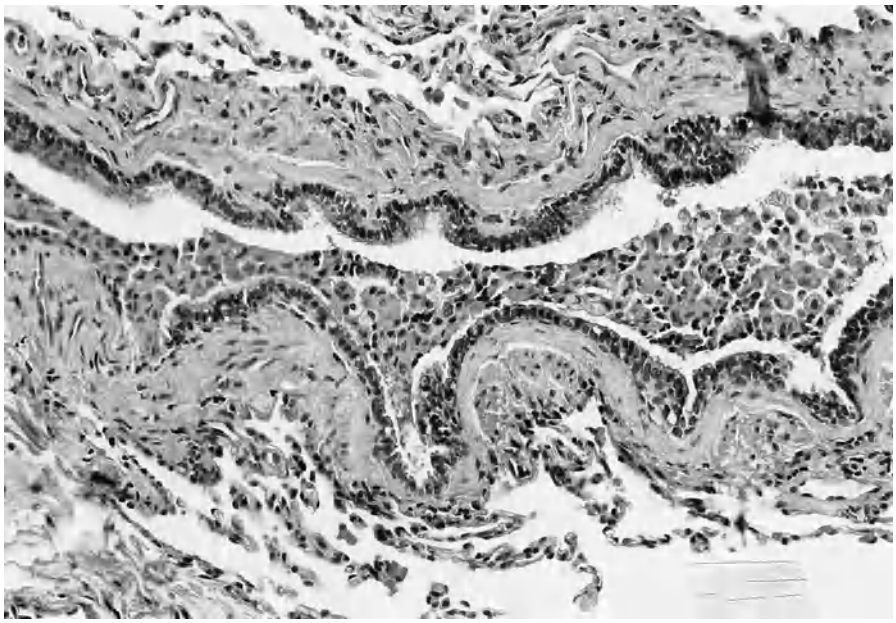
Diagnostic Studies

The chest radiographic findings are normal or nonspecific. Increased bronchial wall thickening may be seen. Hyperinflation (without marked flattening or hyperlucent areas) may be the only abnormality noted. HRCT scanning is normal or shows airway dilatation.

Pulmonary function testing yields a variety of results. Most patients have increased lung volumes and airflow limitation. A few patients who have had pressure-volume curves performed show an upward shift and a normal slope, consistent with airflow limitation. The diffusing capacity is reduced, and resting hypoxemia may be present. Exercise testing shows gas exchange abnormalities associated with an abnormal [dead space/tidal volume ratio (V_D/V_T)].



A



B

Figure 52-6 Cryptogenic constrictive bronchiolitis. *A*. Constrictive bronchiolitis with bronchiolar smooth-muscle hyperplasia and mild submucosal and adventitial bronchiolar scarring. Alveolar parenchymal architecture is preserved; no significant interstitial inflammation or fibrosis is present (H&E stain). *B*. Histiocytes in the lumen of some bronchioles. While intraluminal histocytes are common in smokers, their presence in nonsmokers suggests airway pathology analogous to mucus stasis (H&E stain).

Bronchoalveolar lavage (BAL) studies demonstrate marked neutrophilia associated with an increase in the specific neutrophil products, collagenase, and myeloperoxidase. Most patients have a neutrophil level over 25 percent (normal for nonsmokers is under 4 percent); some have levels exceeding 90 percent.

Pathological Findings

Lung biopsies reveal a cellular constrictive bronchiolitis, often quite subtle, with both acute and chronic inflammatory changes, primarily in the membranous bronchioles (Fig. 52-6). Few cases examined have shown airway obliteration and mucus stasis. The pulmonary parenchyma is normal or shows only mild hyperinflation. Mild focal interstitial fibrosis has been identified in a few subjects. No vascular lesions have been described.

Treatment

Steroids may be of benefit in many patients with adult bronchiolitis. Early treatment may be important, since irreversible structural changes and persistent, progressive breathlessness may develop, often with recurrent bouts of respiratory infection. BAL neutrophilia returns toward normal in patients who respond to treatment. Thus, recognition of these cases and distinction from other small-airway disorders (e.g., RB-ILD, asthma, chronic bronchitis, emphysema, bronchiolitis associated with connective-tissue disease, and diffuse panbronchiolitis) are possible and important.

Respiratory Bronchiolitis-Associated Interstitial Lung Disease

Bronchiolitis has been demonstrated in patients exposed to cigarette smoke. The inflammation and fibrosis lead to distortion and narrowing of small airways. Because respiratory bronchiolitis was initially found at autopsy in young cigarette smokers without known disease, the lesions were considered to be clinically insignificant. Later, it was hypothesized that the lesions in respiratory bronchioles could explain the mild abnormalities in lung function seen in cigarette smokers—so-called small-airway disease (i.e., elevated airflow resistance, airway hyperresponsiveness, and subsequent airflow limitation). More recently, RB-ILD has been recognized as a distinct clinical syndrome found in current or previous cigarette smokers. This disease may be confused with chronic diffuse interstitial fibrosis, desquamating interstitial pneumonitis (DIP), and eosinophilic granuloma of the lung (pulmonary histiocytosis X). The last two disorders also develop almost exclusively in cigarette smokers.

Clinical Findings

The male-to-female ratio is 1.6:1. Most are current or former smokers in the fourth or fifth decade of life. The average exposure is more than 30 pack-years of cigarette smoking. The incidence of RB-ILD is unknown. Patients commonly present with dyspnea (70 percent) and cough (58 percent). Coarse crackles are often heard (33 percent) and occur throughout inspiration; sometimes they continue into expiration. Finger clubbing has not been reported. Routine laboratory studies are usually normal.

Diffuse, fine reticulonodular interstitial infiltrates are found on the chest radiograph in most patients (80 percent), usually with normal lung volumes. Bronchial wall thickening, prominence of peribronchovascular interstitium, small regular and irregular opacities, and small peripheral ring shadows are distinctive features of respiratory bronchiolitis. Diffuse or patchy ground glass opacities or fine nodules are found on HRCT (Fig. 52-7). Mild emphysema, atelectasis, or linear and reticular interstitial abnormalities are also detected. In a study correlating pathological findings with CT abnormalities, areas of ground glass attenuation were related to three main histological features: (1) accumulation of pigmented macrophages and mucus in alveolar spaces, associated with mild interstitial inflammation or fibrosis; (2) thickening of alveolar walls by inflammatory cells; and (3) presence of organizing alveolitis. The parenchymal micronodules corresponded to bronchiolectases with peribronchiolar fibrosis.

Pulmonary function may be normal; however, a mixed obstructive-restrictive pattern is most commonly found. Normal total lung capacity (TLC) and functional residual capacity (FRC) are commonly present, but the residual volume (RV) is usually increased. A normal or slightly reduced diffusing capacity (D_{LCO}) is frequently present. Hypoxemia may be present at rest or with exercise.

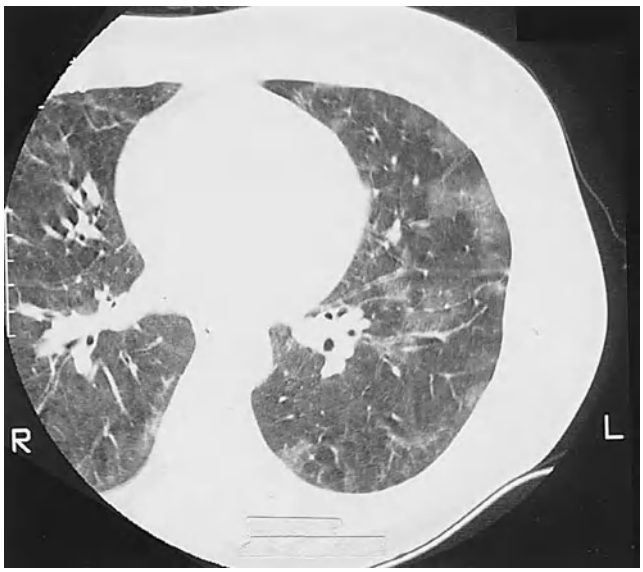


Figure 52-7 Respiratory bronchiolitis-associated interstitial lung disease. High-resolution computed tomography (HRCT) in a 35-year-old woman with a heavy smoking history and progressive dyspnea with exertion. Extensive ground glass opacities are demonstrated. The plain chest film was normal. The diagnosis was confirmed by open lung biopsy. Symptoms improved after smoking cessation.

Histopathological Findings

An inflammatory process in the membranous and respiratory bronchioles is the characteristic histopathological feature of RB-ILD. Tan-brown pigmented macrophages within respiratory bronchioles, neighboring alveolar ducts, and alveoli dominate the pathological findings (a "DIP-like" reaction) (Fig. 52-8). These macrophages stain strongly with diastase-predigested periodic acid–Schiff. The bronchiole may be ectatic with mucus stasis; the walls are mildly thickened. Frequently evidence of extension of the bronchiolar metaplastic epithelium into the immediately surrounding alveoli is observed. Most of the interstitium is usually normal; alternatively, it may demonstrate mild hyperinflation. The findings are sometimes so subtle as to be missed during routine evaluation. On occasion, examination of multiple-step sections may be required. Many cases of respiratory bronchiolitis have actually been misclassified as DIP. Similar pathological findings have been demonstrated in other conditions.

Treatment

The clinical course and prognosis of RB-ILD are unknown. Most studies suggest a favorable response to corticosteroids, with documented improvement in the chest radiograph and in lung function. Since smoking appears to play a role in pathogenesis, smoking cessation is considered to be important in management.

Cryptogenic-Organizing Pneumonia

Cryptogenic-organizing pneumonia (COP), or idiopathic BOOP, is a distinct clinical entity that was described in 1901

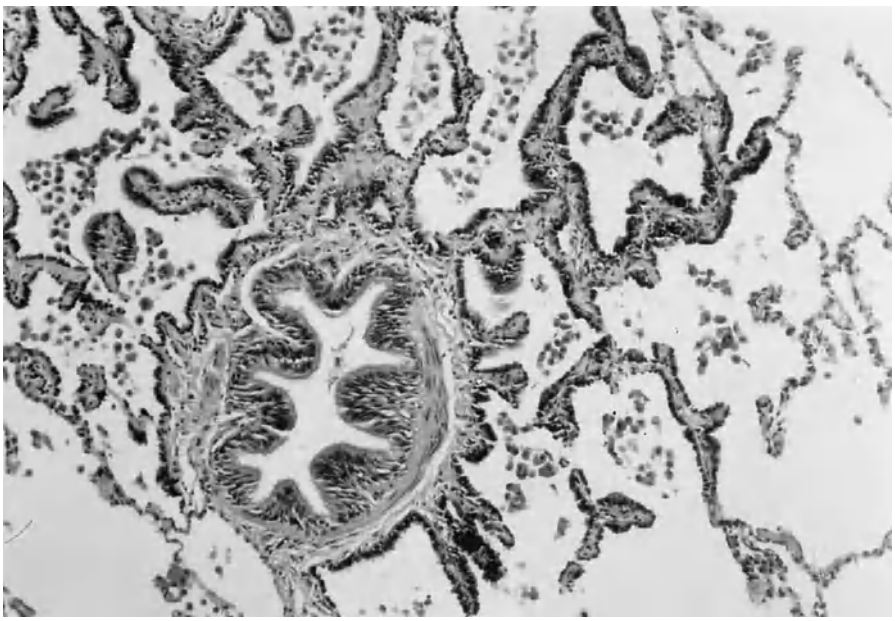

Figure 52-8 Respiratory bronchiolitis-associated interstitial lung disease (RB-ILD). Photomicrograph shows inflammatory process in the membranous and respiratory bronchioles. Bronchiole wall is thickened, and bronchiolar metaplastic epithelium extends into immediately surrounding alveoli. Macrophages are present within the peribronchiolar alveolar spaces (desquamating interstitial pneumonitis ["DIP"]-like reaction) (H&E stain).

by Lange. However, recognition of COP increased in the early 1980s, as several investigators highlighted the characteristic clinical course and suggested that COP is a distinct entity with features of pneumonia, rather than a primary airway disorder. The true incidence and prevalence of COP are unknown; a prevalence of 6 to 7 per 100,000 admissions has been reported.

Clinical Findings

Disease onset is usually in the fifth or sixth decade, with a mean age of 58 years; men and women are affected equally. Almost three-fourths of patients have symptoms for less than 2 months; few have symptoms for more than 6 months before diagnosis. Cigarette smoking is not a precipitating factor, since approximately 50 percent of subjects are never-smokers, 25 percent are ex-smokers, and only 25 percent are current smokers.

The clinical presentation may mimic that of community-acquired pneumonia. A persistent and usually nonproductive cough is the most common presenting symptom (72 percent of subjects). Frequently, patients experience dyspnea with exertion (66 percent). Disease onset is usually described as a flulike illness, with fever (51 percent), malaise (48 percent), fatigue, and cough. Weight loss of greater than 10 lb is a common complaint (57 percent). Physical examination reveals inspiratory crackles (74 percent); wheezing is rare and is usually present in conjunction with crackles. Clubbing is rare (fewer than 5 percent of patients). Twenty-eight percent of patients in one series had normal pulmonary function.

Laboratory Findings

Routine laboratory studies are nonspecific. A leukocytosis is seen in approximately half of patients. The initial erythrocyte sedimentation rate is elevated, frequently reaching or exceeding 100 mm/h; a positive C-reactive protein is observed in 70 to 80 percent of patients. Autoantibodies are usually negative or only slightly positive.

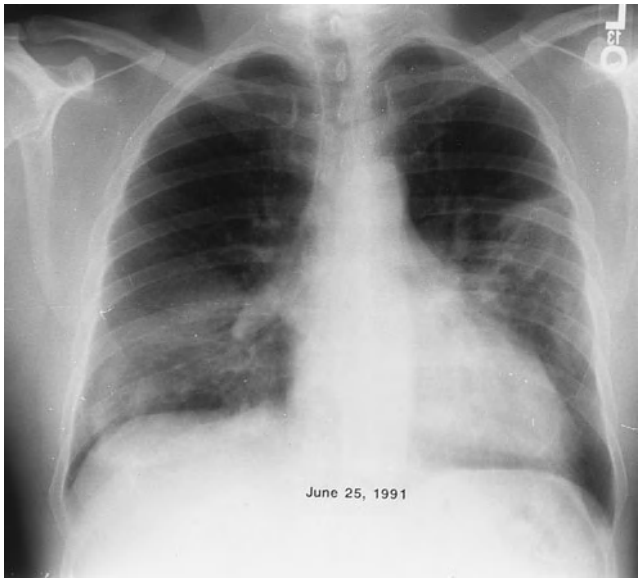
Chest Imaging Studies

The radiographic manifestations of COP are quite distinctive: bilateral, diffuse alveolar opacities in the presence of normal lung volume (Fig. 52-9). This pattern was present in 79 percent of reported subjects for whom the radiographic appearance was detailed. A peripheral distribution of opacities, very similar to that thought to be "virtually pathognomic" for chronic eosinophilic pneumonia, is also seen. The alveolar opacities may be unilateral. In addition, recurrent and migratory pulmonary opacities are common. Fifty percent of Japanese patients with idiopathic BOOP demonstrated migration of radiographic shadows. Irregular linear or nodular interstitial infiltrates were rarely present as the sole radiographic manifestation. Honeycombing is rarely seen at presentation and is discussed only as a late manifestation in the few patients who have progressive disease. Other radiographic abnormalities—such as pleural effusion, pleural thickening, hyperinflation, and lung cavities—seldom occur. Severity of the radiographic abnormalities correlates with the extent of histological involvement of the respiratory bronchioles and alveolar ducts, but not of the larger terminal bronchioles.

CT of the lung reveals patchy airspace consolidation, ground glass opacities, small nodular opacities, and bronchial wall thickening and dilation. These patchy opacities occur more frequently in the periphery of the lung and are often in the lower lung zones (Fig. 52-9). CT may reveal much more extensive disease than is expected from review of the plain chest radiograph.

Physiological Findings

Pulmonary function is usually impaired; a restrictive defect is the most common finding. An obstructive defect (ratio of forced expiratory volume in 1 second to the forced vital



A

B

Figure 52-9 Cryptogenic-organizing pneumonitis (COP) in a 62-year-old man with a 1-month history of dyspnea with exertion, fatigue, and weight loss. *A*. Posteroanterior radiograph reveals bilateral patchy alveolar opacities. *B*. Computed tomography shows bilateral patchy airspace consolidation in the right and left lower lobes. Air bronchograms are present on the right. Corticosteroid therapy resulted in complete resolution.

capacity percent [FEV_1/FVC%] less than 70 percent) is found uncommonly (in fewer than 21 percent of cases) and is seen mostly in patients who are current or former smokers. Lung function is occasionally normal. The pressure-volume curve is shifted downward and to the right, consistent with noncompliant lungs. The maximal transpulmonary pressure and the coefficient of elastic recoil (maximal transpulmonary pressure divided by TLC) are increased. Gas exchange abnormalities are extremely common. The D_{LCO} is reduced in most patients (72 percent). Widening of the resting alveolar arterial oxygen gradient (greater than 20 mmHg) and exercise-related hypoxemia are common abnormalities (83 percent).

Bronchoalveolar Lavage Cellular Findings

Bronchoalveolar lavage (BAL) studies have been reported in only a few subjects with COP. The percentage of instilled fluid recovered from patients with COP is lower than that from healthy volunteers. However, the total number of cells recovered is greater in patients with COP. The proportion of macrophages is lower, while the proportion of lymphocytes, neutrophils, and eosinophils is higher in COP. Patients with COP tend to have higher lymphocyte counts than those with idiopathic pulmonary fibrosis. Other BAL abnormalities in COP include presence of foamy macrophages and, occasionally, mast cells and plasma cells; decreased ratio of CD4 to CD8 cells; normal percentage of CD57+ cells; increased activated T cells, as reflected in human HLA-DR expression; and, occasionally, interleukin-2 (IL-2) receptor (CD25) expression. The findings are similar to those in hypersensitivity pneumonitis; in hypersensitivity pneumonitis, however, CD25 expression is normal, and CD57+ cells are increased. This "mixed pattern" of increased cellularity is thought to be characteristic of COP, especially when associated with multiple alveolar opacities on the chest radiograph.

Histopathological Findings

The histopathological lesion characteristic of COP is an excessive proliferation of granulation tissue within small airways (i.e., proliferative bronchiolitis) and alveolar ducts, along with chronic inflammation in surrounding alveoli. This organizing pneumonia is the most important basis for the clinical and radiographic manifestations of COP. Several additional key features are notable: (1) the distribution of lesions is usually patchy and peribronchiolar; (2) the lesions are usually located predominantly within the airspace; (3) there is a uniform, recent temporal appearance to the changes in that all the lesions look similar, with an inflamed, edematous-appearing stroma with little collagen deposition; (4) the intraluminal buds of granulation tissue consist of loose, collagen-embedding fibroblasts and myofibroblasts that extend through the pores of Kohn from one alveolus to another, giving rise to the characteristic "butterfly" pattern; (5) the bronchiolar lesions are usually secondary to intraluminal plugs of granulation tissue occurring in association with plugs in the alveolar ducts and alveolar spaces; (6) severe fibrotic changes (honeycombing) are unusual at the time of diagnosis; (7) foamy macrophages are very common in alveolar spaces, presumably secondary to the bronchiolar occlusion; (8) giant cells are rare or absent, and no granuloma or vasculitis is present; and (9) the lung architecture is not severely disrupted.

Diagnosis

The clinical and histopathological features of COP may be present in other disorders, such as bacterial pneumonia, hypersensitivity pneumonitis, chronic eosinophilic pneumonia,

viral infection, drug reactions, and connective-tissue disorders. Thus, the diagnosis of COP depends on both the clinical setting and characteristic pathological features, including the prominent finding of the BOOP pattern in the absence of features suggestive of an underlying process.

An open or thoracoscopic lung biopsy is recommended to confirm the diagnosis. Ample lung tissue must be obtained and carefully reviewed to rule out other diseases, especially idiopathic pulmonary fibrosis, hypersensitivity pneumonitis, chronic eosinophilic pneumonia, and diffuse alveolar damage seen in the acute respiratory distress syndrome.

Transbronchial lung biopsies are generally inadequate in confirming COP and ruling out other disorders. The histopathological features of bronchiolitis obliterans associated with areas of organizing pneumonia can be seen in a number of settings; therefore, small biopsies increase the chance of missing the central diagnosis. Step-sectioning of transbronchial biopsies is useful in identifying the lesions of COP.

The biopsies must be reviewed by an experienced lung pathologist who has been given adequate clinical information to guide the search for specific lesions supporting the diagnosis. Once the characteristic findings of proliferative bronchiolitis are confirmed, the clinician must ensure that a thorough search has been performed to rule out the many other diagnostic considerations. Indeed, the clinicopathological syndrome of COP is a diagnosis of exclusion.

Treatment and Clinical Course

Corticosteroid therapy is the most common treatment. Complete clinical recovery, physiological improvement, and normalization of the chest film are seen in two-thirds of patients. Approximately one-third demonstrate persistent disease.

In general, clinical improvement is rapid, within several days or a few weeks. Occasionally, recovery is quite dramatic. Relapses occur commonly when corticosteroids are withdrawn after 1 to 3 months. Most patients who relapse show improvement when re-treated with corticosteroids. Spontaneous improvement in a few patients appears to occur over 3 to 6 months.

Patients with airspace opacities on the chest radiograph have a much better outcome than those with interstitial opacities. The overall prognosis for COP is much better than for other interstitial lung diseases (e.g., idiopathic pulmonary fibrosis). Rapidly fatal COP is uncommon.

Based on our clinical experience and that of others, high-dose oral corticosteroid therapy should be used to treat COP. Therapy is usually initiated with prednisone in a dose of 1 to 1.5 mg/kg per day (using ideal body weight), not to exceed 100 mg daily. The drug is given as a single oral dose in the morning, and the dose is maintained for 4 to 8 weeks. If, after 5 to 8 weeks, the patient's condition is stable or improved, the dose is gradually tapered to 0.5 to 1 mg/kg per day for the ensuing 4 to 6 weeks. High-dose parenteral corticosteroid therapy (e.g., methylprednisolone, 125 to 250 mg intravenously every 6 h for 3 to 5 days) has been recommended as initial treatment for patients with rapidly progressive COP.

For the patient in stable or improved condition, the prednisone is gradually tapered off after 3 to 6 months of therapy. A chest radiograph and pulmonary function tests should probably be performed every 6 to 8 weeks during the first year, and therapy should be reinstituted aggressively with any sign of recurrence. Although therapy with corticosteroids is usually well tolerated, side effects are common; some patients develop side effects more readily than others. If the patient's condition deteriorates despite corticosteroid therapy, a cytotoxic agent should be considered while low-dose (0.25 mg/kg per day) therapy with prednisone is continued. Cyclophosphamide and azathioprine have both been used successfully, although the optimal dose in COP is unknown.

Localized Bronchiolitis Obliterans-Organizing Pneumonia

Occasionally, localized areas of BOOP are found at open lung biopsy, usually performed to rule out carcinoma. These lesions present radiographically as irregular nodules or irregular sublobar areas of airspace consolidation. Surgical resection usually resolves this problem. The origin of the lesions is unknown and may be secondary to resolving pneumonia.

CONNECTIVE-TISSUE DISEASES

Pulmonary impairment is common in many of the connective-tissue disorders. In most cases, the pulmonary dysfunction is related to alveolar, rather than airway, pathology. Bronchiolitis appears to occur infrequently and varies in its manifestations among the connective-tissue diseases. Further, most of the current understanding of bronchiolar disease in this setting is based largely on anecdotal case reports or small case series. Bronchiolitis, both constrictive and follicular, is most common in patients with rheumatoid arthritis. This section reviews the characteristics of bronchiolitis in rheumatoid arthritis, Sjögren's syndrome, systemic lupus erythematosus, progressive systemic sclerosis, polymyositis, and dermatomyositis.

Rheumatoid Arthritis and Constrictive Bronchiolitis

Obstructive pulmonary disease is remarkably prevalent in rheumatoid arthritis. In particular, bronchiolitis obliterans with airway obstruction is an increasingly recognized complication of this connective-tissue disorder. The basic lesion is fibrous narrowing and obliteration of the bronchioles and smallest bronchi. The role of prior penicillamine therapy as a potential etiological factor remains to be confirmed.

Clinical Findings

Most patients are middle-aged women with long-standing seropositive rheumatoid arthritis. This finding is consistent with the increased incidence of rheumatoid arthritis in women, but it is inconsistent with the increased frequency of pulmonary disease in rheumatoid arthritis reported among men. The clinical manifestations of bronchiolitis obliterans associated with rheumatoid arthritis help to distinguish it from other pulmonary processes associated with this disorder. Clinical findings include the rather abrupt onset of dyspnea and dry cough, often associated with inspiratory crackles and a mid-inspiratory "squeak."

The chest radiograph is typically normal, but it may show signs of air trapping. HRCT usually excludes the presence of bronchiectasis. Expiratory CT often shows multiple scattered areas of air trapping consistent with small-airway obstruction.

Pulmonary function studies reveal airflow obstruction and normal pulmonary compliance. Arterial blood gases show moderate hypoxemia and a respiratory alkalosis. The rapid rate of progression in airflow obstruction is atypical for COPD.

Histopathological Findings

A "constrictive" bronchiolitis is most common. Lymphoplasmacytic infiltration of small-airway walls is noted. The lumina are gradually obliterated, and the bronchiolar wall is destroyed by granulation tissue. Lesions are usually confined to the small bronchi and bronchioles. Parenchymal involvement is generally localized to areas surrounding the bronchiolitis. Lesions may be at different stages of development or may appear uniform. Immunofluorescence studies show granular depositions of IgM and a striking linear deposition of IgG in the alveolar wall, suggesting possible direct immune-mediated lung injury.

Treatment and Prognosis

Treatment with antibiotics and bronchodilators is ineffective. Corticosteroid therapy appears effective in some patients. The use of intravenous cyclophosphamide and oral prednisone has been suggested. One case report has described improvement of refractory rheumatoid arthritis-associated bronchiolitis in a patient treated with etanercept (tumor necrosis factor [TNF]-α inhibitor) and methotrexate. The prognosis is poor, with early deaths reported. In most patients, the disease runs a chronic course.

Rheumatoid Arthritis and Bronchiolitis Obliterans-Organizing Pneumonia

Occasionally, in rheumatoid arthritis, patchy organizing pneumonia with granulation tissue plugs extending into the alveolar ducts (BOOP) is the predominant lesion. Rheumatoid arthritis with BOOP appears to have a worse prognosis than does rheumatoid arthritis with constrictive bronchiolitis. In fact, patients with rheumatoid arthritis and BOOP are prone to development of a rapidly progressive, fatal form of pneumonia.

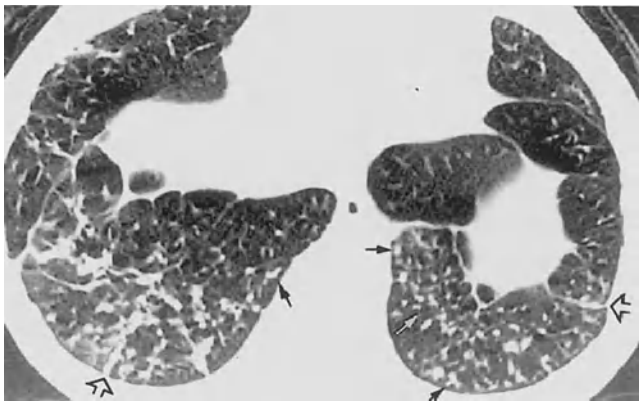


Figure 52-10 Follicular bronchiolitis. Thin-section (1.5-mm-collimation) computed tomography scan through the lower zones in a 61-year-old man with a mixed collagen vascular disease demonstrates multiple well-defined nodules. Several nodules (solid arrows) are clustered and located a few millimeters from the pleura or interlobular septa, which indicates centrilobular distribution. Mild interlobular septal thickening (open arrows) is also present. *(From Howling SJ, Hansell DM, Wells AU, et al: Follicular bronchiolitis: Thin-section CT and histologic findings*. Radiology *212:637–642, 1999.)*

Rheumatoid Arthritis and Follicular Bronchiolitis

Follicular bronchitis and bronchiolitis may occur in patients with rheumatoid arthritis, Sjögren's syndrome, juvenile rheumatoid arthritis, immunodeficiency syndromes, familial lung disorders, chronic infection, and hypersensitivity-type reactions.

Patients with rheumatoid arthritis always present with dyspnea; fever and cough occur occasionally. A positive rheumatoid factor is present, often at high levels (rheumatoid factor titers of 1:640 to 1:2560). The chest film is abnormal, showing bilateral reticular or nodular opacities (Fig. 52-10). Arterial blood gases demonstrate hypoxemia, hypocapnia, and a widened alveolar-arterial oxygen gradient. Both obstructive and restrictive patterns have been identified by spirometry, but the restrictive pattern appears to be more common. Immunofluorescence studies are negative.

The lesions of follicular bronchiolitis produce obstruction by external compression of bronchioles, rather than by direct luminal occlusion, as is characteristic of proliferative bronchiolitis obliterans (Fig. 52-11). In almost all cases, a concentric inflammatory infiltrate of lymphocytes and plasma cells surrounds the bronchiole. Abundant germinal centers in the peribronchiolar regions are present and are characterized by hyperplastic follicles located between bronchioles and pulmonary arteries. The bronchiolar lumen is often compressed into a slitlike or fish-mouth shape. Some have suggested that follicular bronchiolitis may be the precursor of interstitial lymphoid pneumonia or pseudolymphoma. Treatment with

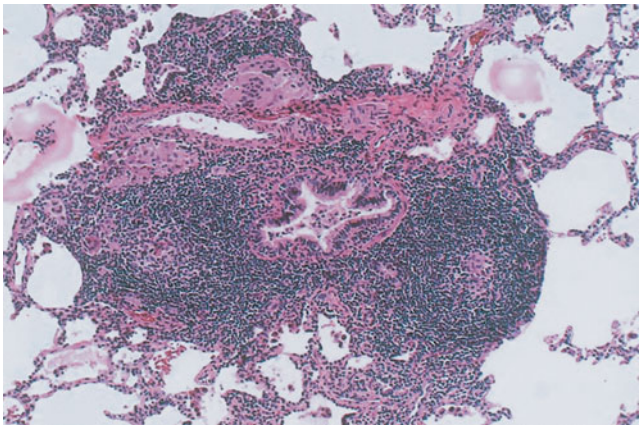

Figure 52-11 Proliferation of lymphoid follicles with germinal centers along the airways and infiltration of the epithelium by lymphocytes (H&E stain). *(Slide courtesy of Jeffrey L. Myers, M.D., Mayo Clinic, Rochester, MN.)*

corticosteroids has yielded variable results. Erythromycin may be useful for the management of this process.

Sjögren's Syndrome

Obstructive airway disease has been reported in patients with Sjögren's syndrome, often in association with other connective-tissue diseases, particularly rheumatoid arthritis. Desiccation of the tracheobronchial tree is very common in Sjögren's syndrome and no doubt accounts for the obstructive findings. Atrophic rhinitis, xerostomia, xerotrachea (manifested by chronic, dry cough), chronic bronchitis (with cough and production of tenacious sputum), atelectasis (with frequent middle-lobe collapse), and recurrent bronchopneumonia are manifestations of the severe mucosal dryness that can occur within the tracheobronchial tree. Secondary BOOP has been reported as a rare complication of Sjögren's syndrome.

The clinical impact of the obstructive airway dysfunction in Sjögren's syndrome is rarely severe. Most symptomatic patients complain only of a dry cough and mild dyspnea. Adequate studies addressing pulmonary function and pathology are limited. However, lung biopsy has revealed a mononuclear cell infiltration around narrowed small airways (i.e., constrictive bronchiolitis).

Systemic Lupus Erythematosus

Fewer than 5 percent of patients with systemic lupus erythematosus (SLE) have airflow obstruction. A patient with SLE who developed rapidly progressive airway obstruction and demonstrated early obliterative bronchiolitis on open lung biopsy has been reported. Hence, this lesion may account for the obstructive dysfunction occasionally seen in SLE. BOOP has also been reported in two patients with SLE. Although one patient responded to corticosteroid therapy, the other died, despite treatment with corticosteroids and cyclophosphamide.

Progressive Systemic Sclerosis

Clinically significant small-airway disease is not often found in nonsmokers with progressive systemic sclerosis, even in the presence of interstitial pulmonary involvement. Focal lymphoid hyperplasia (follicular bronchiolitis) was identified in 23 percent of the open lung biopsies from patients with progressive systemic sclerosis. Interstitial lung disease is the most important pulmonary complication of this disorder.

Polymyositis and Dermatomyositis

BOOP, usual interstitial pneumonia, and diffuse alveolar damage are the most common histological patterns identified in patients with polymyositis and dermatomyositis. BOOP may occur de novo. Patients with polymyositis or dermatomyositis and BOOP present with cough, fever, and dyspnea, in addition to the proximal muscle weakness, malaise, and rash commonly found in this disease. The pulmonary lesion is responsive to corticosteroid therapy.

DRUG-INDUCED CAUSES OF BRONCHIOLITIS

Bronchiolitis, usually with organizing pneumonia, has been reported in association with a number of drugs (Table 52-1). Most reports are of single cases or small case series.

Bronchiolitis Associated with Gold Compounds

Several forms of pulmonary disease occur among patients treated with gold, including chronic interstitial pneumonitis, organizing pneumonia, and bronchiolitis obliterans. Pure bronchiolitis obliterans with airflow obstruction has been associated with gold therapy, especially in patients with rheumatoid arthritis. Since patients with rheumatoid arthritis are prone to develop bronchiolitis obliterans, determination of whether the cases resulted from gold-induced airway injury is difficult.

Amiodarone-Induced Bronchiolitis

An organizing pneumonia with or without bronchiolitis obliterans (BOOP-pattern) is seen in approximately 25 percent of cases of amiodarone-induced lung disease. This presentation is acute and characterized by cough, fever, dyspnea, and patchy alveolar opacities on the chest radiograph. Findings mimic an infectious pneumonitis. Pleuritic chest pain and nonproductive cough are common. Crackles and pleural rub are typically evident on auscultation.

Treatment consists primarily of stopping the drug, provided that alternative treatment options are made for potentially life-threatening arrhythmia. Corticosteroid therapy (prednisone 40 to 60 mg a day, tapering over 2 to 6 months)

can be life-saving for severe cases and for patients in whom withdrawal of amiodarone is not advisable.

Because of the drug's accumulation in fatty tissues and its long elimination half-life (approximately 45 days), pulmonary toxicity may progress despite drug discontinuation; furthermore it may recur upon steroid withdrawal.

Sauropus Androgynus-Induced Bronchiolitis

An outbreak has been reported in Taiwan of rapidly progressive respiratory distress associated with consumption of uncooked Sauropus androgynus, a vegetable claimed to be effective in weight control. Most patients were young or middle-aged women who consumed the juice of uncooked Sauropus androgynus, generally mixed with guava or pineapple juice, for a mean duration of 10 weeks. Progressive dyspnea and persistent cough were the main symptoms on presentation.

Pulmonary function testing uniformly revealed moderate to severe airflow obstruction. Hypoxemia was also present. The chest radiographs were essentially normal. HRCT showed bilateral bronchiectasis and patchy low attenuation of lung parenchyma with mosaic perfusion. The radiographic presence of air-trapping was better correlated with changes in pulmonary function than was bronchiectasis. Findings on ventilation-perfusion lung scans were compatible with obstructive lung disease. Open lung biopsy specimens confirmed the presence of bronchiolitis obliterans. No effective treatment has been reported; the clinical response to prednisolone is limited.

ORGAN TRANSPLANTATION

Pulmonary disease is a common complication of organ transplantation and, consequently, it is a significant source of morbidity and mortality in transplant recipients. Bronchiolitis, manifested by progressive airflow obstruction, is increasingly becoming one of the most frequent noninfectious posttransplant respiratory complications. The BOOP pattern has also been reported in transplant recipients.

Bone Marrow Transplantation

Pulmonary disease is a common complication of bone marrow transplantation, occurring in 40 to 60 percent of patients. Furthermore, pulmonary complications are a significant source of morbidity and mortality in transplant recipients. The disease usually results from an infectious pneumonia (bacterial, fungal, or viral, especially cytomegalovirus) or idiopathic interstitial pneumonitis. Lymphocytic bronchitis and lymphoplasmacytic infiltrates of the trachea and large bronchi are among the earliest pulmonary problems encountered after bone marrow transplantation. Progressive airflow obstruction secondary to bronchiolitis obliterans is one of the most frequent noninfectious posttransplant respiratory complications. Cases appear after the first 100 days following transplantation, usually in the setting of chronic graft-vs.-host disease (GVHD). GVHD has been postulated to play a role in the development of this lung disease. Bronchiolitis obliterans is most prevalent in patients after allogeneic transplantation, but it has been recently reported with autologous bone marrow transplantation, as well.

Clinical Findings

Approximately 10 to 17 percent of long-term survivors with chronic GVHD develop severe obstructive pulmonary disease. Risk factors include older age, recurrent sinusitis, chronic GVHD, methotrexate prophylaxis for GVHD, and acquired hypogammaglobulinemia. Patients usually present with nonproductive cough (60 percent), dyspnea with exertion (51 percent), and nasal congestion. Scattered wheezes are heard in 40 percent of patients; expiratory "squeaks" are also frequently noted. Bibasilar crackles are uncommon.

Radiographic Findings

The chest radiograph may show diffuse interstitial infiltrates; in approximately 80 percent of cases, the lung fields are normal. Hyperinflation may also be seen. Pneumothoraces may complicate the course of advanced disease. HRCT can be helpful in supporting the diagnosis. In established bronchiolitis obliterans, the most striking CT feature is lobular or segmental areas of lung attenuation, associated with narrowing of pulmonary vessels. The attenuation is presumed to represent areas of air trapping and oligemia.

Physiological Findings

The finding of a new obstructive pattern on pulmonary function testing is a significant signal that bronchiolitis obliterans is developing, especially when noted in the presence of GVHD. Reduced flow, often with hyperinflation and air trapping, is the most common manifestation. Bronchial hyperreactivity also has been identified in some patients after transplantation, but most have fixed obstruction unresponsive to bronchodilators. The presence of bronchial hyperreactivity before transplantation has not been associated with the subsequent development of either clinical or pathologically proven posttransplantation bronchiolitis obliterans. The diffusing capacity is reduced, and hypoxemia is common.

Histopathological Findings

Lung biopsy findings are quite variable. The major changes are in and around the bronchioles. In most patients with rapidly progressive obstruction, marked lymphocytic, plasmacytic, or neutrophilic infiltration of the walls of the terminal respiratory bronchioles and obliteration of the bronchiolar lumina with fibrous tissue and surrounding interstitial fibrosis (i.e., "pure" bronchiolitis obliterans) are found. A moderate lymphocytic infiltrate may invade the adjacent pulmonary parenchyma. Other changes characteristic of constrictive bronchiolitis are frequently noted. The BOOP pattern has also been found after bone marrow transplantation.

Transbronchial lung biopsies are usually inadequate for definitive diagnosis. An open or thoracoscopic lung biopsy is

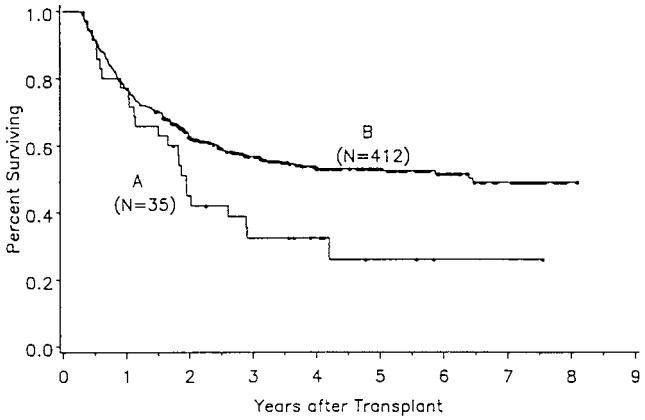

Figure 52-12 Bronchiolitis obliterans associated with bone marrow transplantation. Curve A shows posttransplant survival of 35 patients who developed obstructive lung disease. Curve B shows posttransplant survival of 412 concurrent patients (age 16 years or over) with chronic graft-vs.-host disease who survived at least 80 days after transplantation and who had no evidence of obstructive lung disease. *(Based on data from Clark JG, Crawford SW, Madtes DK, et al: Obstructive lung disease after allogeneic marrow transplantation. Clinical presentation and course.* Ann Intern Med *111:368–376, 1989, with permission.)*

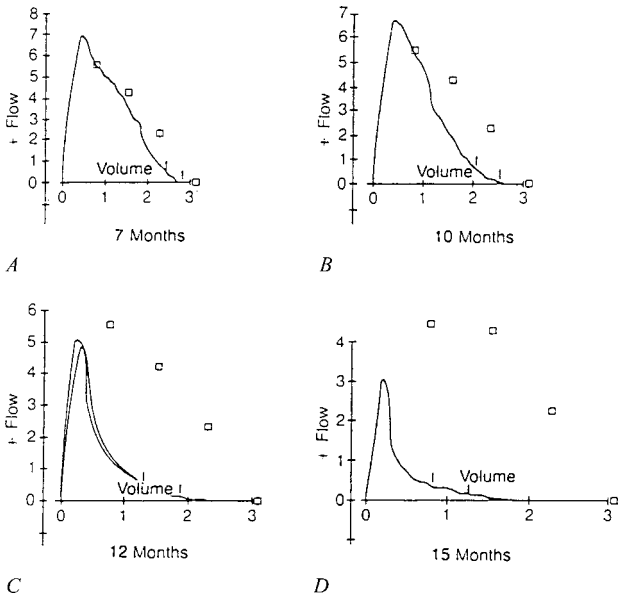

Figure 52-13 Segmented changes in flow-volume loops in bronchiolitis obliterans associated with heart-lung transplantation. Curves are from a 33-year-old woman 7, 10, 12, and 15 months after transplantation. *A*. Upper left figure is essentially normal curve. *B*. Upper right curve shows early ''coving" of the expiratory flow limb over the middle 50 percent of the forced vital capacity. *C* and *D*. Progressive obstruction is present at 12 (lower left) and 15 months (lower right). Small boxes in each panel represent normal flow. Flow is expressed in L/s; volume is expressed in L. *(Based on data from Theodore J, Starnes VA, Lewiston NJ: Obliterative bronchiolitis*. Clin Chest Med *11:309–321, 1990, with permission.)*

often necessary. Since infections are frequent, they should be diagnosed and treated promptly. In this setting, BAL analysis is useful only in ruling out infections. A lymphocytic (i.e., 30 to 50 percent lymphocytes in BAL fluid) or mixed lymphocyte-neutrophil predominance is usual.

Management

The appropriate treatment of bronchiolitis obliterans associated with bone marrow transplantation is unclear. In most cases, bronchodilators and corticosteroids have not improved airflow limitation. Furthermore, use of immunosuppressive agents for the treatment of chronic GVHD has had no consistent beneficial effect on pulmonary function. Consequently, early recognition and management are required if treatment is to be successful.

The prognosis is variable. A significant number of reported patients have had progressive or persistent disease; many have died secondary to respiratory failure (40 to 65 percent of subjects) (Fig. 52-12). Increasing recognition, early treatment, and the introduction of cyclosporine have resulted in a reduction of the incidence of posttransplantation obstructive airway disease.

Heart-Lung Transplantation

The main pulmonary complication in long-term survivors of heart-lung transplantation is a life-threatening obstructive ventilatory defect—bronchiolitis obliterans. The incidence of obliterative bronchiolitis in this setting has declined in recent years from 50 percent to 10 to 23 percent. However, in a recent study, 65 percent of lung transplant recipients (including 48 heart-lung, 18 single lung, and 8 bilateral-lung recipients) who survived longer than 90 days, and who underwent transplantation more than 15 months before data analysis, developed bronchiolitis obliterans.

Clinical Findings

Bronchiolitis obliterans is noted clinically several months to several years after heart-lung transplantation. Cough productive of mucopurulent sputum is most often seen. Progressive dyspnea follows. Most patients experience repeated upper respiratory tract infections, both viral and bacterial in origin. Occasionally, disease onset is identified only from abnormalities in routine pulmonary function testing (Fig. 52-13). With advanced disease, wheezing on exertion is common.

The development of bronchiolitis obliterans frequently is preceded by acute organ rejection. Often, patients have a history of prior lung infection with cytomegalovirus, *Pneumocystis carinii*, or Epstein-Barr virus. Chest examination reveals diffuse, coarse crackles, inspiratory squeaks, and expiratory rhonchi. The classic signs of severe airflow obstruction and hyperinflation are seen in advanced, end-stage disease.

Radiographic Findings

The chest radiograph may be normal in early stages of the disease, but frequently it reveals diffuse, nonspecific peribronchial and interstitial infiltrates and variable pleural thickening. Bronchography and CT reveal central bronchiectasis.

Physiological Findings

Pulmonary function tests show largely irreversible airflow obstruction; however, TLC is reduced. The D_{LCO} is moderately depressed. Hypoxemia and hypocapnia are universally present.

Histopathological Findings

Histopathological changes affect all areas of the lung, but they are frequently patchy. Inspissated mucus and distal obstructive airway changes are often noted. Diffuse increases in peribronchial and interstitial fibrosis are present in most biopsies. Pleural, venous, and arteriosclerotic vascular changes are common. These changes are different from those in acute pulmonary rejection, which is characterized by perivascular lymphocytic cuffing and diffuse alveolar damage. Clinical acute rejection predisposes to subsequent development of bronchiolitis obliterans.

Occasionally, classic BOOP, with patchy organizing pneumonia and granulation tissue plugs extending into the alveolar ducts, is observed as the predominant lesion. The clinical and radiographic features are those seen with BOOP (discussed previously). Usually, known causes of this lesion are identified—e.g., infection, aspiration, drug reaction, etc.

Pathogenesis

Increasing evidence suggests that the key pathogenetic factor is a form of alloreactive injury to the bronchial epithelium. Donor-specific alloreactivity of BAL lymphocytes, manifested by a proliferative response to donor spleen cells, appears to be a useful marker for this process. A number of other possible causes or associations of bronchiolitis obliterans in heart-lung transplantation have been described: (1) recurrent, persistent bacterial or viral infections; (2) immunoreaction to the transplanted lung (e.g., GVHD or transplant rejection); (3) altered mucociliary clearance and impaired ciliary function from injury to the pulmonary nerve supply or from abnormal mucus chemistry and viscosity; (4) bronchial artery ligation and resulting alteration in repair of injured bronchi and bronchioles; (5) reaction to immunosuppressive drugs (especially cyclosporine, which has been shown to have fibroproliferative properties that could cause progressive narrowing and obliteration of affected bronchioles); and (6) loss of cough reflex and aspiration, creating a milieu favorable to continued growth of infectious agents.

Diagnosis

Open or thoracoscopic lung biopsy is required to confirm the diagnosis of bronchiolitis obliterans and to rule out other causes of pulmonary dysfunction in patients who have undergone heart-lung transplantation. With increased recognition of this potential complication, early detection of the disorder through use of serial pulmonary function tests, BAL, and repeated transbronchial lung biopsies can be achieved and may decrease the need for surgical lung biopsy to confirm the diagnosis. The value and role of serial surveillance transbronchial lung biopsies in the absence of clinical symptoms and signs remain unknown. Unsuspected rejection or infection requiring therapy may be seen in 25 percent of surveillance bronchoscopy procedures performed after lung transplantation. Most episodes (68 percent) of unsuspected rejection or infection appear in the first 6 months following transplantation.

Management

No clearly useful treatment protocol has been established. Efforts at preventing repeated episodes of rejection seem most important. Prompt diagnosis and treatment of acute rejection and any infectious complications are paramount. Routine serial lung function testing and fiberoptic bronchoscopy with transbronchial biopsy and BAL are helpful.

The best medical regimen for prevention of bronchiolitis obliterans remains to be defined. Nonetheless, experience suggests that optimal maintenance of immunosuppression requires a regimen that includes azathioprine and cyclosporine. Prednisone is also commonly included. Use of corticosteroids, bronchodilators, antibiotics, antithymocyte globulin, or OKT3 monoclonal antibody has resulted in documented stabilization or reversal of disease in some patients. Retransplantation has been successful. Spontaneous improvement does not occur.

Lung Transplantation

Lung transplant recipients were initially thought not to develop bronchiolitis obliterans. However, this complication is now recognized as the major factor limiting long-term success with this procedure. The incidence of bronchiolitis obliterans among single-lung recipients is approximately 20 percent; in double or bilateral, sequential single-lung recipients, the incidence is 12 percent. Risk factors include recurrent episodes of acute rejection, severe acute rejection, inadequate or fluctuating levels of maintenance immunosuppression, recurrent infections, and ischemic airway injury occurring early after transplantation.

Bronchiolitis Obliterans Syndrome

Progressive airflow limitation secondary to small-airway obstruction is the hallmark of the bronchiolitis obliterans syndrome (BOS). This syndrome has a variable clinical course. Some patients experience rapid loss of lung function and respiratory failure. Others experience either slow progression or intermittent loss of function with plateaus, during which pulmonary function is stable for prolonged periods of time. BOS likely reflects more than one process.

Clinical Findings

The clinical presentation is similar to that described in heart-lung transplantation. Nonproductive cough, mild malaise, and fatigue are common symptoms. Eventually, all subjects develop dyspnea. Results of physical examination are usually normal, but inspiratory squeaks may be heard. Crackles are uncommon.

Radiographic Findings

Decreased peripheral vascular markings, slight volume loss, and subsegmental atelectasis may be early changes. A common radiographic finding in long-standing disease is the gradual progression of pleural-based densities in the middle and upper lung zones. Biopsy reveals subpleural parenchymal fibrosis without active inflammation. The scarring may result from relative ischemia in areas of affected lung. HRCT shows lobular or segmental areas of lung attenuation and narrowing of pulmonary vessels, representing regions of air trapping and oligemia.

Histopathological Findings

Three major kinds of airway injury may be seen in lung allografts: acute rejection, bronchiolitis obliterans, and lymphocytic bronchitis or bronchiolitis. The lesions of bronchiolitis obliterans affect the membranous and respiratory bronchioles. They are characterized by the features of constrictive bronchiolitis (see above). If a submucosal mononuclear cell infiltrate is present, the lesions are considered "active." Their absence may indicate "inactive" disease. Vascular changes are often found and usually consist of fibrointimal thickening of arteries and veins, with or without an active inflammatory component.

A BOOP pattern, with patchy organizing pneumonia and granulation tissue plugs extending into the alveolar ducts, has been reported in some lung transplant recipients. The clinical and radiographic features are progressive respiratory failure, acute or subacute alveolar opacities noted on chest radiograph, and a restrictive pattern of pulmonary function tests. Usually, known causes of this lesion are identifiable, especially infection. Patients respond well to corticosteroid therapy.

Management

Several recent trials have demonstrated significant functional improvement in BOS with treatment of macrolide antibiotics. Prevention of repeated episodes of acute rejection appears important. Prompt diagnosis and treatment of acute rejection and infectious complications are important. A regimen of immunosuppression that includes azathioprine, cyclosporine, and prednisone is most commonly employed. This regimen appears to slow the rate of decline in lung function; however, the overall prognosis remains poor. Approximately 50 percent of all deaths after the first year following transplant are due to bronchiolitis obliterans. Retransplantation has been successfully employed in some patients.

DIFFUSE PANBRONCHIOLITIS

Diffuse panbronchiolitis is a distinctive form of small-airway disease that is relatively common in Japan, China, and Korea; it is rare in other parts of the world. A few case reports of the disease in non-Asians have appeared in the literature. A familial occurrence has been described, with a significant increase in HLA Bw54 (63 percent frequency). The genetic and ethnic background observed with this unique syndrome may be explained on the basis of HLA Bw54 or its related haplotype being confined primarily to some Asian races—e.g., Japanese, Chinese, and Koreans. HLA Bw54 may also be a useful marker in the differential diagnosis of diffuse panbronchiolitis, since the frequency of this haplotype in the general population is very low (11.8 percent). A similar pulmonary lesion has been demonstrated in ulcerative colitis and adult T-cell leukemia. Environmental factors also appear important, since the disorder is very uncommon in persons of Asian ancestry living abroad.

Clinical Findings

Diffuse panbronchiolitis is more prevalent in men, with a 2:1 male-to-female ratio. The peak incidence occurs between the fourth and seventh decades of life; mean age at presentation is 50 years. Chronic sinusitis is present in 75 to 100 percent of cases. Sinus symptoms often precede chest symptoms by years or decades. Chronic cough with expectoration of copious purulent sputum, exertional dyspnea, and wheezing are the most common clinical manifestations. Cigarette smoking or occupational exposures have not been shown to be predisposing factors. Physical examination reveals coarse crackles; clubbing is not a feature.

The most characteristic laboratory abnormality is persistent, marked elevation of serum cold agglutinins; mycoplasmal antibody titers are negative. Rheumatoid factor may be elevated. Immunoglobulin levels are usually normal. BAL studies reveal marked neutrophilia.

Radiographic Findings

The chest radiograph often reveals small nodular opacities up to 2 mm in diameter; the opacities are seen diffusely throughout the lung fields. A reticular "airway" pattern may be evident with more advanced disease. Hyperinflation may also be present. HRCT yields more information about the location and distribution of the pulmonary disease than do conventional radiographic techniques. HRCT also better reflects the clinical stages and pathology. On HRCT, the nodular shadows are distributed in a centrilobular fashion, often extending to small, branching linear areas of attenuation. The nodular and linear densities correspond to thickened and dilated bronchiolar walls with intraluminal mucus plugs. Inhomogeneity in lung density may be apparent as a result of peripheral air trapping. Bronchiectasis may be prominent in advanced disease.

Physiological Findings

Pulmonary function tests reveal marked obstruction. Arterial blood gases show hypoxemia, with or without hypercapnia. In rare instances, a restrictive ventilatory defect is present. The diffusing capacity is variably reduced. In general, patients with diffuse panbronchiolitis exhibit less bronchodilator responsiveness than do patients with COPD.

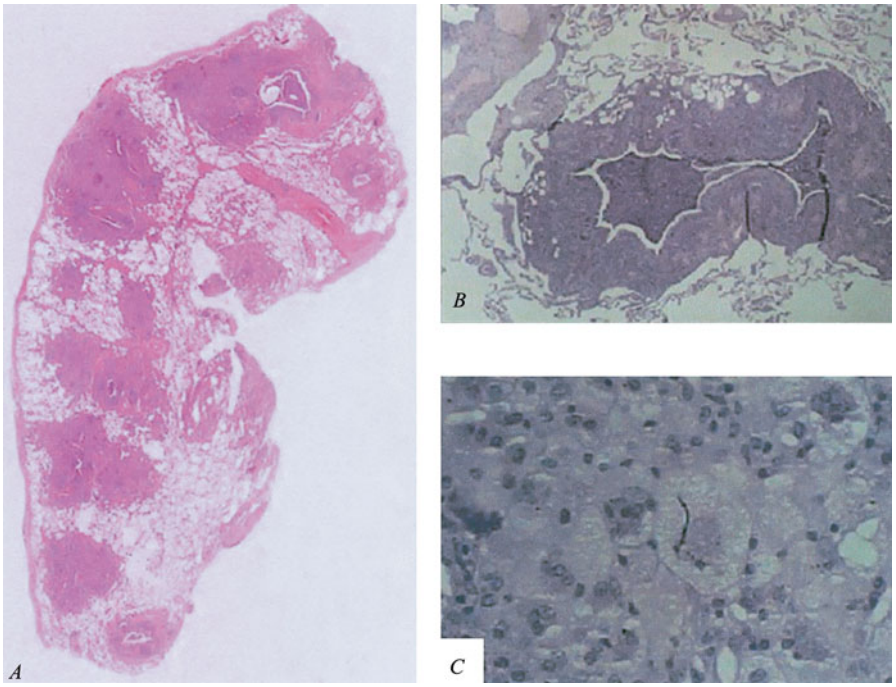

Figure 52-14 *A*. Scanning power microscopy shows the inflammatory process has a predilection for bronchioles (H&E stain). *B*. Inflammatory process characterized by mononuclear cell inflammation of the respiratory bronchioles. Acute inflammation in the lumen of the respiratory bronchiole and chronic inflammation in the wall, including numerous interstitial foam cells, are noted (H&E stain). *C*. Foamy macrophages in the bronchiolar lumina and adjacent alveoli (H&E stain). *(Slide courtesy of Jeffrey L. Myers, M.D., Professor of Pathology, Mayo Clinic, Rochester, MN.)*

Histopathological Findings

Thickening of the walls of the respiratory bronchiole, infiltration with lymphocytes, plasma cells and histiocytes, and extension of the inflammatory changes into peribronchiolar tissue are noted on biopsy (Fig. 52-14). Advanced disease is manifested by secondary ectasia of proximal bronchioles.

Management and Outcome

Optimal therapy for diffuse panbronchiolitis is unclear. Low-dose erythromycin (200 to 600 mg a day) is adequate for most patients. Erythromycin impairs neutrophil chemotaxis, neutrophil superoxide production, and neutrophil-derived elastolytic activity, and it decreases the number of neutrophils in BAL fluid following challenge with gram-negative bacteria. In addition, erythromycin may cause a reduction in mucus production by decreasing glycoconjugate secretion. Finally, erythromycin has been shown to reduce the circulating pool of T lymphocytes bearing HLA-DR, a marker of cellular activation.

Corticosteroids are commonly used in treatment regimens, but evidence supporting their efficacy is lacking. Nonsteroidal anti-inflammatory drugs (NSAIDs) may have a role in controlling the bronchorrhea associated with this disease by altering airway epithelial ion and water transport. No controlled trials with NSAIDs have been performed. Routine use of β_2-agonists or ipratropium bromide should be encouraged to promote mucociliary clearance and bronchodilation in patients with a component of reversible airway disease and as a part of routine pulmonary toilet. In addition, treatment of coexisting sinus disease may help in control of airway disease.

Prompt treatment of bronchial infections is also important. The choice of antibiotics should be guided by results of sputum Gram's stain and culture. The disease progresses insidiously, and the prognosis is often poor, with fatalities due to repeated respiratory infections (particularly with *Pseudomonas aeruginosa*) that result in respiratory failure.

PRIMARY DIFFUSE HYPERPLASIA OF PULMONARY NEUROENDOCRINE CELLS

Primary diffuse hyperplasia of pulmonary neuroendocrine cells is a clinicopathological entity characterized by diffuse hyperplasia and dysplasia of neuroendocrine cells primarily affecting the distal bronchi and bronchioles. The disorder is seen primarily in women in their fifth or sixth decade. Clinical findings include nonproductive cough and long-standing dyspnea (usually of more than 10 years' duration). All reported cases are in never-smokers. The chest examination is unrevealing. Chest radiographs show diffuse reticulonodular opacities in most; multiple nodules are seen in a few cases. HRCT demonstrates diffuse small-airway thickening, with patchy areas of hyperlucency, suggesting air trapping. The most common physiological abnormality is irreversible airflow obstruction. Open or thoracoscopic lung biopsy is required for diagnosis. The spectrum of histopathological changes includes diffuse hyperplasia and dysplasia of neuroendocrine cells, numerous neuroepithelial bodies, prominent carcinoid tumorlets, and even typical carcinoid tumors in the distal bronchi and bronchioles. Pathogenesis, treatment, and prognosis of the syndrome are unknown. Most patients have a relatively benign course characterized by many years of symptoms.

Bullous Disease of the Lung

David M. F. Murphy • Alfred P. Fishman

DEFINITION

A *bulla* is an air-containing space within the lung parenchyma that arises from destruction, dilatation, and confluence of airspaces distal to terminal bronchioles (Fig. 53-1). By definition, a bulla is larger than 1 cm in diameter, and its walls are composed of attenuated and compressed parenchyma.

Bullae occur in several different clinical contexts: (1) with emphysema ("bullous emphysema"), particularly with the acinar (paraseptal) variety; (2) with pulmonary fibrosis, as in the late stages of sarcoidosis or complicated pneumoconiosis; (3) in so-called "vanishing lung," in which the parenchyma is rapidly replaced by multiple bullae; and (4) in lungs that are otherwise normal ("bullous lung disease") and therefore likely secondary to a mechanism different from that of bullae occurring in conjunction with emphysema (Table 53-1).

Distinctions are drawn between bullae, blebs, and cysts (Table 53-2). A *bleb* is an accumulation of air between the two layers of the visceral pleura that arises when the thin covering of the bleb ruptures and permits entry of air (Fig. 53-1). In contradistinction, *cysts* are epithelial-lined cavities that may resemble bullae on the chest radiograph. Many fall into the category of developmental anomalies and include mixtures of mesenchymal and epithelial components that are normally present in the lung. The pathological nature of these cystic lesions is reflected in their names: "cystic adenomatoid malformations," "peripheral bronchogenic cysts," "congenital polycystic disease," and "atypical bronchopulmonary sequestration."

The designation *bullous disease* is reserved for multiple bullae in lungs that are otherwise normal. This entity is different in etiology and pathogenesis from that in which bullae occur in conjunction with underlying chronic obstructive pulmonary disease (COPD).

Confusion occasionally arises between the two entities because some pathologists are inclined to regard bullous disease as a subset of panacinar emphysema. However, this view is not useful clinically on at least three accounts: (1) panacinar emphysema tends to occur in the lower lobes, whereas bullous disease favors the upper lobes; (2) the natural history of the two disorders is quite different; and (3) panacinar emphysema has certain distinctive features not shared by bullous disease (e.g., a "winter tree" appearance on angiography). Bullae may occur not only as part of obstructive lung disease, but also as a complication of fibrotic lung disease (Table 53-1).

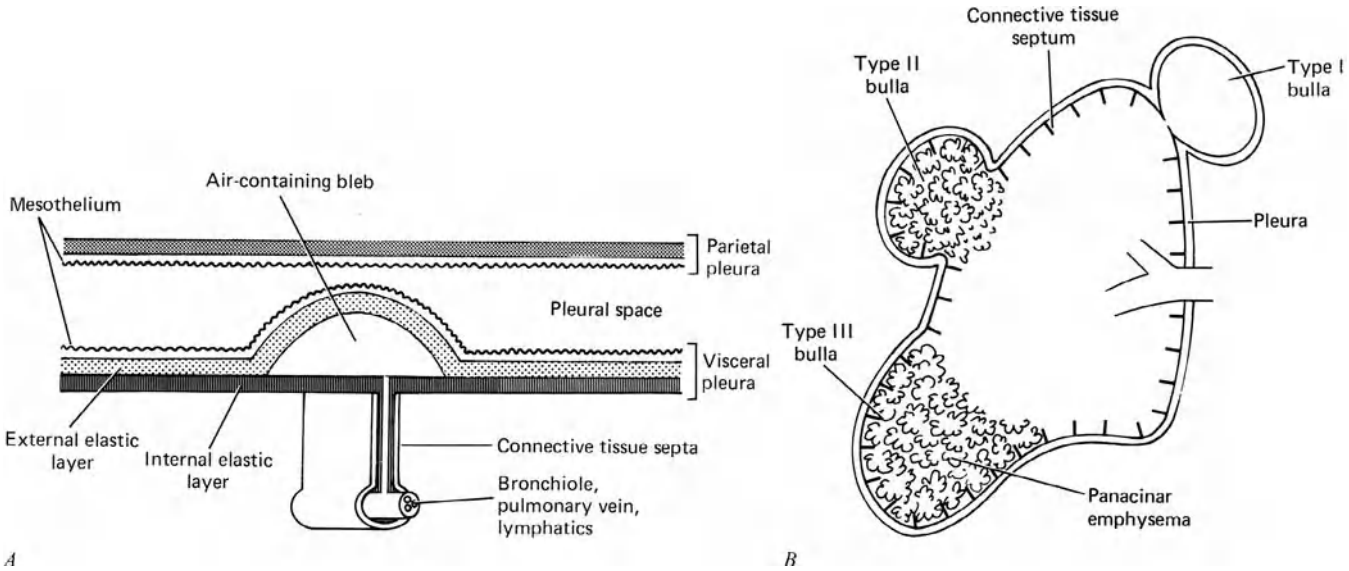

Figure 53-1 Blebs and bullae. *A.* Development of a bleb. A bleb is an accumulation of air within the pleura that is not confined by connective-tissue septa within the lung. Air that escapes within the substance of the lungs makes its way to the surface, separating the internal from the external elastic layers on the visceral pleura. *B.* Different types of bullae. In contrast to a bleb, a bulla is confined by connective-tissue septa of the lung and is deep to the internal elastic layer of the visceral pleura. Three different types of bullae are shown arising from a lung that has been removed from within the chest wall. A type I bulla is shown at the apex, a type II is in the middle zone, and a type III is arising at the base. The short dark lines denote connective-tissue septa. Panacinar emphysematous parenchyma is present within the types II and III bullae. *(Based on data from Reid L:* The Pathology of Emphysema. Chicago, Year Book, 1967, pp 211–240, *with permission.)*

ETIOLOGY OF BULLAE

Bulla may originate in a variety of clinical and pathogenetic settings: (1) with emphysema of distal acini (Fig. 53-2); (2) in the setting of cigarette smoking; (3) in conjunction with scar tissue formation, which "traps" areas of normal lung, enlarges airspaces by traction on surrounding intact alveoli, or produces retraction or shrinkage of intact walls of adherent alveoli; (4) in the setting of intravenous drug abuse; (5) as a result of chronic inflammation and destructive changes in terminal and first-order respiratory bronchioles, resulting in airspace distention from delayed emptying; and (6) with α_1-antitrypsin deficiency in the elderly.

CLASSIFICATION

Bullae are classified anatomically into three main types (Fig. 53-1*B*).

Type I bullae are characterized by a narrow neck that connects the bullae with the pulmonary parenchyma. This type of bulla may be caused by over-inflation of a volume of flawed lung tissue. The bullae behave like a paper bag that is extremely compliant until full, when it then becomes tense. The walls of type I bullae are thin, and their interiors are empty. Type I bullae are usually found at the lung apices and along the edges of the lingula and middle lobes. They often occur in association with paraseptal emphysema. Scanning electron microscopy has demonstrated that the thin neck is a consistent feature and that pleural mesothelial cells on the external surface are either reduced in number or completely absent; bundles of collagen fibers lie naked and separated from one other by small pores or crevices.

In contrast, type II bullae arise from the subpleural parenchyma and are characterized by a neck of panacinar emphysematous lung tissue. Also, the interior of these airspaces consists of emphysematous lung in which blood vessels are still present. In contrast to type I bullae, the outer wall is formed by pleura covered with intact mesothelial cells. Although connective-tissue septae are present within the bullae, they are not found in the wall. Type II bullae may occur anywhere in the lung, but they are most frequent in the upper lobe, at the anterior surface of the middle lobe, and over the diaphragm.

Type III bullae consist of slightly hyperinflated lung connected to the rest of the lung by a broad base extending deep into the parenchyma. This type is believed to represent an atrophic form of emphysema.

PATHOGENESIS

It is unclear how bullous lung disease develops. Several hypotheses have been proposed over the years, but none have

Table 53-1

Classification of Bullae

Primary
- Vanishing lung syndrome
- Single giant bulla
- Bullous lung disease

Secondary
- Emphysema
  - Paraceptal
  - Panacinar
  - Centriacinar

Pulmonary fibrosis
- Sarcoidosis
- Idiopathic pulmonary fibrosis
- Progressive massive fibrosis
- Conglomerate silicosis
- Fibrotic tuberculosis
- Other fibrotic lung disorders

Familial disorders
- α_1-antitrypsin deficiency
- Ehlers-Danlos syndrome
- Salla disease
- Marfan's syndrome
- Fabry's disease
- Cutex laxa

been proved. Among these are the following: (1) Weakness of the alveolar walls predisposes to the formation of bullae, particularly at the apices of the lungs, where pleural pressures are most negative. This theory underscores the proclivity of bullae for the upper lobes and stresses the influence of mechanical forces acting upon flawed tissue. (2) Inflammatory disease of a bronchiole leads to progressive air trapping and "tension airspaces." (3) Disordered collateral ventilation in some way produces the findings. (4) The same mechanisms responsible for generalized emphysema are operative in the formation of bullae. (5) Underlying paraseptal emphysema produces bullous disease.

Of all the hypotheses, that of underlying paraseptal emphysema is the most popular. The hypothesis envisages destruction of alveoli adjacent to connective septae or the pleura, with small "bubbles" developing along the edges of the lung. The pattern relates to the fact that capillaries in alveolar walls that abut connective-tissue septa are less numerous than elsewhere because of a sparse network of arterioles and arteries in peripheral alveoli. Consequently, these regions of the acinus have less vascularity and greater compliance.

Small bullae rarely become visible on the chest radiograph, but they are usually easily visible by computed tomography (Fig. 53-3). As a rule, small bullae usually produce no symptoms, signs, or discernible alterations in pulmonary function. However, rupture of one or more bullae may lead to spontaneous pneumothorax.

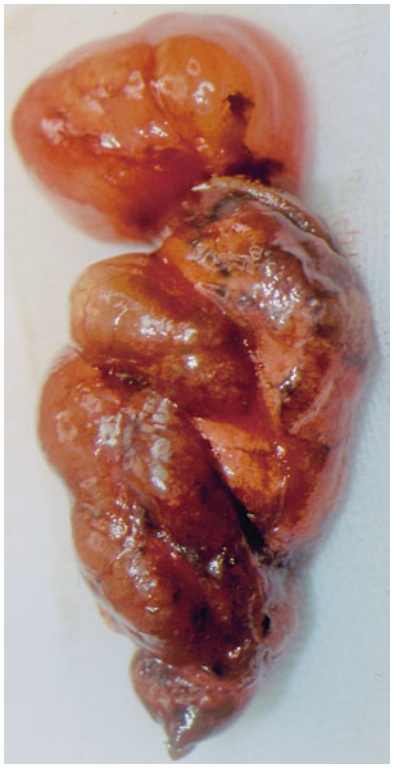
Dynamic computerized tomography and intra-bulla pressure measurements have raised questions about the theory that bullae are formed by positive pressure within the airspace. The lung surrounding a bulla is less compliant than the bullae itself; accordingly, the pressure necessary to inflate the surrounding lung is greater than that necessary to inflate the bulla. The pressure within a giant bulla has been found to be the same as pleural pressure. Therefore, when a bulla and its surrounding lung are exposed to the same negative pleural pressure, the bulla fills preferentially and completely like an inflated paper bag, prior to the surrounding lung inflating. Further inspiration increases the elastic recoil pressure, thereby exerting a greater retractive force on the lung parenchyma and enlarging the airspace. Nevertheless, bullae can be removed from within the lung while still maintaining their volume, indicating a positive intra-bulla pressure.

Bullae within the intact chest are molded and compressed to fit adjacent anatomic configurations. However, if the lung is released from these constraints (e.g., when removed from the chest cavity), bullae project as shiny bubbles

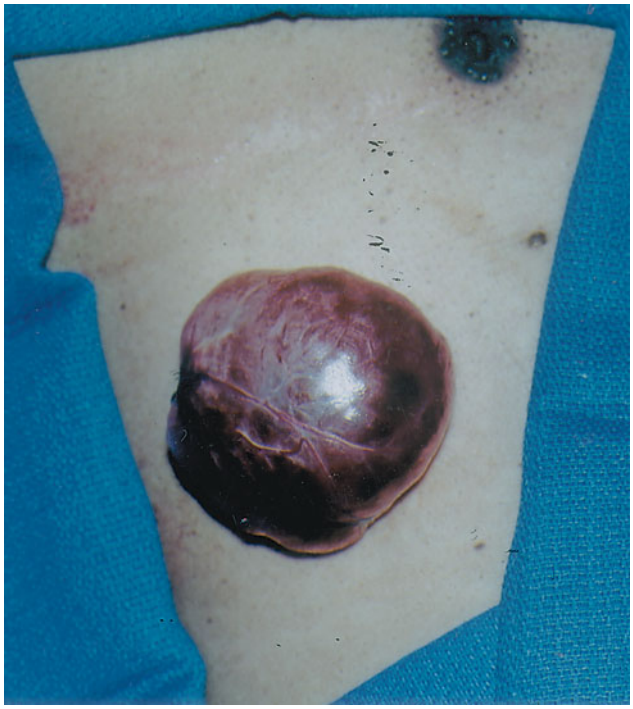
Table 53-2

Characteristics of Blebs, Bullae, and Cysts

	Bleb	**Bulla**	**Cyst**
Site	Within visceral pleura	Arises within secondary lobule	Lung parenchyma or mediastinum
Size	1–2 cm	1 cm to 75% of a lung	2–10 cm
Lining	Elastic laminae of the pleura	Connective tissue septa	Epithelium
Associated condition	Spontaneous pneumothorax	Bronchogenic carcinoma	Respiratory infection

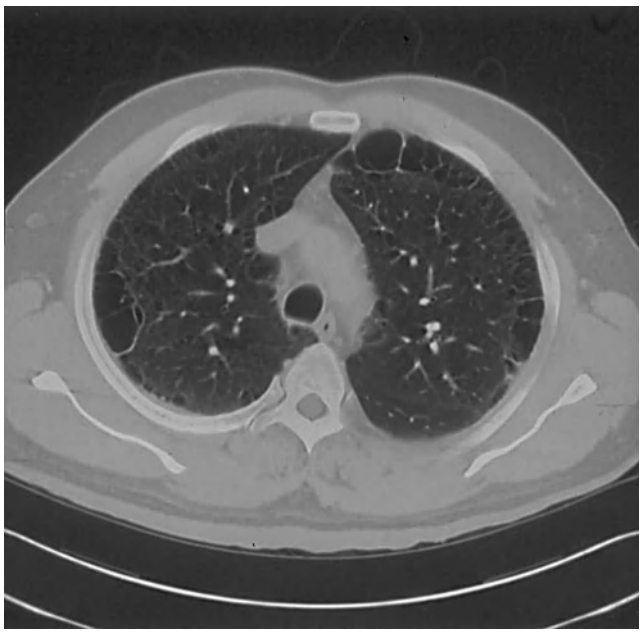


A

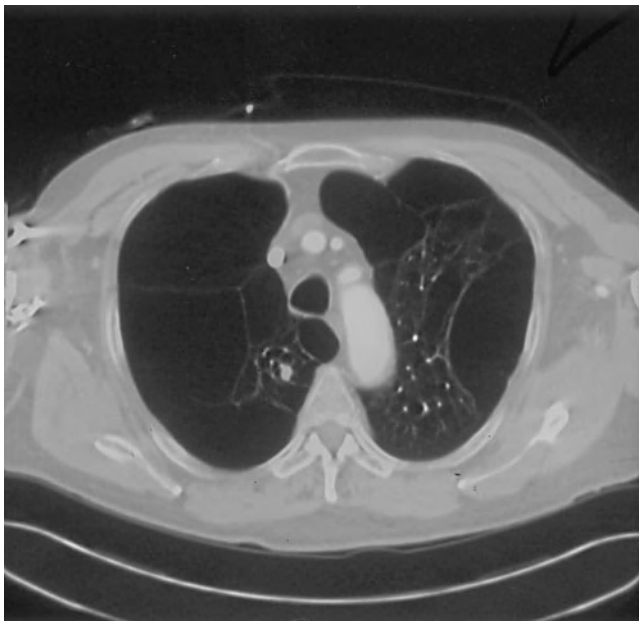


B

Figure 53-2 *A*. Surgically resected specimen with a bulla projecting from the lung surface. *B*. A bulla is shown projecting through a previous chest tube insertion site onto the surface of the skin.



A



B

Figure 53-3 *A*. CT image of the lungs showing paraseptal emphysema visible beneath the visceral pleura and an associated bulla. *B*. CT image of the lungs showing severe bullous emphysema with hairline markings identifying the walls of several bullae.

at the lung surface (Fig. 53-2). Within the thoracic cavity, large bullae cause crowding of adjacent lung parenchyma, and structures such as bronchi are displaced, stretched, and narrowed over the bullae surfaces. Very large airspaces can expand across the midline or even extend into the neck. Bullae represent more than just over-expanded alveoli, because the remnants of bronchioles and their accompanying vessels sometimes persist as trabeculae within the bullae.

Interlobular septae can become incorporated into the wall as the airspace expands from within the secondary lobule.

Two important risk factors for bullous emphysema are cigarette smoking and α_1-antitrypsin deficiency. Many patients with bullous emphysema are cigarette smokers, and most bullous lesions are associated with paraseptal or centriacinar emphysema. Although bullous emphysema is typically found in young males, elderly patients with α_1-antitrypsin deficiency who are lifelong nonsmokers may develop bullous changes in later life. A hereditary predisposition to bullous emphysema is also suggested by its association with a variety of rare familial disorders, including Fabry's disease, Salla disease, cutix laxa, Ehlers-Danlos syndrome and Marfan's syndrome. Giant bullous emphysema has also been reported with histological changes of placental transmogrification of the lung. The tight skin mouse, which has a dominant mutation for the elastase gene and is characterized by multiple connective-tissue abnormalities, serves as a unique model for bullous emphysema. In addition, pups, which have weakness of bronchial cartilage, may constitute a valuable model.

DISTRIBUTION OF BULLAE

As noted previously, the tendency for bullae to occur in the upper lobes is usually attributed to the greater mechanical stresses imposed on the lung apices than bases. Because intrapleural pressure near the lung apices is more negative than at the bases, apical alveoli are subjected to greater expanding stresses than are basal alveoli. Radioactive gas studies and in situ freezing techniques have demonstrated that alveoli in the upper lung zones are considerably larger than those in the lower zones. Gravity also plays a role, as the upright lung behaves like a coiled spring, which, when allowed to dangle in the upright position, shows larger gaps between coils at the top than the bottom.

Engineering techniques used to study the distribution of stresses in aircraft have been applied to the analysis of stresses on the lung. These have shown that the larger expanding stresses at the apices are directed primarily in a vertical direction, and to a lesser extent, laterally. The stresses tend to increase with expansion of the lung, but they are present also when the lung volume decreases below functional residual capacity (FRC). The increase in apical stress at low lung volumes has been attributed to an increase in the rigidity of the lungs as residual volume is approached.

ATMOSPHERIC PRESSURE EFFECTS ON BULLAE

Changes in ambient pressure have effects on bullae size that may be of clinical importance. Bullae, blebs, and cysts increase or decrease in size with decreases (e.g., with ascent to high altitude) or increases (e.g., with diving) in atmospheric pressure, respectively. Boyle's law governs the changes: at constant temperature, the volume of a given mass of gas varies inversely with its pressure. Expressed mathematically,

$$P_1V_1 = P_2V_2 \quad (1)$$

where

V_1 = initial volume
V_2 = final volume
P_1 = initial pressure
P_2 = final pressure

Therefore, a twofold increase in pressure results in a 50 percent decrease in volume.

In addition, Charles's law, which states that at constant pressure, the volume of a gas is proportional to its absolute temperature, should be considered in predicting behavior of bullae:

$$V_1/V_2 = T_1/T_2 \quad (2)$$

where

V_1 = initial volume
V_2 = final volume
T_1 = initial temperature, absolute
T_2 = final temperature, absolute

Combining Boyle's and Charles's laws results in the general gas law, which indicates the relationships among pressure, volume, and temperature for an air-filled structure:

$$P_1V_1/T_1 = P_2V_2/T_2 \quad (3)$$

Finally, an additional relevant consideration is that within body cavities, gas is not "dry," but rather, it is saturated with water vapor, the partial pressure of which is related to body temperature. Since normal body temperature is fairly constant at 37°C, the partial pressure of water vapor is also constant at 47 mmHg. Furthermore, since water vapor is not compressible, "wet" gases respond to pressure changes differently than dry gases. Expressed mathematically,

$$V_1(P_1 - PH_2O) = V_2(P_2 - PH_2O) \quad (4)$$

where

V_1 = initial volume
V_2 = final volume
P_1 = initial pressure of gas in the cavity, mmHg
P_2 = final pressure of gas in the cavity, mmHg
PH_2O = water vapor pressure

Thus, for a given reduction in pressure, wet gas expands to a greater extent than does dry gas. The magnitude of relative gas expansion is the ratio of the final volume of the gas (V_2) to the initial volume (V_1), which can be expressed as:

$$V_2/V_1 = (P_1 - PH_2O)/(P_2 - PH_2O) = (P_1 - 47)/(P_2 - 47) \quad (5)$$

Ascent to 39,000 feet in an unpressurized cabin would result in a fivefold increase in the volume of dry air and a sevenfold increase in the volume of wet air.

With reductions in ambient pressure, a pressure differential develops between the inside of a bulla and the external environment. The pressure differential is relieved if air can escape from the bulla to the external environment. If not, the volume of the bulla increases as ambient pressure declines.

Normally, changes in bulla volume are limited anatomically by the magnitude of chest cavity expansion. However, with chest over-expansion, or with an inability to decompress, increases in bulla volume may lead to its rupture and air entry into the extraalveolar compartments, including the mediastinum (pneumomediastinum), soft tissues of the chest or neck (subcutaneous emphysema), pleural space (pneumothorax), or vascular system (air embolism). The magnitude of the effect is related to the ratio of pressure of the gas within the bulla to ambient pressure.

To some extent, this kind of expansion occurs during commercial air travel, since airplanes are not pressurized to atmospheric pressure but rather to a cabin pressure equivalent to an altitude of 6000 to 8000 feet. However, the incidence of barotrauma in commercial flight is low, probably because bulla volume changes are small. In studies performed in subjects with blebs or bullae who are taken to altitudes of 18,500 feet (at an ascent rate of 1000 feet per minute), little increase in bulla volume is noted, probably reflecting good communication between bullae and airways and adequate pressure equalization. The fact that so little volume change occurs supports the "paper bag" hypothesis for bulla formation, rather than a "ball valve" mechanism. In contrast, with space travel, since spacecraft are maintained at atmospheric pressure, as long as decompression does not occur, no changes in the size of bullae are observed.

CLINICAL FEATURES

In asymptomatic individuals, bullae may be detected in the course of routine chest radiography. However, in some patients, bullae give rise to progressive dyspnea or chest pain (Fig. 53-4). On occasion, a patient with bullous lung disease develops sudden, severe breathlessness secondary to development of a spontaneous pneumothorax (Fig. 53-5) or sudden increase in bulla size due to air trapping. Development of bullae in individuals with obstructive airways disease tends to aggravate existing breathlessness, presumably because of a further decline in expiratory flow rates (Fig. 53-6).

In patients with known bullous disease, the onset of fatigue, generally accompanied by an increase in coughing and sputum production, usually heralds the presence of infection in a bulla. Occasionally, pleuritic chest pain is part of the syndrome, while fever and leukocytosis are often not prominent. A Gram's stain of the sputum often shows only mixed flora, without a predominant organism. Radiographically, infection is usually identified by the appearance of an air-fluid level (Fig. 53-7). Alternatively, the accumulation of fluid may be attributed to impeded drainage of the contents of the bulla secondary to obstruction of microscopic communications between the airspace and pulmonary parenchyma. In some instances, infection of a bulla causes it to disappear completely. More often, the air-fluid level persists for weeks or months after the infection has cleared.

The physical findings in a patient with one or more bullae usually reflect the overall state of the lungs. Only infrequently do giant bullae reach a size sufficient to cause a localized decrease in regional air entry, with absent breath sounds and increased resonance to percussion.

RADIOLOGIC FEATURES

Although routine chest radiography is the most practical method for identifying the presence of bullae, the technique discloses only about 15 percent of bullae identified at autopsy. In a given patient, serial radiographs taken over years are invaluable in tracing evolution of the disease. The presence of the condition is suggested by areas of increased radiolucency which are sharply delineated by fine radiopaque lines representing the walls of the bullae. These lines, or "hairline shadows," are composed of compressed and fused interlobular septae or pleura. Because the hairline shadows appear incomplete on the chest radiograph, they delineate only segments of the bulla wall (Fig. 53-5 *A* and *B*). Distinction between hairline shadows produced by a bulla, and thicker, sometimes irregular, walls of a cavity is usually not difficult. More troublesome is distinguishing bullae from cysts. The presence of other radiologic signs of emphysema or fibrotic lung disorders suggests that the cystic structure is a bulla. Similarly, distinguishing between a large bulla and pneumothorax may be challenging. Observation of "the double wall sign" (i.e., the presence of air on both sides of the bulla wall) may be helpful in identifying the findings as due to a bulla. The differential diagnosis of multiple, enlarged thin-walled airspaces on the chest radiograph in adults is shown in Table 53-3.

Fluid in Bullae

Although a localized air-fluid level on the chest radiograph raises the possibility of infection, the differential diagnosis includes lung abscess, tuberculosis, fungal disease, cavitary lung carcinoma, pulmonary hemorrhage within a bulla, congestive heart failure, and carcinoma arising from within a bulla (Fig. 53-8). The superimposition of a chronic infiltrate and an existing bulla raises the likelihood of concomitant fungal infection or tuberculosis.

The presence of a fluid level within a bulla, especially if the bulla is located subpleurally, occasionally prompts the mistaken diagnosis of a loculated hydropneumothorax. Computed tomography is helpful in separating these two conditions: when locules within the bulla fill with fluid, the

bulla shows characteristic strands or septae, sometimes in a "stepladder" configuration. In contrast, a loculated hydrothorax shows no septae.

Special Techniques

A chest radiograph obtained after forced expiration is sometimes helpful in demonstrating the presence of bullae: air trapping during the expiratory maneuver accentuates their outline by preventing a decrease in their size as the surrounding lung empties. Large bullae sometimes displace the mediastinum contralaterally and may even compress the opposite lung.

Computed Tomography

Computed tomography (CT) provides valuable anatomic information about the size, number, and relationships of bullae, as well as crowding of adjacent lung and disposition of the pulmonary vasculature. Bullae are identified as areas of radiolucency that usually do not contain blood vessels and that are confined by visible walls. High-resolution computed tomography (HRCT) shows that large bullae are frequently associated not only with distal acinar (paraseptal) emphysema, but also with centri-acinar emphysema—the type of emphysema usually associated with cigarette smoking.

These observations are consistent with the hypothesis that peripheral airspaces in paraseptal emphysema may coalesce to form larger bullae that may crowd normal adjacent lung. In addition, CT has shown that when bullae occur in the context of generalized emphysema, the extent of bullous emphysema correlates poorly with measurements of pulmonary function, and that the main determinant of

respiratory function is the severity of emphysema in the bullous-free parts of the lung (Fig. 53-9). In contrast, the severity of emphysema in nonbullous lung, as assessed by CT-density histograms of the lung, correlates well with measurements of air flow limitation and diffusing capacity.

CT has been used to create three-dimensional reconstructions of bullae, which can then be used to calculate bullae volumes.

Nuclear Medicine Techniques

Lung scanning using radionuclide-based techniques may provide useful preoperative information in evaluating patients with bullous lung disease (Figs. 53-10 and 53-11). A lung perfusion scan provides a semiquantitative assessment of regional blood flow; results of ventilation scans vary with the technique: a single-breath scan using ^{133}xenon often fails to demonstrate ventilation of a bulla, whereas a continuous ventilation scan often shows slow filling and emptying of the structure. Complete lack of communication between the airways and bulla is reflected in the absence of filling during all phases of the continuous ventilation scan.

Very occasionally, angiography may be necessary to provide additional information on the pulmonary vasculature (Fig. 53-11). Similarly, a regional bronchogram at the time of bronchoscopy is sometimes helpful in assessing the state of the airways in compressed lung.

PATHOPHYSIOLOGY

Clinical evaluation of bullous lung disease is aided by assessment of pulmonary function, pulmonary mechanics, exercise performance, and the pulmonary circulation.

Pulmonary Function Tests

Pulmonary function tests have considerable practical value in distinguishing between individuals with localized bullae in whom intervening lung is normal (bullous disease), and those in whom localized bullae are part of obstructive airways disease (bullous emphysema) (Tables 53-4 and 53-5). The distinction is important, since those with obstructive airways disease are generally poor surgical candidates because of impaired pulmonary function.

Figure 53-9 CT image showing a giant right upper lobe bulla compressing adjacent pulmonary parenchyma. The bulla was surgically resected with significant improvement in pulmonary function. See Table 53-7.

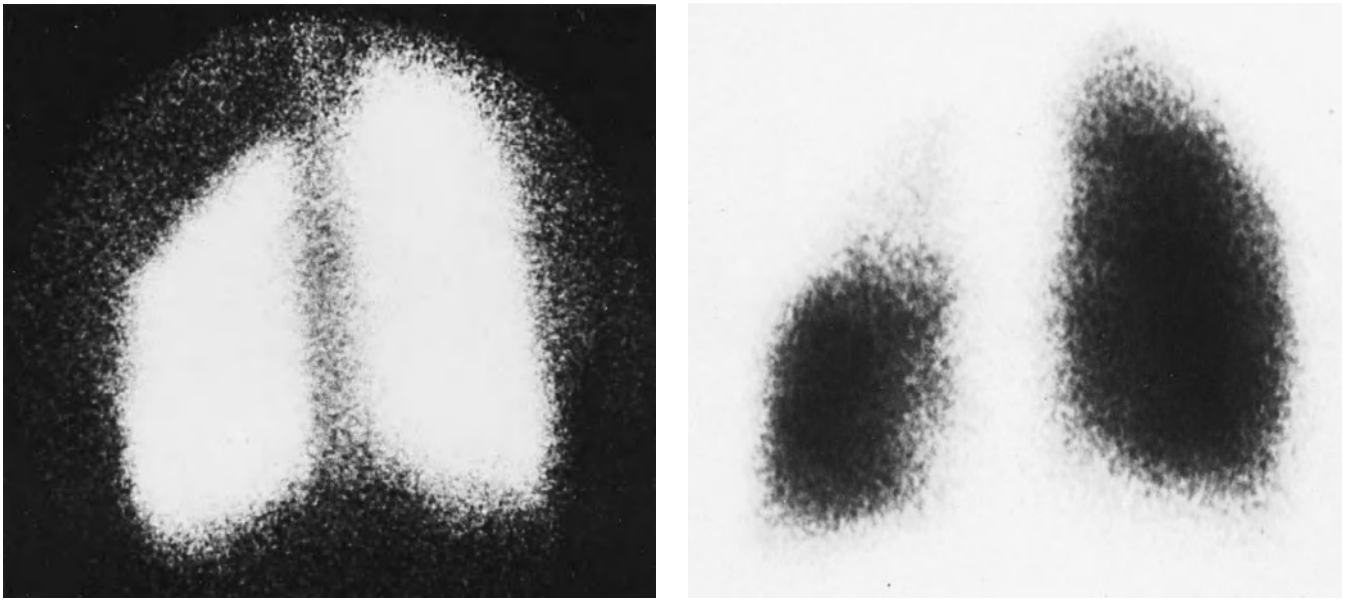
In individuals with bullous disease, the volume of air in the lungs can be estimated using plain radiography, CT, body plethysmography, or other pulmonary function test methods for determining lung volume, including closed circuit (helium dilution) and open circuit (nitrogen washout) techniques. The volume of air trapped in a bulla can be determined as the difference between the functional residual capacities determined plethysmographically and by open or closed circuit methods (Table 53-6). This difference is due to the relative inability of the inert gas used in the circuit methods to enter the bulla.

Although the nitrogen washout curve is usually normal, the concentration of N_2 in alveolar gas at the end of the test's 7-minute period of breathing 100 percent O_2 is often abnormal. Finally, somewhat counterintuitive is the observation that expansion of a large bulla may produce a restrictive pattern on pulmonary function testing—presumably as a result of the bulla compressing intervening normal lung.

Pulmonary Mechanics

Distinction between widespread obstructive airways disease with concomitant bullae and bullous lung disease has practical significance, since surgical lung resection in generalized emphysema offers a less certain therapeutic response than does resection of giant bullae in the absence of widespread obstructive lung disease.

As large bullae expand, they initially cause relaxation of adjacent elastic lung tissue; with continued expansion, adjacent lung is compressed. Relaxation of the surrounding pulmonary parenchyma results in a decrease in radial traction on airways, thereby increasing air flow resistance. The effects of bullectomy on respiratory mechanics are inconsistent. In some patients, removal of a large bulla increases lung static elastic recoil and decreases airways resistance (Table 53-7); in others, bullectomy decreases elastic recoil pressure.



A *B*

Preoperative perfusion lung scan using ^{131}I-macroaggregated albumin. Blood flow is absent in the left upper zone while it is maintained at the left base. *(Courtesy of Dr. A. Alavi.)*

As a practical matter, the diffusing capacity, rather than lung elastic recoil, is usually determined to aid in distinguishing between widespread emphysema and localized bullae; indeed, the diffusing capacity correlates better with morphologic estimates of emphysema than do most other tests. Although the combination of a decreased diffusing capacity and reduced static elastic recoil pressure favors the diagnosis of widespread emphysema rather than localized bullae, both measurements may also be decreased by bullae that compress adjacent normal lung.

Respiratory muscle strength, assessed by measurements of maximal inspiratory and transdiaphragmatic pressures, improves after bullectomy in some patients with bullous emphysema.

Exercise Testing

In patients with a few circumscribed bullae and otherwise normal lungs, exercise testing reveals that the alveolar-arterial difference in Pa_{O_2}, ratio of dead space to tidal volume, diffusing capacity, and arterial oxygenation remain normal or near normal with exercise. On the other hand, in patients in whom bullae are associated with panacinar emphysema, the alveolar-arterial difference in Pa_{O_2} is widened at rest and during exercise. The latter group of patients also may develop arterial hypoxemia during exercise. The Pa_{CO_2} tends to hover around the upper limit of normal at rest and during exercise, and the ratio of dead space to tidal volume is higher than in patients with normal intervening lung. The steady-state diffusing capacity is also reduced and fails to increase normally during exercise.

Patients in whom bullae are associated with chronic bronchitis also show a widened alveolar-arterial difference in Pa_{O_2} and an increase in the ratio of dead space to tidal volume at rest. However, in these patients the decrease in Pa_{O_2} during exercise is modest, even though the Pa_{CO_2} at rest is abnormally high and increases further during exercise (indicating progressive alveolar hypoventilation).

Pulmonary Circulation

As a rule, resting pulmonary arterial pressure and blood flow are within normal limits in patients with bullous lung disease (i.e., the bullae act like "amputated" segments of lung); the volume of the vascular bed available for recruitment as cardiac output increases is limited. However, in patients in whom bullous disease has severely reduced the extent of the pulmonary vascular bed, pulmonary arterial pressure may be elevated at rest and during exercise; in a few instances, pulmonary and cor pulmonale may be observed. Exercise in bullous lung disease is generally associated with an excessive increase in pulmonary arterial pressure as increases in pulmonary blood flow are not effectively accommodated by the restricted vascular bed. Underlying pulmonary disease further exaggerates the increase in pulmonary artery pressure during exercise.

COMPLICATIONS

The major complications of bullous lung disease are infection of the bulla, chest pain, hemorrhage, spontaneous pneumothorax, and lung cancer.

True infections within bullae are rare. The presence of an air-fluid level in a bulla usually is attributable to surrounding pneumonitis. Fluid within the airspace is usually sterile, is frequently resorbed, and may be associated with shrinkage and complete resolution of the bulla. Occasionally, a fungus (usually *Aspergillus* species) colonizes a bulla and may go on to form a mycetoma or "fungus ball" which can lead to hemoptysis.

Chest pain may occur with a bulla and is attributed to over-distention of the structure. The pain is angina-like and located retrosternally. The symptom is sometimes so severe as to constitute an indication for surgical intervention.

Hemoptysis, which is occasionally massive, can result from rupture of blood vessels within the walls of bullae. Pneumothorax secondary to bulla rupture into the pleural space can severely compromise a patient's ventilatory reserve in the setting of generalized emphysema. However, bullae per se do not appear to indicate a predisposition to recurrent pneumothoraces.

Recurrent spontaneous pneumothorax also may be a complication of paraseptal emphysema, particularly in patients who continue to smoke. Lung density measurements in spontaneous pneumothorax demonstrate air trapping, suggesting a ball-valve mechanism due to peripheral airway inflammation, rather than rupture of preexisting bullae. Patients with ruptured bullae also tend to have prolonged air leaks, along with pleural and parenchymal infections.

Primary lung cancer has been reported to be associated with bullous lung disease. In many instances, the bullae are detected only by CT. The increased incidence of lung cancer may be due to the fact that lung cancer occurs more frequently in fibrotic lungs which are, themselves, predisposed to development of bullae. Other explanations for the increased incidence of malignancy include dystrophic changes in lung parenchyma caused by bullous disease or persistence of carcinogens in poorly ventilated bullae.

TREATMENT

Many patients with bullous lung disease can be managed medically. Because the natural history of a bulla is unpredictable, patients with bullous disease should be monitored by chest radiography at regular intervals to ensure that the disease is stable. Occasionally, bullae enlarge suddenly and rapidly for no apparent reason; alternatively, they may shrink or disappear, usually as a result of infection.

Medical Management

The finding of a bulla in an asymptomatic patient calls for reassurance, a recommendation for annual chest radiography, advice to stop smoking, and an alert to the need for a prompt visit to a physician should symptoms develop. Activities that promote rupture of bullae (e.g., contact sports and scuba diving) should be proscribed. Chronic bronchitis, asthma, or emphysema associated with bullae require treatment in their own right. For patients with α_1-antitrypsin deficiency augmentation therapy with antiproteases may be appropriate.

Infection of a bulla requires sputum specimens for culture and Gram's stain. Fiberoptic bronchoscopy is usually performed if sputum samples fail to disclose the nature of the infection; sterile sheathed catheters may be helpful in obtaining noncontaminated respiratory tract secretions for culture. Direct sampling of fluid from within the bulla is rarely useful in making the diagnosis.

Once the diagnosis of an infected bulla has been established, treatment with antibiotics and chest physiotherapy is begun. The choice of antibiotic depends on the findings on Gram's stain and sputum cultures. Treatment is sometimes prolonged and may require parenteral administration, since poor drainage of the bulla inevitably slows resolution of the disease process. The course of the infection should be followed by interval chest radiographs. Most infections eventually respond to medical therapy, but radiographic evidence of an air-fluid level often persists after the infection has resolved. An infected bulla containing a very large amount of fluid may require surgical intervention in order to minimize the risk of the fluid being decanted into the adjacent or contralateral lung and airways.

Surgical Management

In patients with giant bullae who are selected carefully for the presence of localized disease and well-preserved pulmonary function, surgical intervention may provide symptomatic relief, extend exercise tolerance, and improve spirometry, diffusing capacity, and ventilation-perfusion matching.

In general, surgical outcome depends on the size and number of resected bullae, condition of compressed lung, status of the contralateral lung, and development of postoperative complications.

Radionuclide scanning and CT are helpful in preoperative assessment of the compressed lung. Pulmonary angiography is now rarely employed for this purpose.

Localized Bullae with Normal Intervening Lung (Bullous Lung Disease)

In patients with localized bullae and normal intervening lung, acute complications (e.g., spontaneous pneumothorax

or massive hemorrhage) may require urgent surgical intervention, even though the bullae may be small. In non-urgent circumstances, indications for surgical intervention include the following: (1) enlarging bullae that cause dyspnea; (2) enlarging bullae that compress surrounding lung tissue; (3) bullae that cause recurrent pneumothoraces; (4) bullae that become infected and fail to respond to medical treatment; (5) bullae causing acute respiratory insufficiency; (6) bullae that become acutely distended; (7) enlarging bullae that produce severe chest pain; (8) bullae associated with primary lung cancer; and (9) bullae containing very large fluid collections.

The surgical approach depends on the location of the bullae. Median sternotomy, which is associated with less postoperative morbidity than standard thoracotomy, may be appropriate for bilateral upper lobe bullae. As a rule, small wedge excisions or plications of large bullae produce larger increments in expiratory flow rate than lobectomy and may be performed with using video-assisted thoracoscopy (see below). Surgical techniques developed to reduce air leaks following resection of emphysematous lung include use of "buttressed stapling" and application of fibrin glues. Bullectomies are now sometimes combined with lung volume reduction surgery.

The best functional improvement after surgery occurs when the bulla comprises 50 to 100 percent of the hemithorax (Fig. 53-12), where postoperative increments in forced expiratory volume in 1 second (FEV_1) range from 50 to 200 percent. Better results may be anticipated when the involved lung contributes little to overall ventilation, when large volumes of trapped air exist, and when there is crowding and compression of normal lung parenchyma.

Surgical techniques involve buttressing staple lines using bovine pericardium and use of fibrin glues and pleural tents. Attention to postoperative management is critical to good surgical outcomes and includes underwater thoracostomy suction, early and vigorous chest physiotherapy, and early ambulation. Regular postoperative chest radiographs

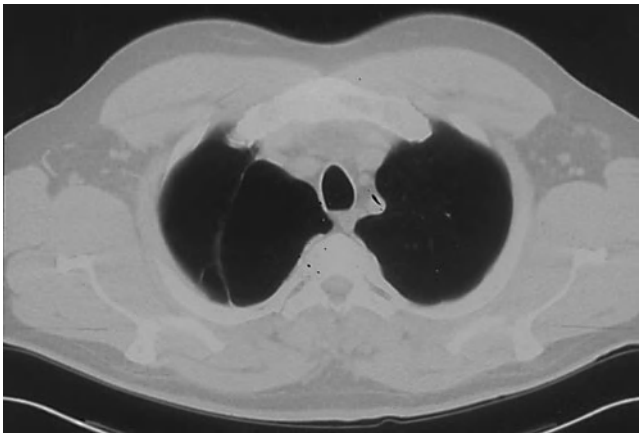

Figure 53-12 CT image showing a single right upper lobe bulla in the medial portion of the lung. See Table 53–6.

identify residual airspaces. Prolonged air leaks may be managed using Heimlich valves following patient discharge from the hospital.

Postoperative complication rates tend to be high (up to 80 percent). Not surprisingly, persistent air leaks and pleuropulmonary infections are common; atrial fibrillation, need for prolonged postoperative mechanical ventilation, massive subcutaneous emphysema, and retention of respiratory secretions also occur.

Overall surgical mortality may be as high as 9 percent, but it is usually approximately 2 to 5 percent. The most common causes of death are infection and respiratory failure; sudden development of a contralateral pneumothorax and herniation of a bulla across the mediastinum are uncommon causes.

Five-year survival is approximately 90 percent, and significant increments in FEV_1 persist in over 80 percent of patients. Residual volume usually returns to baseline. Improvements in dyspnea also persist at 3 years in over 80 percent of patients.

Localized Bullae with Abnormal Intervening Lung

As a rule, bullae that complicate either obstructive or fibrotic lung disease do not require surgical intervention unless a life-threatening complication arises.

When bullae occur in conjunction with widespread panacinar emphysema, usually, but not necessarily, little improvement is seen with bullectomy. This is particularly true in COPD when the FEV_1 is less than 35 percent of predicted. Elderly individuals in whom the bullae are associated with widespread emphysema frequently have a high surgical mortality. When bullae are associated with chronic bronchitis, improvement after surgery is generally short-lived (i.e., less than 6 months). A prolonged, productive cough and secondary pulmonary hypertension are associated with a poor prognosis. The outlook after surgery is better for those who stop smoking than for those who do not (Table 53-7).

Video-Assisted Thoracoscopy

Video-assisted thoracoscopy has become a common surgical approach in plication of bullae. Thoracoscopy requires careful general anesthetic management and introduction of a double-lumen endotracheal tube to permit collapse of one lung. Once a bulla has been identified, the lung is deflated and the bulla excised using a stapling device. Mortality and complication rates are usually lower than with other surgical approaches.

Laser Surgery

Current laser-based surgical techniques have evolved since 1990, when a low energy carbon dioxide laser was used to ablate pleural blebs in treatment of spontaneous pneumothorax. Subpleural bullae collapse when exposed to laser energy, as do multiple bullae occurring in the setting of widespread emphysema. Complications of the technique include postoperative air leaks, bleeding, and acute lung injury.

Patients with large bullae associated with crowding of adjacent lung structures, upper lobe predominance, and minimal underlying emphysema appear to experience the greatest improvement in FVC, FEV_1, maximal voluntary ventilation (MVV), specific airway conductance, and residual volume.

Both the argon beam coagulator and yttrium-aluminum-garnet (YAG) laser have been used in conjunction with video-assisted thoracoscopy in ablating bullae in treatment of bullous emphysema. Procedure-related mortality in using these two devices is 0 and 10 percent, respectively.

External Drainage: Monaldi Procedure

In 1938, Monaldi described a two-stage technique for the open intubation and external drainage of tuberculous cavities. The procedure was subsequently applied to treatment of pyogenic lung abscesses and bullae as a single-stage procedure—endocavitary aspiration with sclerosis and pleurodesis, known as the Brompton technique. The technique is sometimes useful in patients whose pulmonary function precludes thoracotomy. Data indicate a 28 percent improvement in FEV_1 and 12 percent improvement in total lung capacity following the procedure. The mortality rate is approximately 7 percent. Predictors of a poor prognosis are an FEV_1 less than 0.5 L and a Pa_{CO_2} greater than 49 mmHg.

Reduction Pneumoplasty and Lung Transplantation

Other potential treatments for giant bullae include reduction pneumoplasty, following which both symptomatic and functional improvements have been reported. Reduction pneumoplasty is most effective when bullae are larger than one-third of a hemithorax, adjacent lung is compressed, and the FEV_1 is less than 50 percent of predicted. However, the duration of improvement and the late morbidity and mortality are not well defined.

CHAPTER

Occupational Lung Disorders: General Principles and Approaches

Mridu Gulati • Carrie A. Redlich

Hazardous exposures in the workplace and elsewhere in the environment continue to contribute to the burden of lung disease. With increasing concerns regarding the health effects of environmental and occupational exposures, such as exposures following the World Trade Center collapse, clinicians must be prepared to recognize, diagnose, and manage occupational and environmental lung diseases. As patient access to sources of information regarding such exposures expands, health care providers must also be prepared to provide preventive advice and to address patients' concerns regarding such exposures. Most respiratory diseases, including asthma, chronic obstructive pulmonary disease (COPD), interstitial lung disease, and lung cancer may be caused or exacerbated by factors in the workplace, but rarely are such disorders distinguishable pathologically or clinically from idiopathic or nonoccupational causes. Thus a high level of suspicion and knowledge of the basic approaches used in the diagnosis and management of occupational and environmental disorders is essential for all practitioners. This chapter provides an overview to these approaches. Since the last edition, a growing body of literature has expanded our understanding of several aspects of occupational and environmental lung diseases, including a substantial contribution of workplace exposures to the development of COPD and asthma, adverse health effects related to indoor and outdoor air pollution, and greater recognition that work-exacerbated asthma can be as disabling

as primary occupational asthma. Additional information can be obtained from several excellent recent texts on this topic.

CLASSIFICATION OF OCCUPATIONAL AND ENVIRONMENTAL LUNG DISEASE

Environmentally induced lung diseases can be classified according to several schemes. One useful approach is to classify them by clinical presentation or disease, as shown in Table 54-1. A given exposure (asbestos, cobalt, etc.) can cause more than a single disorder. When one is examining a patient, it can also be helpful to consider occupational lung diseases by types of exposures that can cause lung disease, such as mineral dusts (asbestos, silica, coal), biologic factors (animal exposures, microbial agents), metals (beryllium, cobalt, aluminum), or inorganic gases (carbon monoxide, chlorine, nitrogen oxides), or by the type of industry associated with selected respiratory problems, such as mining, agriculture, forestry, or welding. For patients presenting with interstitial lung disease, a classification scheme based on histological pattern, as shown in Table 54-2, may facilitate diagnosis and management.

Occupational and environmental exposures play an important role in many lung disorders. However, accurate estimates of the contribution of such factors to specific lung diseases can be difficult to find. It is generally believed that under recognition and under reporting of occupational lung diseases are widespread. Although historically the pneumoconioses have been the most commonly diagnosed occupational lung diseases, occupational airways diseases have become the most prevalent occupational lung disorder in developed countries. Worldwide, silicosis remains the most common occupational lung disease. In a few instances, such as the rare tumor mesothelioma, most cases can be attributed to occupational exposure to asbestos. However, the contribution of

Table 54-1

Classification of Occupational Lung Disorders

Major Disease Category	Representative Causative Agents
Upper respiratory tract irritation	Irritant gases, fumes, dusts
Airway disorders	
Occupational asthma	
Sensitization	
Low molecular weight	Diisocyanates, anhydrides, wood dusts
High molecular weight	Animal-derived allergens, latex
Irritant-induced, RADS	Irritant gases, smoke
Byssinosis	Cotton dust
Grain dust effects	Grain
Chronic bronchitis/COPD	Mineral dusts, coal, fumes, dusts
Acute inhalation injury	
Toxic pneumonitis	Irritant gases, metals
Metal fume fever	Metal oxides: zinc, copper
Polymer fume fever	Plastics
Smoke inhalation	Combustion products
Hypersensitivity pneumonitis	Bacteria, fungi, animal proteins
Infectious disorders	Tuberculosis, viruses, bacteria
Pneumoconioses	Asbestos, silica, coal, beryllium, cobalt
Malignancies	
Sinonasal cancer	Wood dust
Lung cancer	Asbestos, radon
Mesothelioma	Asbestos

Note: Abbreviations: RADS = reactive airway dysfunction syndrome; COPD = chronic obstructive pulmonary disease.

Table 54-2

Histologic Classification Lung Disorders

Selected Histologic—Clinical Descriptions	Selected Associated Occupational Exposures
Usual interstitial pneumonitis/idiopathic pulmonary fibrosis	Asbestos, radiation
Nonspecific interstitial pneumonitis	Organic antigens
Acute interstitial pneumonitis (diffuse alveolar damage)	Irritant inhalational injury—NO_x, SO_x
Hypersensitivity pneumonitis	Organic antigens (i.e. farmer's lung, wood worker's lung), Animal antigens (birds), Metal working fluids Chemicals—isocyanates, anhydrides
Sarcoid-like granulomatous lesions	Beryllium, organic antigens, aluminum
Giant interstitial pneumonitis	Cobalt (hard metal)
Bronchiolitis obliterans	Toxic fumes (nitrogen dioxide, sulfur dioxide, diacetyl-popcorn lung), painting textiles
Alveolar proteinosis	High level exposure to silica
Diffuse alveolar hemorrhage	Acid anhydrides

occupational and environmental factors to most other lung diseases is much harder to determine. For example, estimates of the proportion of lung cancers attributable to occupational exposures have ranged from 1 to over 40 percent. Occupational factors are estimated to account for 10 to 20 percent of cases of asthma in adults. A growing literature supports the conclusion that occupational exposures account for about 15 percent of COPD, and a higher proportion of COPD in nonsmokers. However, clinicians rarely diagnose occupational asthma, COPD, or lung cancer, especially in patients who smoke.

BASIC PRINCIPLES OF OCCUPATIONAL AND ENVIRONMENTAL LUNG DISEASE

Certain principles apply broadly to the full range of respiratory disorders caused by inhalation exposure to agents in the workplace or environment:

1. While a few environmental and occupational lung diseases may present with pathognomonic features, such as mesothelioma, most are difficult to distinguish from disorders of nonenvironmental origin. In addition, most lung disorders can be caused or exacerbated by environmental or occupational exposures. Thus, environmental and occupational triggers must be constantly sought in the evaluation and management of pulmonary disorders.
2. A given substance in the workplace or environment can cause more than one clinical or pathologic entity. For example, cobalt exposure can cause interstitial lung disease and airway disease.
3. The etiology of many lung diseases may be multifactorial, and occupational factors may interact with other factors. For example, the risk of developing lung cancer in asbestos-exposed workers who smoke is much greater than in those exposed to either asbestos or cigarettes alone.
4. The dose of exposure typically is an important determinant of the proportion of people affected and the severity of disease. Higher doses of exposure usually result in more affected individuals or greater disease severity. Dose generally correlates with severity in patients experiencing nonimmunologic direct toxicity, such as chemical toxic pneumonitis, asbestosis, or silicosis. In those with cancer or immune-mediated disorders, dose more commonly affects incidence than severity.
5. Individual differences in susceptibility to exposures exist. Adverse effects occur in some persons,

while others with similar exposure are spared. Host factors that determine susceptibility to environmental agents are poorly understood but probably include, genetic factors and also acquired factors such as diet, and the presence of other lung diseases and exposures. Occupational diseases, especially immune-mediated processes such as chronic beryllium disease or occupational asthma, can occur or progress at low levels of exposure, below government-set exposure standards.

6. The effects of a given exposure occur after the exposure with a predictable latency interval. For acute diseases such as toxic pneumonitis, there is a short and usually predictable period between exposure and resultant clinical manifestations, which facilitates recognition of a causal relationship between exposure and disease. When symptoms or signs are recurrent with repeated exposures, as with occupational asthma, this temporal relationship can help establish the diagnosis. For chronic diseases such as cancer or most pneumoconioses, long latency periods between the first exposure and subsequent clinical manifestations are common. Consequently, the patient's exposure to the offending agent(s) may have ceased long before the onset of disease, making the diagnosis of such diseases particularly challenging.

IMPORTANCE OF OCCUPATIONAL AND ENVIRONMENTAL LUNG DISEASES

There are several compelling reasons to search for an occupational or environmental cause in all cases of pulmonary disease. First, knowledge of cause may affect patient management and prognosis, and may prevent further disease progression in the affected person. Second, establishment of cause may have significant legal, financial, and social implications for the patient. Third, the recognition of occupational and environmental risk factors can also have important public health and policy consequences. For example, a larger population at risk may benefit from the initiation of preventive measures. In addition, new associations between exposure and disease may be identified, such as the growing recognition that occupational exposures contribute to COPD. Last, occupational and environmental lung diseases can also serve as important disease models. For example, chronic beryllium disease may serve as a model for sarcoidosis.

ESTABLISHING A CAUSE

Diagnostic Criteria

To establish whether a lung disease has an occupational or environmental origin, the disease should first be defined and characterized, and then the degree to which occupational or environmental exposures are causative or contributory should be determined. The following criteria are used to determine whether a disease is caused or exacerbated by agents in the workplace or environment:

1. The clinical presentation and work-up are consistent with the diagnosis.
2. A causal relationship between the exposure and the diagnosed condition has been previously established or strongly suggested in the medical, epidemiological, or toxicological literature (see below).
3. There is sufficient exposure to cause the disease (see below).
4. The details of the particular case, such as the temporal relationship between exposure and disease, are consistent with known information about the exposure-disease association.
5. There is no other, more likely diagnosis.

In addition, for acute diseases such as occupational asthma, improvement away from the exposure or reproduction of the disease manifestations by re-exposure to the suspected agent can provide additional evidence to support the diagnosis. The degree of uncertainty in diagnosing occupational illnesses is generally substantially greater than in other medical settings—a source of uneasiness for clinicians. For example, in the United States, for most workers' compensation systems, a disease is considered occupational if "more probably than not" (greater than 50 percent chance) it is work related.

Determination of Causal Relationship

Three main types of information have been used to support a causal relationship between an exposure and a respiratory condition: case series or reports, epidemiological studies, and toxicology animal studies. Clinical studies of similarly exposed patients have identified potential occupational causes of lung disease, which have then undergone further epidemiological investigation. The clinical practice of occupational and environmental lung disease relies heavily on the field of epidemiology, as well as toxicology to provide databases for diagnostic decision making.

Epidemiology and Toxicology

Epidemiology focuses on the causes of disease in populations. Occupational and environmental epidemiological studies (e.g., cohort or case-control studies) can demonstrate associations between certain exposures or jobs and adverse effects, using industrial hygiene (exposure) records and data such as medical surveillance. Occupational and environmental epidemiological studies may also provide useful information about the magnitude of the risk, the amount of exposure that can cause or exacerbate disease, and the latency between exposure and disease, and whether control measures are effective in reducing the risk of disease. There are three basic study designs of epidemiological studies: (1) cross-sectional observation of a population at one point in time; (2) longitudinal observation of a group (or cohort) over time; and (3)

case control studies comparing cases with the disease to controls. All give some measure of the relative risk of disease in the exposed group compared to the nonexposed group. A relative risk or odds ratio greater than 2 implies that, more probably than not, the abnormality observed can be attributed to the exposure in question.

Toxicology studies are especially relevant for the thousands of new chemicals introduced into production each year, in which human data are often limited. Toxicology studies use animal and in vitro data to characterize the toxicity of individual chemicals. Such studies elucidate dose-response relationships, and the primary organ of toxicity for a given exposure. Serious limitations include potential differences between species, and the use of single or high-dose exposures that do not simulate the long-term, chronic, lower-level mixed exposures seen with humans.

CLINICAL APPROACH TO THE PATIENT

General Approach

There are two important phases in the work-up of any patient with a potential occupational or environmental lung disease. First, as with any patient presenting with a potential disorder of the respiratory tract, its nature and extent should be defined and characterized, regardless of the suspected origin. Although knowledge of exposures may guide the order of the diagnostic work-up, it is important to establish the basic disorder before proceeding to investigate the etiology of the process. Second, the extent to which the disease or symptom complex is caused or exacerbated by exposure(s) at work or in the environment must be determined.

The initial approach to such patients includes a detailed history, physical examination, appropriate laboratory testing, chest radiograph, and spirometry. Initial exposure information can be used to direct the sequence of the work-up and obviate unnecessary procedures when the diagnosis is fairly straightforward. If the initial evaluation does not fully explain the patient's symptoms, other tests are available to better characterize the nature and extent of the respiratory disorder, including additional physiological testing, computed chest tomography, cardiopulmonary exercise studies, bronchoscopy, open lung biopsy, and immunological studies. However, few are specific for any given occupational or environmental diagnosis.

Prior medical records can be extremely helpful in the evaluation of a patient with a potential occupational or environmental lung disease. Such records can establish the patient's complaints at earlier points in time, may provide objective data such as prior pulmonary function testing or chest radiographs for comparison, and may clarify temporal relationships between exposure and effect and rate of progression of disease; factors which may help establish cause. Medical and spirometry surveillance records, if available, can be quite informative in the diagnostic work-up of occupational diseases.

The Occupational and Environmental History

The occupational and environmental history is the single most important tool to determine whether a respiratory problem may be related to an occupational or environmental exposure. A detailed occupational history includes a chronological list of all jobs, including job title, a description of job activities, potential exposures at each job, and an assessment of the extent and duration of exposure (Table 54-3). Given clinicians' time constraints, the history should focus on the jobs and exposures of greatest concern, which vary given the nature of the problem (i.e., cancer with latency vs. acute inhalation injury). The occupational history can provide essential information on whether exposure to one or more environmental agents has occurred, the magnitude and extent of the exposure, and the timing of the exposure in relationship to symptoms or the disease (Table 54-3). A thorough description of the job process or work done is imperative. The length of time (hours to years) of exposure to the agent, the nature and use of personal protective equipment such as respirators, and a description of the ventilation and overall hygiene are all helpful in estimating exposure from the patient's history. Patients should be asked whether they think their problem is related to anything in their home or work environments, and temporal relationships between exposures and symptoms, such as whether or not symptoms improve away from work. Historical and current exposure data in the form of material safety data sheets (MSDS) and industrial hygiene databases often kept for administrative purposes can further characterize an individual's exposure. Whether co-workers have similar symptoms should be clarified. Information about potential exposures outside the workplace, such as in the home or hobbies, should also be obtained.

Physical Examination

With occupational lung diseases, the physical examination is generally unrevealing about specific cause. It is most helpful in ruling out nonoccupational causes of respiratory symptoms or diseases such as cardiac problems or connective-tissue diseases.

Diagnostic Tests

A number of tests can be helpful in the diagnosis of occupational lung disorders, such as chest radiography and pulmonary function tests (PFTs). The use of these diagnostic tests in the occupational setting is discussed below.

Chest Radiography

The chest radiography is the most important diagnostic test for occupational pneumoconioses. It is critical that radiographs of high technical quality be obtained. Under certain circumstances, the chest radiograph can be unique or highly suggestive of an occupational disorder and may be sufficient, along with an appropriate exposure history, to establish a diagnosis. For example, silicosis, coal workers' pneumoconiosis, and asbestosis with pleural disease all have characteristic radiographic findings strongly suggestive of the specific

Table 54-3

Taking an Occupational and Environmental History

General health history
- Does the patient think symptoms/problem is related to anything at work?
- When was the onset of symptoms, and how are they related to work?
- Has patient missed days of work, and why?
- Prior pulmonary problems
- Medications
- Cigarette use

Current or most relevant employment
- Job/process: title and description
- Type of industry and specific work
- Name of employer
- Years employed

Exposure information
- General description of job process and overall hygiene
- Materials by worker used
- Ventilation/exhaust system
- Use of respiratory protection
- Are other workers affected?
- Industrial hygiene samples/OSHA data

Environmental nonoccupational factors
- Cigarettes
- Diet
- Hobbies
- Pets

Specific workplace exposures
- Fumes/dusts/fibers
- Gases
- Metals
- Solvents
- Other chemicals: plastics, pesticides, corrosive agents
- Infectious agents
- Organic dusts: cotton, wood
- Physical factors
- Noise
- Repetitive trauma
- Radiation
- Emotional factors, stress

Past employment
- List jobs in chronologic order
- Job title
- Exposures
- Military service

Figure 54-1 Posteroanterior chest radiograph of a patient with silicosis. Multiple small nodular densities are seen throughout both lungs. Bilateral conglomerate masses of progressive massive fibrosis are also seen. International Labour Office classification of the film is category 3/3 showing category C large opacities.

occupational diagnosis. The finding of small rounded opacities, progressive massive fibrotic lesions in the upper zones, and "eggshell" calcification is highly suggestive of silicosis (Fig. 54-1). Similarly, the finding of bilateral pleural plaques and diffuse small irregular linear opacities in the lower lung zones is highly suggestive of asbestosis (Fig. 54-2). However, the chest radiography findings can also be nonspecific, as with asbestosis without pleural plaques where linear shadows in the lower lobes and honeycombing resemble the findings

Figure 54-2 Posteroanterior chest radiograph of a patient with asbestosis and pleural plaques. Calcified pleural plaques are seen on the diaphragms bilaterally, *en face* in the left thorax, and on the right medial pleural surface. Increased reticular markings greatest at the lung bases are also seen. International Labour Office classification of the film is category 1/1 small irregular opacities predominantly in the lower lung fields.

of idiopathic pulmonary fibrosis, or the hilar adenopathy or diffuse nodules found in beryllium disease are identical to the features of sarcoidosis. Chest radiographs can also be normal in patients with symptomatic pneumoconiosis.

Under the auspices of the International Labour Office (ILO) in Geneva, Switzerland, a uniform classification system has evolved to evaluate chest radiographs for epidemiological studies, clinical evaluation, and screening. The system requires a posteroanterior radiograph and comparison to a standard set of radiographs. Parenchymal opacities are classified according to size, shape (rounded or irregular), extent, and profusion (concentration). Examples of ILO readings are shown in Figs. 54-1 and 54-2. Pleural changes are also graded according to site, pleural thickening, and pleural calcification.

Computed Tomography

There is a growing literature addressing the role of computed tomography (CT) scanning in the evaluation of patients with occupational interstitial lung disease, primarily asbestosis and hypersensitivity pneumonitis. Similar to the nonoccupational setting, conventional CT scanning (8- to 10-mm thick slices) and high-resolution computed tomographic (HRCT) scanning (1- to 3-mm thick slices) can be used to better evaluate pleural and parenchymal abnormalities (see Chapter 30). The use of CT scans for screening for lung cancer is also under investigation.

Conventional CT scanning is more sensitive than chest radiography for the diagnosis of pleural disease and is helpful in distinguishing subpleural fat from pleural fibrosis. HRCT scanning allows improved visualization of the lung parenchyma and is used in the evaluation of patients with suspected asbestosis and other occupational interstitial diseases. HRCT scanning is especially informative in patients with unrevealing chest radiographs and unexplained respiratory symptoms or abnormal physiology (restrictive lung function, abnormal gas exchange, or abnormal response to exercise). CT scan features have been shown to correlate with physiological and histological changes. For example, interlobular septal thickening represents interstitial fibrosis, as seen in asbestosis, and ground-glass opacities likely represent active alveolar inflammation, as seen in hypersensitivity pneumonitis. The specific features and distribution of HRCT changes may be suggestive of a specific cause and narrow the differential diagnosis. For example, centrilobular nodules, ground-glass opacities, and air trapping may suggest hypersensitivity pneumonitis. Additional imaging techniques may also be useful. Inspiratory and expiratory imaging may demonstrate air trapping seen in hypersensitivity pneumonitis, and prone imaging may distinguish lower lung zone reticulations seen in asbestosis from dependent changes. Although less commonly used, classification systems such as the ILO chest radiograph system have been proposed for CT scans.

Physiological Methods

PFTs—including spirometry, lung volumes, and diffusing capacity—are the most important tools to assess functional respiratory status in patients with occupational lung disease, as with nonoccupational diseases (see Chapter 34). PFT findings are generally not specific for a particular cause but are important for evaluating dyspnea, differentiating obstructive from restrictive airway defects, and assessing the degree of pulmonary impairment.

Although in clinical practice obstructive lung disease may be treated before objective physiological documentation, it is especially important to clarify the diagnosis in settings where work exposures may be causative or contributing factors, and management decisions may involve a worker's job. Spirometry with bronchodilator response can document airflow obstruction and reversibility (see Chapter 34). However, the increased use of inhaled steroids, which are effective at reducing airway inflammation, can make reversible airflow obstruction more difficult to confirm, especially in milder asthmatics. Testing can be repeated off inhaled steroids. Forced expiratory flow rates between 25 percent and 75 percent (FEFR 25 to 75) have also been used to determine the presence of small airways disease; however, caution must be used in relying upon FEFR 25 to 75 given the significant variability in the general population.

When spirometry is normal, nonspecific bronchial hyperresponsiveness (NSBH) such as methacholine challenge testing can be helpful in demonstrating the presence of hyperreactive airways. NSBH can also be used to estimate severity as well as to follow improvement away from work.

Peak expiratory flow rate (PEFR) diaries can be particularly useful in the diagnosis of occupational asthma. Use of a peak flow meter and diary for at least 2 to 3 weeks including periods at work and away from work, such as vacation or weekends away from work, can document work-related changes in lung function. The confounding effects of bronchodilator therapy, respiratory protection and patient effort may influence results, and should be noted on the diary.

Specific inhalation challenge with the suspected agent(s) is considered the gold standard for diagnosing sensitizer-induced occupational asthma. However, such testing requires specialized facilities and expertise, carries certain risks, is not widely available, and false-negatives can occur.

With occupational interstitial lung diseases, restrictive ventilatory impairments and reductions in the diffusing capacity of carbon monoxide (D_{LCO}) are highly suggestive of disease. Hence, obtaining full pulmonary function testing are important since screening spirometry and plain chest radiographs may not be sufficiently sensitive to explain the presence of respiratory symptoms. Reductions in D_{LCO} may often be the first sign of disease and present as an isolated abnormality.

Longitudinal testing may be particularly informative given the variation in testing in the population and is often available in working populations undergoing routine medical surveillance. Careful attention must also be paid to several factors that may affect the quality of the testing; these include that spirometry is performed according to ATS guidelines and that the equipment is routinely calibrated. Changes in

technicians and in the equipment can also affect spirometry results.

Cardiopulmonary Exercise Testing

Cardiopulmonary exercise testing can be used to assess functional impairment and disease progression in selected patients with occupational respiratory disorders (see Chapter 35). Exercise testing can help distinguish among cardiac, pulmonary, and deconditioning causes of dyspnea. In patients with significant interstitial lung disease, exercise results in an increase in the alveolar-arterial oxygen gradient and arterial hypoxemia. Cardiopulmonary exercise testing is helpful in evaluating a select group of patients with dyspnea and normal pulmonary function tests or dyspnea that appears out of proportion to the changes in lung function. However, cardiopulmonary exercise testing is not helpful in determining the specific origin of the pulmonary disease.

Bronchoscopy

The diagnosis of major pneumoconioses such as asbestosis, silicosis, or coal workers' pneumoconiosis usually can be made on the basis of the occupational history, chest radiograph, and PFTs, as noted. Under certain circumstances, such as the evaluation of chronic beryllium disease, bronchoscopy with transbronchial biopsy and bronchoalveolar lavage (BAL) may be helpful diagnostically (see Chapter 56). Transbronchial biopsies yield small tissue samples that are most helpful in identifying granulomatous interstitial processes such as sarcoidosis, beryllium disease, and hypersensitivity pneumonitis, or diffuse malignant processes. Sufficient tissue is usually not obtained for analyses for dust or metal content.

Under certain circumstances, BAL can be diagnostically helpful. A predominance of lymphocytes suggests certain diagnoses such as sarcoidosis, hypersensitivity pneumonitis, or chronic beryllium disease, but is not by itself diagnostic. The diagnosis of chronic beryllium disease can be established with the finding of a positive beryllium lymphocyte proliferation test (BeLPT) using BAL cells. Characteristic multinucleated giant cells may be seen in the BAL cells of patients with hard-metal lung disease. BAL cells may contain dust or mineral particles, such as asbestos, which can reflect current and past exposures. For example, asbestos bodies (asbestos particles coated with iron) have been quantitated in BAL, and have correlated variably with disease and symptoms.

Pathologic Examination of Tissues

Open lung biopsy techniques are usually not needed to make a diagnosis of the more common occupational interstitial lung diseases, as noted. However, when there is no clear cause, limited exposure history, atypical features, more than one causative agent, or potentially a newly recognized agent, lung biopsies can be very helpful. Certain histopathologic findings can suggest a specific disease such as hypersensitivity pneumonitis, asbestosis, or hard metal disease. Lung biopsies can also rule in or out certain nonoccupational causes of lung disease, such as pulmonary vascular disease or infection. Open lung biopsy enables sufficient amounts of tissue for histological and mineralogical (qualitative and quantitative) analysis.

Several methods have been used to analyze the dust content of lung tissue. Light microscopic evaluation with polarization is widely available and can provide a qualitative assessment of the presence of dust particles and ferruginous bodies. It does not, however, identify the specific dust particles or enable quantification. Bulk and microanalytic techniques that allow more definitive identification and quantification of minerals and dusts are also available. They include radiographic fluorescence scanning electron microscopy and energy dispersion radiographic spectroscopy. These methods can be used to identify and quantify specific minerals in sections or tissue digests. In a patient with interstitial lung disease of unclear origin in whom an occupational or environmental etiology is being considered, more extensive particle analysis should be considered if light microscopic histological examination is not diagnostic. There are limitations that should be remembered. Only substances that are insoluble and retained in tissue at sufficient concentration will be detected. More soluble agents, such as cobalt, can be underestimated with these techniques. The analytic methods can be tedious and standards to compare findings are limited. Most important, a positive finding documents biologically detectable exposure but does not demonstrate disease or establish a causal relationship.

Other Laboratory Tests

As noted, few laboratory tests exist that diagnose specific occupational lung diseases. Skin tests and detection of specific IgE to a suspected agent, such as large-molecular-weight antigens (i.e., animal or plant proteins) can demonstrate exposure and a specific immunological reaction, but does not confirm a clinical disease, and a negative finding does not rule out either exposure or disease. The BeLPT is quite sensitive and specific for beryllium sensitization, but does not distinguish asymptomatic sensitization from chronic beryllium disease.

Exposure Assessment

A careful occupational and environmental history is the single best way to evaluate a patient's exposures, as noted. Substantial information regarding work and home exposures can usually be obtained directly from the patient.

Other Sources of Exposure Information

There are a several other sources for additional workplace exposure information. In the United States, employers are required by federal law to provide employees with information about the potential toxicity of all materials used in the workplace, called Material Safety Data Sheets (MSDS). Patients should obtain an MSDS on any substances of concern. For recent or current exposures, a site visit is usually most helpful in providing information about the nature and extent of potential exposures and other exposed workers. A number of methods and sampling strategies exist to measure

particular exposures in either the work or home environment. They include personal and area sampling devices, and direct monitoring devices. It should be remembered that sampling variability and analytic errors can occur, and that the exposure information obtained usually reflects a narrow window of time during which monitoring was performed.

Another potential source of information is the results of inspections by health and regulatory agencies such as the Occupational Safety and Health Administration (OSHA). Unions, insurance groups, and community groups may also provide exposure information. In addition, epidemiological data on coworkers or workers with similar types of jobs can be used to assess the nature and extent of exposure for a given patient.

Compliance with established occupational exposure limits does not exclude the possibility of disease. Low levels of exposure can induce disease in susceptible individuals. Also exposures are often variable and high levels of brief exposure may not be noted in industrial hygiene records.

There has been great interest in developing biologic markers that attempt to more accurately identify and quantify exposure(s), or an early effect of the exposure, such as sensitization to a specific antigen. Such markers can be measured in the target organ, such as the lung or BAL fluid, or in blood or urine. In general, although of great research interest, most markers have relatively limited use in the clinical practice of occupational and environmental medicine and associations between these markers of exposure and disease is not always clear.

Once the available information is obtained, the clinician has to make a final determination about whether occupational or environmental exposures are causing or contributing to the patient's disease process. As noted, there are several criteria to determine whether work or environmental exposures are causative, including a consistent clinical picture, sufficient exposure, and appropriate temporal relationships. The diagnosis of an occupational lung disease frequently entails a greater degree of diagnostic uncertainty than physicians are generally used to in other settings. In most workers' compensation cases in the United States, the standard of certainty is greater than 50 percent likelihood that the disorder is related to an occupational or environmental exposure. Thus, occupational or environmental diseases are diagnosed even in the presence of a significant degree of uncertainty.

PREVENTION

Social, Economic, and Public Health Considerations

It is important for the clinician to remember that making the diagnosis of an occupational or environmental respiratory disease almost invariably has important social, economic, legal, and public health considerations. Many countries and selected states in the United States require reporting of occupational illnesses and injuries. For the individual patient, such a diagnosis can have a profound impact on the patient's work, income, and social situation.

Many countries, including the United States, have a workers' compensation no-fault system of insurance to provide medical, lost work time and other benefits for workers with injury or illness caused by work. Physicians are obligated to diagnose and treat work-related illness, inform the patient of such an illness, and assist with documentation to obtain benefits. Physicians are asked to determine the presence and severity of respiratory impairment, a loss of physical or physiological function (see Chapter 39). Disability refers to the impact of the impairment on the person's life and is determined by administrators based on the information provided by physicians, requirements of the job and other factors, discussed in Chapter 39.

Prevention

Prevention is central to the practice of occupational and environmental medicine. There are two main strategies for prevention: primary prevention, which entails removal or modification of the hazardous risk or exposure before disease has occurred, such as product substitution or engineering controls to reduce exposures. Secondary prevention depends on early detection, and prompt treatment after some adverse effect of the exposure has occurred. The physician can play an important role in both primary and secondary prevention. The physician should also consider the relevant public health issues when a patient is diagnosed with an occupational or environmental lung disease, such as whether others are currently or in the future similarly exposed and at risk of disease. Reporting of occupational illnesses is critical in identifying problem areas that need further investigation and improved preventive strategies. Physicians are essential for secondary prevention. With knowledge of workplace hazards and appropriate monitoring of patients, early abnormalities can be detected, and treatment instituted, typically with removal from further exposures. Reporting of occupational illnesses is critical in identifying problem areas that need further investigation and improved preventive strategies.

Regulatory Issues

In the United States, several federal and state laws and agencies regulate hazardous substances in the environment and workplace, including the Environmental Protection Agency and OSHA, which was established in 1970 by the Occupational Safety and Health Act to reduce the risk of injury and illness to workers. The National Institute for Occupational Safety and Health (NIOSH), also established in 1970, is charged with performing research and teaching, and evaluating occupational hazards. Several organizations recommend occupational exposure limits. OSHA establishes enforceable permissible exposure limits (PELs). In addition, the American Conference of Governmental Industrial Hygienists (ACGIH) and NIOSH recommend threshold limit values (TLVs) and recommended exposure limits (RELs), respectively.

Respirators

The best strategy for reducing inhalation exposures is to prevent or contain the exposure or substitute a less harmful material for a toxic one. Respiratory protective devices (respirators) are used to provide protection from exposure by inhalation when adequate engineering control of airborne contaminants is not feasible, or in an emergency or temporary situation. There are two main types of respirators: air-purifying respirators, which remove contaminants from the air using filters or chemical absorbents, and atmosphere supply respirators, which supply breathable air from another source, such as an air cylinder. Types of air-purifying respirators include dust masks, cartridge respirators, and high-efficiency particulate air (HEPA) filters. Physicians may be asked to determine a worker's fitness for respirator use. OSHA regulations require that a worker not be assigned to a job requiring use of a respirator unless the worker is able to perform the work with a respirator. It should first be determined whether appropriate engineering controls and an appropriate respiratory protection program are in place. No spirometry or other specific criteria exist to determine respirator fitness. The physician must use clinical judgment in determining whether a given worker will be able to use a respirator. Respirators can increase the work of breathing, and they can interfere with the worker's ability to perform the job (by reducing vision, range of motion, and hearings). Factors that can limit respirator use include facial hair, inability to tolerate the respirator, claustrophobic reactions, and particular medical conditions, such as pulmonary or cardiovascular disease. Reassessment after a brief trial of respirator use is indicated if the patient is having problems or concerns.

Asbestos-Related Lung Disease

William N. Rom

EFFORTS AT ASBESTOS CONTROL

Asbestos is a fibrous hydrated magnesium silicate with more than 3000 commercial uses due to its indestructible nature, fire resistance, and spinnability. It has been used for centuries: the ancient Greeks called asbestos *amiantos*, and the Greek biographer Plutarch (A.D. 46–120) commented on its use in wicks for oil lamps and napkins that could be cleansed in a fire. Mining and milling that began in the late nineteenth century used asbestos in textiles and insulation materials. Cooke described the first case of asbestosis in 1924 in a 33-year-old textile worker with 25 years of exposure to asbestos and extensive pulmonary fibrosis.

Approximately 98 percent of the asbestos used in the United States has been chrysotile, a serpentine form of asbestos. Other asbestos types are the amphiboles—notably amosite, mined in South Africa, and crocidolite, mined in the Cape Province of South Africa and in Western Australia. Anthophyllite in minimal amounts has been used commercially in Finland. These asbestos fiber types have strikingly different physical characteristics: chrysotile tends to be wavy and long, and occurs in bundles; crocidolite is needle-shaped with many long fibers; and amosite is similar to crocidolite but generally thicker.

Initially, asbestos was widely used in fireproof textiles and later as insulation for boilers and pipes. Thereafter, asbestos was used in yarn, felt, paper, millboard, shingles, paints, cloth, tape, filters, and wire insulation. More recently, asbestos has been used in cement pipes for potable water, in gaskets, and in friction materials, including brake linings, and roofing and floor products. Asbestos was extensively used for ship construction during World War II. World consumption of asbestos declined in the 1990s to approximately 50 percent of the peak in 1973. In 1994, approximately 2.7 million tons

were produced, with the United States consuming less than 27,000 metric tons. Worldwide production by mining in 1994 was led, in order, by Russia, Canada, Kazakhstan, China, and Brazil.

TYPES OF EXPOSURE

Asbestos exposure has occurred in a variety of settings. Primary exposures occurred in miners and millers. Secondary exposures occurred in manufacturing plants using asbestos in the production of textiles, friction materials, tiles, and insulation materials. Epidemiological studies focused on cohorts in these plants, since asbestos fiber type was often specified and dust measurements were obtained. These studies demonstrated that intensity and duration of exposure play an important role in the prevalence of asbestos-related disease. In a study of 1584 insulation workers and 1330 sheet-metal workers, 83.5 percent of the insulators had abnormal chest radiographs (55 percent with parenchymal opacities), whereas 42 percent of the sheet-metal workers had abnormal chest radiographs (17 percent with parenchymal opacities).

Although measurements of airborne asbestos fibers were seldom made, the most significant exposures appear to have occurred in the construction trades. These trades included asbestos insulators (called "laggers" in the United Kingdom), who mixed asbestos cement on site to insulate joints and elbows on pipes; boilermakers and sheet-metal workers, who worked adjacent to the asbestos workers; and electricians, carpenters, plumbers, and others who worked in the vicinity of work requiring asbestos exposure. These exposures were mainly to chrysotile asbestos, since practically no crocidolite was imported into the United States, and only small amounts of amosite were admixed.

Asbestos workers and other construction workers wore their asbestos-covered clothes home, so their wives and children were exposed either upon greeting them or while washing their garments. These household contact exposures are often referred to as *indirect exposures,* and those exposed while working near asbestos workers are called *bystander exposures.* In the United States, approximately 14 million persons who were exposed to asbestos in the workplace between 1940 and 1979 were alive in 1980. From this cohort, estimates have been projected for the late 1990s of a peak incidence of approximately 3000 mesothelioma deaths and 5000 asbestos-related lung cancer deaths. Pleural fibrosis remains a relatively common finding among asbestos-exposed blue-collar workers, whereas asbestosis is becoming increasingly uncommon.

NONMALIGNANT PLEURAL MANIFESTATIONS

Pleural disease is the most common manifestation of asbestos exposure. The nonmalignant manifestations of asbestos exposure in the pleural space include circumscribed pleural plaques, diffuse pleural thickening, rounded atelectasis, and asbestos-related pleural effusions.

Pleural Plaques

Pathology

Pleural plaques are the most common manifestation of asbestos exposure. They are focal, irregular, raised white lesions found on the parietal and, rarely, the visceral pleura. The plaques may be small or extensive; commonly they occur in the lateral and posterior midlung zones, where they may follow rib contours and the diaphragm. They commonly enter lobar fissures and can invade the mediastinum or pericardium; rarely do they invade the apices or costophrenic sulci. Histologically, asbestos-related pleural plaques are characterized by a paucity of cells, extensive collagen fibrils arranged in a basket-weave pattern, and a thin covering of mesothelial cells. The parietal pleura is uniformly involved, with minimal thickening of the visceral pleura. The two pleural surfaces are free of adhesions. Pleural calcifications frequently develop in these fibrohyaline lesions as the length of time from exposure increases. Exposure to asbestos is the most frequent cause of pleural plaques. These plaques, although typical of asbestos, are not specific for asbestos exposure.

Pathogenesis

Two theories have been proposed for the pathogenesis of pleural plaques. The most plausible is based on the direct effects of fibers that reach the pleural space. Asbestos fibers—the short, thin ones in particular—have been shown to be transported by subpleural lymphatics to the pleural space. In the pleural space, it is believed that they scratch, injure, and irritate the pleural surface, leading to hemorrhage, inflammation, and eventually fibrosis. The plaques are submesothelial. Cell-cell interactions appear to play an important role in this response. In the absence of macrophages, pleural reactions tend to be disorganized and widespread. Mesothelial cells also appear to play an important role in the pathogenesis of these lesions: they internalize asbestos fibers via an integrin receptor that recognizes vitronectin; in vitro pleural mesothelial cells also can synthesize collagens (types I, III, and IV), elastin, laminin, and fibronectin. In keeping with the submesothelial location of the plaques, cultured mesothelial cells can organize these macromolecular connective-tissue components into an assemblage of extracellular matrix that is limited to the base of the cell.

Epidemiology and Natural History

In the 1960s, hyaline and calcified pleural plaques were noted to be an index of exposure to asbestos. In shipyard workers, the frequency of pleural abnormalities was approximately 10 times that of parenchymal disease. The greater the exposure, the more likely the worker was to have extensive calcified pleural plaques as well as parenchymal fibrosis. The intensity of the exposure has been noted to be an important

determinant of the prevalence of these abnormalities. For example, among British shipyard workers, 36 percent of those with continuous exposure as "laggers" developed pleural plaques, while extensive pleural thickening and pulmonary fibrosis were seen in 5 and 7 percent, respectively. In contrast, those with intermittent exposure had a 6 percent prevalence of plaques and no pulmonary fibrosis. On average, the latency time for the appearance of plaques is 30 years, but the time can vary greatly. This variation can also be appreciated from studies of British shipyard workers in whom the prevalence of pleural plaques increased from 17 percent at 10 years after the first exposure to 70 percent at 30 years among those with continuous exposure; for those with intermittent exposures, the prevalence increased from 1 percent at 10 years to 16 percent at 30 years.

All asbestos fibers are equally capable of inducing pleural plaques: pleural plaques are found in US insulators or shipyard workers exposed to chrysotile or amosite, as well as miners in Western Australia who were exposed to crocidolite. Circumscribed pleural plaques are not associated with pleural effusions. They increase in size slowly, usually over decades, and rarely, if ever, give rise to diffuse malignant mesothelioma.

In addition to occupational exposures, domestic and residential exposures have, on rare occasions, been implicated in the production of pleural plaques. Evidence for the latter is the remarkably high rates of pleural calcification (up to 30 percent) in some rural areas of Greece, Bulgaria, and Turkey.

Clinical and Physiological Features

In the absence of concomitant asbestosis or obliteration of the costophrenic angle, pleural plaques are usually asymptomatic. Most often they are incidental findings on chest radiographs. In addition, they do not cause significant abnormalities such as pleural rubs, rales, or rhonchi on auscultation of the chest.

Pleural disease has been recognized as a cause of reduced pulmonary function since the 1970s. Among 998 shipyard workers in Groton, Connecticut, who had 15 or more years of asbestos exposure, 17 percent of those with pleural changes had a forced vital capacity (FVC) under 80 percent of predicted; for those with normal chest radiographs, 9 percent had decreased vital capacities ($p > 0.05$). In those with normal chest radiographs, the values were significantly reduced only among smokers and ex-smokers. Recent studies that have applied stepwise regression analysis to data from insulation workers have disclosed a significant inverse relationship between FVC and an integrative pleural index for patients with circumscribed pleural plaques. Even among those with pleuroparenchymal abnormalities, the pleural index was found to make a significant contribution to decrements in FVC, independent of that due to parenchymal abnormalities.

In nonsmoking asbestos workers with circumscribed or diaphragmatic pleural plaques, flow rates (FEV_1, $FEF_{25–75\%}$, and $FEF_{75–85\%}$) have been reported to be reduced. In an epidemiological study of 1211 sheet-metal workers, pleural fibrosis was detected in 334 and was related to age, duration of exposure, more pack-years of smoking, and the presence and degree of interstitial fibrosis. After controlling for these confounders, multivariate regression analysis found that both plaques and diffuse thickening were independently associated with decrements in FVC, but not with decrements in the FEV_1/ FVC ratio. Furthermore, diffuse pleural thickening was associated with a decrement in FVC twice as great as that seen with circumscribed pleural plaques. After confounding variables such as age, height, smoking status, and the presence of parenchymal abnormality as assessed by chest radiography and gallium scintography were taken into account, there was a significant decrease in FEV_1 and FVC (222 and 402 ml, respectively) among workers who had pleural plaques or diffuse pleural fibrosis.

Radiographic Features

The visualization of plaques on routine chest radiography depends on their thickness, location, and the orientation of the radiographic beam. As a result, they can be viewed in profile along the lateral chest wall or on en face with a rolled or holly-leaf pattern, especially if calcified (Fig. 55-1). Only a modest proportion of plaques detected at autopsy can be seen on standard posteroanterior (PA) chest radiograph. Oblique views and computed tomographic (CT) scanning increase plaque detection.

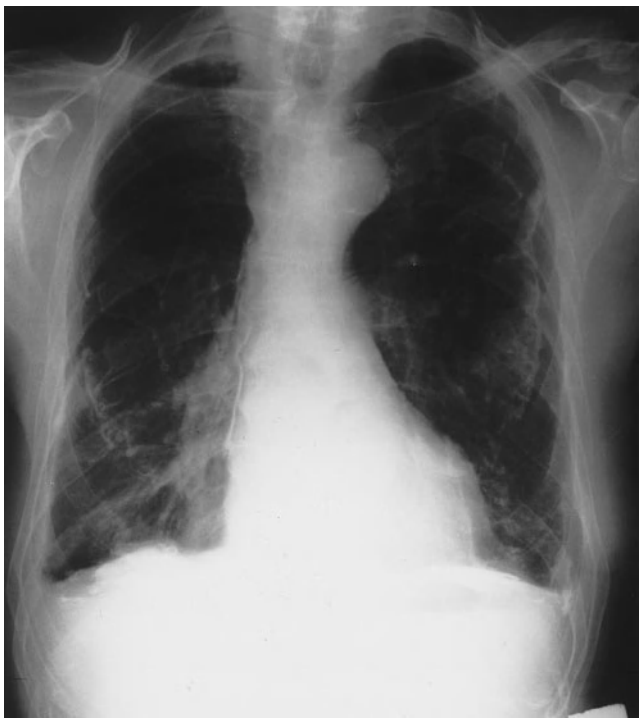

Figure 55-1 Posteroanterior (PA) chest radiograph of a 75-year-old man who worked in a shipyard during World War II insulating ships. The radiograph shows bilateral calcified pleural plaques en face and on top of the diaphragm. The pleura is diffusely thickened bilaterally and the costophrenic angles are blunted. Mediastinal pleural calcification is present on the right. *(Courtesy of Dr. Timothy Harkin.)*

The CT scan can recognize plaques at a much earlier and less well-defined state than the conventional chest radiograph. The CT scan is particularly useful for perivertebral and pericardiac plaques, and high-resolution CT scanning (HRCT) helps to establish the presence of diaphragmatic lesions. In all cases, the CT scan can help to differentiate plaques from extrapleural fat pads and can detect concomitant parenchymal abnormalities that may be difficult or impossible to see on the PA chest radiograph.

Diagnosis

Pleural plaques due to asbestos exposure are usually bilateral (80 percent of the time), whereas unilateral pleural plaques may be due to trauma, previous tuberculosis, or, rarely, other causes, such as collagen vascular disease. The lesions are usually stable and will remain the same size for months. This helps to differentiate plaques from pleural tumors. Histological tissue examination is not necessary for diagnosis the vast majority of the time.

Treatment

No specific treatment is required for asbestos pleural plaques. Since they are markers of asbestos exposure and identify patients at risk for other asbestos-related disorders, medical surveillance, including periodic chest radiographs, is recommended.

Diffuse Pleural Thickening

Pathology

Pleural fibrosis in persons who have been exposed to asbestos has been well described. The fibrotic responses can be localized or diffuse and either unilateral or bilateral. Macroscopically, the lesions vary in thickness from a whitish discoloration of the lung surface to a thick white peel that can encase significant pulmonary structures. Diffuse pulmonary thickening is most often seen as a continuous sheet that is 5 to 10 cm in craniocaudal extent, and in 90 percent of patients it affects the costophrenic angle. Interlobar and interlobular fissures are commonly involved. Whereas pleural plaques predominantly affect the parietal pleura, diffuse pleural thickening or fibrosis is a disease of the visceral pleura. Diffuse pleural fibrosis occurs most commonly as part of a fibrotic process of the visceral pleura and subadjacent interstitium. It may occur, however, and be quite severe, in patients with minimal pulmonary parenchymal fibrosis. Asbestos bodies or fibers are often found in the visceral pleura, the underlying parenchyma, or both.

Pathogenesis

Diffuse pleural thickening has been proposed to result from three different mechanisms. The first is the confluence of large pleural plaques. This is believed to account for 10 to 20 percent of the cases. The second is the extension of subpleural fibrosis to the visceral pleura. This probably accounts for 10 to 30 percent of cases. The most common pathogenic mechanism is thought to be the fibrotic resolution of a benign pleural effusion, producing diffuse pleural thickening. The importance of this mechanism is highlighted by the finding that about one-third of patients with diffuse pleural thickening have had a prior benign asbestos-related pleural effusion diagnosed by thoracentesis or on serial chest radiographs. The pathogenic mechanisms differentiating diffuse pleural thickening from circumscribed pleural plaques are not well defined. However, the fundamental irritative mechanism of asbestos fibers is likely to be important in both. In the case of diffuse pleural responses, these fibers are deposited mainly in the parenchymal subpleural areas of the lung.

Clinical and Physiological Manifestations

Diffuse pleural fibrosis most often occurs long after short-term heavy exposure to asbestos. When mild, diffuse pulmonary fibrosis can be asymptomatic and discovered as an incidental finding on a chest radiograph obtained for another reason. The diffuse nature of the lesion, however, often leads to pulmonary symptoms, including dyspnea on exertion, chronic dry cough, and chest pain. As noted above, diffuse pleural thickening can cause a restrictive physiological abnormality. The degree of physiological abnormality varies with the degree of fibrotic response. On rare occasions, in patients with severe bilateral disease, respiratory insufficiency and death have occurred. Diffuse pleural fibrosis can increase in severity over time. In miners heavily exposed to crocidolite asbestos, however, progression of diffuse pleural thickening has been noted to level off as much as 15 years after the initial exposure.

Radiographic Features

On the routine chest radiograph, diffuse pleural fibrosis presents as a continuous pleural opacity extending over more than 25 percent of the pleural surface of a lung, often blunting the costophrenic angle. It can be unilateral or bilateral and seen in the presence or absence of concomitant asbestosis and pleural calcifications. Rarely, the pleural fibrosis will produce a fibrotic pseudotumor with a pleural basis (rounded atelectasis) (see below). CT scanning is particularly useful in delineating the relationship between diffuse fibrosis and other pleural abnormalities and differentiating pleural fibrosis from fat deposits.

Diagnosis

The diagnosis of diffuse pleural fibrosis is usually based on the clinical presentation and chest radiograph. In more than 30 percent of cases, a history of asbestos-related pleuritis can be obtained. The lesions of diffuse pleural fibrosis are not unique to asbestos-exposed persons and can represent old inflammatory reactions from tuberculosis, thoracic surgery, hemorrhagic chest trauma, or drug reactions. Differentiation among these causes is frequently based on a careful clinical history. Radiographic patterns are also helpful, since bilateral interstitial changes in the lower lung zones in association with

pleural plaques or calcifications strongly support a diagnosis of asbestos exposure. A biopsy may be required when the thoracic lesion is progressing or when malignancy is in the differential.

Treatment

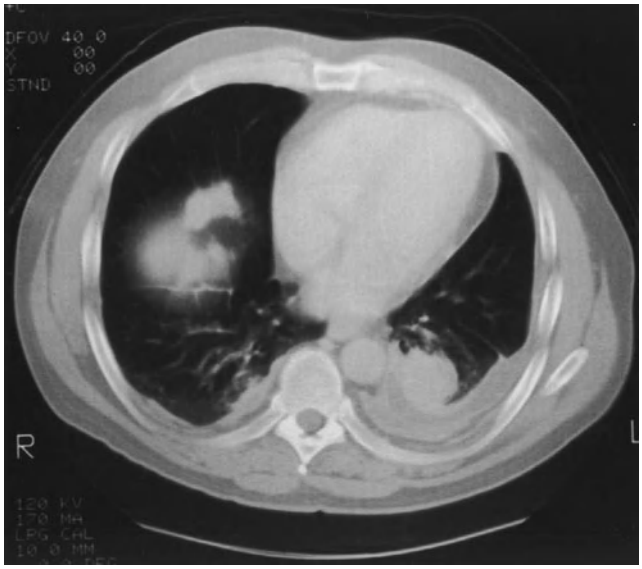
As seen with circumscribed pleural plaques, there are no specific therapies for asbestos-related diffuse pleural fibrosis. Medical surveillance is required to detect disease progression and observe for other asbestos-related disorders. In the rare extremely severe case, pleurectomy may be required.

Rounded Atelectasis

Rounded atelectasis is a rare complication of asbestos-induced pleural disease. It is caused by scarring of the visceral and parietal pleura and the adjacent lung, with the pleural reaction folding over on itself. The pleural surfaces then fuse to one another, trapping the underlying lung and leading to atelectasis. As a result of this alteration, a mass lesion that mimics lung cancer can be seen on the PA chest radiograph (Fig. 55-2). This lesion is most easily appreciated to be a pseudotumor with use of CT scanning. HRCT can noninvasively demonstrate continuity to areas of diffuse pleural thickening, evidence of volume loss in the adjacent lung, or a characteristic comet tail of vessels and bronchi sweeping into a wedge-shaped mass (Fig. 55-2).

CT scanning can also demonstrate stability over time (from months to years), which supports the diagnosis of a benign lesion, and pleural plaques or parenchymal changes, which support a diagnosis of asbestos exposure. In one clinical series of 74 patients with rounded atelectasis, 64 had significant asbestos exposure, and the lingula or right middle lobe was affected in 49 of the patients. HRCT scans localized most cases of rounded atelectasis to the lower, posterior portion of the lung (Fig. 55-2); moreover, in one-third of the patients, the lesions were multiple. In most patients, rounded atelectasis occurs suddenly on a background of only plaques or a normal chest radiograph. In others, a slowly increasing pleural effusion may precede its appearance. If the benign nature of the lesion cannot be assured by chest radiography, the patient may require fiberoptic bronchoscopy with a transbronchial biopsy or transthoracic needle aspiration to rule out a malignant process.

A



B

Figure 55-2 Rounded atelectasis and other pleural abnormalities in an asbestos worker. The chest radiograph (*A*) shows a left-sided pleural effusion, bilateral pleural thickening, greater on the left than on the right, and a mass in the left midlung field. HRCT (*B*) demonstrates the mass to be rounded atelectasis, with bronchovascular structures entering the trapped lung. It also reveals the pleural effusion, bilateral pleural thickening, and pleural plaques, one of which is on the right hemidiaphragm. *(Chest radiograph and HRCT courtesy of Dr. Coralie Shaw.)*

Acute Benign Pleural Effusions

Acute benign pleural effusions are common pleural manifestations in asbestos-exposed persons between 20 and 40 years of age. The latency period for these effusions is shorter than for pleural plaques, malignant mesotheliomas, or pulmonary malignancies. Benign pleural effusions generally occur earlier after exposure than do other asbestos-related processes—12 to 15 years after the first asbestos exposure. However, benign effusions can also occur as long as 30 years after first exposure. The effusions may be small to moderate in size or may be manifested as an increase in the extent or severity of an existing pleural reaction.

About 50 percent of the patients with acute benign pleural effusions are asymptomatic. When patients are symptomatic, the manifestations may be those of a pleurisy (chest pain, chest tightness, dyspnea, cough, and fever). Physical examination reveals the signs of a pleural effusion; a pleural friction rub may be heard. The effusions are exudative and often bloody; glucose concentrations are normal. Mesothelial

cells are found in about 50 percent of patients. In about 25 percent of patients, the fluid is eosinophilic. Rarely are asbestos bodies found even though they may be present in underlying lung tissue.

The designation "benign" refers to the lack of evidence of malignancy. The collections may persist for 6 months or more. They frequently clear spontaneously, only to recur on the contralateral side. Benign asbestos pleural effusions do not presage the development of malignant mesotheliomas. Moreover, patients with effusions have the same risk of developing asbestosis as do patients with chronic pleural fibrosis. However, a benign asbestos pleural effusion is a risk factor for the development of pleural thickening, especially diffuse pleural fibrosis. The diagnosis of acute benign pleural effusions is one of exclusion. Thoracentesis is essential. Pleural biopsy is frequently required to rule out other causes of pleural effusions, including mesothelioma. The usual pathological findings are a chronic fibrous pleurisy with minimal cellularity. Long-term follow-up is also a diagnostic requirement, since the diagnosis of a benign pleural effusion cannot be fully established until a tumor-free interval of 3 years has elapsed.

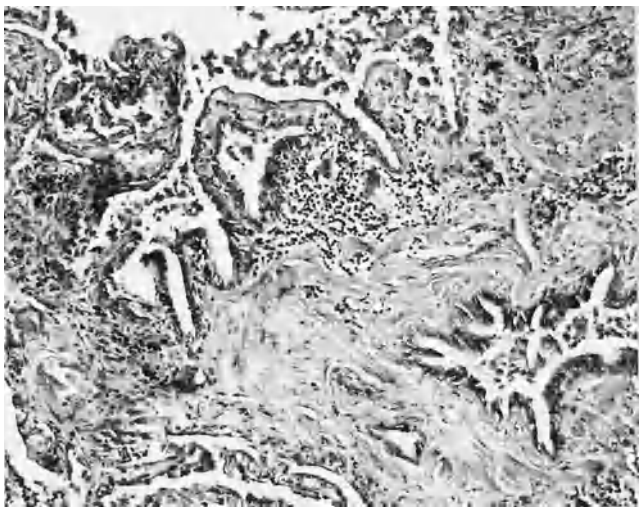


Figure 55-3 Lung tissue from a 64-year-old asbestos insulator with 46 years of exposure to asbestos while insulating pipes. His chest radiograph revealed extensive irregular opacities and bilateral pleural thickening. The figure illustrates peribronchiolar fibrosis, interstitial chronic inflammation, accumulation of macrophages in the airspaces, and proliferation of type II pneumocyte. *(Based on data from Rom WN, Travis WD, Brody AR: Cellular and molecular basis of the asbestos-related diseases: State of the art.* Am Rev Respir Dis *143:408–422, 1991, with permission.)*

ASBESTOSIS

Pathology

Asbestosis is the interstitial pneumonitis and fibrosis caused by exposure to asbestos fibers. Early lesions are characterized by discrete areas of fibrosis in the walls of respiratory bronchioles. The septi adjacent to the respiratory bronchioles are often thickened, and the fibrosis sometimes appears to spread outward from the bronchioles. In addition to the peribronchiolar fibrosis, there is an intense peribronchiolar cellular reaction that may narrow and obstruct the airway lumen. Macrophage accumulation is a prominent feature of this cellularity. Proliferation of type II alveolar epithelial cells is enhanced. The interstitium may contain collections of lymphocytes; smooth-muscle proliferation may be prominent in areas of remodeling; and buds of loose connective tissue may be seen within the alveoli (Fig. 55-3). Initially, the disease usually involves first-order bronchioles; subsequently, second- and third-order bronchioles are affected. As the disease progresses, the fibrosis becomes diffuse, the architecture of the lung undergoes extensive remodeling, and honeycombing supervenes. In contrast to other pneumoconioses, lymph node enlargement and progressive massive fibrosis do not occur. Pathologically, the alterations seen in asbestosis cannot be differentiated from many other interstitial fibrotic disorders except for the presence of asbestos bodies and uncoated asbestos fibers.

Pathogenesis

Asbestos fibers are deposited at airway bifurcations and in respiratory bronchioles and alveoli by impaction, sedimentation, and interception. Fibers then migrate into the interstitium, in part via an uptake process involving type I alveolar epithelial cells. This causes alveolar macrophages to accumulate in the alveolar ducts, peribronchiolar interstitium, and alveolar spaces, constituting an alveolar macrophage alveolitis. Following this initial macrophage alveolitis, most fibers are cleared, leaving the lungs unscarred. If clearance is incomplete, fibrosis can ensue. The degree of fibrosis in asbestosis relates, in general, to the lung dust burden. If the dust load is small, the tissue reaction may be limited and the disease may be mild and not progress. If the retained dust load is great, tissue reaction and macrophage alveolitis are proportionately more intense, greater injury occurs, and chronic and progressive lung disease can develop.

The macrophage alveolitis that is seen in early stages of asbestosis results from monocyte recruitment from the blood and in situ macrophage replication. These cells appear to play an important role in the pathogenesis of the inflammation and fibrosis seen in this disorder. Morphologically, they express an activated phenotype characterized by cellular multinucleation and a striking increase in membrane ruffling, surface blebbing, and lysosomes and phagolysosomes. These macrophages are presumably attempting to engulf and clear the asbestos fibers. This process is not uniformly successful, however. First, the fibers induce apoptosis in the cells. Although the coating of asbestos fibers to form asbestos bodies makes them less toxic, the vast majority of fibers in the lung remain uncoated. Second, the long fibers cannot be completely phagocytosed. Finally, chrysotile asbestos fibers tend to split longitudinally. This generates additional fibers that can multiply the asbestos effect even after exposure has ceased. As

a result, asbestos has a prolonged residence and surprising mobility and penetrates the interstition of the distal lung.

These characteristics probably contribute to the pathogenesis of the disease, since—in contrast to inert particles, which can be ingested by macrophages and cleared without generating a significant response—asbestos fibers stimulate macrophages to produce a variety of important moieties. These include cytokines, such as platelet-derived growth factor (PDGF), insulin-like growth factor-1 (IGF-1), interleukin-1β (IL-1β), tumor necrosis factor (TNF), and IL-8, the matrix molecule fibronectin, oxygen free radicals, and plasminogen activators. The oxygen radicals contribute to tissue injury via direct cell cytotoxicity and lipid peroxidation of membrane components. The IL-8 recruits granulocytes to sites of disease activity. The PDGF, IGF-1, IL-1, TNF, and fibronectin contribute to tissue fibrosis by stimulating fibroblast proliferation and chemotaxis and collagen biosynthesis.

Bronchoalveolar lavage (BAL) in asbestosis has demonstrated an alveolar macrophage alveolitis with a modest increase in neutrophils. This neutrophilia correlates with the finding of rales on physical examination and oxygenation parameters and is apt to be more pronounced in patients with advanced disease. In patients with asbestosis, ^{67}gallium lung scans may also be positive. Clinically apparent asbestosis occurs only after a significant latent period. However, studies using BAL, CT scanning, and ^{67}gallium scanning have demonstrated that inflammatory events occur well before the onset of clinical disease. Thus, it is likely that the initial exposure induces inflammation and injury that persist through the latent or subclinical phase and develops into the clinical disease diagnosed by classic radiography and other techniques. Current concepts of the pathogenesis of the disease link inflammation and fibrosis in a causal fashion.

Epidemiology

The prevalence of parenchymal asbestosis among asbestos workers increases as the length of employment increases. This is illustrated in an early report in which investigators analyzed the chest radiographs of 1117 New York and New Jersey asbestos insulation workers. They found asbestosis in 10 percent of the workers who had been employed for 10 to 19 years, in 73 percent of those who had worked for 20 to 29 years, and in 92 percent of those who had worked 40 or more years. A similar dose-response relationship was found in the asbestos cement industry. Among "bystanders" (i.e., among sheet-metal workers who worked in close proximity to insulation workers) the overall prevalence of asbestos-related changes was 31 percent, including 9 percent who had only pleural abnormalities and 12 percent who had parenchymal abnormalities. Among those who had been in the trade for 40 years or more, 41.5 percent had radiographic signs of asbestos-related disease.

Cigarette smoking can affect the expression of asbestosis. Smokers without dust exposure may have a few irregular radiographic opacities, probably representing acute or chronic bronchitis or bronchiectatic changes in the lung parenchyma. Both smokers and ex-smokers have a higher frequency of asbestos-related irregular opacities on their chest radiographs than do their nonsmoking colleagues. Among asbestos insulation workers, lower grades of radiographic small opacities predominated. Smoking does not alter the expression of asbestos-induced pleural fibrosis. The effects of smoking on asbestosis may be clinically important, since the mortality from asbestosis is higher in asbestos workers who have smoked than in their nonsmoking coworkers. This risk declines if the worker quits smoking. The mechanism of interaction of asbestos and cigarette smoking is poorly understood. However, cigarette smoking may interfere with the clearance of inhaled asbestos, thereby potentiating the effects of the dust in the lung.

Natural History

Following asbestos exposure, asbestosis becomes evident only after an appreciable latent period. The duration of exposure and its intensity influence the prevalence of radiographically evident parenchymal pulmonary fibrosis. Because work sites around the world increasingly meet recommended control levels, high-level exposure to asbestos is now uncommon and clinical asbestosis is becoming a less severe disease that manifests after a longer latent interval. In Western Australian crocidolite workers, a median of 14 years elapsed before asbestosis was detectable radiographically (range, 2 to 34 years). In retired Quebec chrysotile miners and millers, the frequency of pleuroparenchymal lesions was 31 percent, and progression of parenchymal opacities occurred in 9.3 percent; progression was confined to the more heavily exposed group.

One approach to the study of low-level exposure is to evaluate the outcome from short-term exposure. In such a study in an amosite asbestos factory, employment for even as little as 1 month resulted in a 20 percent prevalence of parenchymal opacities: one-third of the participants had pleural abnormalities after 20 years of follow-up; it is significant that both "first attacks" and progression of established radiographic abnormalities occurred 20 and more years after exposure had ceased.

Radiographic asbestosis, once established, may remain static or progress. Rarely has regression been recorded. The factors that determine the outcome are poorly understood. The level and duration of exposure (i.e., cumulative exposure) appear to be prognostic factors. Progression is also considerably more common in persons who already have radiographic abnormalities. This fact provides the basis for the advice that further exposure is to be avoided once the diagnosis of parenchymal asbestosis has been made.

Clinical and Physiological Features

Dyspnea on exertion is the earliest, most consistently reported, and frequently the most distressing symptom of asbestosis. Often dyspnea is accompanied by a persistent cough, which can be spasmodic, and sputum production. Chest tightness is not uncommon, and wheezing also can occur.

In a cross-sectional survey of 816 asbestos-exposed workers using the respiratory symptom questionnaire of the American Thoracic Society, cough, phlegm, wheeze, and dyspnea were inversely related to pulmonary function. Cough, phlegm, and chronic bronchitis were associated with a 2 to 8 percent reduction in FVC and FEV_1; the reduction in these measurements was more significant with wheeze and dyspnea, which caused an 11 to 17 percent reduction. Similarly, based on the British Medical Research Council questionnaire for dyspnea, the prevalence of grade 3 dyspnea among asbestos insulators increased in stepwise fashion from 19.4 percent in patients with category 1 chest radiographic abnormalities (1/0 to 1/2 abnormalities by International Labor Organization [ILO] classification) to 34.5 percent in patients with category 2 chest radiographs and to 49.4 percent in patients with category 3 radiographic abnormalities.

Rales are a distinctive feature of asbestosis. They are usually bilateral, late to paninspiratory in timing, heard best at the posterior lung bases, and not cleared by coughing. They differ in quality and timing from the crackles of bronchitis, which tend to be fewer and earlier. The crackles of asbestosis appear first at the bases in the midaxillary line and tend to spread toward the posterior bases. In prevalence surveys, approximately 83 percent of patients with higher radiographic categories of asbestosis have bilateral rales. In a study of 42 patients with a clinical diagnosis of asbestosis, in 40 the chest radiograph showed at least 1/0 profusion of irregular opacities, 36 had rales, 36 had dyspnea, and 22 had digital clubbing. Rales and clubbing were almost as common among those with less as those with more advanced categories of asbestosis.

In years past, asbestosis-induced respiratory failure was a frequent cause of death in patients with this disorder. In recent years, as the severity of asbestosis appears to have attenuated, cancer has become an increasingly common terminal event. It is important to appreciate that the clinical features of asbestosis and the findings on physical examination are not unique to this disorder and resemble those of a variety of other diffuse interstitial inflammatory and fibrotic processes.

The characteristic pulmonary function changes of asbestosis are a restrictive impairment with a reduction in lung volumes (especially FVC and total lung capacity), decreased lung diffusing capacity (D_{LCO}), and arterial hypoxemia. Large-airway function, as reflected in the FEV_1/FVC ratio, is generally well preserved. In one of the earliest studies, approximately 50 percent of asbestos workers had a reduced FVC and the vital capacity was decreased, on average, by 18 percent as predicted over the next 10 years. Among the 1117 asbestos insulators in New York and New Jersey, the frequency of an abnormal FVC increased to more than 50 percent as follow-up was prolonged. In a larger cohort of 2611 asbestos insulators, the FVC percent predicted decreased as the profusion of irregular opacities on the chest radiograph increased; pleural thickening exaggerated the decrease for each category of profusion. For each category of profusion, diffuse pleural thickening caused a further decrease (at least 10 percent) in FVC percent predicted compared to circumscribed plaques.

Mild airway obstruction can also be seen in nonsmokers with asbestosis. These patients usually have a restrictive pattern of lung function, increased isoflow volume, and increased upstream resistance at low lung volumes. Open lung biopsies from a limited number of these patients suggest that these obstructive findings may be due to peribronchiolar fibrosis, since they revealed peribronchiolar infiltrates with macrophages and fibrosis that extended into the adjacent interstitium. Therefore, it is not surprising that lesser grades of asbestosis can show a mixed restrictive and obstructive abnormality.

Long-term medical surveillance is recommended for all asbestos-exposed persons, especially those with radiographic abnormalities. Periodic physiological assessments play an important role in these evaluations. Although complex physiological abnormalities can be seen in these patients, for prospective assessments of asbestosis carried out in the clinical context, simple measurements of lung volume, such as the FVC, seem to be the most useful.

Radiographic Features

In asbestosis, the standard PA chest radiograph reveals bilateral diffuse reticulonodular opacities, predominantly in the lower lung zones. In 2000, the International Labor Organization (ILO) revised the International Classification of the Radiographs of the Pneumoconioses to make provisions for reading the radiographic features of asbestosis. It used the term *small irregular opacities* to describe the irregular linear shadows that develop in the lung parenchyma and obscure the normal bronchovascular branching pattern seen in disease-free lungs. This schema categorized the irregular rounded opacities found on PA chest radiographs according to size and expressed them on a 12-point scale. Category 0 was defined as a normal radiograph and category 1 as mild asbestosis. Typically, a profusion of irregular opacities at the level of 1/0 is taken as the break point between normal and abnormal. Moderate asbestosis and advanced asbestosis were defined as category 2 and 3 chest radiographs, respectively. As duration from onset and intensity of exposure increase, there is an increase in prevalence and severity of asbestosis as reflected in the chest radiograph.

CT scanning has improved the sensitivity for detecting asbestos-related lesions (Fig. 55-4). It eliminates a common problem with PA chest radiographs—i.e. the superimposition of pleural abnormalities over parenchymal lesions. It also enhances the attenuation discrimination for parenchymal opacities. As a result of more than 300 HRCT evaluations of persons with asbestos exposure, five HRCT features of asbestosis have been identified: (1) curvilinear subpleural lines, (2) increased intralobular septa, (3) dependent opacities, (4) parenchymal bands and interlobular core structures, and (5) honeycombing. These changes have recently been corroborated by histological examination. This spectrum of radiographic findings stands in contrast to the fine irregular opacities that are so prominent on the PA chest radiographs of these persons. In asbestos-exposed workers, abnormal HRCT

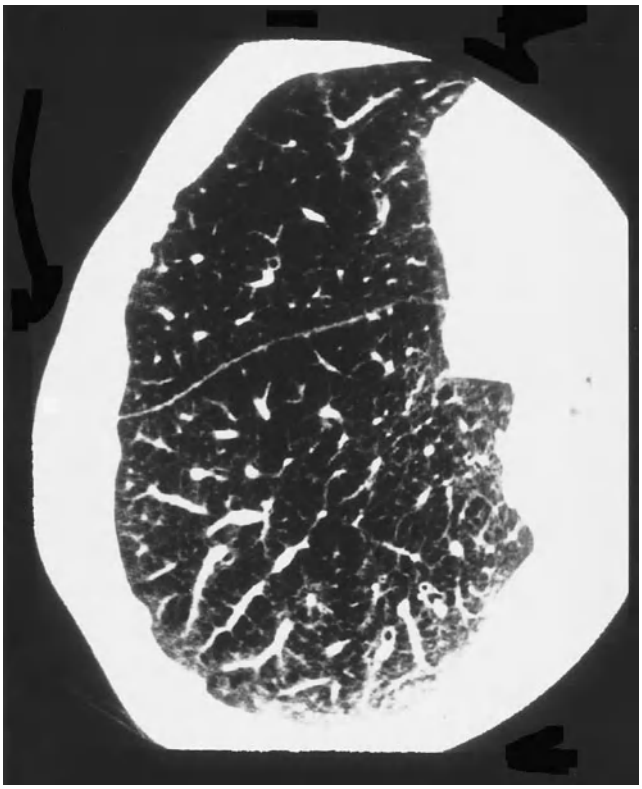

Figure 55-4 HRCT scan with irregular opacities of the lung parenchyma and interlobar structure. The PA chest radiograph was graded 2/1 on the ILO International Classification of the Radiographs of the Pneumoconioses. *(Courtesy of Dr. David Naidich.)*

has been shown to correlate with restrictive physiological abnormalities and abnormal diffusing capacities. HRCT is also extremely sensitive in documenting the asbestos-related pleural abnormalities discussed above. The presence of pleural plaques (particularly if they are bilateral) provides useful evidence that the parenchymal process is asbestos related. Hilar node enlargement is not a feature of asbestosis, and progressive massive fibrosis is also uncommon.

Diagnosis

Asbestosis is defined as parenchymal fibrosis, with or without pleural thickening, usually associated with dyspnea, bibasilar rales, and pulmonary function changes. To diagnose this disorder, one must establish the presence of pulmonary fibrosis and determine whether exposure has occurred of a duration and intensity sufficient to put the person at risk for developing this syndrome. The PA chest radiograph and its interpretation are the most important factors. As noted above, a profusion of irregular opacities at the level of 1/0 is used as the break point between normal and abnormal in the evaluation of lung fields on the chest radiographs of asbestos-exposed persons. When radiographic or lung function changes are marginal, CT scanning often reveals characteristic parenchymal abnormalities as well as pleural plaques and/or pleural fibrosis. These lesions, particularly when bilateral, are strongly suggestive of asbestos exposure.

The diagnosis of asbestosis must always be based on an appropriate exposure history. The features of the history that need to be defined include the duration, onset, type, and intensity of exposure experienced by the patient. Convincing occupational exposures include manufacture of asbestos products, asbestos mining and milling, construction trade worker (insulator, sheet-metal worker, electrician, plumber, pipe fitter, carpenter), power plant worker, boilermaker, and shipyard worker. In performing this evaluation, it is important to keep in mind that intensity of exposure can be heavy even if duration of exposure is short. For example, heavy exposures were experienced by shipyard workers engaged in insulation application or removal in contained areas for brief periods aboard ship and by asbestos insulators during their apprenticeship when they unloaded asbestos sacks into troughs and mixed asbestos cement. Short, intense exposures of this sort, which lasted from several months to 1 or 2 years, can be sufficient to cause asbestosis. Exposures over 10 to 20 years are, however, usually necessary. The timing of the exposure is also relevant. Industrial hygiene controls in the 1950s and 1960s, especially in the construction trades, were not widely applied or enforced. Thus, workers exposed during these periods may have received a heavy asbestos load. Time since onset of exposure is also crucial. Cohort studies have identified latency to be an important factor, with the prevalence of asbestosis increasing with time since the onset of exposure.

The specificity of the diagnosis of asbestosis increases as the number of clinical criteria (symptoms, signs, chest radiograph, pulmonary function) increase. In addition, as the accuracy of the diagnosis increases, the more significant the asbestos exposure. The more trivial the asbestos exposure, the less likely it is to be causal. Misclassification and diagnostic difficulty occur in patients with a heavy cigarette-smoking history and concurrent emphysema (which also reduces the diffusing capacity). Patients with idiopathic pulmonary fibrosis (IPF) may have a history of asbestos exposure. These patients tend to be younger, however, and their asbestos exposure is usually casual, brief, and recent and can often be discounted. Since patients with IPF require a lung biopsy for confirmatory diagnosis, an asbestos fiber count per milligram of dry lung can be helpful (see below). An open lung biopsy is not required in most cases when a significant exposure history can be identified.

In the absence of an adequate exposure history or in the presence of a confusing clinical presentation, biopsy material may be helpful in identifying the nature of the disease. It allows the pulmonary interstitial process to be compared to the known features of asbestosis and other interstitial disorders. It also allows the pathologist to look for the presence of asbestos materials. Asbestos fibers exist in the lung in two forms: uncoated or bare fibers, which, for practical purposes, are visible only on electron microscopy, and coated fibers, which are also called asbestos bodies. The latter are visible by light microscopy (Fig. 55-5). Uncoated fibers are much

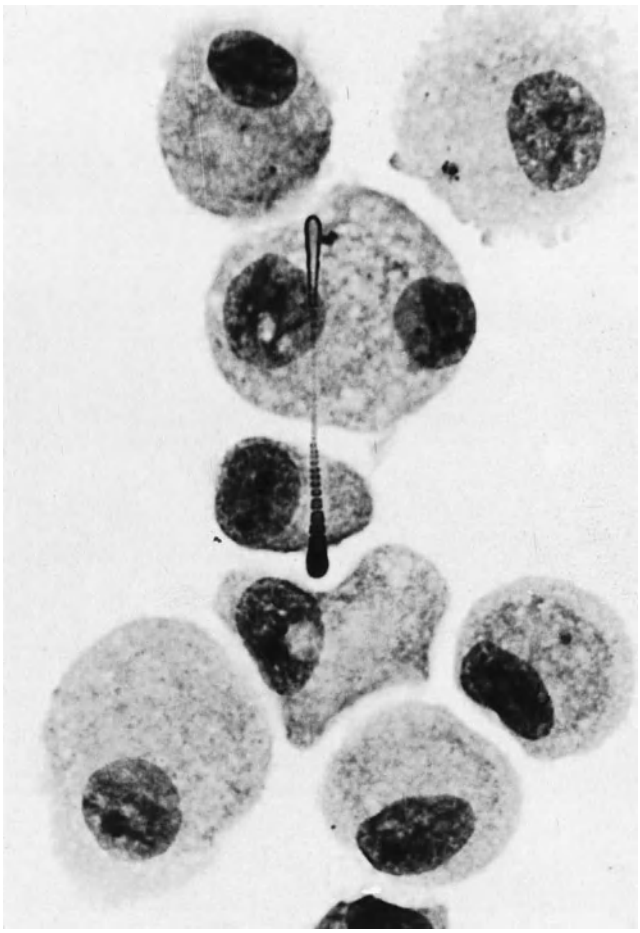

Figure 55-5 Light microscopic appearance of an asbestos body in a cytocentrifuged preparation of alveolar macrophages lavaged from a nonsmoking asbestos insulator (Wright-Giemsa stain, ×400). *(Courtesy of Dr. T. Takemura and Dr. V. Ferrans.)*

more common, exceeding the frequency of coated fibers by anything from 5- to 10,000-fold. Although other inhaled particles may also become coated, most coated fibers found in human lungs have an asbestos core. Thus, the presence of asbestos bodies or asbestos fibers is considered the hallmark of exposure, past or current. The presence of more than one coated fiber has been cited as a necessary criterion for the pathological diagnosis of asbestosis, even in a subject with an obvious exposure history. This may be inappropriate, however, since asbestos bodies may not be able to be detected even after heavy exposure. Cases have been described in which the load of uncoated fibers was high in the absence of asbestos bodies, and asbestos bodies have been noted in the tissues of people without significant asbestos exposure. Thus, although asbestos bodies probably reflect exposure, their absence by no means excludes it.

Asbestos bodies can also be detected in BAL samples. In some studies, these asbestos bodies correlate with heavy exposure and asbestosis. This is illustrated in a large series of 563 patients: those with asbestosis had a mean of 120 asbestos bodies per milliliter; those with pleural disease, 5 asbestos bodies per milliliter; and those with malignant mesothelioma or lung cancer, 8 asbestos bodies per milliliter of lavage fluid. Of 49 patients with more than 100 asbestos bodies per milliliter of lavage fluid, 30 had asbestosis, 8 had pleural disease, 13 had mesothelioma or lung cancer, and 3 had an exposure history only. Others have estimated that one asbestos body per milliliter of BAL fluid correlates with 1000 to 3000 asbestos bodies per gram of dry lung tissue. The problems inherent in counting asbestos bodies in an attempt to establish a diagnosis of asbestosis were noted above. Thus, the utility of BAL asbestos body counts in diagnosing asbestos awaits further definition.

Treatment and Prognosis

Major causes of morbidity and mortality in patients with asbestosis include the progression of the underlying lung disease and the development of lung cancers and malignant mesotheliomas. Longitudinal observations of asbestos-exposed trade workers have demonstrated accelerated declines in pulmonary function. In a study of 77 workers with a mean of 31 ± 1 years of occupational exposure, linear regression demonstrated a mean annual decline of 92 ± 28 ml per year in FVC, 66 ± 22 ml per year in FEV_1, and 14 ± 53 ml per year in total lung capacity. Although corticosteroids and colchicine have been used for the treatment of IPF, they have not been demonstrated to be beneficial in asbestosis. At present, there is no established treatment for this disorder. Because of the risk of lung cancer and mesothelioma, however, medical surveillance is recommended.

MALIGNANT MESOTHELIOMA

Pathology

Most instances of mesothelioma occur in persons who have been exposed to asbestos fibers. In its early stage, the mesothelioma appears as multiple, small, grayish nodules on the visceral and parietal pleura that evolve to coalesce and form larger masses of tumors. These tumors then invade thoracic and other structures by direct extension, causing the morbidity and mortality of disease. Fewer than 25 percent of malignant mesotheliomas are peritoneal in origin.

Mesotheliomas are conventionally classified into three histological patterns: epithelial, sarcomatous, and mixed or biphasic; these patterns account for 50, 20, and 30 percent, respectively. The epithelial variant—in which neoplastic cells are arranged in papillary, tubular, or solid nest configurations—is most easily confused with metastatic adenocarcinoma. The sarcomatous variant has spindle-shaped cells that may be pleomorphic, with considerable mitotic activity.

The pathological diagnosis of malignant mesothelioma may be difficult. In particular, the differentiation of malignant mesotheliomas, adenocarcinomas, and other tumors may be problematic. Histochemistry and immunohistochemistry

may be helpful in making the distinction. Thus, in contrast to mesotheliomas, adenocarcinomas contain neutral mucin that stains positive with the periodic acid–Schiff stain and is often resistant to diastase. Hyaluronic acid, the major acid mucopolysaccharide in mesotheliomas, can be identified with the Alcian blue or colloidal iron stain. Removal by prior digestion with hyaluronidase increases the specificity of the reaction. In contrast, adenocarcinomas are negative for Alcian blue and colloidal iron. Mesothelial cells contain cytoskeletal filaments, including cytokeratin and vimentin; staining for these structures is not specific, since other tumor types are also positive. Carcinoembryonic antigen is absent in malignant mesothelioma but is present in up to 90 percent of adenocarcinomas. Similarly, the monoclonal antibody B72.3, generated against a membrane fraction of human metastatic breast cancer, was positive in 19 of 22 pulmonary adenocarcinomas but none of 20 mesotheliomas. Monoclonal antibody Leu MI is frequently positive in lung carcinomas and nonreactive with mesotheliomas.

The ultrastructural features of malignant mesotheliomas are also noteworthy. Malignant mesotheliomas contain abundant tonofilaments, often organized into perinuclear bundles, and long, sinuous, slender surface microvilli. The microvilli sometimes show secondary and tertiary branching and may interdigitate with stromal collagen. Malignant mesothelial cells produce collagen, a prominent feature of the sarcomatous variant.

Malignant mesotheliomas are locally invasive, spreading along the pleural wall and invading the lung, mediastinal lymph nodes, and other thoracic and nearby structures. At autopsy, tumor may be found in the diaphragm, heart, liver, spleen, adrenals, gastrointestinal tract serosa, bone, pancreas, and kidneys. Between 50 and 80 percent of patients also have metastases.

About 10 percent of patients with a malignant mesothelioma are alive at 24 months. Survival is significantly longer for patients with an epithelial subtype or with a pleural rather than a peritoneal mesothelioma, and for those under 65 years of age.

The incidence of mesothelioma is increasing because of the cohort exposed to asbestos between 1940 and 1970. Incidence rates vary from a low of 11 to 13 per million per year in the United States to 33 per million per year in South Africa and to 66 per million per year in Western Australia. These rates reflect mining and manufacturing industries and the location of crocidolite mines. Although the peak incidence in the United States may have passed since imports decreased after 1945, imports of asbestos in the United Kingdom reached their peak in the 1960s to 1970s. Thus, the peak of mesothelioma deaths in the United Kingdom is expected to occur in 2020, when up to 1 percent of men may die of the disease. Chrysotile was the major asbestos import to the United Kingdom, and half of this material went into the construction industry. Amosite was the leading amphibole import, and most of it went into insulation board. Thus, workers in the construction industry in the United Kingdom seem to be at greatest risk.

Epidemiology

In 1960, Wagner and colleagues published a landmark paper demonstrating an association between malignant mesothelioma and asbestos exposure. They reported on 33 patients from South Africa, 28 of whom were exposed in the crocidolite mining region and 4 of whom were exposed in asbestos factories. They observed that mesotheliomas occurred 20 to 40 years after exposure to asbestos dust and found asbestos bodies in lung tissue from 8 of 10 patients from whom lung tissue was available for study. Subsequently, the importance of direct asbestos exposure was confirmed and the potential importance of indirect exposure to asbestos was recognized.

Evaluations of asbestos fiber content have shown a clear association between asbestos exposure and the occurrence of mesothelioma. Epidemiological studies have shown that crocidolite may be the more potent fiber type among asbestos miners. Most mesotheliomas have occurred from chrysotile-amphibole mixtures, since chrysotile is the most common fiber in commercial use. Few controversies in medicine are as intense as the disagreements concerning the relation between asbestos fiber type and carcinogenic risk. Nonetheless, associations between malignant mesothelioma and other (noncrocidolite) fiber types have been reported. For example, the incidence of malignant mesotheliomas among chrysotile workers who came before the Workers' Compensation Board of Quebec was similar to that in Western Australian crocidolite miners. Studies of Canadian cohorts have also indicated that high concentrations of chrysotile, or an amphibole contaminant, are required to cause mesothelioma, suggesting that chrysotile has weaker biopersistence than does tremolite, which is merely a contaminant in most ores. In the United States, amosite is the predominant amphibole found in lung tissue: in one study it was identified in 81 percent of 90 patients with mesothelioma; in this population, it accounted for 58 percent of all fibers at least 5 μm in length.

Cigarette smoking is a confounding variable in studies that relate asbestos-exposed persons to cancer risk. The contribution that cigarettes make to the risk of lung cancer is impressive (see below). It is universally accepted, however, that mesothelioma is not associated with cigarette smoke per se.

Pathogenesis

Insight into the pathogenesis of malignant mesothelioma has come from experiments in which asbestos fibers were introduced into the pleural space of animals. These studies have demonstrated that amosite, anthophyllite, crocidolite, and Canadian chrysotile can all cause these pleural malignancies. Studies of fiber size have shown that the most carcinogenic fibers in the pleural space are 1.5 μm or less in diameter and more than 8 μm in length. Inspection of electron micrographs of asbestos fibers has shown that crocidolite and amosite possess needlelike characteristics, whereas anthophyllite has a more boxlike appearance and chrysotile has a long, curly appearance. These variations in size are also consistent with epidemiological studies indicating that crocidolite and amosite

may have greater risk for mesothelioma than do other types of asbestos, although these studies are often confounded by intense exposures to these amphibole types.

One theory concerning the mechanism of asbestos-induced carcinogenesis focuses on the observation that asbestos fibers become entangled in the mitotic spindle during interphase, thereby causing chromosomal abnormalities. Electron microscopic evaluations have shown fibers penetrating between multiple lobes of the nucleus and associating, along their length, with the outer surface of the nuclear envelope. Structural chromosomal abnormalities in mesothelioma are clonal and complex, and include both chromosomal gains (chromosome 22) and losses (chromosome 7). Deletions of the short arm of chromosome 3, the break point 1p11 to p22, chromosome 17, and structural and numeric changes in chromosome 7 have been described. The last is quite interesting, since the tumor suppressor gene *p*53 is located in the region of 17p13. In asbestos insulators, sister chromatid exchanges in circulating lymphocytes are increased: larger chromosomes are more susceptible, and in the largest chromosome group, there is a significant interactive effect between asbestos exposure and cigarette smoking.

Cell lines established from malignant mesotheliomas have been shown to constitutively up-regulate the PDGF B-chain gene and, to a lesser extent, the PDGF A-chain gene. High levels of transforming growth factor-β_1 (TGF-β_1), TGF-β_2, and TGF-β_3 mRNA and bioactivity have been reported for cell lines derived from malignant mesotheliomas. These TGF-β moieties may be involved in the considerable matrix formation that accompanies mesothelial tumors. Mesothelioma cell lines also release IGF-1 and express mRNA for the IGF-1 receptor. This is consistent with an IGF-1–based autocrine loop for mesothelioma cell proliferation.

Clinical and Radiographic Features

Pleural mesotheliomas are found mainly in males (ratio, between 3 and 4 to 1) and are most commonly diagnosed in patients between 50 and 70 years of age. Chest pain is the most common symptom experienced by patients with mesotheliomas. Dyspnea is next in frequency. Less common symptoms are cough, weight loss, and fever. A pleural effusion is usually present and can be massive. The effusion is an exudate, can be hemorrhagic, and may have high levels of hyaluronic acid (Fig. 55-6). Malignant mesothelioma is locally invasive, spreading along the pleural wall and invading the lung and nearby structures. Metastases are less common but can give rise to symptoms due to tumor in the diaphragm, heart, liver, spleen, adrenals, gastrointestinal tract, bone, pancreas, and kidneys. The syndrome of inappropriate antidiuretic hormone secretion, clubbing, or hypoglycemia is rare. Thrombocytosis is common—in 90 percent of cases in one series—and thromboembolic complications can occur. Ascites and weight loss are characteristic features of peritoneal mesothelioma.

A variety of radiographic abnormalities are found in malignant mesothelioma. They include a thick pleural peel along the lateral chest wall that can extend to the apex with an irregular nodular surface, multiple pleural nodules or masses, plaquelike opacities, and pleural effusion(s). As the disease progresses, the lung parenchyma may be involved, the affected hemithorax may decrease in size, and the mediastinum or hilar may be invaded. Pericardial thickening or effusion, abdominal extension, and chest wall invasion are common. The HRCT can help in differentiating pleural effusion from tumor and in determining the extent of tumor progression. The presence of asbestosis or of pleural plaques on the opposite side can assist in establishing the diagnosis of malignant mesothelioma.

Diagnosis

The diagnosis of malignant mesothelioma requires cytological or histological validation. Obtaining a cytological diagnosis from the pleural exudate is difficult because reactive mesothelial cells and malignant cells are not easy to distinguish. Biopsy is required. Because mesothelioma has been shown to invade the track of the needle on about 20 percent of patients in whom biopsy was performed by transthoracic needle, open biopsy is preferable. Thoracoscopy is probably the procedure of choice in establishing the diagnosis of mesothelioma. Its diagnostic rates are greater than 80 percent—a value similar to that of open pleural biopsy. Local radiation after biopsy significantly reduces spread in needle tracks or incisions.

Treatment and Prognosis

Median survival time is approximately 8 to 12 months for all patients with malignant mesothelioma. Overall, fewer than 20 percent of patients are alive at 2 years. Pleurectomy or pneumonectomy, combined with radiation therapy, has failed to significantly influence survival rates. Chemotherapy

with doxorubicin (Adriamycin) has shown variable responses without prolonging survival.

Interventions, such as gene therapy or the use of cytokines, for the treatment of malignant mesothelioma are currently being investigated. Thus, in 89 patients, the intrapleural instillation of γ-interferon twice weekly for 8 weeks resulted in eight histologically confirmed complete responses and nine partial responses, with at least a 50 percent reduction in tumor size. The overall response rate was 20 percent, increasing to 45 percent in stage I disease. In 15 patients, a phase I clinical trial of continuous infusion into the pleural space of recombinant IL-2 for 5 days, when evaluated at 36 days after infusion, revealed one complete remission and six partial remissions. The main side effect was fluid retention, no greater than 10 percent, in one-third of the patients. In mice with severe combined immune-deficiency, gene therapy, using a replication-defective adenovirus carrying the herpes simplex–thymidine kinase gene followed by the antiviral drug ganciclovir, was used successfully to treat malignant mesothelioma. A significant antitumor effect occurred with clinically achievable dose ranges, even in bulky tumors. The virus did not spread from the serosal cavity following instillation. In mice with subcutaneously implanted mesothelioma, tumor regression occurred when only 10 percent of cells were infected—a result consistent with a *bystander effect.* A phase I clinical trial has shown this therapy to be safe. However, humoral and cell-mediated immune responses that developed against viral surface proteins compromised the therapeutic effectiveness of this approach. Also, the thymidine kinase gene in vivo had no effect on promoting regression of the tumor. These promising areas of research need further development before they can be applied as standard therapy.

LUNG CANCER

Epidemiology

The association between asbestos exposure and the development of lung cancer is based on a number of successive epidemiological investigations. Case reports of lung cancer and asbestos deaths occurred as early as 1935. Series of patients with asbestosis who went to autopsy were reported by 1947. In 1955, an epidemiological cohort study of 113 men exposed to asbestos for 20 years disclosed 11 deaths due to cancer (compared with 0.8 expected), all of which had evidence of asbestosis. In 1965, a retrospective cohort study in two asbestos insulator unions in the United States reported that deaths from lung cancer were 6.8 times the expected rate and that the incidence of lung cancer increased with time after exposure. In 1968, a follow-up of men in this cohort demonstrated an important synergy between asbestos exposure and cigarette smoking, since the risk of lung cancer was almost entirely borne by those who had a history of cigarette smoking.

The largest survey of asbestos-related deaths looked at a North American asbestos insulator cohort. This study demonstrated a threefold excess of cancer deaths that were due primarily to pulmonary malignancies. Comparatively few of these excess deaths were observed among those less than 25 years after the start of exposure. Lung cancer peaked at 40 years from exposure and mesothelioma at 45 years. In contrast, death rates from asbestosis increased progressively with time. This study confirmed the multiplicative effect of smoking plus asbestos exposure on the risk of lung cancer. Moreover, it showed that deaths from lung cancer dropped by almost two-thirds for asbestos insulators who subsequently stopped smoking.

Additional insights were provided by a study of amosite workers who were exposed to concentrations of 50 fibers per milliliter. These patients experienced a fivefold increase in lung cancer. Long-term follow-up showed: (1) a latency period of about 20 years before the increase in cancer occurred; (2) the greater the dose or the longer the exposure, the greater risk of developing lung cancer; and (3) the greater the dose or exposure time, the shorter the latency period before the tumor developed. Malignancies were also noted in the wives and children of these workers who were exposed to asbestos in the household, primarily on work clothes. In addition, men employed for less than 1 month between 1941 and 1945 developed lung cancer at an increased rate. Studies of a variety of other cohorts have confirmed the increased incidence of lung cancer in asbestos-exposed populations. They have also demonstrated an increased frequency of digestive cancers and cancer of the larynx; in the latter, asbestos has been found in laryngeal tissue. As in the case of cancer of the lung, cigarette smoking has a strong association with the occurrence of these laryngeal malignancies.

Epidemiological studies have also provided information about dose-response relationships and about the importance of asbestos-processing techniques and fiber type in the pathogenesis of pulmonary malignancies. A number of investigators have observed linear dose-response relationships for lung cancer. Different dose-response relationships have, however, been found in other studies. These differences may be the result of differences in processing techniques. For example, studies in a South Carolina plant demonstrated that the steeper dose-response relationship of miners vs. textile weavers was probably due to the manufacturing process, which resulted in high levels of brief exposure during the opening of asbestos bags and the sudden separation of the asbestos fibers. Similarly, differences in lung cancer mortality in asbestos cement product plants in Louisiana were found to be associated with the addition, in one of these plants, of crocidolite to the asbestos cement pipe mixture. Other risk factors in the work place—such as concomitant metals, ionizing radiation, and other chemicals—may also contribute to the differences that have been noted. It has been argued that there is a difference in lung cancer risk for different asbestos fiber types; however, the risk of lung cancer increases most clearly with cumulative asbestos exposure. Despite these uncertainties, however, it is clear that each of the asbestos fiber types causes lung cancer.

Pathology

Asbestos-related lung cancers are not distinct from lung cancers that occur in cigarette smokers and otherwise normal persons in type, nature, or location. All histological types of lung cancer occur with increased frequency, but adenocarcinoma has the highest incidence. In the vast majority of patients, there is histological evidence of asbestosis and asbestos bodies are frequently found. Asbestos-related lung cancer can occur in the absence of asbestosis.

Pathogenesis

Animal experiments using several types of asbestos have succeeded in reproducing pulmonary malignancies. In one study, approximately one-third of rats exposed by inhalation to asbestos (amosite, anthophyllite, crocidolite, Canadian chrysotile, or Rhodesian chrysotile) for periods ranging from 1 day to 24 months developed adenocarcinomas or squamous cell carcinomas of the lung. In these experiments, a clear dose-response relationship existed between asbestos dose and the occurrence of tumors. The mechanisms responsible for the induction of these malignancies are poorly understood. However, DNA injury and activation of nuclear transcription factors may play an important role. The former appears to relate to the physical properties of the asbestos fibers, which enable DNA, RNA, and chromatin to bind to asbestos. Reactive oxygen species may also play an important role in this process, since chrysotile asbestos, along with cigarette smoke, synergistically increases the number of breaks in DNA strands, and oxidant scavengers—such as mannitol, catalase, iron chelators, and dimethylsulfoxide—prevent this DNA damage. Asbestos also induces nuclear factor-κB (NF-κB) DNA binding in tracheal epithelial cells in vitro. NF-κB is an important transcription factor for cytokines, growth factors, and protooncogenes that could contribute in a variety of ways to malignant transformation.

Clinical Features

The patterns of presentation of lung cancer among asbestos workers are similar to those of high-risk patient populations: cough, chest pain, dyspnea, hemoptysis, recurrent bouts of pneumonia, and localized wheezing are major symptoms that frequently bring patients to medical attention. However, patients can also be asymptomatic at the time of initial discovery, the abnormality being noted on a routine or screening chest radiograph. Other manifestations of carcinoma—such as rib invasion, shoulder-arm pain, and paraneoplastic syndromes—can also occur in asbestos-related malignancies.

One of the most vexing questions in asbestos-related lung cancers is the relationship between the lung cancer and asbestosis. Asbestosis can be detected radiographically or histologically in the vast majority of patients with asbestos-related lung cancer. Most, but not all, patients with lung cancer in the Quebec asbestos mining district had small parenchymal opacities on the chest radiograph before death. In addition, in amphibole miners from South Africa with carcinoma of the lung who were evaluated by stepwise regression analysis for exposure variables, asbestosis was by far the most striking variable. Moreover, a dose-response relationship was found between the severity of asbestosis and the frequency of lung cancer. However, in keeping with the high frequency of asbestosis that cannot be seen on the chest radiograph (i.e., asbestosis that can be detected only in vivo by HRCT or biopsy) it is clear that radiographic evidence of asbestosis cannot be detected in all patients with asbestos-related lung cancer. Thus, in the North American insulator cohort, 18 percent of the patients who died of lung cancer did not have radiographic evidence of parenchymal fibrosis. Similarly, in a case control study of 271 patients with lung cancer, a small but definite increase in cancer risk was noted in patients whose chest radiographs were not definitely abnormal (0/1 or less by ILO classification). This study indicated that asbestos exposures that do not cause small opacities on the chest radiograph may nevertheless increase the risk of lung cancer.

Radiographic Features

The radiographic manifestations of asbestos-induced lung cancers do not differ, per se, from those of lung cancers associated with other carcinogens. Mass lesions, atelectasis, postobstructive pneumonia, and pleural effusions are all seen. As noted above, these lesions are frequently superimposed on a background of asbestosis or asbestos-induced pleural abnormalities. Confusion with lung cancer may arise from en face pleural plaques or rounded atelectasis. In contrast to lung cancer, however, these abnormalities are stable over time. Newer techniques, such as the helical CT scan, which can evaluate the chest in a single breath, may increase the early detection rate of lung cancer in this high-risk patient population.

Diagnosis

The principles employed in the diagnosis of lung cancer in asbestos workers are identical to those in the diagnosis of pulmonary malignancies in patients exposed to other carcinogenic agents. Appropriate cytological or histological specimens are required. This can be accomplished by sputum analysis or by bronchoscopy with brushings, biopsy, or lavage. Transthoracic needle aspirates, thoracoscopic parenchymal biopsies, or open lung biopsies may be required for definitive diagnosis.

Treatment and Prognosis

The therapeutic approaches utilized for asbestos-related lung cancers are similar to those employed for lung cancers induced under other circumstances. When one is dealing with non–small-cell malignancies, patient operability and resectability need to be evaluated and, if appropriate, surgical extirpation undertaken. The impact of other asbestos-related pulmonary processes must always be taken into account. For

example, severe asbestosis may limit operability, and diffuse pleural thickening may make surgical intervention problematic. Overall, however, lung cancer has a poor prognosis—15 percent survival at 5 years.

EFFORTS AT ASBESTOS CONTROL

In order to control the risk of exposure to asbestos, the US Occupational Safety and Health Administration regulates the usage of all types of asbestos fibers.

Industrial hygiene efforts to control exposure have focused on engineering controls, including enclosure of the process lines, especially all sites where asbestos is introduced into a system, increasing ventilation, and the use of wet manufacturing methods. Personal respirators are used as a last resort in achieving control of exposure in the workplace. Most of the insulation-manufacturing industry has switched to alternative materials, especially fibrous glass, rock and slag wool, and refractory ceramic fibers. Animal experiments have generally shown these asbestos substitutes to be safe, except that refractory ceramic fibers were able to produce mesotheliomas in hamsters. Asbestosis and asbestos-related cancers may occur at increased rates in the future, owing to the increased use of asbestos in developing countries.

Chronic Beryllium Disease and Hard-Metal Lung Diseases

Mary Elizabeth Kreider • Milton D. Rossman

CHRONIC BERYLLIUM DISEASE

History

Beryllium is the lightest weight metal and has an atomic number of 4. Gem stones, such as aquamarine, emerald, and beryl, contain beryllium and have been recognized since ancient times. But beryllium as an element was first discovered in 1798 by the French chemist, Vauquelin, and reduced to its metallic form and named beryllium in 1828 by the German metallurgist, Wohler. Beryllium became a commercial product when it was used as an alloy first with aluminum and later with copper, nickel, and cobalt after World War I. The industry grew in the 1930s due to the increased use of beryllium-copper products during World War II and the use of beryllium oxide in the refractory and fluorescent lamp industries. During and after World War II, beryllium was used in the nuclear industry because of its ability to function as a neutron multiplier. Beryllium was used for both civilian nuclear reactors and for military weapons.

With an increased industrial need for beryllium, acute chemical pneumonitis was first described by Weber and Engelhardt in Germany in 1933 and in the United States by van Ordstrand et al in 1943. This condition was usually limited to the upper respiratory tract, though it could extend to the bronchi, bronchioli, and alveoli if there was sufficient exposure. This condition peaked in the 1940s and with the implementation of industrial hygiene standards will now only be seen if there are plant explosions or other serious lapses in procedures. The last reported possible case in the United States occurred in the early 1980s.

A second pulmonary complication of beryllium exposure was first described by Hardy and Tabershaw in 1946. This disease differed from the acute chemical pneumonitis because of the delayed onset, granulomatous response, and chronic course. Now known as chronic beryllium disease (CBD), this condition is a hypersensitivity reaction to beryllium and is the major hazard facing beryllium workers today.

Clinical Presentation

CBD is primarily a pulmonary granulomatous disorder. Although involvement of other organ systems has been reported (e.g., lymph node, skin, and liver), the lungs are the principal organ affected and account for the morbidity and mortality of this disease. In the early stages, CBD may be asymptomatic. A positive blood proliferative response to beryllium (evidence for beryllium hypersensitivity) may be the earliest sign of

CBD. Radiologic changes can also be detected on routine chest radiographs. Symptomatic disease usually begins with nonspecific respiratory complaints, such as exertional dyspnea and cough. Early in the disease process, routine chest radiography may not be helpful. Pulmonary function testing early in the disease may be normal or have an isolated abnormality of the diffusing capacity (D_{LCO}). As the disease progresses, symptoms become more characteristic for chronic interstitial lung disease with a nonproductive cough, substernal burning pain, and progressive exertional dyspnea. At this stage dry bibasilar crackles are observed on physical examination. A rare patient may have asthmatic-type complaints and physical findings. With advanced disease progressive weakness, easy fatigability, dyspnea at rest, anorexia, and weight loss may occur and acrocyanosis and clubbing may be observed. As cor pulmonale develops, peripheral edema, hepatomegaly, and distended neck veins are seen. Fever is unusual but can be seen. Hypercalcemia and nephrocalcinosis, hyperuricemia, joint pains, and severe cachexia have been described. Severe liver involvement has not been seen, but liver granulomas with mild elevation of the liver function tests occur. Skin involvement may occur in 10 to 30 percent of cases and frequently involves small granulomatous nodules on the hands, arms, and chest.

Radiography

Radiographic changes in CBD are nonspecific and cannot be differentiated from sarcoidosis (Fig. 56-1). The most common radiographic abnormalities are diffuse round and reticular abnormalities. While most patients have both round and reticular nodules, opacities may be only round or only reticular. These opacities are usually present diffusely throughout the lung but may be confined to the upper lobes. Hilar adenopathy similar to what is commonly observed in sarcoidosis may also be seen in up to 50 percent of cases. However, the large "potato type" node involvement is not seen. As the disease advances, radiologic evidence of scarring and retraction can be seen. The hila are retracted upward and conglomerate mass and emphysematous bullae may be present. Gross architectural distortion can occur from severe fibrosis. Pleural thickening can be seen in the presence of long-standing disease. In early disease complete resolution of radiographic abnormalities can occur secondary to corticosteroid therapy and may recur as the corticosteroids are

C

Figure 56-1 A 61-year-old male smoker who had worked at a beryllium processing facility for 20 years. He had a productive cough for 10 years but denied any shortness of breath. He had a positive response of both blood and bronchoalveolar lavage (BAL) cells to beryllium (SI for blood BeLPT = 13.8 [NI < 3.0], SI for BAL BeLPT = 306 [NI < 5.0]. His BAL also demonstrated a marked lymphocytosis (cell yield = 6×10^5 cells/ml [NI < 3.0×10^5 cells/ml], lymphocytes = 55.2% [NI < 20%]. *A*. Chest radiograph demonstrating nodular interstitial disease with adenopathy. *B*. Chest CT mediastinal window demonstrating calcified bilateral hilar and mediastinal lymph nodes. *C*. Chest CT lung window demonstrating a diffuse, fine-nodular pattern of interstitial lung disease that was most prominent in the mid and upper lung zones.

tapered. Complete spontaneous disappearance of the radiographic lesions has not been observed. The computed tomographic appearance of CBD includes upper lobe or diffuse fibrosis, pulmonary nodularity, and hilar and mediastinal adenopathy. However, in biopsy-proven CBD the computed tomographic findings may be normal or demonstrate ground-glass changes.

Immunopathogenesis

There are three important characteristics of CBD. First, this disease is usually associated with industrial exposure to beryllium. The only cases that have been described in nonindustrial workers have been in individuals who lived near beryllium plants and were either exposed to the airborne emissions from the plant or from family members who brought contaminated work clothes into the home. All other cases have been described in individuals who have been involved in the heating, grinding, abrading, or handling of beryllium metals, alloys, salts, or oxides. In addition, workers not directly handling beryllium may be exposed from processes occurring near them. Industrial hygienic practices today include efforts to remove potential airborne beryllium at the source to prevent beryllium from becoming airborne, limiting the number of workers with potential exposure to beryllium, limiting skin exposure, and trying to keep the airborne levels as low as possible. Recently the Department of Energy has used 0.2 $\mu g/m^3$ as an action level because of the repeated reports of CBD with possible exposure below the Occupational Safety and Health Administration (OSHA) recommended threshold level of 2 $\mu g/m^3$/8 h shift.

A second important characteristic of CBD is the long time interval or latency that occurs between initial exposure and the onset of disease. The average time to the onset of clinical symptoms is 10 years. This fact combined with the lack of a clear-cut dose-response relationship to CBD has hampered efforts to determine a safe level of beryllium. Thus, it is uncertain whether a peak exposure level or a total accumulated dose is more important for the development of CBD. Individuals have been described (i.e., secretaries with apparently little exposure) who have worked in industry for less than 1 year and yet still develop disease years to decades later.

A third important characteristic of CBD is that not all exposed workers will develop the disease. Only 1 to 8 percent of exposed workers will ever develop the disease. This percentage appears to have remained the same despite dramatic efforts by industry to reduce the potential exposure in their workers. This last characteristic of CBD may be due to a genetic predisposition (see below).

The suspicion that an immunologic reaction to beryllium caused CBD was based on the following observations. (1) Beryllium painted on the skin (patch testing) could elicit delayed-type hypersensitivity reactions in patients with CBD. However, because of the concern that patch testing could sensitize individuals to beryllium, skin testing has not been widely used. (2) CBD was associated with "immunologic granuloma." (3) Finally, animal studies demonstrated that a hypersensitivity could be demonstrated in animals and that this could be passed with cells.

In vitro studies that simulated patch testing were developed in the 1970s and applied to patients with CBD. The blood cells from a large percent of patients with CBD had positive proliferative responses to beryllium. In addition, after stimulation with beryllium, blood cells from many patients with CBD could release the lymphokine, macrophage inhibition factor. However, all patients with CBD did not have positive responses with their blood cells.

The confirmation that CBD was due to a cell-mediated response to beryllium came in the 1980s when cells harvested from the bronchoalveolar lavage fluid (BALF) from patients with CBD were examined. Not only was a marked increase in the number and percent of CD4+ T lymphocytes in the BALF noted, but also a positive proliferative response of bronchoalveolar lymphocytes to beryllium was observed. Positive proliferative responses to beryllium were observed in all cases of CBD and negative responses were noted in beryllium workers with biopsy-proven non-beryllium lung disease, patients with sarcoidosis and no history of beryllium exposure, and normal volunteers. Not only did all patients with CBD have a positive proliferative response of their bronchoalveolar cells to beryllium, but this response was more pronounced in their lung cells than their blood cells. Thus, there was the suggestion that there was an accumulation of beryllium-specific cells in the lungs of all patients with CBD. This has recently been confirmed using ELISPOT analysis.

The CD4+ T-cell response to beryllium suggested that specific HLA class II molecules might be involved in CBD since HLA class II molecules present antigenic peptides to CD4+ T cells. A strong association of CBD with the marker HLA DPB1-glu 69 was first shown by Richeldi and subsequently confirmed in three other laboratories. However, rather then just a marker for CBD, this marker appears to be associated with the ability to develop an immune response to beryllium. However, individuals homozygous for this marker may be more likely to develop CBD rather than just have sensitization with no apparent disease. For the 10 to 20 percent of individuals with beryllium sensitization who are DPB1-glu-69–negative, recent studies suggest that DR may be important in these individuals.

Recent studies suggest that HLA DPB1-glu 69 is not just a marker for beryllium sensitization, but is strongly associated with the ability of beryllium to cause T-cell proliferation. The beryllium-induced T-cell response is blocked by anti-DP antibodies but not by anti-DR or anti-DQ antibodies. Only DPB1-glu 69 containing B-cell lines are able to stimulate sensitized T cells in the presence of beryllium. In addition, beryllium was shown to stimulate the release of the CLIP molecule only from glu-69–containing DP molecules. Finally, the DPB1 molecules containing glu-69 are necessary not only for the T-cell proliferative response but also for these cells to secrete interferon-γ (IFN-γ), tumor necrosis factor-alpha (TNF-α), interleukin-2 (IL-2), and numerous surface markers.

The above studies suggest the following model for the pathogenesis of CBD. Beryllium is inhaled and deposited in

Table 56-1

Laboratories Performing Beryllium Proliferation Testing

the periphery of the lung. Beryllium, either alone as a crystal or combined with a normal lung protein(s), is bound by glu-69–containing DPB1 molecules and presented to beryllium-specific T cells. The beryllium protein or beryllium crystal is poorly digestible and cannot be removed by the immune response. Persistent inflammation leads to granuloma formation. The cells of the granuloma secrete enzymes that cause tissue destruction and fibrosis.

Diagnosis

Because of the frequent need for corticosteroid treatment of patients with CBD, all patients should have tissue confirmation of their diagnosis. A confirmed diagnosis of CBD requires demonstration of a granulomatous reaction secondary to beryllium hypersensitivity. The former requires biopsy material. The latter can be most convincingly demonstrated by testing the proliferative response of bronchoalveolar cells to beryllium. If bronchoalveolar lavage cells cannot be easily or safely obtained, testing of blood proliferative responses to beryllium is a reasonable alternative. Laboratories performing these tests are listed in Table 56-1. In cases where biopsy demonstration of granulomatous inflammation is not possible, radiologic evidence of granulomatous inflammation may substitute.

Because immunologic tests of beryllium hypersensitivity have been available only since the late 1980s, their use for screening worker populations is not clear. However, studies to date indicate that blood proliferative response to beryllium is the most sensitive screening test for CBD. The major difficulty with using the blood proliferative response to beryllium as a screening tool is that not all individuals with beryllium sensitization will go on to develop CBD. In addition, the number of workers with beryllium sensitization that ultimately develop symptomatic CBD that requires treatment is unknown. In addition, the justification for a screening test requires that there must be some action that will alter the course of the disease. While it is generally believed that early treatment of CBD will alter the natural course of this condition this is not certain. In addition, removal from further exposure, a prudent but unproven practice, is possible for current workers but would not be applicable to former workers. Thus, the strongest recommendation for use of the beryllium lymphocyte proliferation test as a screening test can be made for current workers. Recommendations for screening former workers and residents of communities with past beryllium exposure from the ambient air are less certain. Nevertheless, because the risk of developing CBD is lifelong, the question of appropriate screening for exposed individuals remains.

Differential Diagnosis

The major challenge to making the diagnosis of CBD is to think of the possibility of beryllium exposure. Most cases of CBD that are misdiagnosed are diagnosed as sarcoidosis because either the exposure to beryllium was not known by the patient or the physician failed to elicit an occupational history. Because the radiographic and clinical presentation of CBD (Table 56-2) is similar to sarcoidosis, the differential diagnosis includes upper-lobe fibrotic processes (Table 56-3). In addition, as for sarcoidosis, other causes of granulomatous disease must be searched for and eliminated. The differential between sarcoidosis and CBD is the result of proliferation testing to beryllium. Patients with sarcoidosis do not respond to blood proliferation to beryllium, while CBD patients do. Cases of sarcoidosis among beryllium workers can be diagnosed in this manner. However, caution should always be used and repeatedly negative blood and lung tests should be determined before accepting a case of granulomatous lung disease in a beryllium worker as sarcoidosis.

Treatment

No standard approach to the use of corticosteroids has been adopted in the treatment of CBD. Because of the side effects, corticosteroids should be reserved for patients with documented pulmonary impairment or those with progressive deterioration. Doses of corticosteroids should be tapered to the lowest dose that controls signs of active disease. Monitoring of patients with chest radiographs, pulmonary function tests, exercise tests, and serum angiotensin-converting enzyme may be useful. Most cases of CBD will be arrested with corticosteroid treatment. In cases of corticosteroid resistance or end-stage disease discovered at initial diagnosis, lung transplantation may be a reasonable approach.

The long-term prognosis for CBD is uncertain. Follow-up of cases that were diagnosed in the 1940s and 1950s suggest that the mortality of the disease might be as high as 30 percent. Whether a similar mortality will be present in patients with

Table 56-2

Comparision of Chronic Beryllium Disease and Sarcoidosis

Manifestations	Sarcoidosis	Chronic Beryllium Disease
Erythema nodosum	10–20%	Absent
Hilar adenopathy	50–75%	< 50%
Peripheral adenopathy	Occasional	Rare
Hypercalcemia	Occasional	Rare
Nephrocalcinosis	Rare	Rare
Bone changes	In chronic disease	Absent
Parotid involvement	Occasional	Absent
Posterior uveitis	Occasional	Absent
Liver involvement	Common	Frequent
Splenomegaly	Rare	Rare
Skin	Uncommon	Unusual
Central nervous system	Occasional	Absent
Response to steroids	Only active disease	Only active disease

disease diagnosed in the 1980s or 1990s is not certain. Newer techniques to diagnose CBD (immunologic testing) enable the disease to be detected earlier. The natural history of this condition detected at the presymptomatic stage is unknown.

Table 56-3

Differential Diagnosis of Chronic Beryllium Disease

Sarcoidosis
Hypersensitivity pneumonitis
Tuberculosis
Histoplasmosis
Silicosis
Talc granulomatosis
Eosinophilic granuloma
Idiopathic pulmonary fibrosis

The two major questions are whether or not the disease detected early is inevitably progressive and whether the disease will be more responsive to corticosteroid therapy.

Beryllium and Lung Cancer

Animal studies have clearly indicated that beryllium is carcinogenic. Whether beryllium is carcinogenic in humans is not clear. A National Institute for Occupational Safety and Health (NIOSH) study suggests that a small increase in lung cancer (SMR = 1.26) may occur in beryllium workers. However, this finding has been challenged because of the poor data with regard to cigarette smoking. This issue will remain controversial, as additional studies are not currently planned. Whatever the risk of cancer is in beryllium workers, the more significant medical concern is CBD.

HARD-METAL LUNG DISEASE

Introduction and Overview

Hard metal is an alloy of tungsten carbide in a matrix of cobalt into which smaller amounts of chromium, molybdenum, nickel, niobium, tantalum, titanium, and/or vanadium may be added. These components are milled to a fine powder, mixed together, pressed into the desired shape, and heated under pressure to between 800 and 1000°C, yielding a product with a chalklike consistency. The material may then undergo additional machining before being baked at 1500°C, which is above the melting point of cobalt and leads to the formation of an alloy that is 90 to 95 percent as hard as a diamond. Because of this property, hard metal is an important component in cutting tools, drill bits, armor plate, and jet engine parts.

Hard metal was developed in the 1920s, and interstitial lung disease was first reported in hard-metal workers in 1940. Lung disease has been noted to occur in those working in both the initial production of hard metal and the machining and maintenance of hard-metal tool components. In addition, although hard metal is not used in the diamond-polishing industry, a similar spectrum of disease has been reported in diamond polishers using steel polishing disks whose cutting surfaces consist of microdiamonds cemented into a fine cobalt mesh. In contrast, workers in the cobalt-producing industry, who are more likely to be exposed to cobalt alone, may develop occupational asthma but appear to be much less likely to develop interstitial lung disease.

The industrial processes associated with hard-metal lung disease produce respirable fine metallic dust particles. They also produce metallic ions that accumulate in the coolants used in the metalworking procedure and are absorbed through the skin or inhaled in vaporized coolant fluids. To counteract these exposures, the American Conference of Government Industrial Hygienists (ACGIH) have established current permissible exposure limits for cobalt metal, dust, and fumes at an 8-h threshold-weighted average (TWA) of 0.02 mg/m^3. NIOSH recommends an exposure limit of 0.05

mg/m^3 as a TWA for a 10-h workday and a 40-h workweek and OSHA requires an 8-h TWA of 0.1 mg/m^3.

Clinical Manifestations in Hard-Metal—and Cobalt—Exposed Persons

A variety of respiratory syndromes have been associated with exposure to hard metal, most commonly: (1) asthmatic reactions; (2) a form of hypersensitivity lung disease; and (3) interstitial pulmonary fibrosis. The last two forms may be a continuum of the same process with subclinical or unrecognized hypersensitivity alveolitis proceeding to the development of fibrotic lung disease. *Hard-metal disease* has been used to describe all types of lung disease but is most often used to reference the parenchymal or interstitial lung disease rather than the airway-related manifestations of hard-metal inhalations.

Interstitial Lung Disease
