FOURTH EDITION

Fishman's PULMONARY DISEASES AND DISORDERS

VOLUME ONE & TWO

Alfred P. Fishman
Jack A. Elias
Jay A. Fishman
Michael A. Grippi
Robert M. Senior
Allan I. Pack

Fishman's Pulmonary Diseases and Disorders

Volume 1

Notice

Medicine is an ever-changing science. As new research and clinical experience broaden our knowledge, changes in treatment and drug therapy are required. The authors and the publisher of this work have checked with sources believed to be reliable in their efforts to provide information that is complete and generally in accord with the standards accepted at the time of publication. However, in view of the possibility of human error or changes in medical sciences, neither the authors nor the publisher nor any other party who has been involved in the preparation or publication of this work warrants that the information contained herein is in every respect accurate or complete, and they disclaim all responsibility for any errors or omissions or for the results obtained from use of the information contained in this work. Readers are encouraged to confirm the information contained herein with other sources. For example and in particular, readers are advised to check the product information sheet included in the package of each drug they plan to administer to be certain that the information contained in this work is accurate and that changes have not been made in the recommended dose or in the contraindications for administration. This recommendation is of particular importance in connection with new or infrequently used drugs.

Fishman's Pulmonary Diseases and Disorders

Fourth Edition

Volumes 1 & 2

Editor-in-Chief

Alfred P. Fishman, MD
William Maul Measey Professor of Medicine
University of Pennsylvania Medical Center
Philadelphia, Pennsylvania

Co-Editors

Jack A. Elias, MD
Waldemar Von Zedtwitz Professor of Medicine
Chair, Department of Internal Medicine
Yale University School of Medicine
New Haven, Connecticut

Jay A. Fishman, MD
Associate Professor of Medicine
Harvard Medical School
Director, Transplant Infectious Disease and Compromised Host Program
Massachusetts General Hospital
Associate Director, MGH Transplantation Center
Boston, Massachusetts

Michael A. Grippi, MD
Vice Chairman, Department of Medicine
Pulmonary, Allergy, and Critical Care Division
University of Pennsylvania Health System
Chief of Medicine, Philadelphia VA Medical Center
Philadelphia, Pennsylvania

Robert M. Senior, MD
Dorothy R. and Hubert C. Moog Professor of Pulmonary Diseases in Medicine
Professor of Cell Biology & Physiology
Washington University School of Medicine
St. Louis, Missouri

Allan I. Pack, MB, ChB, PhD
Professor of Medicine
Chief, Division of Sleep Medicine/Department of Medicine
Director, Center for Sleep and Respiratory Neurobiology
University of Pennsylvania School of Medicine
Philadelphia, Pennsylvania

Volume 2

Contributors

Muhanned A. Abu-Hijleh, MD, FCCP
Director, Interventional Pulmonology and Special Procedures Unit
Clinical Assistant Professor of Medicine
Rhode Island Hospital/Brown Medical School
Division of Pulmonary, Sleep, and Critical Care Medicine
Providence, Rhode Island

Masazuni Adachi, MD, ScD
Professor of Pathology
State University of New York
Downstate Medical Center
Consultant
Department of Laboratories
Isaac Albert Research Institute
Kingsbrook Jewish Medical Center
Brooklyn, New York

Sheela Y. Ahmed, MD
Fellow, Division of Pulmonary and Critical Care Medicine
Oregon Health and Sciences University
Portland, Oregon

Abass Alavi, MD
Professor of Radiology and Director of Research Education
Division of Nuclear Medicine
Hospital of the University of Pennsylvania
Philadelphia, Pennsylvania

Steven M. Albelda, MD
William Maul Measey Professor of Medicine
Pulmonary, Allergy, and Critical Care Division
University of Pennsylvania Medical Center
Philadelphia, Pennsylvania

Murray D. Altose, MD
Professor of Medicine
Case Western Reserve University School of Medicine
Chief of Staff
Cleveland VA Medical Center
Cleveland, Ohio

Andrea J. Apter, MD, MSc
Associate Professor of Medicine
University of Pennsylvania
Section of Allergy and Immunology
Division of Pulmonary Allergy Critical Care Medicine
University of Pennsylvania Health System
Philadelphia, Pennsylvania

Jeffrey J. Atkinson, MD
Assistant Professor
Division of Pulmonary and Critical Care
Washington University School of Medicine
St. Louis, Missouri

Santhosh M. Baby, PhD
Postdoctoral Research Fellow
Department of Physiology and Pennsylvania Muscle Institute
University of Pennsylvania School of Medicine
Philadelphia, Pennsylvania

John R. Bach, MD
Professor of Physical Medicine and Rehabilitation
Professor of Neurosciences
Vice Chairman
Department of Physical Medicine and Rehabilitation
UMDNJ-New Jersey Medical School
Newark, New Jersey

Zubair W. Baloch, MD, PhD
Associate Professor Pathology and Laboratory Medicine
University of Pennsylvania School of Medicine
Staff Pathologist
Hospital of the University of Pennsylvania
Philadelphia, Pennsylvania

Alan F. Barker, MD
Professor of Medicine
Division of Pulmonary and Critical Care Medicine
Oregon Health and Sciences University
Portland, Oregon

Michael F. Beers, MD
Associate Professor of Medicine
Pulmonary and Critical Care Division
Department of Medicine
University of Pennsylvania School of Medicine
Philadelphia, Pennsylvania

Lisa M. Bellini, MD
Associate Professor of Medicine
University of Pennsylvania School of Medicine
Philadelphia, Pennsylvania

Saverio Bellusci, PhD
The Developmental Biology Program
Saban Research Institute
Children's Hospital of Los Angeles
University of Southern California Keck School of Medicine and School of Dentistry
Los Angeles, California

John A. Belperio, MD
Assistant Professor of Medicine
Division of Pulmonary and Critical Care Medicine
David Geffen School of Medicine at UCLA
Los Angeles, California

Jeffrey S. Berman, MD
Professor of Medicine
Boston University School of Medicine
Chief, Pulmonary Medicine and Associate Chief, Medical Service
Boston Veterans Administration Health Care
Boston, Massachusetts

Luca Bigatello, MD
Department of Anesthesia and Critical Care
Massachusetts General Hospital
Department of Anesthesia
Harvard Medical School
Boston, Massachusetts

Reshma Biniwale, MD
Cardiothoracic Surgery Fellow
Department of Cardiothoracic Surgery
Montefiore Medical Center
Bronx, New York

Richard C. Boucher, MD
Kenan Professor of Medicine
Director, Cystic Fibrosis/Pulmonary Research and Treatment Center
University of North Carolina
Chapel Hill, North Carolina

Sidney S. Braman, MD, FCCP
Director, Division of Pulmonary
Pulmonary, Sleep, and Critical Care Medicine
Professor of Medicine
Rhode Island Hospital/Brown Medical School
Providence, Rhode Island

Peter H. Burri, MD
Institute of Anatomy
University of Bern
Bern, Switzerland

William W. Busse, MD
Professor and Chair of Medicine
University of Wisconsin Medical School
Madison, Wisconsin

Francis A. Caccavo, MS
Chief of the Core Laboratory
Kingsbrook Jewish Medical Center
Brooklyn, New York

Hilary C. Cain, MD
Assistant Professor
Department of Internal Medicine
Section of Pulmonary and Critical Care Medicine
Yale University School of Medicine
New Haven, Connecticut

Jeffrey P. Callen, MD
Professor of Medicine (Dermatology)
Chief, Division of Dermatology
University of Louisville
Louisville, Kentucky

Edward J. Campbell, MB, BS, FRACP, PhD
Department of Internal Medicine
University of Utah Health Care
Salt Lake City, Utah

Kenneth G. Castro, MD
Centers for Disease Control and Prevention
Division of Tuberculosis Elimination
Atlanta, Georgia

David M. Center, MD
Chief, Pulmonary, Allergy, and Critical Care Medicine
Gordon and Ruth Snider Professor of Pulmonary Medicine
Professor of Medicine and Biochemistry
Boston University School of Medicine
Boston, Massachusetts

Robert J. Cerfolio, MD, FACS, FCCP
Professor of Surgery
Department of General Surgery
Division of Cardiothoracic Surgery
Chief of Section of Thoracic Surgery
University of Alabama
Birmingham, Alabama

Richard E. Chaisson, MD
Professor of Medicine
Epidemiology and International Health
Johns Hopkins University School of Medicine
Baltimore, Maryland

Georgios Chamilos, MD
Postdoctoral Research Fellow
Department of Infectious Diseases
Infection Control and Employee Health
The University of Texas M. D. Anderson Cancer Center
Houston, Texas

Neil S. Cherniack, MD
Case Western Reserve University
Cleveland, Ohio
New Jersey School of Medicine
University of Medicine and Dentistry
Newark, New Jersey

Jason D. Christie, MD, MSCE
Assistant Professor of Medicine
Division of Pulmonary
Pulmonary, Allergy and Critical Care Medicine Department of Medicine
Assistant Professor of Epidemiology
Department of Biostatistics and Epidemiology
Senior Fellow
Center of Epidemiology and Biostatistics
University of Pennsylvania School of Medicine
Philadelphia, Pennsylvania

Geoffrey Chupp, MD
Associate Professor of Medicine
Director, Yale Center for Asthma and Airways Disease
Division of Pulmonary and Critical Care Medicine
Yale School of Medicine
New Haven, Connecticut

Andrew Churg, MD, PhD
Professor, Department of Pathology
University of British Columbia
Vancouver, British Columbia, Canada

John P. Chute, MD
Associate Professor of Medicine
Assistant Professor of Pharmacology and Cancer Biology
Division of Cellular Therapy
Duke University Medical Center
Durham, North Carolina

James M. Clark, MD
Institute for Environmental Medicine
University of Pennsylvania School of Medicine
Philadelphia, Pennsylvania

J. Allen D. Cooper, Jr., MD
University of Alabama Hospital
Birmingham, Alabama

Gregory P. Cosgrove, MD
Assistant Professor and Assistant Director
Interstitial Lung Disease Program
National Jewish Medical and Research Center
University of Colorado Health Sciences Center
Denver, Colorado

Gerard J. Criner, MD
Professor of Medicine
Chair, Division of Pulmonary and Critical Care Medicine
Temple University School of Medicine
Philadelphia, Pennsylvania

Kristina Crothers, MD
Assistant Professor of Medicine
Section of Pulmonary and Critical Care
Department of Internal Medicine
Yale University School of Medicine
New Haven, Connecticut

Thomas A. Cumbo, MD
Clinical Associate Professor of Medicine
University at Buffalo
State University of New York
Buffalo, New York

Jeffrey L. Curtis, MD
Professor
Department of Internal Medicine
University of Michigan Medical School
Ann Arbor, Michigan

David M. Daughton
University of Nebraska Medical Center
Ohama, Nebraska

Ian C. Davis, DVM, PhD
Assistant Professor
Department of Anesthesiology
University of Alabama at Birmingham
Birmingham, Alabama

Malcolm M. DeCamp, Jr., MD
Chief, Division of Cardiothoracic Surgery
Beth Israel Deaconess Medical Center
Boston, Massachusetts

Marc Decramer
Respiratory Division University Hospital
Katholieke Universiteit Leuven
Afdeling Pneumologie
Leuven, Belgium

Stijn DeLanghe, PhD
The Developmental Biology Program
Saban Research Institute
Children's Hospital Los Angeles
University of Southern California Keck School of Medicine and School of Dentistry
Los Angeles, California

Pierre Del Moral
The Developmental Biology Program
Saban Research Institute
Children's Hospital Los Angeles
University of Southern California Keck School of Medicine and School of Dentistry
Los Angeles, California

Horace M. DeLisser, MD
Pulmonary, Allergy, and Critical Care Division
Hospital of the University of Pennsylvania
Philadelphia, Pennsylvania

Clifford S. Deutschman, MS, MD, FCCM
Professor of Anesthesiology and Critical Care and Surgery
University of Pennsylvania School of Medicine
Philadelphia, Pennsylvania

Robert P. Dickson, MD
Department of Medicine
University of Washington
Seattle, Washington

Camillo DiGiulio, MD
Professor
Department of Biomedical Sciences
G. d'Annunzio University
Chieti-Pescara, Italy

Francis W. DiPierro, MD
Eastern Maine Medical Center
Bangor, Maine

Scott H. Donaldson, MD
Assistant Professor of Medicine
University of North Carolina
Chapel Hill, North Carolina

Marlene L. Durand, MD
Assistant Professor
Harvard Medical School
Director, Infectious Disease Service
Massachusetts Eye and Ear Infirmary
Associate Physician
Massachusetts General Hospital
Boston, Massachusetts

Ghassan El-Haddad, MD
Department of Nuclear Oncology
Division of Nuclear Medicine
Hospital of the University of Pennsylvania
Philadelphia, Pennsylvania

Jack A. Elias, MD
Waldemar Von Zedtwitz Professor of Medicine
Chair, Department of Internal Medicine
Yale University School of Medicine
New Haven, Connecticut

Richard I. Enelow, MD
Associate Professor of Medicine
Yale University School of Medicine
New Haven, Connecticut
VA Connecticut Health Care System
West Haven, Connecticut

Perenlei Enkhbaatar, MD, PhD
Assistant Professor
The University of Texas Medical Branch
Galveston, Texas

Paul E. Epstein, MD
Clinical Professor of Medicine
University of Pennsylvania
Philadelphia, Pennsylvania

John J. W. Fangman, MD
Assistant Professor of Medicine
Division of Infectious Disease
Medical College of Wisconsin
Milwaukee, Wisconsin

Peter F. Fedullo, MD
Director
Medical Intensive Care Unit
Professor of Clinical Medicine
University of California
San Diego, California

Alan M. Fein, MD
ProHealth Care Associates
Lake Success, New York

Steven H. Feinsilver, MD
Associate Professor of Medicine (Clinical)
New York University School of Medicine
New York, New York
Director
Pulmonary and Sleep Medicine
Cardiovascular Medical Associates
Garden City, New York

Alfred P. Fishman, MD
William Maul Measey Professor of Medicine
University of Pennsylvania Medical Center
Philadelphia, Pennsylvania

Jay A. Fishman, MD
Associate Professor of Medicine
Harvard Medical School
Director
Transplant Infectious Disease and Compromised Host Program
Massachusetts General Hospital
Associate Director
MGH Transplantation Center
Boston, Massachusetts

Douglas B. Flieder, MD
Department of Pathology
Fox Chase Cancer Center
Philadelphia, Pennsylvania

Barry D. Fuchs, MD
Pulmonary, Allergy, and Critical Care Division
Hospital of the University of Pennsylvania
Philadelphia, Pennsylvania

Gregory P. Geba, MD
Assistant Professor of Pulmonary Medicine
Department of Internal Medicine
Yale University
New Haven, Connecticut

Charles F. P. George, MD, FRCPC, FCCP, DABSM
Professor of Medicine
University of Western Ontario
Director
Sleep Medicine Clinic and Laboratory
London Health Sciences Centre
London, Ontario, Canada

Stanley Goldfarb, MD
Associate Dean
Clinical Education
University of Pennsylvania School of Medicine
Philadelphia, Pennsylvania

Mitchell Goldman, MD
Associate Professor of Medicine
Indiana University School of Medicine
Indianapolis, Indiana

Daniel M. Goodenberger, MD
Professor and Chair
Department of Internal Medicine
University of Nevada School of Medicine
Las Vegas, Nevada

Reginald E. Greene, MD
Radiology Division
Massachusetts General Hospital
Boston, Massachusetts

Michael A. Grippi, MD
Vice Chairman, Department of Medicine
Pulmonary, Allergy, and Critical Care Division
University of Pennsylvania Health System
Chief of Medicine, Philadelphia VA Medical Center
Philadelphia, Pennsylvania

Mridu Gulati, MD, MPH
Assistant Professor of Medicine
Pulmonary and Critical Care Medicine
Occupational and Environmental Medicine
Department of Medicine
Yale University School of Medicine
New Haven, Connecticut

Prabodh K. Gupta, MB, MD
Professor Pathology and Laboratory Medicine
University of Pennsylvania School of Medicine
Director Cytopathology and Cytometry
Hospital of the University of Pennsylvania
Philadelphia, Pennsylvania

Jesse B. Hall, MD
Professor of Medicine
Department of Medicine
Section of Pulmonary and Critical Care
University of Chicago
Chicago, Illinois

C. William Hanson III, MD
Professor of Anesthesiology and Critical Care
Surgery and Internal Medicine
University of Pennsylvania School of Medicine
Philadelphia, Pennsylvania

Judith Hellman, MD
Department of Anesthesia and Critical Care
Massachusetts General Hospital
Charlestown, Massachusetts

Lisa M. Hepp
University of Nebraska Medical Center
Omaha, Nebraska

Michael P. Hlastala, PhD
Professor of Physiology and Biophysics and Medicine
University of Washington
Seattle, Washington

Robert J. Homer, MD, PhD
Associate Professor of Pathology
Department of Pathology
Yale University School of Medicine
Director of Anatomic Pathology
VA Connecticut Healthcare System
New Haven, Connecticut

Michael F. Iademarco, MD, MPH
Centers for Disease Control and Prevention
Division of Tuberculosis Elimination
Atlanta, Georgia

Louise C. Ivers, MD, MPH, DTM&H
Partners In Health
Harvard Medical School
Division of Infectious Diseases
Massachusetts General Hospital
Boston, Massachusetts

Bruce E. Johnson, MD
Associate Professor of Medicine
Harvard Medical School
Boston, Massachusetts

David H. Johnson, MD
Cornelius A. Craig Professor of Medicine
Director
Division of Hematology and Oncology
Vanderbilt-Ingram Cancer Center
Nashville, Tennessee

JeRay J. Johnson, MD
Fellow in Pulmonary and Critical Care Medicine
Section on Pulmonary, Critical Care
Care, Allergy and Immunologic Diseases
Department of Internal Medicine
Wake Forest University School of Medicine
Winston-Salem, North Carolina

Larry R. Kaiser, MD
John Rhea Barton Professor and Chairman
Department of Surgery
University of Pennsylvania
Philadelphia, Pennsylvania

Petros C. Karakousis, MD
Assistant Professor
Center for Tuberculosis Research
Johns Hopkins University School of Medicine
Baltimore, Maryland

Michael P. Keane, MD
Department of Medicine
Division of Pulmonary and Critical Care Medicine
UCLA
Los Angeles, California

Steven M. Keller, MD
Department of Cardiothoracic Surgery
Montefiore Medical Center
Bronx, New York

Mark A. Kelley, MD
Executive Vice President
Henry Ford Health System
Detroit, Michigan

Steven G. Kelsen, MD
Division of Pulmonary Medicine
Temple University Hospital
Philadelphia, Pennsylvania

Jeffrey A. Kern, MD
Professor, Case Western Reserve University
Division Chief, Pulmonology/Critical Care and Sleep Medicine
University Hospitals
Cleveland, Ohio

Brent W. Kinder, MD
Pulmonary Fellow
Department of Medicine
University of California
San Francisco, California

Talmadge E. King, Jr., MD
The Constance B. Wofsy Distinguished Professor and Vice-Chairman
Department of Medicine
University of California
San Francisco
Chief, Medical Services
San Francisco General Hospital
San Francisco, California

Robert A. Klocke, MD
Professor Emeritus of Medicine and Physiology nd Biophysics
University of Buffalo
Erie County Medical Center
Buffalo, New York

Kenneth Knox, MD
Richard L. Roudebush Veterans' Administration Hospital
Indianapolis, Indiana

Dimitrios P. Kontoyiannis, MD, ScD, FACP, FIDSA
Associate Professor of Medicine
Director of Clinical Mycology
Department of Infectious Diseases
Infection Control and Employee Health
The University of Texas M. D. Anderson Cancer Center
Houston, Texas

Robert M. Kotloff, MD
Professor of Medicine
Pulmonary, Allergy, and Critical Care Division
Department of Medicine
University of Pennsylvania Medical Center
Philadelphia, Pennsylvania

Camille Nelson Kotton, MD
Infectious Diseases Unit
Massachusetts General Hospital
Boston, Massachusetts

Richard Kradin, MD
Associate Professor
Harvard Medical School
Director of Infectious Disease Pathology
Department of Pathology and the Pulmonary and Critical Care Unit
Massachusetts General Hospital
Boston, Massachusetts

Mary Elizabeth Kreider, MD
Pulmonary and Critical Care Section
Hospital of the University of Pennsylvania
Philadelphia, Pennsylvania

John P. Kress, MD
Assistant Professor of Medicine
Department of Medicine
Section of Pulmonary and Critical Care
University of Chicago
Chicago, Illinois

Meir H. Kryger, MD, FRCPC
Sleep Disorders Center
St. Boniface General Hospital
Section of Respiratory Diseases
University of Manitoba, Winnipeg
Manitoba, Canada

Sukhamay Lahiri, D Phil (Oxon), D Phil (Cal)
Professor
Department of Physiology
University of Pennsylvania School of Medicine
Philadelphia, Pennsylvania

Kenneth S. Landreth, PhD
Professor of Microbiology
Immunology and Cell Biology
West Virginia University School of Medicine
Morgantown, West Virginia

John D. Lang, Jr., MD
Associate Professor
Department of Anesthesiology
University of Alabama at Birmingham
Birmingham, Alabama

Paul N. Lanken, MD
Professor of Medicine
Division of Pulmonary
Allergy and Critical Care Medicine
Department of Medicine
Professor of Medical Ethics
Department of Medical Ethics
Senior Fellow, Center for Bioethics
University of Pennsylvania School of Medicine
Philadelphia, Pennsylvania

Richard S. Lazzaro, MD
Attending Surgeon
Maimonides Medical Center
Brooklyn, New York

James W. Leatherman, MD
Hennepin Faculty Associates
Hennepin County Medical Center
Minneapolis, Minnesota

Deborah J. Levine, MD
Assistant Professor
Division of Pulmonary Disease
Department of Medicine
The University of Texas Health Science Center
San Antonio, Texas

Frederic F. Little, MD
Assistant Professor of Medicine
Boston University School of Medicine
Boston, Massachusetts

Leslie A. Litzky, MD
Associate Professor
Department of Pathology and Laboratory Medicine
Director
Section of Medical Pathology
University of Pennsylvania Medical Center
Philadelphia, Pennsylvania

Philip A. LoBue, MD
Centers for Disease Control and Prevention
Division of Tuberculosis Elimination
Atlanta, Georgia

Joseph LoCicero, III, MD
Director Surgical Oncology Maimonides Cancer Center
Brooklyn, New York

Nicholas W. Lukacs, PhD
Department of Pathology
University of Michigan Medical School
Ann Arbor, Michigan

Joseph P. Lynch III, MD
Professor of Clinical Medicine
Associate Chief, Division of Pulmonary, Critical Care Medicine, and Hospitalists
David Geffen School of Medicine at UCLA
Los Angeles, California

Mitchell Machtay, MD
Walter J. Curran Associate Professor and Vice Chair
Department of Radiation Oncology
Jefferson Medical College
Philadelphia, Pennsylvania

Scott Manaker, MD, PhD
Associate Professor of Medicine
Pulmonary, Allergy and Critical Care Division
University of Pennsylvania Medical Center
Philadelphia, Pennsylvania

Nathaniel Marchetti, DO
Assistant Professor of Medicine
Division of Pulmonary and Critical Care Medicine
Temple University School of Medicine
Philadelphia, Pennsylvania

Thomas J. Marrie, MD
Dean
Faculty of Medicine and Dentistry
Walter C. Mackenzie Health Sciences Center
Edmonton, Alberta, Canada

Fernando J. Martinez, MD, MS
Professor of Internal Medicine
University of Michigan Medical School
Ann Arbor, Michigan

Sadis Matalon, PhD
Professor
Department of Anesthesiology
University of Alabama at Birmingham
Birmingham, Alabama

Sameer K. Mathur, MD, PhD
Clinical Instructor
University of Wisconsin Medical School
Madison, Wisconsin

Michael A. Matthay, MD
Professor
Medicine and Anesthesia
Senior Associate
Cardiovascular Research Institute
Associate Director
Intensive Care Unit
University of California
San Francisco, California

Martin L. Mayse, MD
Assistant Professor of Medicine and Surgery
Director, Interventional Pulmonology
Washington University
St. Louis, Missouri

John R. McArdle, MD
Assistant Professor of Medicine
Pulmonary and Critical Care Section
Yale University School of Medicine
New Haven, Connecticut

F. Dennis McCool, MD
Professor of Medicine
Brown University Medical School
Chief, Pulmonary Critical Care Medicine
Memorial Hospital of Rhode Island
Pawtucket, Rhode Island

Paul B. McCray, Jr., MD
Professor
Department of Pediatrics
Roy J. and Lucille A. Carver College of Medicine
University of Iowa
Iowa City, Iowa

Geoffrey McLennan, MD, PhD
Professor, Pulmonary, Critical Care, and Occupational Medicine
University of Iowa
Iowa City, Iowa

Ranee Mehra, MD
Associate Member
Fox Chase Cancer Center
Philadelphia, Pennsylvania

Eric B. Meltzer, MD
Fellow
Department of Medicine
Division of Pulmonary, Allergy, and Critical Care
Duke University Medical Center
Durham, North Carolina

Wallace T. Miller, MD
Emeritus Professor
Department of Radiology
University of Pennsylvania School of Medicine
University of Pennsylvania Medical Center
Philadelphia, Pennsylvania

David R. Moller, MD
Associate Professor of Medicine
Johns Hopkins University School of Medicine
Baltimore, Maryland

David G. Morris, MD
Assistant Professor of Medicine
Director
Interstitial Lung Diseases Program
Yale University School of Medicine
Division of Pulmonary and Critical Care Medicine
Yale-New Haven Hospital
New Haven, Connecticut

Adrian R. Morrison, DVM, PhD
Professor
Laboratory for Study of the Brain in Sleep
Department of Animal Biology
School of Veterinary Medicine
University of Pennsylvania
Philadelphia, Pennsylvania

Ahmad Munir
Assistant Professor of Medicine
University of Tennessee Health Science Center
Memphis, Tennessee

David M. F. Murphy, MD
Deborah Heart and Lung Center
Browns Mills, New Jersey

Timothy F. Murphy, MD
UB Distinguished Professor of Medicine
Chief, Division of Infectious Diseases
University at Buffalo
State University of New York
Buffalo, New York

Michael A. Nead, MD, PhD
Senior Instructor in Medicine
Pulmonary and Critical Care
Department of Internal Medicine
University of Rochester Medical Center
Strong Memorial Hospital and Highland Hospital
Department of Pulmonary and Critical Care
Rochester, New York

Patrick Neligan, MD
Department of Anesthesia
Hospital of the University of Pennsylvania
Philadelphia, Pennsylvania

Michael S. Niederman, MD
Professor and Vice-Chairman
Department of Medicine
SUNY at Stony Brook
Stony Brook, New York
Chairman
Department of Medicine
Winthrop-University Hospital
Mineola, New York

Paul W. Noble, MD
Professor of Medicine and Division Chief
Department of Pulmonary, Allergy, and Critical Care Medicine
Duke University School of Medicine
Durham, North Carolina

Matthias Ochs, MD
Lecturer
Experimental Morphology Unit
Institute of Anatomy
University of Berne
Berne, Switzerland

David Ost, MD
Department of Cardiothoracic Surgery
Division of Thoracic Surgery
New York University
New York, New York

Allan I. Pack, MB, ChB, PhD
Professor of Medicine
Chief, Division of Sleep Medicine/Department of Medicine
Director
Center for Sleep and Respiratory Neurobiology
University of Pennsylvania School of Medicine
Philadelphia, Pennsylvania

Kevin Palka, MD
Instructor in Medicine
Division of Hematology and Oncology
Vanderbilt-Ingram Cancer Center
Nashville, Tennessee

Reynold A. Panettieri, Jr., MD
Pulmonary, Allergy and Critical Care Division
University of Pennsylvania Medical Center
Philadelphia, Pennsylvania

Annie Pardo, PhD
Facultad de Ciencias
Universidad Nacional Autónoma de México
Ciudad Universitaria, Mexico

John E. Parker, MD
Professor and Section Chief
Section of Pulmonary and Critical Care Medicine
Robert C. Byrd Health Sciences Center
West Virginia University School of Medicine
Morgantown, West Virginia

Rodolfo M. Pascual, MD
Assistant Professor of Medicine
Section on Pulmonary
Critical Care, Allergy and Immunologic Diseases
Department of Internal Medicine
Wake Forest University School of Medicine
Winston-Salem, North Carolina

Mark S. Pasternack, MD
Associate Professor of Pediatrics
Division of Infectious Diseases
Massachusetts General Hospital
Boston, Massachusetts

Aalpen A. Patel, MD
Assistant Professor of Radiology and Surgery
Department of Radiology
Interventional Radiology
University of Pennsylvania School of Medicine
Philadelphia, Pennsylvania

Nirav P. Patel, MD
Division of Sleep Medicine
University of Pennsylvania
Philadelphia, Pennsylvania

Rakesh P. Patel, PhD
Assistant Professor
Department of Pathology
University of Alabama at Birmingham
Birmingham, Alabama

Jay Peters, MD
Division Chief and Fellowship Director
Division of Pulmonary Disease/Critical Care
Professor, Department of Medicine
The University of Texas Health Science Center
San Antonio, Texas

Stephen P. Peters, MD, PhD, FACP, FCCP, FAAAAI, FCPP
Professor of Medicine and Pediatrics
Director of Research
Section on Pulmonary, Critical Care
Allergy and Immunologic Diseases
Training Program Director, Allergy and Immunology
Department of Internal Medicine and Center for Human Genomics
Wake Forest University School of Medicine
Winston-Salem, North Carolina

Edward L. Petsonk, MD
Adjunct Professor
Section of Pulmonary and Critical Care Medicine
Robert C. Byrd Health Sciences Center
West Virginia University School of Medicine
Senior Medical Officer
Division of Respiratory Disease Studies
National Institute for Occupational Safety and Health
Morgantown, West Virginia

Jennifer A. Philips, MD, PhD
Associate Physician
Department of Medicine
Division of Infectious Diseases
Brigham and Women's Hospital
Boston, Massachusetts

Gerald B. Pier, PhD
Professor of Medicine (Microbiology and Molecular Genetics)
Harvard Medical School
Channing Laboratory
Department of Medicine
Brigham and Women's Hospital
Boston, Massachusetts

John Popovich, Jr., MD, MACP
Chair
Department of Internal Medicine
Henry Ford Hospital
Detroit, Michigan

Gregory Priebe, MD
Assistant Professor of Anaesthesia (Pediatrics)
Harvard Medical School
Channing Laboratory
Department of Medicine
Brigham and Women's Hospital
Departments of Anesthesiology (Critical Care) and Medicine (Infectious Diseases)
Children's Hospital
Boston, Massachusetts

Jonathan Puchalski, MD
Fellow in Pulmonary Medicine
Division of Pediatric Pulmonary Medicine
Cincinnati Children's Hospital
Division of Pulmonary and Critical Care Medicine
University of Cincinnati College of Medicine
Cincinnati, Ohio

Carrie A. Redlich, MD, MPH
Professor of Medicine
Pulmonary and Critical Care Medicine
Occupational and Environmental Medicine
Department of Medicine
Yale University School of Medicine
New Haven, Connecticut

Steven I. Rennard, MD
Pulmonary and Critical Care Medicine
University of Nebraska Medical Center
Omaha, Nebraska

Herbert Y. Reynolds, MD
Professor of Medicine Emeritus
The Pennsylvania State University College of Medicine and Milton S. Hershey Medical Center
Hershey, Pennsylvania
Adjunct Professor of Medicine
Uniformed Services University of the Health Sciences
Bethesda, Maryland

Mary L. Ricardo-Dukelow, MD
Clinical Instructor
Department of Internal Medicine
University of Nebraska Medical Center
Omaha, Nebraska

Andrew L. Ries, MD, MPH
Associate Dean for Academic Affairs
Professor of Medicine and Family and Preventive Medicine
University of California
San Diego
Medical Director
Pulmonary Rehabilitation Program
University of California
San Diego Medical Center

John R. Roberts, MD, MBA
The Surgical Clinic, PLLC
Nashville, Tennessee

Kenneth B. Roberts, MD
Associate Professor of Therapeutic Radiology
Yale University School of Medicine
Attending Physician
Yale-New Haven Hospital
New Haven, Connecticut

Carolyn L. Rochester, MD
Associate Professor of Medicine
Section of Pulmonary and Critical Care
Department of Internal Medicine
Yale University School of Medicine
New Haven, Connecticut

Sara Rockwell, PhD
Professor
Department of Therapeutic Radiology
Yale University School of Medicine
New Haven, Connecticut

William N. Rom, MD, MPH
Sol and Judith Bergstein Professor of Medicine and Professor of Environmental Medicine
Departments of Medicine (Pulmonary Disease) and Environmental Medicine
New York University Medical Center
New York, New York

Daniel B. Rosenbluth, MD
Associate Professor of Medicine
Division of Pulmonary and Critical Care Medicine
Washington University School of Medicine
St. Louis, Missouri

Milton D. Rossman, MD
Pulmonary and Critical Care Section
Hospital of the University of Pennsylvania
Philadelphia, Pennsylvania

Eric J. Rubin, MD, PhD
Associate Professor of Immunology and Infectious Diseases
Harvard School of Public Health
Boston, Massachusetts

Mark E. Rupp, MD
Professor
Department of Internal Medicine
University of Nebraska Medical Center
Nebraska Medical Center
Omaha, Nebraska

Edward T. Ryan, MD
Assistant Professor of Medicine
Harvard Medical School
Assistant Professor of Immunology and Infectious Diseases
Harvard School of Public Health
Director
Tropical and Geographic Medicine Center
Massachusetts General Hospital
Boston, Massachusetts

Steven A. Sahn, MD
Professor of Medicine and Director
Division of Pulmonary, Critical Care Allergy and Sleep Medicine
Medical University of South Carolina
Charleston, South Carolina

Edward Y. Sako, MD, PhD
Professor
Department of Surgery
The University of Texas Health Science Center
San Antonio, Texas

Jonathan M. Samet, MD, MS
Professor and Chairman
Department of Epidemiology
Director
Institute for Global Tobacco Control
Jacob I and Irene B. Fabrikant Professor in Health Risk and Society
Johns Hopkins Bloomberg School of Public Health
Baltimore, Maryland

Paul E. Sax, MD
Associate Professor of Medicine
Harvard Medical School
Clinical Director
Division of Infectious Diseases and HIV Program
Brigham and Women's Hospital
Boston, Massachusetts

Thomas F. Scanlin, MD
Professor of Pediatrics
University of Medicine & Dentistry of New Jersey
Chief, Division of Pulmonary Medicine and Cystic Fibrosis Center
Bristol-Myers Squibb Children's Hospital at Robert Wood Johnson University Hospital
New Brunswick, New Jersey

Johannes C. Schittny, PhD
Institute of Anatomy
University of Bern
Bern, Switzerland

Edward S. Schulman, MD
Professor of Medicine
Director
Division of Pulmonary and Critical Care Medicine
Drexel University College of Medicine
Philadelphia, Pennsylvania

Richard J. Schwab, MD
University of Pennsylvania Medical Center
Pulmonary, Allergy and Critical Care Division
Philadelphia, Pennsylvania

David A. Schwartz, MD
Director
National Institute of Environmental Health Sciences
Research Triangle Park
North Carolina

Marvin I. Schwarz, MD
The James C. Campbell Professor of Pulmonary Medicine
Director
Pulmonary Sciences and Critical Care Medicine Fellowship
University of Colorado Health Sciences Center

Preface

This book is now in its fourth edition. The first edition appeared in print in 1980. Each edition since then has provided a contemporary update of the growth of understanding of pulmonary disease and of the management of its clinical manifestations. Advances have been made in leaps and bounds. A 2006 review (Lopez et al.) summarized the impressive progress made in three key subsets of pulmonary medicine, chronic obstructive pulmonary disease (COPD), asthma, and critical care medicine.

COPD affords a practical illustration of the growth in understanding of a prevalent disease. The designation COPD, originally adopted as a convenient term for communication about the spectrum of chronic bronchitis and emphysema, now covers a wide range of clinical entities, ranging from predominant inflammation of the airways to disruption and over-expansion of the pulmonary paremchyma in emphysema.

COPD is the fourth leading cause of chronic morbidity and mortality in the United States. More than 12 million people have COPD and an additional 12 million do not know that they have the disease. Of all the leading killers, COPD is the only disease with mortality rates that are on the rise. World Health Organization projections indicate COPD will become the third leading cause of mortality worldwide by 2020.

Smoking is a predominant etiologic factor for COPD. However, as many as one of six people with COPD have never smoked. It is also understood that not all who smoke pay the price in terms of lung disease. The rates among women have dramatically increased since World War II. Vulnerability to harmful effects of smoking is believed to be rooted, at least in part, in genetic predisposition. This likelihood is currently under active investigation.

One particular limitation of the term "COPD" was recently highlighted by the advent of lung volume reduction surgery (LVRS) for the treatment of emphysema. It was clear from the outset that not all patients with emphysema are suitable candidates for LVRS. A major step toward the identification of those patients with emphysema who can be expected to benefit from the procedure was taken by the National Emphysema Treatment Trial (NETT). This trial, unique in its cosponsorship by three federal agencies—The National Heart, Lung & Blood Institute (NHLBI), The Health Care Finance Agency (HCFA) and the Agency for Health Care Policy and Research (AHCPR), began by excluding those patients with emphysema who were not likely to benefit from LVRS. These proved to be patients with a low FEV in conjunction with either homogeneous emphysema or a very low diffusing capacity for carbon monoxide (DLCO). In patients who proved to be eligible for LVRS, NETT took into account the risks posed by the surgical procedure and the fact that it affords no guarantee of successful outcome.

A second major study addressed the global impact of COPD. It has been estimated that in the United States almost 12 million people have COPD Smoking has long been known to be the predominant cause of COPD, but attempts at promoting widespread smoking cessation have largely been ineffective. Currently, COPD is being attacked on a variety of research fronts. Among these is the link between COPD and lung cancer. Other research is directed at clarifying the role of inflammation in the pathogenesis of COPD and trials of therapeutic interventions to minimize the ravages of the disease. Among the on-going trials are investigations which seek to determine the therapeutic effectiveness of novel agents, such as the phosphodiesterase inhibitors (PDE4 inhibitors). Other trials, using monoclonal antibodies seek to modify the inflammatory component of COPD. The global impact of COPD continues to provide impetus to the search for mechanisms that can be attacked therapeutically.

Looking back, the growth of pulmonary medicine has been punctuated and accelerated by certain iconic breakthroughs. Diagnostic radiology was revolutionized in the early 1990's by the introduction of spiral-computed tomography (CAT scan), which afforded a novel way to image the lung. Since then, improvements in the technology of the apparatus have enhanced its value as a diagnostic tool while enabling smaller doses of radiation to be delivered to the patients. Because of its ease of use and its availability, the use of the CAT scan has become widespread. In addition, continuing refinements hold promise of enhancing the

visualization of the microarchitecture of the lungs in health and disease.

Technological advances have played a key role in affording insights not only into the microarchitecture of the lungs but also into their physiological functions. Recent advances hold promise of even more to come. For example, the advent of virtual bronchoscopy has brought with it the likelihood of access to information about the bronchial tree and its surrounding structures without subjecting the patient to the stress of direct bronchoscopy. Moreover, the meaning of "virtual" continues to enlarge. Originally, the term referred to two-dimensional representations of the bronchial tree obtained by x-ray computed tomography (CT). Currently, the term also applies to more detailed images and less-intrusive methods obtained by such techniques as ultrasound or magnetic resonance imaging (MRI).

The newer imaging techniques not only afford static representations of the details of the airways and pulmonary parenchyma but also hold promise for functional studies, e.g., dynamic studies of pulmonary mechanics. Such studies would deal not only with the mechanics of the entire lung but also with the mechanics of regions of the lung. The increase in resolution on the one hand, and in the ease of acquisition of data on the other, has also enabled application of noninvasive imaging to the exploration of such functions of the lungs as ventilation-perfusion relationships.

Pulmonary medicine continues to be on the march. In recent years, the inclusion of sleep-disordered breathing has widened the scope of pulmonary medicine. National meetings devoted to pulmonary medicine attract ever-increasing audiences. This edition of "Pulmonary Diseases and Disorders" deals with the current understanding of lung diseases and the management of these diseases. Even a cursory comparison of this edition with previous editions reveals that considerable progress has been made in recent years. Despite this impressive progress, it is clear that much remains to be done. Patients and pulmonologists can look forward to further developments in the years ahead.

The experience and knowledge of each of the editors have been directed at ensuring that the specialized, as well as the general, aspects of pulmonary medicine have been expertly covered and well presented. Although the book is a collective arbeit, discussion and debate among the editors and authors have led to a collaborative and comprehensive work, integrated by a meeting of the minds and the sharing of the experiences. By the process of peer review, the book aspires to provide a readable and balanced coverage of what is latest and most meaningful in pulmonary diseases and disorders.

I have already indicated how much this book owes to the experts who comprise the editorial board. The editors, in turn, would have little to work with were it not for the splendid chapters contributed by the individual authors. And, in this edition, we also were aided by several medical fellows. My special thanks to Charles De La Cruz, Colin Gillespie, Howard Huang, Josh Kayser, Bianca Monteiro, Stephen Ryan, and Rael Sundy for their assistance. The editors also benefited greatly from close collaboration with the publisher whose personnel have listened carefully and implemented with patience and understanding.

I owe a great deal to those close to home. Betsy Ann Bozzarello, a collaborator for more than 20 years, managed to free time for me to devote to the book while she catalyzed and orchestrated the efforts of others. My family has provided the encouragement and peace of mind that such an effort inevitably calls for. My wife, Linda, has been unwavering in her tolerance and support. My daughter, Hannah, who is in her junior year at the University of Michigan and is trying her own hand at writing, is impressed by the enormity of the undertaking but remains optimistic about the outcome of such a venture. My sons, Mark and Jay, authors and editors in their own rights, share my conviction that this book is a worthwhile undertaking. Their spouses, Gayle and Martha, the former a nurse and the latter a pediatric pulmonologist, have also been supportive. I am greatly indebted to all of the above.

Milestones in the History of Pulmonary Medicine

Alfred P. Fishman

It has taken medicine more than 2000 years to reach its present level of clinical, scientific, and technologic sophistication. From the beginning, pulmonary medicine has been an integral part of this growth and development. About three hundred years ago, progress toward scientific medicine accelerated markedly, and it has continued to gain speed ever since: In the seventeenth century, research and experimentation began to tilt clinical medicine toward the exact sciences; by the eighteenth century, pathology had become an integral part of clinical medicine, and clinical-pathologic correlations began to succeed empiricism, dogmatism, and metaphysics in medicine. The age of the great clinicians dawned in Europe early in the nineteenth century, when autopsies became legally permissible and socially acceptable, and when physicians who cared for the patients ultimately performed the autopsy.

The road to current understanding and practice has been convoluted. Progress has been punctuated by delays, detours, and reversals. But it is possible to retrace the scientific trail by using iconic figures and discoveries to draw the map. Chapter 1 uses these milestones to trace the course of scientific pulmonary medicine up to the early twentieth century. The chapter goes no further, since more recent advances are more a matter of reporting than history. These advances are left to subsequent chapters in this book. This chapter deals only with certain of the key components of modern pulmonary medicine: alveolar-capillary gas exchange, lung volumes, mechanics of breathing, control of breathing, ventilation-perfusion relationships, and scientific clinical medicine.

ALVEOLAR-CAPILLARY GAS EXCHANGE

Ancient Greek Medicine

The beginnings of scientific medicine can be traced to ancient Greece in the sixth century B.C. Natural philosophers then speculated that air or some essential ingredient in air was inspired to generate a vital essence for distribution throughout the body.

Hippocrates, the "father of medicine," is as much a symbol of the Greek physician of the fifth and fourth centuries B.C., as the name of a real figure (Fig. 1-1). As an individual, he exemplified the caring physician who kept accurate records, made cautious inferences, and relied more on nature, rest,

Figure 1-1 The Hippocrates of Ostia. This damaged bust is believed to represent Hippocrates as perceived in antiquity. It was found in a family tomb in excavations near Ostia. *(Courtesy of Dr. Dickinson W. Richards.)*

and diet than on drugs for therapy. His name has been immortalized by affixing it to three major components of Greek medicine, even though none of these seems to be the work of a single individual. The first is the *Hippocratic corpus*, a collection of about 70 works that includes case reports, textbooks, lectures, and notebooks. The collection contains a description of Cheyne-Stokes breathing and the use of *Hippocratic succession* for the diagnosis of fluid and air in the pleural cavity. The second item is a collection of aphorisms, a compilation of brief generalizations relating to medicine. The third, which seems more attributable to Pythagoras (c. 530 B.C.) than Hippocrates, who lived about a century later (Table 1-1), is the *Hippocratic oath*, which not only represents the spirit of the physician of ancient Greece but has endured to modern times as a reflection of the ethical code of the physician.

Aristotle needs mention at this juncture because of his enduring influence on the intellect of humankind in his own time and for two millennia thereafter. Not until the seventeenth century were his doctrine of the four elements (earth, air, fire, and water) and that of Hippocrates (blood, phlegm, yellow bile, and black bile) laid to rest, thereby clearing the way for modern scientific medicine. Soon after Aristotle, about 300 B.C., an extraordinary medical school was founded at Alexandria in Egypt. One of the first teachers at this school, Erasistratus, postulated that the pneuma or spirit essential for life is somehow generated from interplay between air and blood. About four centuries after Erasistratus, Galen (Fig. 1-2) drew upon the medical, philosophic, and anatomic knowledge of his day to fashion a remarkable physiological schema. His construct was largely teleological. Unfortunately, it was so convincing that even though it was ultimately proved to be fanciful, it sufficed to retard scientific progress for a millennium and a half. Galen was a talented individual, well-educated, well-read, and well-positioned in society to popularize his beliefs. Moreover, his concepts fit well into the tenets of Christianity which was then beginning its ascendency; to contravert his authority was tantamount to blasphemy. Among his long-lasting, albeit erroneous, postulates, were the following: invisible pores in the ventricular septum that enabled the bulk of the blood to flow from the right ventricle to the left ventricle, thereby bypassing the lungs; a diminutive pulmonary circulation that served only to nourish the lungs; and two-way traffic in the pulmonary veins that enabled inspired air and effluent waste vapors to go their respective ways in the pulmonary veins (Fig. 1-3).

Every now and then, a voice did rise in protest—but without lasting effect. In the thirteenth century, Ibn An Nafis, writing in his *Canon of Avicenna*, objected that blood does not traverse the ventricular septum from right to left as Galen had proposed. However, this insight attracted little attention. Three hundred years later, Vesalius voiced similar misgivings. In the sixteenth century, Michael Servetus, a polymath trained in theology, geography, and anatomy, pictured the pulmonary circulation as the vehicle by which the inhaled spirit could be distributed throughout the body. In his theological treatise, *Christianismi Restitutio*, he pointed out that blood could not traverse the septum between the right and

Figure 1-2 Galen of Pergamon as depicted in medieval times. No authentic reproduction exists of Galen in ancient times. *(From Galen's Therapeutica, published in Venice in 1500.)*

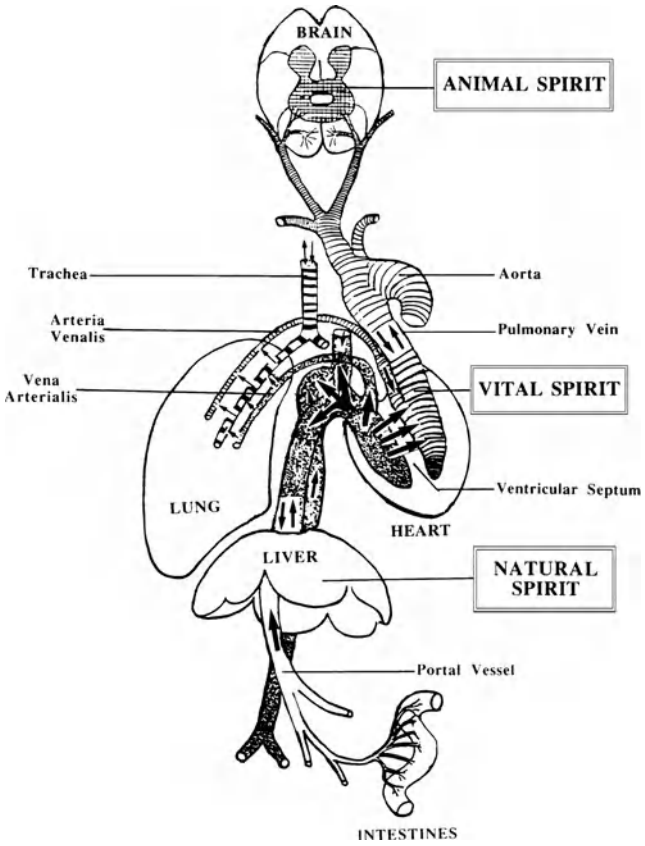

Figure 1-3 Galen's scheme of the circulation. The diagram shows the source and distribution of the three types of spirits. The validity of this scheme depended on invisible pores in the ventricular septum, two-way traffic in the pulmonary vein, and selective permeability of the mitral valve for sooty wastes but not for spirit-containing blood. Vena arterialis = pulmonary vein; arteria venalis = pulmonary artery. *(Modified after Singer C: A Short History of Scientific Ideas to 1900. London, Oxford University Press, 1959.)*

left ventricles and the lumen of the pulmonary artery was too large for a nutrient vessel. He became a hunted heretic, wanted for execution by both the Catholic Church and Calvin. He was warned by Calvin to stay out of Geneva. Both Servetus and Calvin then behaved predictably: Servetus showed up at a church where Calvin was preaching and Calvin had him captured and burned at the stake. In 1559, Realdus Columbus of Cremona, pupil of Vesalius, rediscovered the pulmonary circulation, as did Andreas Caesalpinus in 1571. Despite these challenging observations, Galen's schema was to last for more than another half century, i.e., until the physiological experiments of William Harvey.

William Harvey and the Oxford Physiologists

William Harvey (Fig. 1-4) was led to the discovery of the circulation of the blood by anatomic observations on the valves in systemic veins made by his mentor, Fabricus ab Aquapedente. Harvey's small book, *De Motu Cordis*, published in 1628, not only corrected a self-perpetuating error in Galenical teaching, but also marked the birth of modern physiology. However, the time was not yet ripe to relate the function of the heart to the physiology of breathing. To his dying day, Harvey clung to the idea that the main function of breathing is to cool the heart. Moreover, since he made no use of the microscope, he could not picture how the pulmonary arteries made connection with the pulmonary veins. Galileo invented the compound microscope in 1610. In 1661, using the compound microscope, Marcello Malpighi reported that alveoli were covered by capillaries and that blood and air were kept separate by the continuous alveolar-capillary barrier.

Harvey's description in 1628 of the circulation of the blood had three major consequences for pulmonary medicine: (1) it oriented pulmonary medicine toward the basic sciences and away from philosophy and empiricism; (2) it demolished the Galenic concept of the movement of the blood; and (3) it set the stage for an upcoming generation

Figure 1-4 William Harvey (1578–1657). This portrait of William Harvey is part of a family group in which William Harvey and his five brothers are gathered around their father, William Harvey.

of physiologists at Oxford University to explore breathing in terms of chemistry and physics.

The physiologists working at Oxford in the 1660s were greatly impressed by Harvey's disciplined approach to scientific inquiry. Many of these were medical practitioners who conducted research as a sideline. Four in particular began the systematic study of air and its constituents, thereby laying the foundations for contemporary respiratory physiology and medicine: Robert Boyle (Fig. 1-5), Robert Hooke, Richard Lower, and John Mayow. In 1660, Robert Boyle proved by means of his air pump that air is necessary for life. In 1667, Robert Hooke showed that insufflation of the lungs with air while breathing movements were arrested could keep an open-chest animal alive, i.e., that movement of the lungs was not essential for life. Richard Lower, the first to practice blood transfusion, took advantage of Hooke's continuously inflated lung preparation in the dog to observe that the dark venous blood becomes bright red as it traverses lungs insufflated with air. In 1674, Mayow interpreted the change in the color of blood from venous to arterial as due to the uptake of "nitro-aerial particles" (later to be called "oxygen") from the air.

Phlogiston: The Rise and Fall

Unfortunately, the discoveries and insights of the Oxford physiologists went largely unnoticed during the century that followed, overshadowed by the phlogiston theory of combustion. This theory, advanced by Stahl, postulated that all combustible materials were composed of two ingredients: phlo-

Figure 1-5 Robert Boyle (1627–1691). This engraving, from an original painting by Johann Kerseboom, hangs in the Royal Society, London. Boyle's invention of a pneumatic air pump and his publications concerning "the spring of air and its effect" stimulated considerable research on the physical properties of air and its role in respiration and combustion. He strongly influenced Hooke, Lower, and Mayow at Oxford.

giston, a principle that transformed into fire when heated, and an ash that was left behind after the fiery phlogiston escaped. The phlogiston theory was sufficiently malleable to accommodate almost every new discovery that could have overthrown it, including the rediscovery of carbon dioxide in 1754 by John Black and the independent discoveries of oxygen by Priestley and Scheele. Although the respiratory gases had been discovered by the end of the eighteenth century and many of their properties characterized, the discoveries were misapplied to support, rather than destroy, the phlogiston theory. The phlogiston theory was finally demolished by the experiments of Lavoisier.

Respiration and Metabolism

From the time of Hippocrates until early in the twentieth century, debate had continued about the site of heat production in the body. In 1777, Lavoisier suggested that air was composed of one respirable gas (which he later named "oxygine") and another (nitrogen) that remained unchanged in the

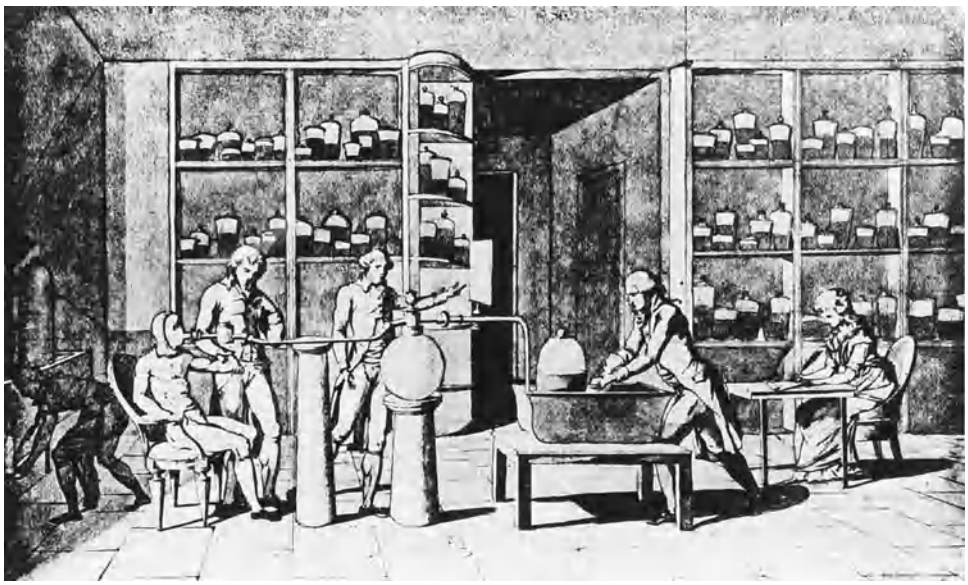

Figure 1-6 Scene from the laboratory of Antoine Laurent Lavoisier (1743–1794). His wife is acting as his assistant, and Sequin is the subject. Studies such as this led to the conclusion that respiration and circulation are similar processes.

course of respiration. Between 1782 and 1784, Lavoisier and Laplace concluded, on the basis of calorimetric experiments on guinea pigs, that "respiration is therefore a combustion, admittedly very slow, but otherwise exactly similar to that of charcoal" (Fig. 1-6). The similarity between respiration and combustion had previously been recognized by the Oxford physiologists, especially Mayow. By 1783, Lavoisier was accumulating evidence against the phlogiston theory and began to replace it with an entirely new system of chemistry.

As noted above, the ancients pictured the heart as the heat generator. Lavoisier favored the lungs. Others held that combustion occurred in the blood. Although Spallanzani had shown in the eighteenth century that isolated tissues take up oxygen and give off carbon dioxide; the idea that combustion occurred in the tissues was slow in gaining acceptance. Strength was infused into this hypothesis by Pflüger in 1878. He measured oxygen consumption and carbon dioxide production in dogs and calculated respiratory quotients. His research substantiated a concept that had been enunciated, but not named, by Lavoisier.

Once the idea that oxidation occurred in the tissues became generally accepted, investigators began to delve into the process involved in the utilization of foodstuffs by the tissues, energetics, growth, and repair. Carl von Voit and Max von Pettenkofer, using a respiration chamber, drew upon chemical balances and respiratory quotients in humans to distinguish the nature of the foodstuffs being burned and to show that the amounts of fat protein and carbohydrate burned varied with the mechanical work done by the subject. The law of conservation of energy was formulated by Julius Robert von Mayer between 1842 and 1845. Subsequently, Max Rubner showed that the law applied to the living body, and Herman von Helmholtz showed how its relevance to metabolism could be demonstrated experimentally. Application of these principles at the bedside was greatly facilitated by the development of a portable metabolic apparatus by Nathan Zuntz. Pioneering bedside studies of diverse metabolic states were conducted by a succession of distinguished investigators, including Magnus-Levy, Graham Lusk, F. G. Benedict, and Eugene F. DuBois.

The Blood Gases

The Oxford physiologists set the stage for the discovery of the blood gases. Using his vacuum pump, Robert Boyle extracted "air" from blood. John Mayow came close to discovering oxygen by showing that only part of air was necessary for life and that this part, his "nitro-aerial spirits," was removed both by respiration and fire (combustion). One of his famous experiments entailed enclosing a mouse and a lighted lamp in an air-tight container; the lamp went out first and then the mouse died. However, Mayow did not realize that the "nitro-aerial spirits" could be isolated as a gas.

One hundred years after Mayow, Joseph Priestley (Fig. 1-7) exposed a mouse to the gas released from heated mercuric oxide and found that the gas supported life better than did air; he also noticed that a flame burned more vigorously in this gas than in air. Priestley was not alone in his preoccupation with flame. In 1773, about a year before Priestley had obtained oxygen by heating mercuric oxide, Scheele discovered oxygen independently because of his interest in fire, and he designated oxygen as "fire air."

In 1662, Van Helmont, a Capuchin friar and talented chemist—a mystic with a drive to quantify—discovered carbon dioxide, coined the word *gas*, and called carbon dioxide "wild gas" ("gas sylvestre"). In 1755, Joseph Black rediscovered carbon dioxide. He showed that calcium carbonate (limestone) and magnesium carbonate (magnesia alba) lost

Figure 1-7 Joseph Priestley (1733–1804), the discoverer of oxygen. This figure shows a silver medal struck in his honor in 1783. A Presbyterian minister, he was radical in his religious and political beliefs, inventive in science, and conservative in the interpretation of his findings. *(From Fishman AP, Richards DW: Circulation of the Blood: Men and Ideas, New York, Oxford University Press, 1964, with permission.)*

Figure 1-8 Christian Bohr (1855–1911). At work in his laboratory, Bohr (far right) and his associates systematically explored the interplay between the respiratory gases and hemoglobin that led to the discovery of the ''Bohr effect." *(From Fishman AP, Richards DW: Circulation of the Blood: Men and Ideas, New York, Oxford University Press, 1964, with permission.)*

weight on heating, releasing "fixed air" (CO_2) in the process. This fixed air extinguished both flame and life. Lavoisier knew of the observations of Black and of Priestley and Scheele. He decided in 1778 that the gas obtained from heating mercuric oxide was not "fixed air" or "common air," but "highly respirable air" (oxygen).

The story of hemoglobin, the essential element in the transport of the respiratory gases by the blood, begins with Hoppe-Seyler, who, between 1866 and 1871, crystallized hemoglobin, explored its chemical properties, and assigned it a proper role in the transport of oxygen by the blood. At the turn of the nineteenth century, Dalton reported his experiments with the respiratory gases, which led to the development of his atomic theory. In 1872, taking advantage of Dalton's law, Paul Bert published the first oxygen dissociation curve, i.e., oxygen content at different barometric pressures; he pictured the curve as hyperbolic. Christian Bohr subsequently identified its s-shaped contour (Fig. 1-8) and in 1904, together with Hasselbach and August Krogh, showed that increasing carbon dioxide tension in blood drives out oxygen, i.e., the "Bohr effect." Shortly thereafter, the various influences, e.g., temperature and electrolytes, on the affinity of oxygen for hemoglobin—and consequently the position of the oxygen dissociation curve—began to be explored in detail by Barcroft and his associates. In 1914, Christiansen, Douglas, and Haldane reported that an increase in the oxygen tension of the blood drives out carbon dioxide, i.e., the "Haldane effect." In 1967, a new dimension was added to the understanding of the position and configuration of the oxygen dissociation curve by the demonstration that diphosphoglycerate, a chemical constituent of red cells, regulates the release of oxygen from oxyhemoglobin.

Diffusion or Secretion of Oxygen

Bohr is a central figure as an investigator and mentor in respiratory physiology. In 1904, he raised a troublesome issue that was not easily resolved, primarily because of limitations in methodology. He postulated that even though diffusion could account for the oxygen uptake at rest, it could not suffice during strenuous exercise, particularly at altitude. He held that oxygen secretion had to be involved. He held to this misconception during his lifetime, a conviction supported by two major lines of evidence. The first was indirect, i.e., oxygen secretion by the swim bladder of fish, which showed by extrapolation that active transport of oxygen in the lungs was possible. The second was based on observations made during his expedition to Pike's Peak in 1912, which showed (erroneously) that during exercise at altitude, arterial oxygen tension exceeded alveolar oxygen tension.

But, even before the report from high altitude, Bohr's former assistant August Krogh and his wife, Marie Krogh (Fig. 1-9) had marshaled new evidence to show that "the absorption of oxygen and the elimination of carbon dioxide in the lungs takes place by diffusion and diffusion alone." The final blow to the secretion theory was delivered by Marie Krogh. Based on the single-breath carbon monoxide method for determining diffusing capacity that she and her husband

Figure 1-9 August and Marie Krogh in 1922, at the time of their first visit to the United States so that August Krogh could deliver the Silliman Lecture at Yale. They demonstrated that diffusion, without secretion, could account for the transfer of O_2 and CO_2 across the alveolar-capillary membranes of the lungs. *(Courtesy of their daughter, Dr. Bodil Schmidt-Nielsen.)*

had developed in 1910, she was able to account for oxygen uptake in the lung by diffusion alone, even during strenuous exercise under conditions of low oxygen tension. Refinements in the carbon monoxide method by Roughton and others extended its clinical applicability and provided further evidence against the secretion theory. But Haldane would not let go. Throughout his life, despite mounting evidence to the contrary, he adhered to the idea that oxygen was secreted by the alveolar membrane.

Finally, the issue was settled by Joseph Barcroft (Fig. 1-10). Using a chamber to reproduce the hypoxic-strenuous exercise circumstances of the Pike's Peak expedition, he found that under all conditions, the arterial oxygen saturation of arterial blood was less than that of blood exposed to a sample of alveolar gas obtained at the same time. He subsequently confirmed these results by experiments done at high altitude, i.e., at Cerro de Pasco (1921–1922).

The Physical-Chemical Synthesis

Lawrence J. Henderson undertook the herculean task of depicting the reactions of oxygen and carbon dioxide in blood not as cause and effect but as interplay among physiochemical variables and functions (Fig. 1-10). In his theoretical considerations and practical applications via the Fatigue Laboratory at Harvard, he was greatly abetted by close collaboration with Van Slyke, Wu, and McLean at the Rockefeller Institute in New York, who were exploring the exchanges of blood constituents between red cells and plasma. In 1828, Henderson presented his synthesis in the form of a D'Ocagne nomogram that displayed the changes in the various elements that entered into the exchange of the respiratory gases between alveolar gas and blood: plasma; the red cell; hemoglobin; and chloride, bicarbonate, and hydrogen ions. He presented

Figure 1-10 Two founders of contemporary respiratory physiology in 1936. Sir Joseph Barcroft (1872–1947) *(left)* proved, in experiments on himself, that diffusion was the mechanism for gas exchange in the lungs and pioneered current understanding of the respiratory functions of the blood. Lawrence J. Henderson (1878–1942) *(right)* provided a mathematical analysis of blood as a physiochemical system and stimulated research on the complex interplay involved in respiratory gas exchange during exercise. *(From Fishman AP, Richards DW: Circulation of the Blood: Men and Ideas, New York, Oxford University Press, 1964, with permission.)*

nomograms not only for the normal subject at rest and during exercises, but also for individuals with anemia, nephritis, diabetic coma, and other major clinical entities. Henderson dealt with steady-state observations. Roughton and associates enlarged the physiochemical horizons further by discovering carbonic anhydrase in the red cell and dealing with transient phenomena relating to the transport of the respiratory gases and carbon monoxide in blood.

LUNG VOLUMES

Although Humphrey Davy had determined his own lung volume using hydrogen as the test gas in 1800, it was not until the 1840s that John Hutchinson laid the groundwork for modern pulmonary function testing: He devised a spirometer and used it to determine the subdivisions of the lung in a large number of healthy subjects, relating the measurements to height and age (Fig. 1-11). The many refinements since then are too numerous for mention in this chapter. A big step forward was the invention of the body plethysmograph many years later, which made possible the determination of the thoracic gas volume along with airway resistance and pulmonary capillary blood flow.

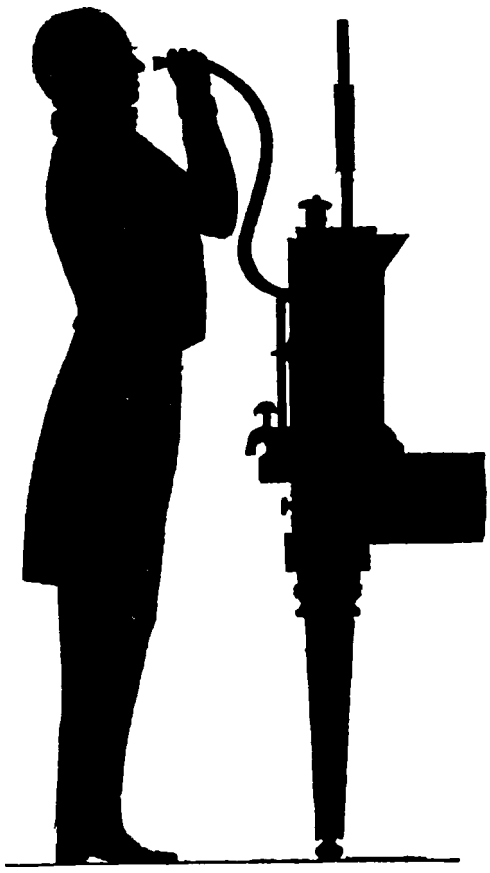

Figure 1-11 John Hutchinson's illustration of a subject about to undergo measurements of lung volumes. *[From Hutchinson J: Med Chir Soc (Lond) trans 29:137, 1846.]*

MECHANICS OF BREATHING

The ancients wondered about how air moved into and out of the lungs, and as far back as Erasistratus the diaphragm was recognized to be involved in breathing. Galen was aware that the lungs fill the chest cavity, they are moved by the actions of the thorax, and the large airways enlarge and lengthen during inspiration. He marveled at the long course of the nerves to the diaphragm and the innervation of the intercostal muscles. After Galen, interest in the mechanics of breathing waned except for sporadic observations and experiments by anatomists, notably Leonardo da Vinci and Andreas Vesalius. Interest resumed in the sixteenth century largely as a result of progress in physics and mathematics exemplified by the works of Borelli and Galileo.

The Respiratory Muscles

Mayow, one of the Oxford physiologists (Fig. 1-5), drew heavily on the work of colleagues, such as Boyle and Hooke, to develop considerable insight into the mechanics of breathing. He also built the first model on record of the chest as a bellows, which contained a bladder within it (Fig. 1-12). He understood that air moved into the lungs as the chest expanded because of the pressure and elasticity of ambient air, the chest expands because of the action of the intercostal muscles (internal and external), the diaphragm is the primary muscle of inspiration, and normal expiration is passive. After Mayow, little research was done on the role of the respiratory muscles in breathing until the mid-nineteenth century, when Donders distinguished between the respective roles played by the inspiratory muscles and elastic forces.

Elastic Properties of Lungs and Chest

Until the twentieth century, observations on the elastic properties of the lungs and chest cage in humans were fragmentary. Access to the pleural space was the major limiting factor. With few exceptions—notably Neergaard and Wirz, who used pleural pressures to determine elastic recoil in normal

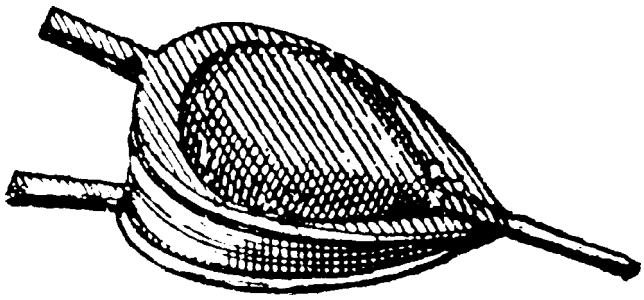

Figure 1-12 Mayow's model of the chest and lungs. The bellows encloses a bladder, the neck of which opens to the outside. A glass window on the upper side makes it possible to observe the bladder during inflation and deflation. *(From Mayow J: Medico-Physical Works, Crum A, Brown, Dobbin L (trans). Edinburgh, Alembic Club, Reprints, no 17, 1957. (Translated from Tractatus quinque medico-physics, 1674.)*

human subjects, and Christie, who recorded pleural pressures to demonstrate loss of pulmonary elasticity in emphysematous patients—measurements in humans were largely confined either to therapeutic interventions, e.g., induction of a pneumothorax or aspiration of pleural fluid, or experiments done at autopsy. The number of observations on the mechanical properties of the lungs increased dramatically when it was shown by Buytendijk, in 1949, and again by Dornhurst and Leathart, in 1952, that esophageal pressures provided an accurate measure of pleural pressures.

The role of alveolar surface tension in determining the elastic forces in the lungs began to be widely appreciated in the late 1950s, although the stage had been set long before then. In 1812, Laplace had published the law of surface tension. The implications of this law for the lungs began to be appreciated in 1929 when Neergaard compared pressure-volume curves of lungs filled with air with those filled with fluid. He concluded that unopposed surface tensions would favor alveolar collapse. Then, between 1954 and 1960, a remarkable outpouring of papers from different laboratories showed that a unique surfactant lined the alveoli, and this material was absent in premature infants with hyaline membrane disease (and alveolar collapse); these papers prompted extensive research, which continues to this day, on the chemical and physical properties of surfactant and on its sites of formation and removal.

Airway Resistance

A giant step forward began in 1916 when Rohrer, as part of his doctoral dissertation, presented a conceptual framework for determining flow/resistance in airways. His equations were based on precise anatomic measurements of airway dimensions in a human cadaver coupled with aerodynamic principles. During the following decade, he and his coworkers, Neergaard and Wirz, applied Poiseuille's law for laminar flow and his equations to the determination of airway resistance. Fleisch's pneumotachygraph with periodic interruptions of airflow was used as a strategy for measuring alveolar pressure. Measurements of alveolar pressure that were more useful clinically became available in 1956 with the introduction by DuBois and associates of the whole-body plethysmograph, which they coupled with the application of Boyle's law.

Synthesis of Mechanics

During the decade between 1915 and 1926, Rohrer and his colleagues provided a remarkably comprehensive synthesis of respiratory mechanics that included a description of the static pressure-volume characteristics of the respiratory system, the work of breathing; they also developed the principle of optimal frequencies of breathing to minimize respiratory work. Together with von Neergaard and Wirz, Rohrer developed and tested experimentally concepts involving pressures, flows, and volumes. The full significance of Rohrer's work was not appreciated until the publications by Fenn and his group at the University of Rochester starting in the 1940s. Although it is still premature to evaluate the contributions of W. O. Fenn, H. Rahn, and A. B. Otis to our present understanding of the mechanics of breathing, there is little doubt that this group shaped much of the contemporary thinking of respiratory physiologists and pulmonary physicians along this line.

CONTROL OF BREATHING

The control of breathing is a complex process that depends on the integrity of the entire respiratory system—lungs, airways, circulation, and control systems. Two dominant control systems exist: One is in the central nervous system, and the other is outside the brain. Control mechanisms in the central nervous system are influenced by the state of wakefulness or alertness and are subject to voluntary control. These mechanisms also are influenced reflexively by peripheral receptors of different kinds.

Localization of the Central Respiratory Centers

In 1812, Legallois, apparently intrigued by the gasping movements of the head after decapitation, identified an area in the medulla that was essential for life. In 1923, Lumsden systematically explored the effects of serial sections of the brain stem on respiration. This report marks the beginning of current lines of research on rhythmic breathing. He designated an area in the caudal pons responsible for a sustained inspirated drive as the "apneustic center" and an area in the rostral and lateral portions of the pons that presumably inhibited the apneustic drive as the "pneumotaxic center"; section of the vagi exaggerated the inhibition of the apneustic drive by the pneumotaxic center. Sixteen years later, Pitts and coworkers, using stereotactic stimulation of the cat medulla, identified inspiratory and expiratory centers and proposed a theory that could account for both rhythmic breathing and apneusis.

Chemical Stimulation of the Respiratory Centers

The chemical stimuli to breathing have been known for more than a century. In 1885, Miescher-Ruesch showed in humans that ventilation at rest is primarily regulated by carbon dioxide. Between 1887 and 1901, cross-perfusion experiments by Leon Fredericq underscored the role of carbon dioxide. But it was not until 1905 to 1909 that Haldane, Priestley, and Douglas paved the way to the modern understanding of the role of carbon dioxide under a variety of experimental conditions. In their experiments on humans, they relied heavily on the Haldane gas analyzer and an alveolar gas sampler of their own invention. However, their experiments did not distinguish clearly between CO_2 or H^+ in the stimulation of the respiratory centers. Winterstein and later Gesell advanced the idea that the chemical regulation of respiration is by the concentration of hydrogen ions within the respiratory centers.

The Winterstein theories provide a good example of the evolution of ideas prompted by new discoveries and

inventions. The original theory in 1911 attributed increments in ventilation caused by hypoxic or hypercapnic inspired mixtures to a single mechanism, i.e., acidification of arterial blood by either carbonic acid or lactic acid. In 1921, largely because of chemoreceptors, Jacob's demonstration of the rapid diffusion of carbon dioxide into starfish eggs implicated acidity within the respiratory centers, as well as arterial blood acidity, as the sites of stimulation. In order to account for the stimulation of breathing by hypoxia (the peripheral chemoreceptors had not yet been discovered), he invoked the release of asphyxiating substances (*Erstickungsstoffen*) within the respiratory centers themselves. A third theory in 1949, which attempted to incorporate the discovery of the peripheral chemoreceptors, finally gave way in 1955 to his fourth theory, which explained the effects of acid or hypoxia on both the central and peripheral chemoreceptors.

A major consequence of Winterstein's research was the impetus it gave to subsequent explorations of the chemical control of breathing. These explorations led to the identification of central chemoreceptors, distinct from mechanoreceptors, on the ventral surface of the medulla and clarification of the role of hydrogen ion activity as the central stimulus to breathing. It also prompted a search, which continues to this day, not only for the drives to ventilation arising from respiratory and metabolic acidosis, but also for a unifying theory for the chemical control of breathing.

The Reflex Regulation of Breathing

A considerable and diverse number of peripheral receptors can influence breathing reflexively by supplying information to respiratory centers located in the brain. These include pain receptors, stretch receptors in the muscles and distensible structures, and organs and chemoreceptors in major systemic arteries.

Mechanoreceptors

Until the work of Hering and his student, J. Breuer, little was known about the role of afferent impulses to the central control mechanisms in the control of breathing except that electrical stimulation of the vagus nerves influenced respiration. In 1868, Hering and Breuer reported that inflation of the lungs stopped respiration in expiration and promoted expiration and that, conversely, a decrease in lung volume ended expiration and promoted inspiration. They inferred that inflation had mechanically stimulated nerve endings in the lungs and the resulting impulses ascending the vagi were inhibitory to inspiration.

Peripheral Chemoreceptors

In 1841, Volkmann suggested the existence of chemoreceptors in the systemic circulation that were sensitive to blood-borne stimulants to respiration. In 1927, J. F. Heymans and C. Heymans first showed that the aortic bodies served this function, and in 1930, C. Heymans and Bouckaert demonstrated the peripheral chemoreceptive function of the carotid bodies. These were physiological observations that tallied well with the observations of F. De Castro, a student and later a colleague of Ramón y Cajal, who was sufficiently impressed by the histologic structure, location, and rich innervation of the carotid body to propose that it might be stimulated by blood-borne substances (Fig. 1-13).

VENTILATION-PERFUSION RELATIONSHIPS

In 1946, William Dock attributed the apical localization of tuberculosis to hypoperfusion of well-ventilated alveoli in the lung apices in the upright position. Shortly thereafter, ventilation–blood flow relationships were described in quantitative terms in papers by two separate groups: Rahn and Fenn, and Riley and Cournand.

SCIENTIFIC CLINICAL MEDICINE

Four remarkable figures may serve to illustrate different stages in the evolution of scientific pulmonary medicine: Morgagni, Laënnec, Koch, Cournand, and Richards. They represent pathologic anatomy, microbiology, and physiology.

Pathologic Anatomy

Two figures, almost a century apart, stand out in the contributions of pathologic anatomy to pulmonary medicine.

Morgagni

In the eighteenth century, a major contribution to scientific clinical medicine was made by Morgagni, a student of Valsalva (Fig. 1-14). Morgagni veered away from the undisciplined case reports of his predecessors. Instead, he adopted a logical system for relating findings at autopsy to their clinical manifestations. At age 79, he published a compilation of his lifelong experience in his famous work, *De Sedibus et Causis Morborum per Anatomen Indagatis. De Sedibus* includes about 700 cases. The clinical-pathological correlations in this work benefited greatly from the fact that Morgagni was both a seasoned clinician and a pathologist. One of the compilation's five books is devoted to diseases of the thorax. Among his descriptions were those of a tubercle undergoing liquefaction and the hepatization stage of pneumonia.

Laënnec

René Théophile Laënnec invented the stethoscope in 1816 (Fig. 1-15). At that time, clinical medicine in Europe, especially in France, was turning from metaphysic concepts and doctrinal systems to pathology as its scientific foundation. Eminent physicians, such as Bichat, Bayle, and Corvisart in France, and William and John Hunter and Baillie in England, were turning to the anatomic findings at autopsy to understand the signs and symptoms of their patients.

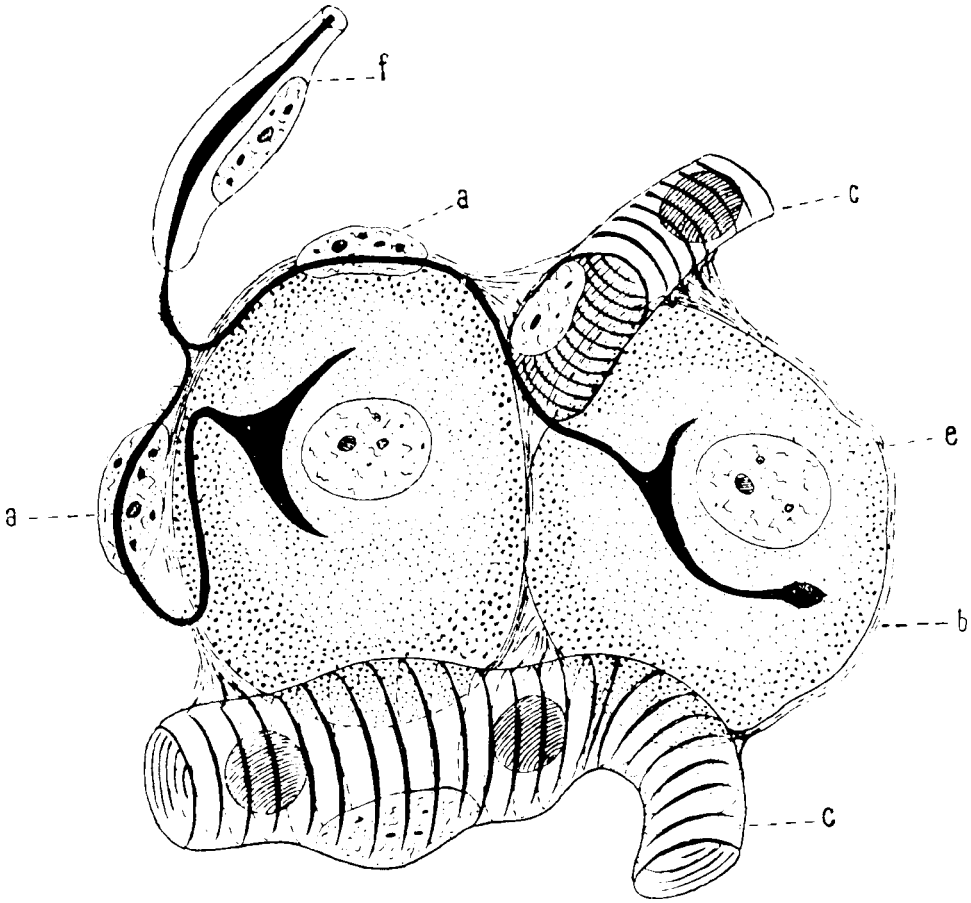

Figure 1-13 Drawing by De Castro showing the structure of the chemoreceptor. The glomus cells (*e*) present an ample cytoplasmic surface for contact with the perfusing blood delivered by the capillary (*c*); sensory nerve fiber (*f*) with sheath of myelin; Schwann cells (*a*) surround the unmyelinated fibers which form the terminal menisci; cell membrane (*b*). *(From De Castro F: Sur la structure de la synapse dans les chemocepteurs: leur mécanisme d'Excitation et R™ le dans la circulation sanguine locale. Acta Physiol Scand 22:14, 1951.)*

Percussion had been rediscovered by Corvisart: Although Auenbrugger had reported his "new invention" in 1761 in Latin, the idea had not caught on until Corvisart—eminent clinician and teacher and personal physician to Napoleon—published a translation in French in 1808. Corvisart's approach to medicine strongly influenced Laënnec. Laënnec applied the stethoscope and Corvisart's "sounding of the chest" to study individual patients with diseases of the lungs and heart throughout their clinical course to anatomical examination at autopsy. This was no simple matter. Since there were no pathologists in those days, the physician not only had to provide continuous care during the patient's lifetime but also had to arrange for and perform the autopsy, and then gather all that he had seen and learned and prepare it for publication.

In 1819, 2 years after the invention of the stethoscope, Laënnec published his famous monograph, *De l'Auscultation médiate*, which drew lessons from carefully documented cases that were studied throughout their clinical course and at autopsy. In this work, Laënnec built upon the monumental tome of Morgagni, who, a generation before, had related the clinical features of the diseases he described to the morbid anatomy, but had not been able to take the next step of relating the clinical course of individual patients to the anatomic findings after death.

Laënnec's monograph contains descriptions of physical signs, clinical-pathological correlations for tuberculosis, pneumonia, bronchiectasis, emphysema, and cancer of the lung, and instructions for the treatment of these conditions. The descriptions of tuberculosis were outstanding in the history of tuberculosis before Koch discovered the causative agent of the disease.

Microbiology

Tuberculosis provides a remarkably illuminating example of the impact of a novel basic science on clinical medicine. The disease can be traced back to the ancients, who were familiar with the diverse clinical syndromes that we now take for granted as due to tuberculosis, but had no way to relate them to a common etiologic agent. A synthesis by Morton in 1685 of all that was then known about tuberculosis focused on cavitary lesions, emaciation ("consumption"), and the tubercle but was shrouded in Galenic humors. Understanding of

Figure 1-14 Giovanni Battista Morgagni (1682–1771). The five volumes of his *De Sedibus* contain the clinical and pathologic descriptions of approximately 700 cases. *(Courtesy of the Library of the College of Physicians of Philadelphia.)*

Figure 1-15 Rene T.H. Laënnec (1781–1826). *[Drawn from life in 1825 by Charles James Blasius Williams (1805–1889) and reproduced in his autobiography, Memoirs of Life and Work, London, Smith, Elder & Co, 1884.]*

the disease accelerated in the eighteenth century when clinicians such as William Cullen began to sort out the various syndromes relating to phthisis, recognizing hemoptysis, empyema, catarrh, and asthma.

The tempo of discovery increased dramatically in the nineteenth century after the French Revolution. During the Napoleonic era, distinguished Parisian clinicians, including Bichat, Bayle, Louis, Broussais, and Laënnec, reported clinical-pathological correlations of tuberculosis. Both Bayle and Laënnec died of tuberculosis. However, little advance was made in understanding the pathogenesis of tuberculosis until Villemin, who, impressed by the analogy between glanders and syphilis on the one hand and tuberculosis on the other, and the fact that two of the three diseases had been shown to be infectious in origin, undertook experiments that showed that tuberculosis was an infectious disease that could be transmitted from humans to animals and from animals to animals.

Koch

In 1876, Koch was a general practitioner in the German township of Wollestein in the province of Posen, where he was responsible for the health care of 4000 inhabitants (Fig. 1-16). Between obstetrical deliveries and satisfying the medical and surgical needs of patients of all ages, he managed to conduct research on the microbial causes of communicable diseases. His laboratory was homemade, either the barn or living room; his major instrument was a microscope to examine bacteriologic and tissue specimens. In pursuing his research, he kept in mind the dictum of Jacob Henle, one of his teachers in medical school, who counseled that, "Before microscopic organisms can be regarded as the cause of contagion in man, they must be found constantly in the contagious material, they must be isolated from it and their strength tested." This lesson was to be the keynote of the future Koch postulates.

In 1876, Koch, the busy medical practitioner, sent a letter to Professor Ferdinand Cohn, director of the Botanical Institute in Breslau, indicating that he had discovered "the process of development of bacillus anthracis" and requesting permission to present his findings to Professor Cohn, "the foremost authority on bacteria." Koch had discovered the spores of anthrax bacilli. Cohn arranged for him to present his results before a formidable room full of distinguished scientists, i.e., Julius Cohnheim, Carl Weigert, Moritz Traube, Ludwig Lichtheim, and Leopold Auerbach. Koch's demonstration of the complete life history of the anthrax bacillus, including sporulation, was entirely convincing to these scientists. After the meeting, Cohnheim, upon his return home, announced to his colleagues, "This man has made a splendid discovery which is all the more astonishing because Koch has had no scientific connections and has worked entirely on his own initiative and has produced something absolutely complete. There is nothing more to be done. I consider this the greatest discovery in the field of bacteriology."

During the next 2 years, Koch described novel procedures for the examination, preservation, and photography

Figure 1-16 Robert Koch (1843–1910), announcing his discovery of the tubercle bacillus as the cause of tuberculosis. Berlin, March 28, 1882. *(Reproduced with permission from Knight D: Robert Koch: Founder of Bacteriology. New York: Franklin Watts, Inc., 1961, p 10.)*

of bacteria and demonstrated the role of microorganisms in traumatic infections while continuing his dual existence as a country doctor and an independent investigator. In 1880, Cohn and Cohnheim arranged for him to move to Berlin as a member of the Imperial Sanitary Commission. This move freed more time for research. By 1881, he made another breakthrough. This was the pour-plate method for isolating pure cultures. The ability that this technique afforded of producing transparent solid media coupled with his invention of new staining methods paved the way for him to tackle the microbial cause of tuberculosis.

His scientific approach, which has become immortalized as the "Koch postulates," consisted of four essential steps:

1. To prove that a microbe is the cause of a disease, it must be present in all cases of the disease. (He showed this for the tubercle bacillus using methylene blue and a counter stain.)
2. The microbe must be grown outside of the body in pure culture. (He devised blood-serum jelly as a culture medium for the slow-growing tubercle bacillus.)
3. The pure culture must be capable of causing the disease in healthy animals. (He proved this initially by inoculation and subsequently by allowing animals to breathe contaminated air.)
4. The same microbe must then be isolated from the inoculated (infected) animal and grown outside of the body in pure culture.

Koch's discovery of the tubercle bacillus and its modes of transmission revolutionized the treatment of tuberculosis. Before the discovery, tubercular patients were treated in sanitaria, which offered fresh air and altitude. Those who ran the sanitaria did not know that tuberculosis was a contagious disease: Sanitation was unregulated; neither sterilization nor fumigation was practiced; there were no laws about spitting; diagnostic capabilities were limited. Koch's discovery of the tubercle bacillus revolutionized therapy. For the rest of his life, while pursuing the causes of other diseases around the world—rinderpest in South Africa, Texas fever, tropical malaria, blackwater fever, bubonic plague in Bombay—he maintained his interest in tuberculosis. His interest led him into a major mistake, i.e., advocacy of tuberculin as a vaccine instead of its present use as a diagnostic test. In 1905, he was awarded the Nobel Prize. On April 7, 1910, the year of his death, he delivered a final address on the epidemiology of tuberculosis before the Berlin Academy of Sciences.

Physiology of the Pulmonary Circulation

Starting with William Harvey, studies of the pulmonary circulation have gone hand in hand with advances in pulmonary physiology and medicine. For many years, research on the pulmonary circulation was confined to animal experimentation. A giant step forward was made by the introduction of cardiac catheterization in humans.

Accurate measurement of pulmonary blood flow is a sine qua non for assessing pulmonary and cardiac performance in health and disease. The use of nitrous oxide in humans by Krogh and Lindhard was an important beginning in this direction, but not until mixed venous blood could be sampled for application of the Fick principle could reliable determinations of pulmonary blood flow be made.

Claude Bernard in 1846 and Chauveau and Marey in 1861 had catheterized the right side of the heart in animal experiments. Whether this technique could be used safely in humans was not known until 1929, when Werner Forssmann, a young surgeon in Germany, introduced a ureteral catheter into his own right atrium. In the 1940s, Cournand, Richards and their colleagues, resorted to right heart catheterization in order to obtain mixed venous blood for the determination of cardiac output by the Fick principle (Fig. 1-17). As everyone knows, the technique opened the way not only to the accurate determination of cardiac output, but also to exploring the heart and lungs in a wide variety of clinical cardiac and pulmonary disorders.

Until 1946, when von Euler and Liljestrand reported the effects of hypoxia and hypercapnia on the pulmonary

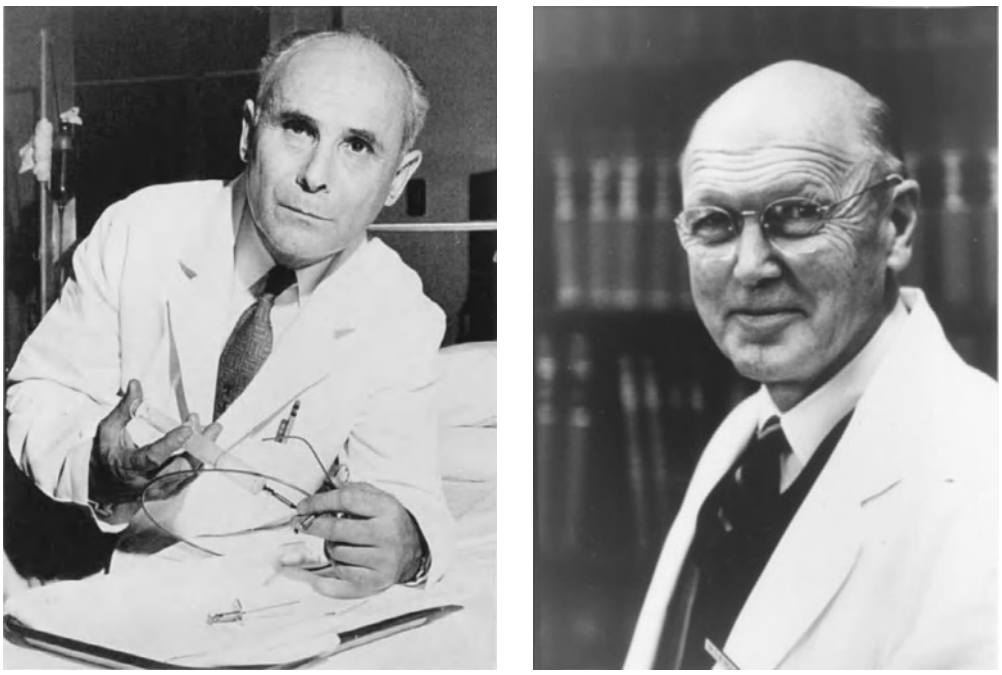

Figure 1-17 André Frederic Cournand (1895–1988) and Dickinson W. Richards (1895–1973). After Forssman's report of the uneventful catheterization of his own right heart, Cournand and Richards pioneered the use of cardiac catheterization for the study of the normal and abnormal pulmonary circulation and the standardization of pulmonary function tests.

circulation of the open chest of an anesthetized cat (Fig. 1-18), there was little understanding of the regulation of the pulmonary circulation. However, these studies, and the proposition of local control of the pulmonary circulation by local concentrations of the respiratory gases, paved the way to understanding pulmonary hypertension and the behavior of the pulmonary circulation on the one hand, in normal individuals at rest, after birth, during exercise, and at altitude, and on the other, in individuals with heart and/or lung disease.

The interposition of the pulmonary circulation between the right and left sides of the heart, an eventual step for life on earth, is not only prerequisite for gas exchange, but also serves a variety of other functions, e.g., mechanical, as a filter for particulate matter in blood returning to the heart, and metabolic, for the synthesis uptake, and breakdown for vital biologic functions and ingredients. Extensive studies have been conducted over the last few decades on the nonrespiratory functions of the lungs. From these studies has emerged considerable understanding of the diverse functions served by the branching pulmonary circulation and by its components, i.e., endothelium and smooth muscle and their interplay in the pulmonary circulation.

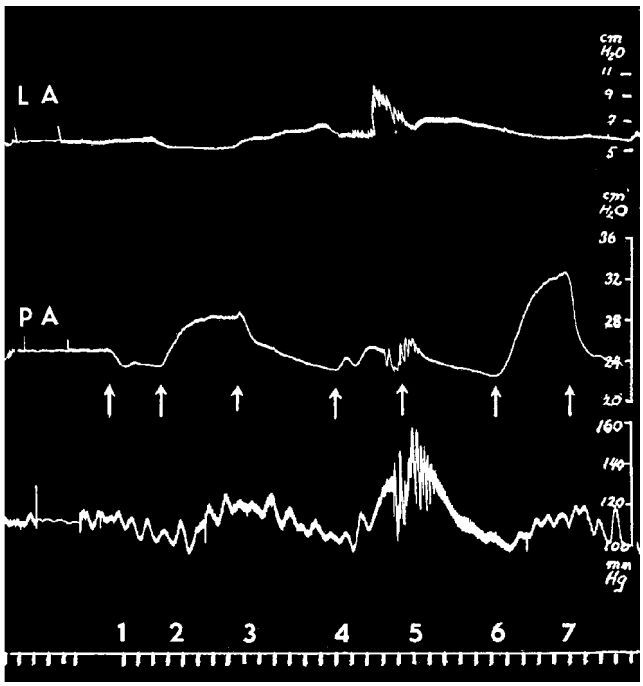

Figure 1-18 Effects of the blood gases on pulmonary arterial pressure in the open-chest cat, artificial respiration. LA = left atrial pressure; PA = pulmonary arterial pressure; lower trace = systemic arterial blood pressure. Numbers along the baseline represent the administration of test gases: 1 = O_2 (from air); 2 = 6.5% CO_2 in O_2; 3 = O_2; 4 = 18.7% CO_2 in CO_2; 5 = O_2; 6 = 10.5% O_2 in N_2; 7 = O_2. *(From Von Euler, US and Liljestrand, G: Observations on the pulmonary arterial blood pressure in the cat. Acta Physiol Scand 12:310, 1946.)*

TECHNOLOGICAL INVENTIONS AND IMPROVEMENTS

The road to contemporary pulmonary medicine could be just as easily traced by using technological advances as landmarks instead of people and discoveries. For example, the

introduction of the manometer for pressure recording, the use of chambers to simulate high altitude, the development of accurate blood-gas analyzers, and the application of sophisticated optical systems for viewing the lumens of the airways and the inside of the chest cavity are all notable milestones. However, probably no better example exists than the discovery of radiographs and the application of this discovery to the diagnosis, prevention, and management of pulmonary tuberculosis.

Wilhelm Conrad Roentgen (1845–1923) discovered radiographs in 1895 while experimenting with cathode ray tubes in his physics laboratory at the University of Wurzburg. Although others before him had seen radiographs as early as 1890, Roentgen was apparently the first to grasp the full significance of the discovery, and his publication, quite unpretentious, immediately attracted worldwide attention because of its prospects for the study of anatomic structures and pathological changes.

Within 2 years after Roentgen's discovery, fluoroscopy of the chest had been introduced into clinical practice, and its value in the early detection of tuberculosis and the diagnosis of pleural effusions was appreciated. In 1901, an atlas of chest radiographs was published, and the use of chest radiography increased greatly with each subsequent improvement in hot-cathode radiograph tubes and intensifying screens. The radiographic evaluation of tuberculosis was superior to physical examination per se for the diagnosis and characterization of pulmonary tuberculosis. By 1910, all patients admitted to sanatoriums were undergoing chest radiographic examination, and by 1917 tuberculosis was being classified according to radiograph findings.

CHAPTER 2

Functional Design of the Human Lung for Gas Exchange

Matthias Ochs • Ewald R. Weibel

At the end of a deep breath, about 80 percent of the lung volume is air, 10 percent is blood, and only the remaining 10 percent is tissue. Because this small mass of tissue is spread over an enormous area—nearly the size of a tennis court—the tissue framework of the lung must be extraordinarily delicate. It is indeed remarkable that the substance of the lung manages to maintain its integrity in the face of the multitude of insults that inevitably accompany a lifetime of exposure to ambient air and the complex necessity of keeping air and blood in intimate contact, but separate, for the sake of gas exchange.

Part of this success is undoubtedly attributable to the unique design of the lung, which ensures mechanical stability as well as nearly optimal conditions for the performance of the lung's primary function: to supply the blood with an adequate amount of oxygen even when the body's demands for oxygen are particularly high, as during heavy work.

THE LUNG AS AN ORGAN

At total lung capacity, the lung fills the entire chest cavity and can reach a volume, in the adult human, of some 5 to 6 L, largely depending on body size. Upon expiration, the lung retracts, most conspicuously from the lower parts of the pleural cavity, the posterior bottom edge of the lung moving upward by some 4 to 6 cm. This preferential lifting of the bottom edge is caused by retraction of the tissue throughout the entire lung, the surfaces of which are freely movable within the thoracic cavity.

The structural background for this mobility of a healthy lung is the formation, during morphogenesis, of a serosal space that is lined on the interior of the chest wall and on the lung surface by a serosa, the parietal and visceral pleurae,

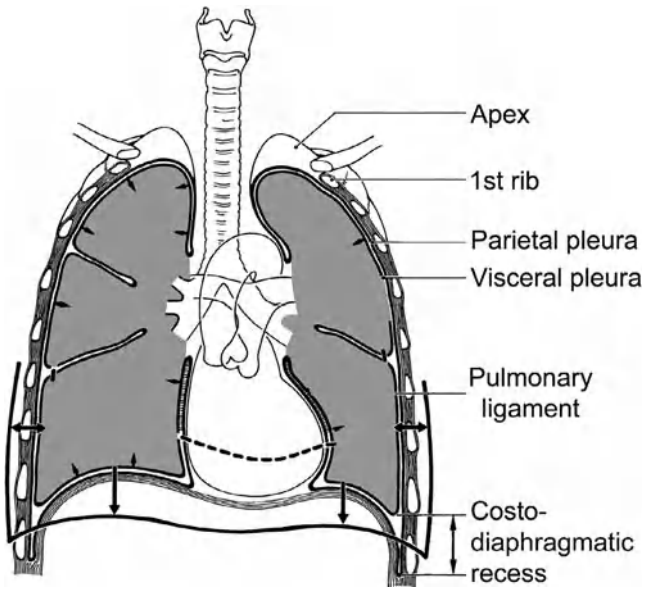

Figure 2-1 Frontal section of chest and lung showing pleural space. Single arrows indicate retractive force. Double arrows show the excursion of the lung bases and periphery between deep inspiration and expiration.

respectively (Fig. 2-1). However, this serosal space is minimal, since the visceral pleura is closely apposed to the parietal pleura, with only a thin film of serous fluid intercalated as a lubricant between the two surfaces. Both pleural surfaces are lined by a squamous epithelial layer, often called *mesothelium*, whose surface is richly endowed with long microvilli. The apical microvilli increase the surface area available, suggesting that pleural mesothelial cells are capable of participating in active transserosal transport of solutes. The total volume of pleural fluid is about 15 to 20 ml, with approximately 1700 cells/mm^3 (75 percent macrophages, 23 percent lymphocytes, 1 percent mesothelial cells). The volume and composition of the pleural fluid have to be tightly controlled to ensure an efficient mechanical coupling between chest wall and lung. Pleural fluid originates from pleural capillaries through microvascular filtration. Drainage occurs mainly via lymphatic stomata in the parietal pleura. Transcytosis through mesothelial cells in both directions might represent another mechanism involved in pleural fluid homeostasis.

The connective tissue of the visceral pleura consists of three layers. A superficial layer of predominantly elastic fibers follows the mesothelium, thereby forming an elastic "bag" that enwraps each lobe. A deep sheet of fine fibers follows the outline of alveoli and extends into the depth of the lung. Between these sheets lies a bed of loose connective tissue, containing free cells (histiocytes, plasma cells, and mast cells), that is often close to lymphatics and systemic arterial branches from the bronchial arteries.

The lung is maintained in a stable position within the chest by the hilum, where airways and blood vessels enter from the mediastinum, and by the pulmonary ligament, a long, narrow band of attachment between visceral and mediastinal pleura that extends downward from the hilum. Because of these attachments, a pneumothorax causes the lung to retract

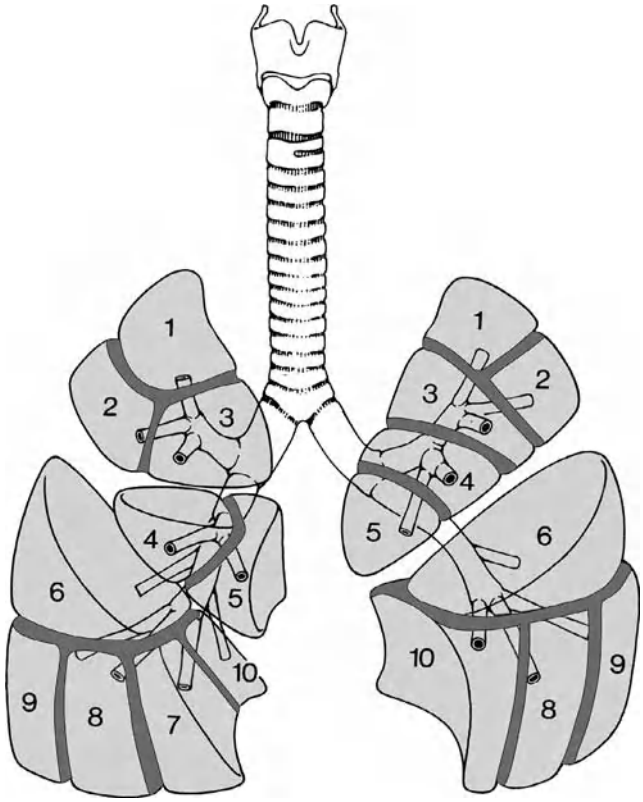

Figure 2-2 Bronchopulmonary segments of human lung. Left and right upper lobes: *(1)* apical, *(2)* posterior, *(3)* anterior, *(4)* superior lingular, and *(5)* inferior lingular segments. Right middle lobe: *(4)* lateral and *(5)* medial segments. Lower lobes *(6)*: superior (apical), *(7)* medial-basal, *(8)* anterior-basal, *(9)* lateral-basal, and *(10)* posterior-basal segments. The medial-basal segment *(7)* is absent in the left lung. (Note: The lungs are represented as turned inward slightly in order to display part of the lateral face.)

and form a lump of tissue that is attached to the mediastinal wall of the thoracic cavity.

The shape of the lung is congruent with that of the fully expanded pleural cavity. This shape is preformed in lung tissue and is hence also evident if an excised lung is inflated, revealing its three faces: the convex thoracic face apposed to the rib cage, the concave diaphragmatic face modeled by the diaphragmatic dome, and the mediastinal face, on which the contours of the heart are impressed beneath the hilum.

As the lung retracts during deflation, the acute edges between the thoracic face and the diaphragmatic and (anterior) mediastinal faces of the lung withdraw; the thoracic and diaphragmatic leaflets of the parietal pleura become apposed, thereby forming a costodiaphragmatic recess on each side (Fig. 2-1). Similarly, as the ventral edge of the lung retracts, the costal and mediastinal pleurae form a recess on each side, corresponding topographically to the borders of the sternum.

The port through which airways and blood vessels enter the lung is the hilum, i.e., the attachment of lung tissue to the mediastinum (Fig. 2-1). The airways reach the two hili by the mainstem, or principal, bronchi (Figs. 2-1 and 2-2). The left mainstem bronchus is longer than the right because it must pass under the aortic arch before it reaches the lung. The

two principal bronchi course downward and begin to divide sequentially shortly after entering the lung, first releasing the lobar bronchus to the upper lobe (Fig. 2-2). Since a middle lobe is formed only on the right side, there is no middle lobe bronchus on the left; instead, the corresponding parts form the lingula, which receives its airways from the superior bronchus of the upper lobe (Fig. 2-2). The last branch of the stem bronchus goes to the lower lobe.

The branching pattern of the human bronchial tree and of the pulmonary artery and veins are shown in a resin cast in Fig. 2-3. The pulmonary artery joins the bronchi while still in the mediastinum (Fig. 2-4*A*); its trunk lies to the left of the ascending aorta, and the right pulmonary artery turns dorsally to course between ascending aorta and right principal bronchus. In the hilum, the right pulmonary artery lies anterior to the right principal bronchus; the left pulmonary artery, however, "rides" on the principal bronchus and crosses over the superior lobar bronchus to the posterior side. From there on, the pulmonary artery branches in parallel with the bronchi; characteristically, each bronchus is associated with one closely apposed pulmonary artery branch, and this relationship is strictly maintained to the periphery, i.e., to the respiratory bronchioles.

In contrast, the pulmonary veins (Fig. 2-4*B*) follow a course independent of the bronchial tree; rather, they lie about midway between two pairs of bronchi and arteries; this

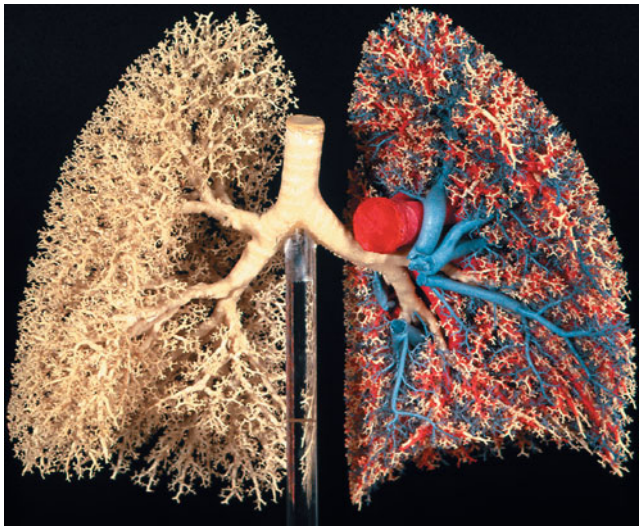

Figure 2-3 A resin cast of the human airway tree shows the dichotomous branching of the bronchi from the trachea and the systematic reduction of airway diameter and length with progressive branching. In the left lung the pulmonary arteries *(red)* and veins *(blue)* are also shown.

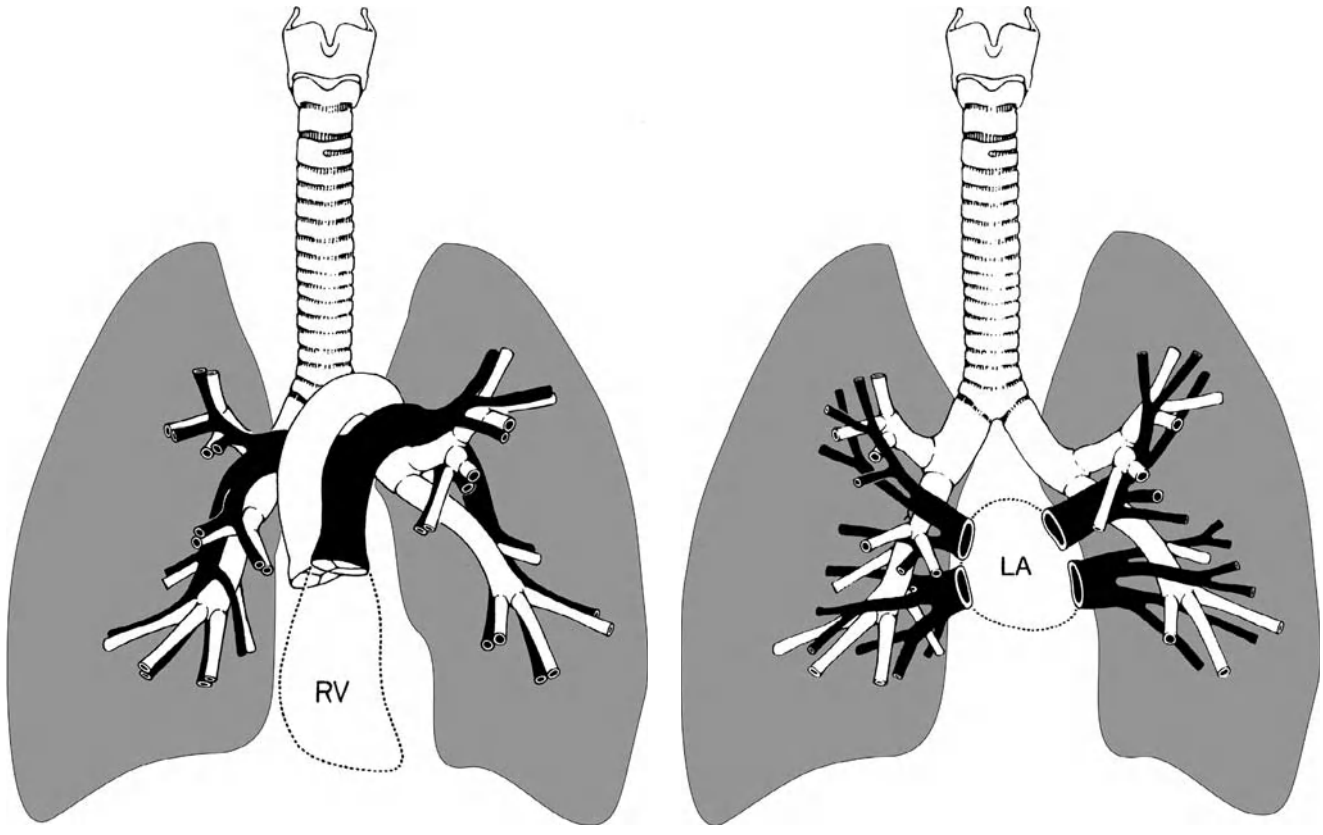

Figure 2-4 Schematic diagrams of the relation of the main branches of pulmonary arteries *(A)* and pulmonary veins *(B)* to the bronchial tree. The arteries follow the airways. Two main stems of pulmonary vein penetrate independently into the lung on each side. LA = left atrium; RV = right ventricle.

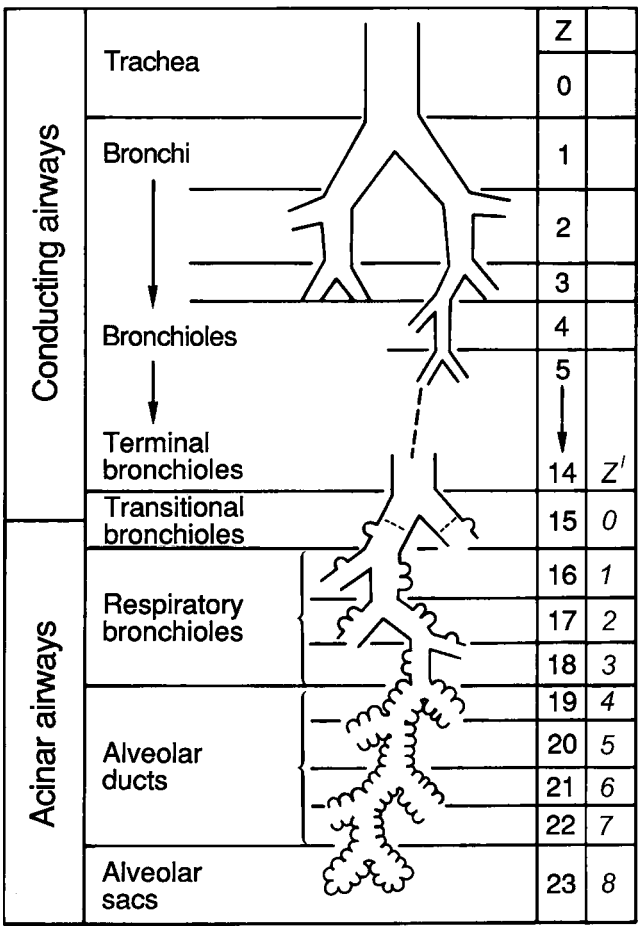

Figure 2-5 Model of airway branching in human lung by regularized dichotomy from trachea (generation z = 0) to alveolar ducts and sacs (generations 20 to 23). The first 14 generations are purely conducting; transitional airways (generation 15) lead into the acinar airways with alveoli that branch over eight generations (z′). *(Modified after Weibel ER: Morphometry of the Human Lung. Heidelberg, Springer-Verlag, 1963.)*

position is maintained to the periphery of the airway system. In the hilum, these veins are collected into at least two main veins on either side, which lead into the left atrium located at the back of the heart.

The airways systematically branch over an average of 23 generations of dichotomous branching, ending eventually in a blind sac (Fig. 2-5). The last nine generations of these airways are connected to tightly packed alveoli, airway chambers in which gas exchange takes place, whereas the central airways serve the function of conducting the air to the gas-exchange parenchyma. In such a system of sequential branching, the unit of lung parenchyma could be defined according to the portion of parenchyma that is supplied by a particular branch of the bronchial tree, and it is possible to conceive of as many types of units as there are generations unless clear definitions for such units are proposed. However, two units appear to be natural:

1. The *lobes*, which are demarcated by a more or less complete lining of pleura. There are three lobes on the right (superior, middle, and inferior lobes), and two on the left (superior and inferior lobes).
2. The *acinus*, which is defined as the parenchymal unit in which all airways have alveoli attached to their wall and thus participate in gas exchange. Along the airway tree, the acinus begins with a transitional bronchiole (Fig. 2-5).

Since all other units are somewhat arbitrarily defined, it is not surprising that some ambiguity exists in the literature about their meanings. Nonetheless, a certain convention has been adopted with respect to the following:

1. The *lung segments*, which are considered as the first subdivisions of lobes. Fig. 2-2 shows the location and distribution of the segments to the various lobes. The symmetry is imperfect because on the left the two segments corresponding to the right middle lobe are incorporated into the superior lobe as the lingula (segments 4 and 5) and because the medial-basal segment of the lower lobe is generally missing on the left (segment 7).
2. The *secondary lobule*, an old anatomic unit. It was introduced in the nineteenth century because "lobules" of about 1 cm^3 are visible on the surface of the lung. These lobules are delineated by connective tissue septa that are connected to the pleura. The secondary lobule is difficult to define in terms of the bronchial tree, but it does seem to comprise about a dozen acini. With reference to bronchograms, secondary lobules are supplied by airway branches that are about 1 mm in diameter.

The pulmonary blood vessels show a characteristic relationship to these units (Figs. 2-3 and 2-4). The pulmonary arteries, following the airways, course through the centers of the units and finally fan out into the capillaries located in the delicate alveolar septa of lung parenchyma. In contrast, the veins lie in the boundary between units and collect the blood from at least two or three adjacent units. This arrangement applies to acini and secondary lobules as well as to lung segments.

Therefore, it is evident that the units of lung parenchyma are bronchoarterial units, which share their venous drainage with neighboring units. This architecture has important functional and practical consequences. Except for the lobes, none of the units are separated from each other by complete connective tissue septa.

ORGANIZATION OF LUNG TISSUE

Basic Structural Elements

In looking at the tissue organization of the lung, we must first consider that the airways and the blood vessels each have their own lining by an uninterrupted cell layer. These layers extend all the way out to the gas-exchange region, but they show different properties in conducting as compared with respiratory structures. Likewise, the connective tissue forms a continuum throughout the lung all the way out to the pleura, but it, too,

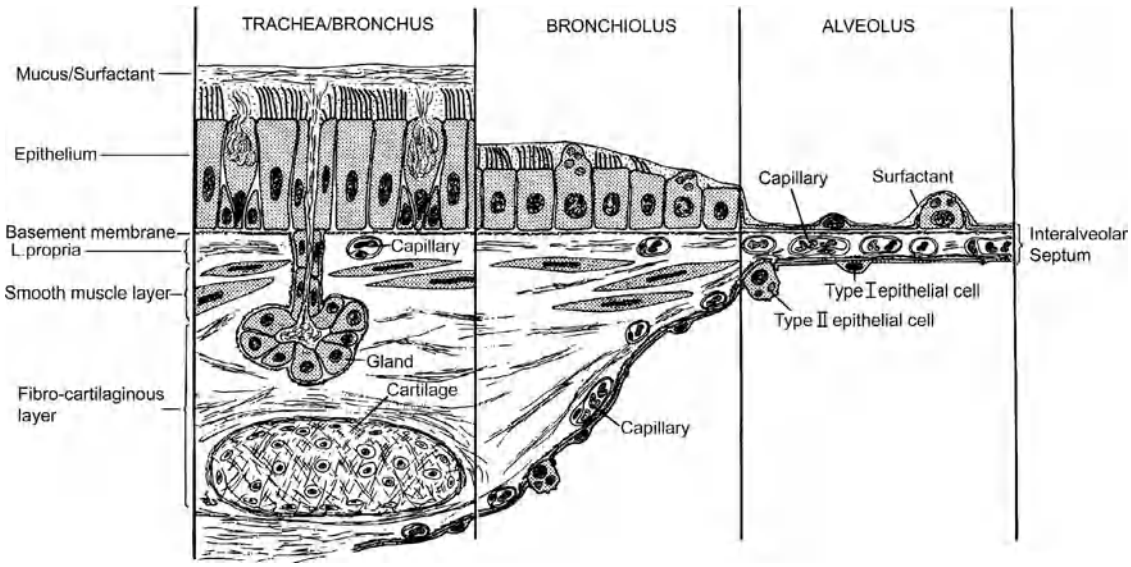

Figure 2-6 Airway wall structure at the three principal levels. The epithelial layer gradually becomes reduced from pseudostratified to cuboidal and then to squamous but retains its organization as a mosaic of lining and secretory cells. The smooth muscle layer disappears in the alveoli. The fibrous layer contains cartilage only in bronchi and gradually becomes thinner as the alveolus is approached.

will be differently organized in the different functional zones; whereas it is reduced to a minimum in the alveolar walls, it contributes a number of different ancillary structures to the wall of conducting airways and blood vessels, such as smooth muscle sheaths or cartilage. This connective tissue space also houses the nutritive vessels and nerves as well as the elaborate defense system related to lymphatic vessels. In the gas-exchange region, however, very few of these accessory structures are found.

The complexity of lung structure is also reflected at the cell biological level. There is no such thing as a standard "lung cell." Instead, we find some 40 different cell types, highly specialized both structurally and functionally, in the lung.

A word of caution is also necessary with respect to the extrapolation of structural findings in experimental animals, especially rodents, to the human lung. Noteworthy species differences include the bronchial circulation, the presence of respiratory bronchioles, the ultrastructural composition and distribution of non-ciliated bronchiolar (Clara) cells, the expression of surfactant proteins by Clara cells, the frequency of certain cell types like alveolar brush cells and lipid-containing interstitial cells (lipofibroblasts), and the ultrastructural organization of lamellar bodies in type II alveolar epithelial cells. All these structural elements have features characteristic for the human lung that are not found in rodents.

Wall Structure of Conducting Airways

The wall of conducting airways consists of three major components (Figs. 2-6 and 2-7): (1) a mucosa composed of an epithelial and a connective tissue lamina; (2) a smooth-muscle sleeve; and (3) an enveloping connective tissue tube partly provided with cartilage.

Epithelium

Although derived from one and the same anlage, the airway epithelium modifies its differentiation characteristics as we proceed from large bronchi over bronchioles to the alveolar region (Fig. 2-6). A simple epithelium exists as a lining of smaller bronchioles: as we move upward toward larger bronchi, the epithelium becomes higher and some basal cells appear, making the epithelium pseudostratified; at the point of transition into the gas-exchange region; that is, at the entrance into the complex of alveoli—the epithelium abruptly becomes extremely thin.

Fig. 2-6 also shows that the epithelium is not made of a uniform cell population but that it is, at each level, rather a mosaic of at least two cell types, in that secretory cells as well as some rarer special cells are interspersed into the complex of lining cells.

If we first have a closer look at the epithelium of larger conducting airways, we see that the lining cells are provided with a tuft of kinocilia at their apical cell face, whereas the secretory cells are goblet cells that produce and discharge to the surface a sticky mucus (Figs. 2-7, 2-8, and 2-9). This mucus spreads out as a thin blanket on top of the cilia and is capable of trapping dust particles that are still contained in the air entering the lung. Kinocilia (Fig. 2-10) are organelles of movement that are known to beat rhythmically in a given direction and at a frequency of about 20 Hz. In the airway epithelium, the cilia are oriented in such a fashion that their beat is directed outward. It is interesting that the cilia of airway epithelia develop at their tip fine claws with which they can grasp the mucus blanket in the phase of their forward beat, whereas on their return to the upright position they glide past the mucus blanket. The result of this is that the mucus blanket, together with trapped foreign material, moves outward or "up the

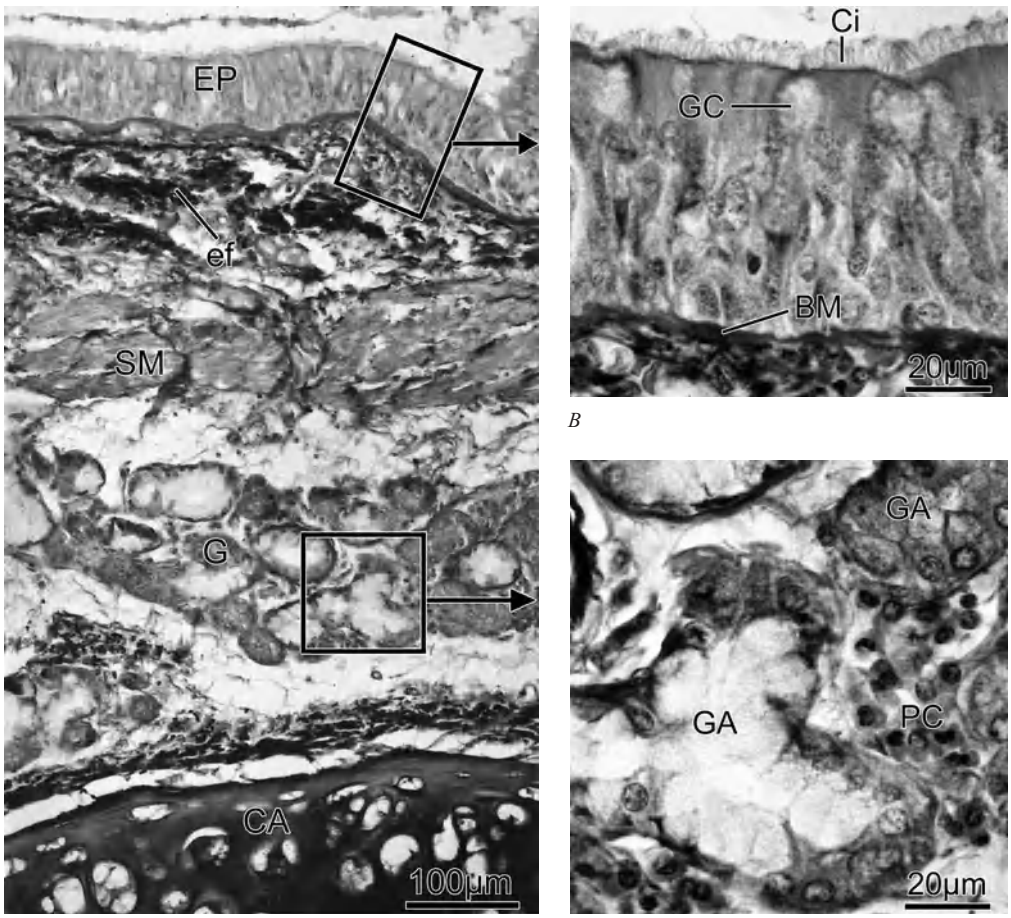

Figure 2-7 Light micrographs of bronchial wall. *A*. The layers from epithelium (EP) to cartilage (CA) with elastic fibers (ef), smooth-muscle bundles (SM), and glands (G). *B*. A

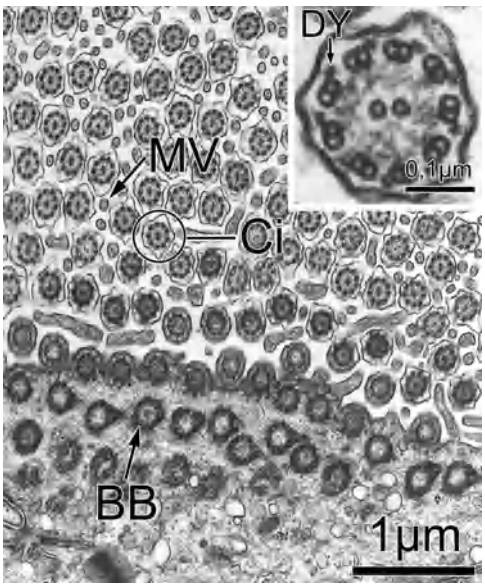
B



C

Figure 2-10 Cilia (Ci) from human bronchial epithelium seen on sections of epithelial cells in scanning electron micrograph *(A)*, and on thin sections in longitudinal *(B)*, and oblique cross section *(C)*. They are implanted in the epithelial cell by a basal body (BB). Cross-sectioned cilium at high power *(inset, C)* reveals its membrane, which is enveloping a typical set of two axial tubules and nine peripheral duplex tubules with dynein arm (DY) attached. Note abundant short microvilli (MV) interspersed between cilia.

airways" in a steady stream, a feature appropriately called the mucociliary escalator. Since the lining by ciliated cells is uninterrupted from the bronchioles, up the bronchi, to the trachea, this mucociliary escalator ends at the larynx, so that the normal fate of bronchial mucus is to be steadily discharged into the pharynx, whence it is swallowed, usually unnoticed. Only when an excessive amount of mucus accumulates in the trachea or in larger bronchi do we have to assist the system by coughing.

The secretory cell population shows a number of specialized features. In the bronchi of all sizes and in larger bronchioles one finds goblet cells interspersed between the ciliated cells; they form the mucus in their endoplasmic reticulum and Golgi complex, store it as droplets in their apical part, and discharge it in bulk (Figs. 2-8 and 2-9). In larger bronchi, one finds, in addition, small mucous glands located in the connective tissue; they are connected to the bronchial surface by long and narrow ducts (Figs. 2-6 and 2-7). In the normal bronchus the glandular acini are relatively small and composed of serous and mucous cells; enlargement of the acini and a relative increase of mucous cells are characteristics of chronic bronchitis.

Finally, a special secretory cell appears in the smaller bronchioles, the nonciliated bronchiolar (Clara) cell (Fig. 2-11). This cell population is very heterogeneous, thus displaying both interspecies and intraspecies variations. In the human lung, Clara cells account for about 11 and 22 percent of the total epithelial cell number in terminal and respiratory bronchioles, respectively. Besides the absence of cilia, Clara cells in conventional preparations are characterized by their dome-shaped apex that protrudes into the airway lumen. In contrast to rodents, where this cell is rich in smooth endoplasmic reticulum, Clara cells in the human lung lack significant amounts of smooth ER. They possess short lateral cytoplasmic extensions while their basal surface that rests on the basement membrane is practically free of infoldings.

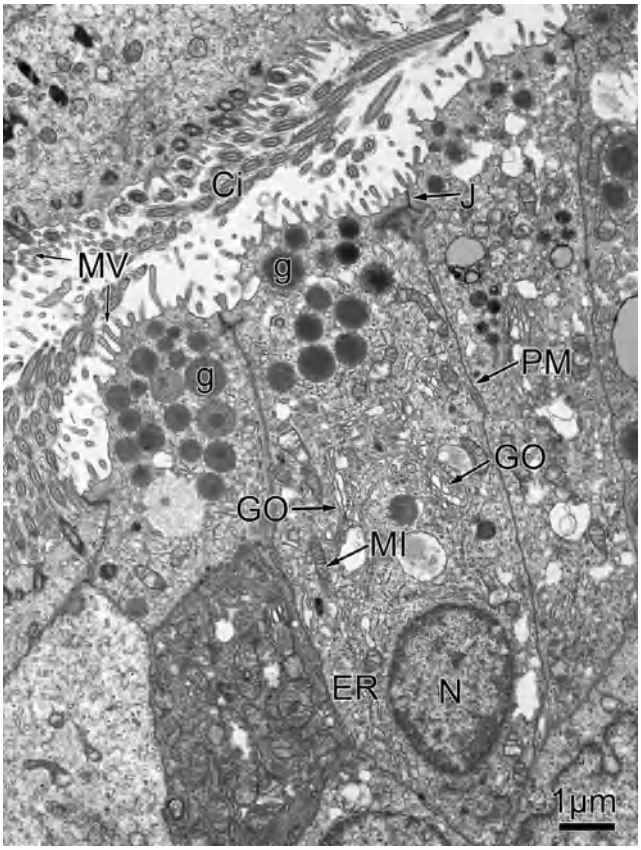


Figure 2-11 Clara cells from human bronchiolar epithelium contain dense secretion granules (g) at apex. Note abundant cytoplasmic organelles such as mitochondria (MI), Golgi complex (GO), or endoplasmic reticulum (ER) as well as microvilli (MV) at surface. Cell membranes are closely apposed and form tight junctions (J) at apical edge. Ci = cilia; N = nucleus; PM = plasma membrane.

Membrane-bound electron-dense granules of about 500 to 600 nm diameter are present, which underlines their secretory activity. Our understanding of the functions of Clara cells is still incomplete. In many aspects, Clara cells appear to be functionally related to the secretory cell type of the alveoli, the type II alveolar epithelial cell; ultrastructural features and expression patterns of lung adenocarcinoma cells show characteristics of both Clara and type II cells. Clara cell secretions add to the lining layer of the distal lung. Clara cells synthesize and secrete the so-called Clara cell secretory protein (CCSP), which has been shown to be structurally similar to rabbit uteroglobin. The exact function of CCSP in the human lung still remains to be elucidated. CCSP levels in BAL fluid are decreased in smokers and in patients with COPD or interstitial lung diseases. Animal studies suggest immunomodulatory functions for CCSP. Within the lung, the Clara cell is the primary site of cytochrome P450 monooxygenase activity. Thus, they are heavily involved in detoxification of xenobiotics. Clara cells, especially subpopulations associated with neuroepithelial bodies or localized at bronchiolo-alveolar duct junctions, also appear to act as progenitor cells for the bronchiolar epithelium.

There are also some additional rarer cells. Neuroendocrine cells are capable of secreting mediators (amines and

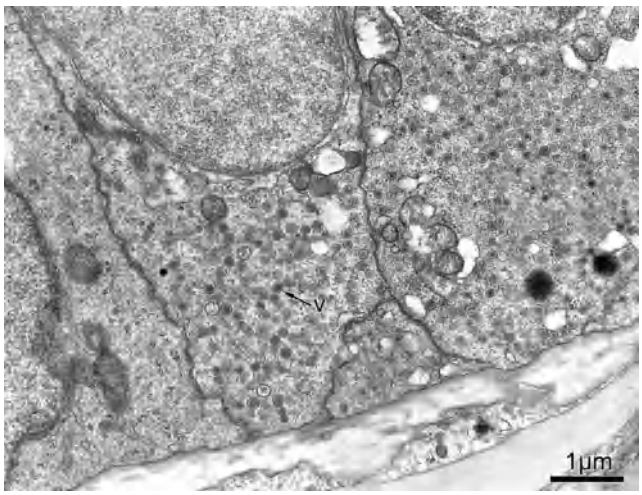

Figure 2-12 Basal part of neuroendocrine cell of human bronchiolar epithelium showing dense-cored vesicles (v). *(From Weibel ER: Lung cell biology, in Fishman A, Fisher AB (eds): Handbook of Physiology. Section 3: The Respiratory System. Bethesda, MD: American Physiological Society, 1985, vol 1, pp 47–91.)*

neuropeptides) into subepithelial capillaries. Prior to secretion, the bioactive substances are stored in dense-cored vesicles (Fig. 2-12). Occasionally, but only rarely in the adult human lung, these cells are organized in extensively innervated groups, then termed neuroepithelial bodies. Although it seems clear that neuroepithelial bodies have sensory, most likely oxygen-sensing, properties, their exact physiological function is still poorly understood. Another rare cell type of the airway epithelium is the brush cell. These cells are characterized by the presence of an apical tuft of blunt, broad microvilli with rootlike structures composed of filaments extending into the cytoplasm (Fig. 2-13). Glycogen

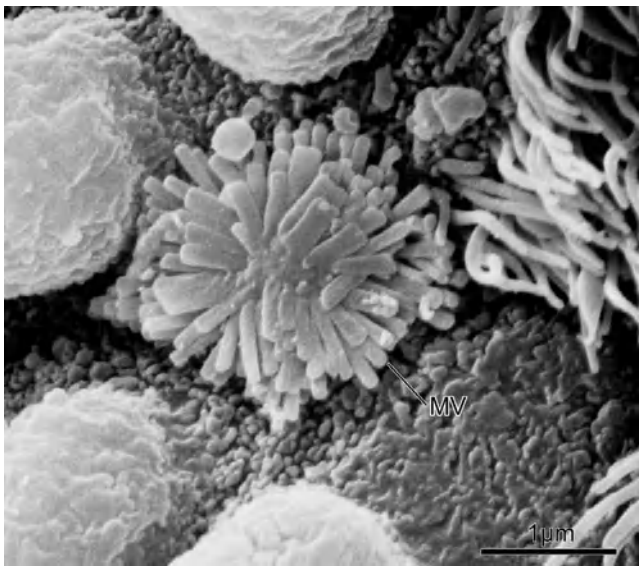

Figure 2-13 Brush cell from small bronchiole of rat lung containing broad microvilli (MV). *(From Weibel ER: Lung cell biology, in Fishman A, Fisher AB (eds): Handbook of Physiology. Section 3: The Respiratory System. Bethesda, MD: American Physiological Society, 1985, vol 1, pp 47–91.)*

granules, vesicles, and smooth endoplasmic reticulum are usually present as well. There is species variation in the occurence of brush cells. While common in rodents, they are only rarely found in the human lung. Their function still remains speculative. Owing to their ultrastructure and their strategic localization in the airways and at alveolar duct bifurcations, sensory/chemoreceptor as well as sentinel/immune surveillance functions have been proposed.

Interstitium

The layer of connective tissue in the bronchial mucosa consists predominantly of elastic fibers that are oriented longitudinally; these fibers serve to maintain a smooth outline of the longitudinal profile of the bronchial lumen no matter how much the bronchi are stretched as the lungs are inflated. In this connective tissue lamina there are foci of lymphoid cells; often they form small lymphoid follicles. However, bronchus-associated lymphoid tissue (BALT) is usually absent in normal adult human lungs and develops only after stimulation when inducible BALT might organize local immune responses.

Smooth-muscle bundles form a continuous sleeve in the connective tissue underlying the epithelial tube that extends from the major bronchi to the respiratory bronchioles; beyond the respiratory bronchioles, the bundles extend into the wall of alveolar ducts where the muscle fibers lie in the alveolar entrance rings. The bundles have an oblique course and encircle the mucosal tube in a criss-cross pattern; hence, their contraction results primarily in a narrowing of the lumen.

In the small bronchioles there is little else to the airway wall; the smooth muscle layer is ensheathed by a layer of delicate connective tissue that is in direct contact with adjacent alveoli (Fig. 2-6). In the larger bronchioles and even more in the bronchi, the outer connective tissue sheath forms a strong layer of fibers; in the bronchi, rings or plates of cartilage are incorporated into this layer.

The wall structure in the respiratory bronchioles is identical to that of terminal bronchioles except that in some regions the cuboidal epithelium is replaced by an alveolar epithelium of squamous cells (type I cells) closely apposed to capillaries. Very often, these single alveoli constitute outpouchings in these regions; sometimes simple "respiratory patches" form in the bronchiolar wall (see below).

Wall Structure of Conducting Blood Vessels

The endothelial lining of pulmonary arteries and veins is basically similar to that of capillaries. It is, however, thicker, and parts of its cytoplasm are richly endowed with organelles of various kinds (Fig. 2-14). Clearly, these cells are metabolically more active than those of the capillary endothelium. They are particularly rich in membrane-bound rod-shaped granules termed Weibel-Palade bodies, which represent the regulated secretory organelles of endothelial cells (Fig. 2-14). The lumen of Weibel-Palade bodies is filled with longitudinally arranged tubules. These tubules most likely represent von Willebrand factor, packed in a highly organized state. Other components of Weibel-Palade bodies include tissue-type plasminogen activator, endothelin-1, the leukocyte adhesion receptor P-selectin, interleukin-8, the tetraspanin CD63/LAMP-3, and the small GTPase Rab27a. Thus, Weibel-Palade bodies are actively involved in hemostasis as well as in vasoactive and inflammatory responses.

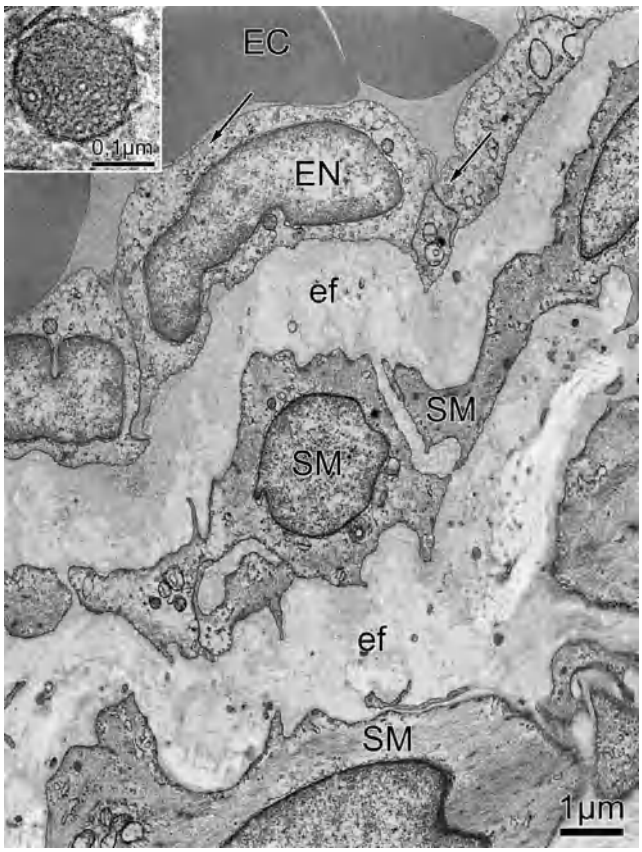

Figure 2-14 Part of wall of pulmonary artery from human lung. Endothelial cells (EN) form thick layer; their cytoplasm is rich in organelles. Specific granules of endothelium *(arrows),* a cross section of one of which is shown at high power in the inset, are enveloped by a membrane and contain tubules. The arterial wall is of the elastic type, formed of alternating layers of smooth muscle (SM) and elastic fibers (ef). EC = erythrocyte.

Many of the nonrespiratory metabolic functions of the lung—particularly the transformation of certain bioactive substances, such as angiotensin and prostaglandins—are performed in endothelial cells. Caveolae (or plasmalemmal vesicles) have been implicated in these processes. Caveolae are omega-shaped plasma membrane invaginations and associated vesicles with an outer diameter of about 70 nm. Their structural framework consists of members of the caveolin family of proteins associated with cholesterol and sphingolipids. Caveolae perform transport and signalling functions. All endocytic activity mediated by caveolae (thereby bypassing the clathrin-coated vesicle pathway) is pooled under the term potocytosis.

Accessory structures develop in the wall in accord with the functional properties of the vessels. Thus, the walls of the major pulmonary arteries that are close to the heart, and therefore exposed to the pressure oscillations of large amplitude prevailing in the outflow tract of the right ventricle, are

of the elastic type, i.e., layers of elastic lamellae are interconnected with smooth muscle cells as in the aorta; the tone of the smooth muscle regulates the elastic modulus of the vessel wall, thereby controlling the shape of the pulse wave. In the pulmonary arterial tree, this pattern prevails out to branches of about 1 mm diameter.

In contrast, branches less than l mm in diameter are of the muscular type, i.e., the smooth-muscle fibers encircle the vessel lumen; they can modify the vessel's cross section and can thus regulate blood flow through this vessel. Compared with systemic arteries, the thickness of the pulmonary arterial wall is reduced about in proportion to systolic pressure, i.e., by about a factor of 1:5; in pulmonary hypertension, the wall becomes thicker. Although arterioles are a well-defined entity in the systemic vascular bed, where they constitute the major site of arterial resistance, pulmonary arterioles are more difficult to locate and define. A single muscle layer—the histologic definition of an arteriole—does occur in branches about 100 μm in diameter, but the arterial bed continues out to the precapillaries, which consist of vessels 20 to 40 μm in diameter that are enwrapped by an incomplete smooth muscle sheath. This poverty of smooth muscle contributes importantly to the low resistance to blood flow that is normally afforded by the pulmonary arterial tree.

The structure of pulmonary veins is similar to that of systemic veins in the upper half of the organism. Their walls are rich in connective tissue and contain irregular bundles of smooth muscle. Larger veins contain a large amount of elastic tissue. More extensive in rodents, but to a certain degree also in humans, cardiac muscle tissue from the left atrial myocardium forms sleeves in the adventitia of pulmonary veins where they overlap with the smooth muscle of the venous wall. The arrangement of the myocardial sleeves correlates with the distribution of foci of ectopic beats initiating atrial fibrillation.

Nutritive Vessels and Nerves

The tissue of lung parenchyma is very well supplied with blood; the fact that it is venous is of no disadvantage, because O_2 is easily obtained from the air. Thus, nutrient supply from pulmonary arteries combined with O_2 supply from air appears to suffice not only for the parenchyma but also for bronchioles and the smaller pulmonary vessels, whose outer surface is almost directly exposed to air. The thicker-walled bronchi, with their glands and cartilage, require a nutrient blood supply from bronchial arteries. These derive in part directly from anterior branches of the aorta and partly from the upper intercostal arteries. They course alongside the esophagus and penetrate on both sides into the hilum. The bronchial arteries extend to the most peripheral bronchi but not into the walls of bronchioles. On the other hand, some branches supply large pulmonary vessels as *vasa vasorum,* whereas others course along larger septa to reach the pleura. Some bronchial arteries form anastomoses with peripheral branches of the pulmonary arteries. There have been long discussions about the role that such anastomoses may play. It seems that in the normal lung their importance has been overrated. However, in certain pathological conditions, such as bronchiectasis and tumors, the bronchial arteries and perhaps the bronchopulmonary anastomoses appear to play an important role. They also enlarge to form a collateral circulation when branches of the pulmonary artery are obliterated. The peribronchovascular space around larger pulmonary artery branches and bronchi with its capillaries from the bronchial circulation has also been proposed as a unique compartment since it is a preferential site of leukocyte infiltration and edema formation under pathological conditions. Furthermore, the bronchial circulation attenuates ischemia-reperfusion lung inujury. Consequently, interruption of the bronchial circulation without revascularization during lung transplantation often leads to bronchial anastomotic complications.

Except for a few bronchial veins in the hilar region, the bronchial system does not have its own venous drainage into the systemic veins. Instead, the bronchial veins, which begin as a peribronchial venous plexus, drain into pulmonary veins; this drainage seems to constitute one source of normal venous admixture to arterial blood.

The lung is innervated by the autonomic nervous system. The parasympathetic fibers are derived from the vagal nerves and the sympathetic fibers from the upper thoracic and cervical ganglia; together they form the pulmonary nervous plexus in the region of the hilum before entering the lung. The fiber bundles follow the major bronchi and blood vessels, finally penetrating into the acini; some nerves also supply the pleura. In addition, motor nerves influence the smooth-muscle tone of airways and blood vessels, and sensory nerves are involved in reflex functions (e.g., cough reflex, Hering-Breuer reflex). Moreover, the secretory function of glands as well as of type II alveolar epithelial cells is at least partly under control of this nervous system. Nerve fibers are easily found in the wall of bronchioles and bronchi, where they often follow the course of bronchial arteries. However, fibers in alveolar septa are small and scarce.

The Cells of the Alveolar Region

Basic Design of the Gas-Exchange Barrier

Efficient gas exchange in the lung depends on a very thin barrier of very large surface between air and blood. Actually, the barrier is so thin that it cannot be resolved into its constituents by light microscopy. Nevertheless, this barrier must be built of the three minimal tissue layers: an endothelium lining the capillaries, an epithelium lining the airspaces, and an interstitial layer to house the connective tissue fibers. The guiding principle in designing these cells must evidently be to minimize thickness and maximize extent. However, there is definitely a limit to this, set by the need to make the barrier and its constituent cells strong enough to resist the various forces that act on it: capillary blood pressure, tissue tension, and surface tension, in particular. Furthermore, the barrier must remain intact for a lifetime, and this requires continuous repair and turnover of the cells and their components. As a result, about half of the surface of the air-blood barrier

Table 2-1

Estimated Cell Volumes in the Human Lung

Cell or Tissue	Volume, ml	Percent Septal Tissue
Tissue (excl. blood)	284	—
Nonparenchyma	99	—
Alveolar septa	185	—
Cells	213	—
Nonparenchyma	50	—

is optimized for gas exchange in that the thin epithelial and endothelial cell extensions are only separated by a fused basement membrane. These areas are termed the thin parts of the air-blood barrier. Cell nuclei and connecting tissue fibers are concentrated in the so-called thick parts of the air-blood barrier.

In spite of this delicacy of tissue structure, we find that three-quarters of all the lung cells by volume or weight are contained in the lung parenchyma (Table 2-1). We also note that epithelium and endothelium make up about one-quarter each of the tissue barrier in the alveolar walls, whereas interstitial cells amount to 35 percent; the interstitial space with the connective tissue fibers makes up no more than 15 percent of the barrier.

Alveolar Epithelium

The alveolar epithelium is a mosaic of different cell types. The vast majority of the total surface is lined by a single layer of squamous cells; the remaining fraction—only about 3 percent (Table 2-2)—is occupied by cuboidal secretory cells; one usually calls the squamous lining cells type I and the secretory cells type II alveolar epithelial cells or pneumocytes. Type I and II cells occur with a numerical frequency of about 1:2. A very rare third cell type, the brush cell, can be found in some specific regions near the entrance of the acinus (see above).

The fine structural details of the different types of alveolar epithelial cells can only be fully visualized by electron microscopy, whereas molecular markers selective for either type I or II cells or some of their constituents can be detected and localized by light microscopy (Fig. 2-15; Table 2-3).

Type I Alveolar Epithelial Cells

At first glance, the squamous type I cells show rather simple design features (Fig. 2-16). Their small, compact nucleus is surrounded by a slim rim of cytoplasm, where one finds a modest basic set of organelles, a few small mitochondria,

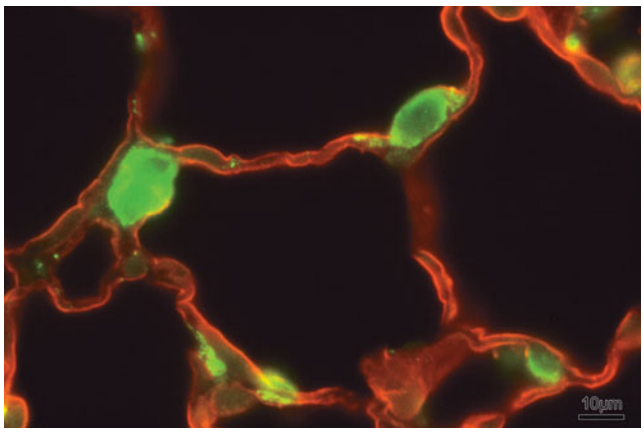

Figure 2-15 Immunofluorescent double labeling of alveolar epithelial cells. Type I cells are stained for Lycopersicum esculentum lectin (red), type II cells are stained for SP-D (green). Compare with Table 2-3. *(Micrograph courtesy of H. Fehrenbach.)*

and some cisternae of endoplasmic reticulum, seemingly the picture of a quiescent cell with no great metabolic activity.

At the edge of the perinuclear region, a very attenuated cytoplasmic leaflet emerges (Fig. 2-16) and spreads out broadly over the basal lamina. This leaflet is made essentially of the two plasma membranes forming the apical and basal cell face, respectively, with a very small amount of cytoplasmic ground substance interposed (Fig. 2-17). Here one rarely finds any organelles except for the numerous plasmalemmal vesicles implied in the transcellular transport of molecules. In fact, besides capillary endothelial cells, type I alveolar epithelial cells are among the richest in caveolae.

Table 2-3

Markers for Alveolar Epithelial Cells

Type I Cell	Type II Cell
HTI-56 (human)	Surfactant proteins:
T1α/RTI-40 (rat, mouse)	SP-A
Aquaporin 5	SP-B
Caveolin 1	SP-C
Receptors for advanced glycation end products (RAGE)	SP-D
	ABCA3
Carboxypeptidase M	RT II-70 (rat)
Lectins:	MMC4 (rat)
Lycopersicon esculentum	Alkaline phosphatase
Bauhinia purpurea	CD44
Ricinus communis 1	Lectins:
	Maclura pomifera

These markers allow a selective distiction between type I and type II alveolar epithelial cells and can be visualized at a light microscopic level by immunohistochemistry, enzyme histochemistry, or lectin histochemistry. However, other cell types of the distal bronchiolar and alveolar region, e.g., Clara cells, capillary endothelial cells or alveolar macrophages, might also stain positive for some of these markers.

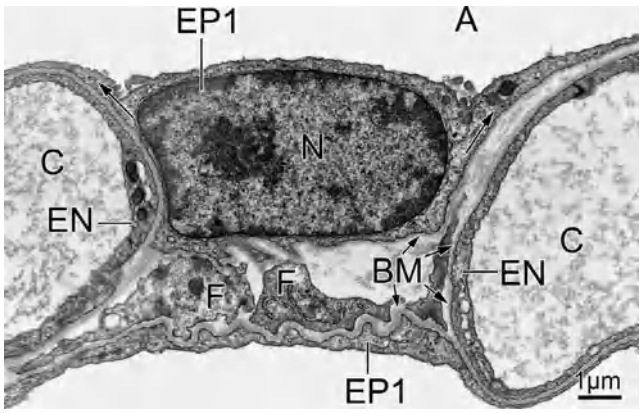

Figure 2-16 A type I alveolar epithelial cell (EP1) from human lung. The nucleus (N) is surrounded by very little cytoplasm, which extends as thin leaflets *(arrows)* to cover the capillaries (C). Note the basement membranes (BM) of the epithelium and endothelium (EN), which become fused in a minimal barrier. Interstitial space contains fibroblast processes (F).

The surface covered by one type I epithelial cell is about 4000 to 5000 µm^2. In some texts one may find the type I cell called the "small alveolar cell" because of its small nucleus; clearly this is a misnomer, as the type I cell is a rather large cell indeed, with respect to both surface and cell volume (Table 2-2). Terminal bars are formed where the cytoplasmic leaflets of epithelial cells meet (Fig. 2-18). If one looks at the surface of the alveolar epithelium in scanning electron micrographs (Fig. 2-19), one notes that the patches covered by single type I cells are variable in size and that even the largest are much smaller than the 4000 to 5000 µm^2 given above, a number derived by dividing the total alveolar surface by the total number of type I cell nuclei. Why is this? There seem to be three to four times as many type I cell domains

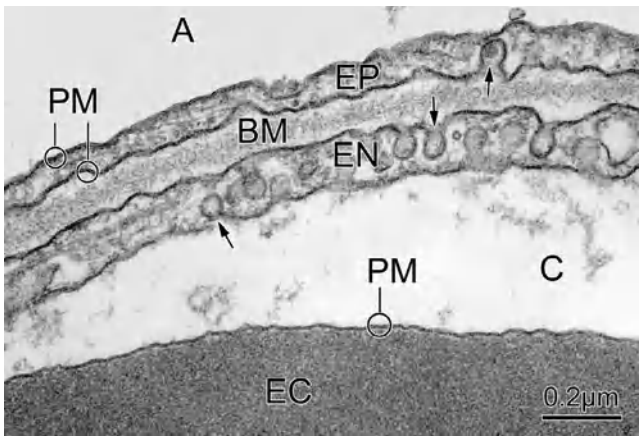

Figure 2-17 Thin, minimal tissue barrier between alveolar air (A) and capillary blood (C) is made of cytoplasmic leaflets of epithelium (EP) and endothelium (EN), joined by fused basement membranes (BM). Note that the epithelial and endothelial leaflets are bounded by plasma membranes (PM), as is the erythrocyte (EC). Arrows point to pinovytotic vesicles/caveolae. *(From Weibel ER: The Pathway for Oxygen. Cambridge, MA, Harvard University Press, 1984.)*

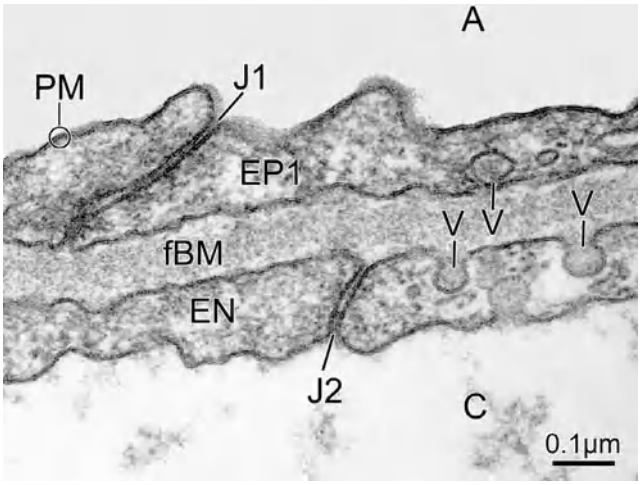

Figure 2-18 Minimal barrier part showing intercellular junctions. Between type I epithelial cells, a ''tight" junction (J1) is formed by close apposition of the cell membranes over a comparatively wide band; the junction between endothelial cells (J2) is ''leaky" because membranes become apposed over a narrow strip only. Note trilaminar structure of plasma membranes (PM), the occurrence of pinocytotic vesicles/caveolae (V) in both epithelium and endothelium (EN), and the fused basement membranes (fBM). A = alveolus; C = capillary; EP1 = type I epithelial cell.

encircled by terminal bars as there are nuclei. Indeed, this observation was already made some 125 years ago by Albert Kölliker; his interpretation was that part of the alveolar surface was lined by "non-nuclear" cytoplasmic plates rather than by complete cells. It turns out that an alternative explanation is possible. One finds that type I cells are not simple squamous cells but rather branched cells with multiple apical faces, as

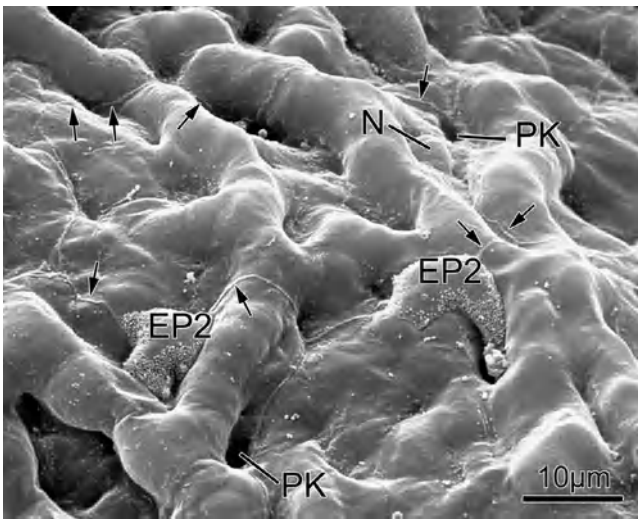

Figure 2-19 Surface of the alveolar wall in the human lung seen by scanning electron microscopy reveals a mosaic of alveolar epithelium made of type I and type II (EP2) cells. Arrows indicate boundary of the cytoplasmic leaflet of the type I cell which extends over many capillaries (C). Note the two interalveolar pores of Kohn (PK). N = nucleus of type I cell.

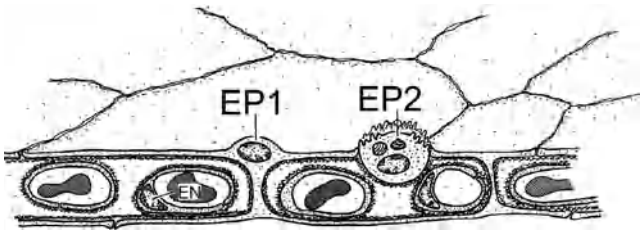

Figure 2-20 Diagram of the alveolar wall showing the complexity of a type I epithelial cell (EP1) and its relation to a type II cell (EP2) and endothelial cell (EN). *(From Weibel ER: The Pathway for Oxygen. Cambridge, MA, Harvard University Press, 1984.)*

shown diagrammatically in Fig. 2-20. Thus, what appears as non-nucleated plates are cytoplasmic domains connected to the perinuclear region by a stalk, spreading out on one side of the alveolar wall or the other; it is evident that several such domains may share a nucleus.

Although type I cells cover about 97 percent of the alveolar surface area, they have long been neglected as being "silent," providing solely a barrier function. Although their overall function in the human lung remains to be determined, recent animal and in vitro studies strongly suggest that type I cells are actively involved in alveolar ion and fluid homeostasis.

Type I cells are easily damaged, particularly because of their extensive surface area and their complex branching architecture. However, there is an additional problem: one finds that type I cells are not capable of multiplying by mitosis, neither during lung growth when more cells are needed to coat the expanding alveolar surface nor upon damage in the adult lung when cells need to be replaced. In both instances new type I cells are made by mitotic division and transformation of type II cells, a process that takes about 2 to 5 days.

This seems to work under normal circumstances. There are, however, conditions where this repair mechanism is too slow to cope with excessive damage, so that a syndrome of severe catastrophic respiratory failure, acute respiratory distress syndrome (ARDS), develops, which requires intensive care treatment. In such patients one finds large parts of the type I cell lining of the alveolar surface to be destroyed. As a consequence, the barrier has become leaky and the alveoli fill with alveolar edema, so that they can no longer take part in gas exchange.

With proper medical care, this alveolar edema can often be resolved within a few days. The alveoli become again filled with air, but in spite of this, gas exchange does not improve. What has happened is that the repair of the severely damaged alveolar epithelium requires a lot of new cells to be made by division of type II cells. These form a rather thick cuboidal lining of the barrier surface, a phenomenon termed cuboidal metaplasia, and this thick barrier offers a high resistance to O_2 flow. It takes several weeks until a thin barrier is restored by transformation of the cuboidal cell lining into delicate type I cells. During this process, the cells go through intermediate stages where they are often positive for both type II and type I cell markers.

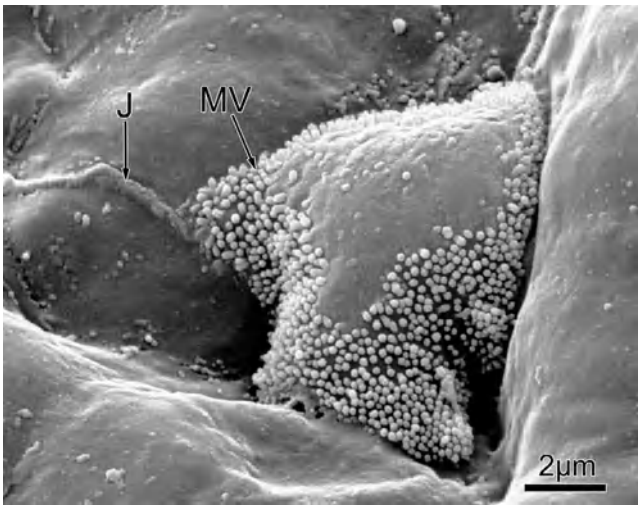

Figure 2-21 Higher magnification of a type II cell reveals a "crown'' of short microvilli (MV) and a central ''bald patch." Note junction lines of type I cells (J) meeting with the type II cell.

Type II Alveolar Epithelial Cells

The type II alveolar epithelial cell is a conspicuous but in fact relatively small cell whose mean volume is less than half that of the type I cell (Table 2-2), although it is often called the "large alveolar cell." Its shape is cuboidal, the apical cell surface bulges toward the lumen and is provided, mostly around its periphery, with a tuft of microvilli (Figs. 2-21 and 2-22). Often, type II cells seem to be preferentially located in the corners of alveoli or in close proximity to interalveolar pores of Kohn. They are usually found as solitary cells; only in cases of alveolar epithelial damage, proliferation of type II cells leads to focal clusters during the repair process. Occasionally, a single type II cell might supply two or even three adjacent alveoli with its apical surface. The basement membrane beneath type II cells is occasionally interrupted. Through these apertures, foot processes of type II cells can extend to the interstitium and come in close proximity to interstitial cells.

Type II cells contain a wealth of cytoplasmic organelles of all kinds (Fig. 2-22): mitochondria, a lot of endoplasmic reticulum with ribosomes, and a well-developed Golgi complex surrounded by a set of small lysosomal granules among which so-called multivesicular bodies—membrane-bounded organelles containing a group of small vesicles—stand out (Fig. 2-23). In addition, one finds the characteristic lamellar bodies, larger membrane-bounded secretory organelles that contain densely packed phospholipid lamellae. There are notable species differences in the ultrastructural organization of lamellar bodies. In rodents, the lamellae are mostly arranged in parallel stacks whereas in humans, concentrically arranged lamellae are mostly found which are attached to a projection core consisting of randomly arranged short stacks of densely packed membrane segments (Fig. 2-24). The periodicity of the lamellae is in the range of 4 to 6 nm. One human type II cell contains between 200 and 500 lamellar bodies, making up a total volume of about 2 cm^3 in the entire lung. With a diameter of approximately 1 µm, lamellar bodies are among the largest secretory organelles of all cells in the body. Owing to their equipment with lysosomal enzymes (e.g., acid phosphatase, cathepsins) and proteins (e.g., members of the LAMP protein family) and their acidic pH of about 5.5, lamellar bodies are regarded as secretory lysosome-related organelles.

Type II cells have two main functions: they serve as the cellular source of pulmonary surfactant and they contribute to the regeneration of the alveolar epithelium under physiological and pathological conditions. These properties form the basis of the concept of the type II cell as the "defender of the alveolus."

Surfactant prevents alveolar atelectasis by a surface area-dependent reduction of the alveolar surface tension (see below). Another function of surfactant as a result of the reduction of alveolar surface tension is to prevent the formation of intra-alveolar edema. In addition, certain surfactant components have important immunomodulatory functions in the innate host defense system. Taken together, the main functions of surfactant might be summarized as to keep alveoli open, dry, and clean. Surfactant is composed of around 90 percent lipids, mainly saturated phosphatidylcholine, and around 10 percent proteins, including the surfactant apoproteins termed SP-A, SP-B, SP-C, and SP-D. Besides its biochemical complexity, surfactant is also morphologically very heterogeneous, consisting of different surfactant subtypes with highly organized structure that represent different stages in metabolism (Figs. 2-24, 2-25, and 2-26).

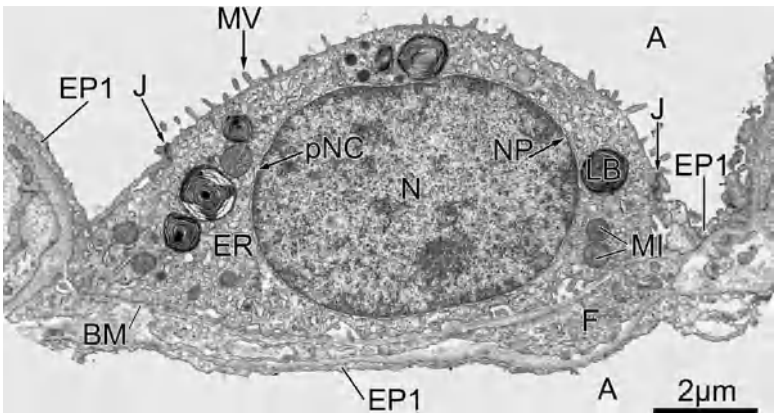

Figure 2-22 A type II epithelial cell from the human lung forms junction (J) with type I epithelial cells (EP1). Its cytoplasm contains osmiophilic lamellar bodies (LB) and a rich complement of organelles: mitochondria (MI), endoplasmic reticulum (ER), and so on. The nucleus (N) is surrounded by a perinuclear cisterna (pNC) which is perforated by nuclear pores (NP). A = alveolus; BM = basement membrane; F = fibroblast; MV = microvilli.

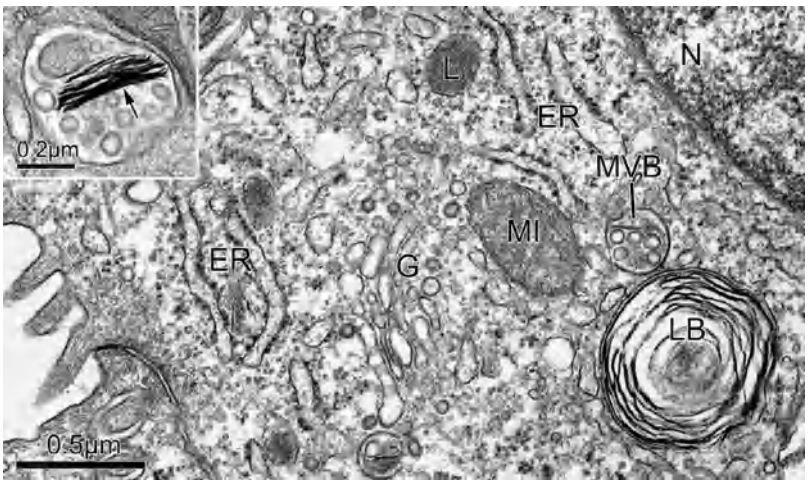

Figure 2-23 Cytoplasmic organelles of the type II cell implicated in the synthesis of surfactant are the endoplasmic reticulum (ER), Golgi complex (G), lysosomes (L), multivesicular bodies (MVB), and finally lamellar bodies (LB). The inset shows a large composite body with a stack of phospholipid lamellae (*arrow*). N, nucelus. *(From Weibel ER: The Pathway for Oxygen. Cambridge, MA, Harvard University Press, 1984.)*

The alveolar epithelium (including interalveolar pores of Kohn) is lined by a thin but apparently continuous fluid layer inserted between the apical cell membrane and the surface film, thus forming a duplex lining layer. Surfactant functions in and on this layer. It is synthesized, stored, secreted, and to a large extent recycled by type II cells. Therefore, an intracellular surfactant pool present in type II cells and an intra-alveolar surfactant pool present at the surface of the fluid alveolar lining layer as well as within its hypophase can be distinguished. The intracellular storage form of surfactant is represented by lamellar bodies. Prior to storage, the synthesis of surfactant material involves endoplasmic reticulum

B

Figure 2-24 Immunogold labeling for SP-A (5-nm gold particles) and SP-B (15-nm gold particles) in the human lung. *A*. Within type II cells, SP-B is localized in the projection core (PC) of lamellar bodies (LB). *B*. In the alveolar lumen, SP-A is associated with tubular myelin figures (TM) whereas SP-B is found in the projection core (PC) of freshly secreted lamellar bodies (LB) and dense core particles (arrow) close to tubular myelin. UV = unilamellar vesicle.

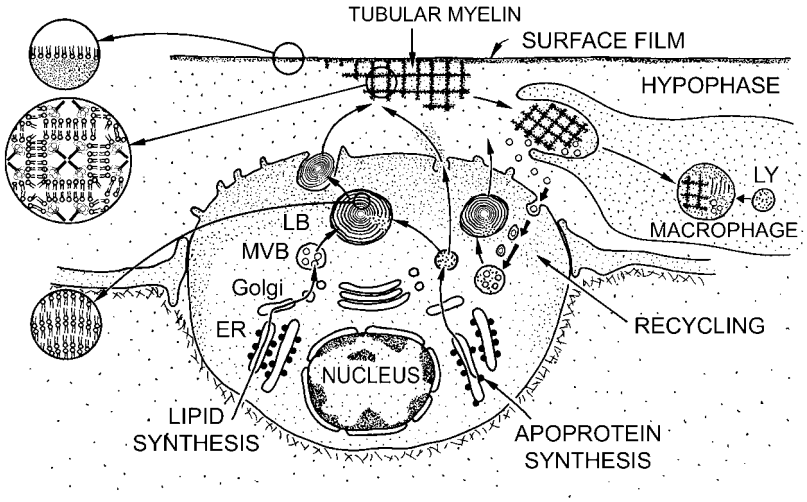

Figure 2-25 Schematic diagram of pathways for synthesis and secretion of surfactant lipids and apoproteins by a type II cell, for their recycling by type II cells, and for their removal by macrophages. Note the arrangement of phospholipids and apoproteins in the lamellar bodies, in tubular myelin, and in the surface film. *(Modified from Weibel ER: The Pathway for Oxygen. Cambridge, MA, Harvard University Press, 1984.)*

(at least partly), Golgi complex, and multivesicular bodies. In type II cells, multivesicular bodies participate in the post-translational processing of surfactant proteins as well as in endocytosis and subsequent recycling and/or degradation of surfactant material; thus, most probably representing the junction point between the biosynthetic and endocytotic pathway. In addition, transitional forms between multivesicular bodies and lamellar bodies, termed composite bodies, have been described. Surfactant material present in lamellar bodies is secreted into the alveolar lumen via exocytosis (Figs. 2-25 and 2-26).

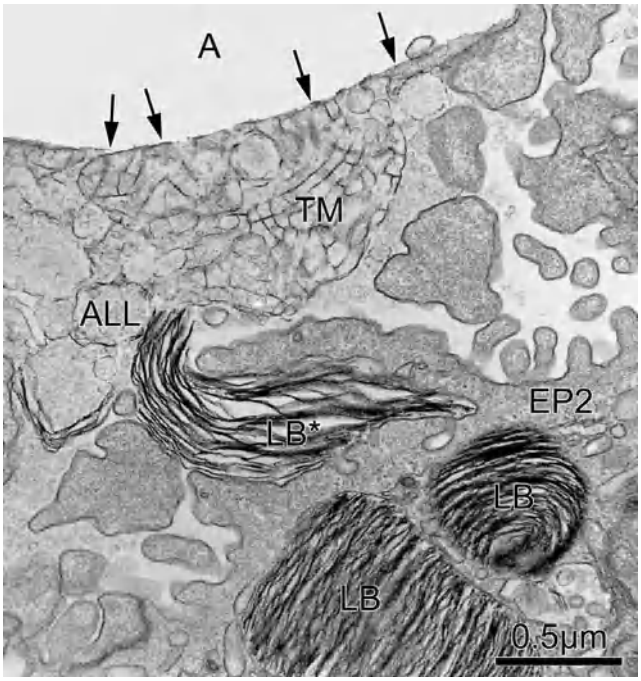

Figure 2-26 Apical part of type II cell (EP2) with lamellar bodies (LB); one of these (LB*) is seen in the process of being secreted into the alveolar surface lining layer (ALL). The free surface of the lining layer is covered by a thin black film of lipids (*arrows*), which is connected with tubular myelin (TM) in the hypophase. *(From Weibel ER, Gil J: Structure-function relationships at the alveolar level, in West JB, ed.: Bioengineering Aspects of the Lung. New York, Marcel Dekker, 1977, pp 1–81.)*

Most surfactant components are assembled in lamellar bodies prior to secretion (Figs. 2-24, 2-25, and 2-26)—at least the lipid fraction and the hydrophilic surfactant proteins SP-B and SP-C, whereas the hydrophilic surfactant proteins SP-A and SP-D seem to be secreted independently via a constitutive pathway bypassing the regulated exocytosis of lamellar bodies. Lamellar body secretion starts with the fusion of its limiting membrane with the apical plasma membrane, followed by formation of a fusion pore, and finally the slow release of surfactant material through the pore. The diameter of the pore is considerably smaller than that of the lamellar body. Thus, surfactant seems to be squeezed through the pore. The mechanisms that regulate surfactant secretion in vivo are still not fully elucidated. It seems that, among the various stimuli that can act via several different signalling pathways, mechanical stretch during ventilation—either as a direct effect on type II cells or indirectly via type I cells or capillary endothelial cells—is the physiologically most relevant.

Intraalveolar surfactant consists of several subtypes, namely freshly secreted lamellar body-like forms, tubular myelin, the surface film, and small unilamellar vesicles. After secretion, lamellar body-like forms in the hypophase associate with SP-A, which is separately secreted by type II cells, and undergo a major structural transformation into tubular myelin figures with a unique lattice-like structure. The precise physiological function of tubular myelin, however, is still unclear. Tubular myelin is thought to be the immediate precursor of the surface film, although the existence of an additional multilayered surface-associated surfactant reservoir underneath the surface film has been suggested. "Spent" surfactant components are found in the hypophase as small unilamellar vesicles. The major route of surfactant clearance is reuptake by type II cells. Within type II cells, surfactant material can either be recycled or degraded. Other routes of surfactant clearance include ingestion and lysosomal degradation by alveolar macrophages and clearance via the airways.

After differential centrifugation of intraalveolar surfactant material harvested by bronchoalveolar lavage, surface active large aggregates (LA), ultrastructurally largely corresponding to lamellar body-like forms and tubular myelin, and inactive small aggregates (SA), ultrastructurally largely corresponding to unilamellar vesicles, can be distinguished. Thus, the SA/LA ratio can be used to assess the biophysical activity of surfactant.

A surfactant film, most likely mainly transported upward from the alveoli, is also present in the airways. Here, surfactant prevents collapse of smaller airways, prevents transepithelial fluid influx, enhances mucociliary transport, and interacts with inhaled pathogens and particles. At least some of the surfactant proteins are also synthesized and secreted by Clara cells. Clara cells express SP-B, but not SP-C, which is exclusively expressed by type II cells. There is some controversy whether Clara cells express SP-A and SP-D. Although this is obviously the case in rodents, Clara cells in the normal adult human lung most likely express very low or no SP-A and SP-D. It seems that Clara cells are not involved in reuptake or recycling of surfactant components. However, the overall role of Clara cells in surfactant biology is not yet defined.

The surfactant apoproteins as the "smart molecules in the surfactant system" have important functions in surfactant subtype assembly, surfactant biophysics, surfactant homeostasis, and innate immunity. The hydrophilic proteins SP-A and SP-D belong to the collectin protein family involved in innate immunity. In addition, SP-A, together with SP-B, is important for tubular myelin formation, thus stabilizing active surfactant forms, while the hydrophobic proteins SP-B and SP-C and, in conjunction, SP-A enhance the adsorption of phospholipids into the surface film. SP-A might also inhibit surfactant secretion and stimulate surfactant reuptake by type II cells.

Differences in the ultrastructural organization of intracellular and intra-alveolar surfactant subtypes between humans and rodents are also reflected by a different distribution of surfactant proteins (Fig. 2-24). In the human lung, SP-A within type II cells is mainly found in small vesicles and multivesicular bodies and only rarely at the periphery of lamellar bodies. In the alveolar lumen, SP-A is associated with peripheral membranes of lamellar body-like forms in close proximity to tubular myelin, in the corners of the tubular myelin lattice structure, and partly at the surface film and unilamellar vesicles. SP-B in the human lung is localized in the projection core of lamellar bodies within type II cells and in dense core particles associated with tubular myelin in the alveolar lumen.

The crucial role of the surfactant system for the maintenance of the functional integrity of the lung is clearly demonstrated by surfactant dysfunction disorders, which can be caused either at birth by developmental deficiency (owing to lung immaturity or mutations affecting surfactant synthesis or secretion) or later by acquired dysfunction (owing to damage of type II cells or inhibition/inactivation of intraalveolar surfactant). A primary deficiency of surfactant in the immature lungs causes the respiratory distress syndrome of premature neonates (RDS). Surfactant dysfunction mutations causing either acute respiratory failure or chronic lung disease after birth have recently been identified in the genes encoding for SP-B, SP-C, and the ATP-binding cassette transporter ABCA3, which is present at the limiting membrane of lamellar bodies. Impairment of an originally intact surfactant system is involved in the pathogenesis of a variety of other lung diseases, such as acute lung injury/ARDS as well as obstructive, infectious, and interstitial lung diseases. Mechanisms leading to impaired surfactant activity include apoptotic or necrotic cell death of type II cells, damage of surfactant proteins and lipids by reactive oxygen and nitrogen species, and enzymatic damage by phospholipases or neutrophil elastase. In addition, plasma proteins entering the alveolar space during edema formation are also known to inactivate surfactant.

With a turnover time of about 4 to 10 hours and only a rather small intracellular surfactant reserve available for secretion onto the large alveolar surface, the ability to cope with a lack of active surfactant during lung injury is limited. Hence, there is a rationale to supplement the surfactant material available in cases of surfactant deficiency or damage. One of the major advances in neonatology in our time has been the development of surfactant replacement therapy for the treatment of RDS. The story of the treatment of premature babies with exogenous surfactant is indeed a paradigmatic example in which discoveries from basic research were successfully applied to an important clinical problem. The indications for surfactant replacement therapy have widened in recent years, with promising results in forms of respiratory failure not caused by a primary deficiency of endogenous surfactant but rather by impairment of an originally intact surfactant system. In these cases, however, the efficacy of exogenous surfactant therapy very much depends on the ability of the surfactant preparation to resist the inhibition/inactivation that caused alterations of the endogenous system.

Capillary Endothelium

The alveolar septa of the adult lung contain a single capillary network. The capillary endothelium is of the continuous (non-fenestrated) type. Alveolar capillaries are provided with pericytes, but they are rarer and less densely branched than pericytes of the systemic circulation. Pericytes are related to vascular smooth muscle cells in that they both are contractile perivascular cells. Thus, pericytes protect microvessel wall integrity by providing some mechanical support. However, in contrast to vascular smooth muscle cells, pericytes are embedded within the endothelial basement membrane, frequently forming contacts with capillary endothelial cells. They seem to contribute components to the capillary basement membrane and extracellular matrix and secrete vasoactive substances. In addition, pericytes are thought to be involved in the regulation of endothelial cell proliferation and differentiation and to act as progenitor cells for other cell types.

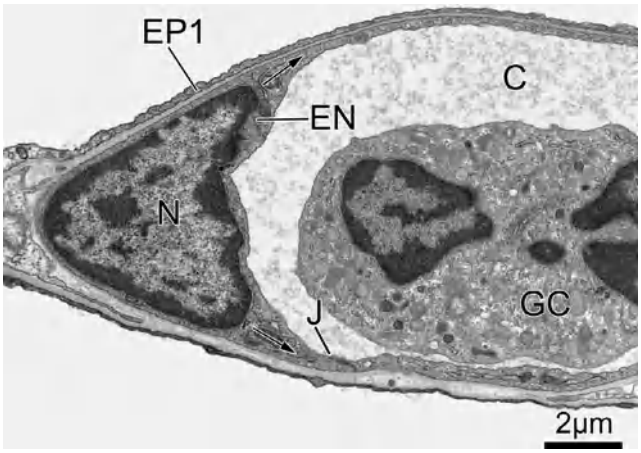

Figure 2-27 An endothelial cell (EN) of capillary (C) is similar in basic structure to a type I epithelial cell (EP1). The nucleus is enwrapped by little cytoplasm but thin leaflets extend as capillary lining *(arrows)*. Note the intercellular junction (J) and a white blood cell/granulocyte (GC), in the capillary. *(Modified from Weibel ER: The Pathway for Oxygen. Cambridge, MA, Harvard University Press, 1984.)*

Capillary Endothelial Cells

At first glance, capillary endothelial cells resemble type I alveolar epithelial cells, but in contrast to type I cells with their complex branching architecture, capillary endothelial cells form simple sheets (Fig. 2-27). Moreover, compared with the tight occluding junctions between alveolar epithelial cells that constitute a powerful seal of the intercellular cleft, the occluding junctions between capillary endothelial cells are rather leaky, allowing a nearly uninhibited exchange of water, solutes, and even some smaller macromolecules between the blood plasma and the interstitial space (Fig. 2-18). Occluding junctions between capillary endothelial cells are often located at the transition of the thin to the thick part of the air-blood barrier and are often covered by pericytes.

There is another notable and important difference between the two basically similar lining cells on the epithelial and endothelial side of the gas-exchange barrier: their size. Although the capillary surface is some 10 to 20 percent smaller than the alveolar surface, the capillary endothelial cells are about four times more numerous than type I cells; this means that the surface covered by one type I epithelial cell must be about four times larger, namely 4000 to 5000 μm^2, as compared with about 1000 μm^2 in endothelial cells (Table 2-2).

Numerous caveolae are found in capillary endothelial cells (Figs. 2-17 and 2-18). However, at the bulging part of the capillaries, some parts of the endothelial cell extensions are free of caveolae and are thinned down to a thickness of about 20 to 30 nm, basically consisting of the two plasma membranes with only a minute amount of cytoplasm in-between. These areas, rarer in human lungs than in rodents, are termed the avesicular zone of the alveolar capillary endothelium. In contrast to the endothelium of conducting vessels, Weibel-Palade bodies are missing in capillary endothelial cells, thereby underscoring the structural and functional differences between alveolar and extra-alveolar endothelial cells.

Interstitium

The interstitium of the alveolar septum is for the most part extremely thin. At the thick parts of the air-blood barrier where epithelial and endothelial basement membranes are separated, one finds elastic fibers and bundles of collagen fibrils in the extracellular matrix as well as interstitial cells, mainly fibroblasts, the cells responsible for production of extracellular matrix components (Figs. 2-28 and 2-29). The precise arrangement of the connective tissue fibers will be

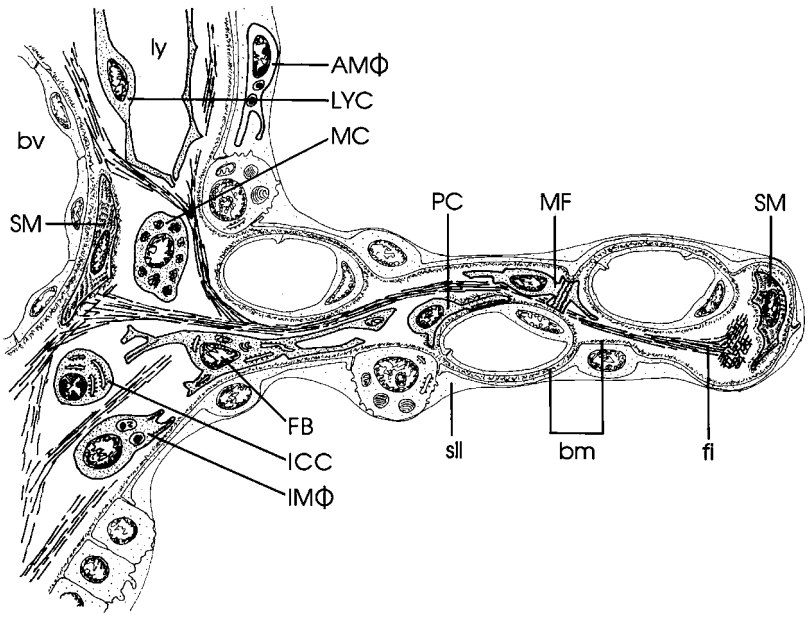

Figure 2-28 Schematic diagram of the structural organization of the alveolar interstitium. The alveolar septum extends between a free edge *(right)* and a perivascular connective tissue sleeve *(left)*, enwrapping a blood vessel (bv). Basement membranes (bm) are associated with epithelium and endothelium, and they bound the interstitial space. Fiber strands (fi) form a continuum. Interstitial cells include: fibroblasts (FB), myofibroblasts (MF), smooth muscle cells (SM), pericytes (PC), various kinds of immune competent cells (ICC), mast cells (MC), lymphatic endothelial cells (LYC), and histiocytes or interstitial macrophages (IMΦ). Alveolar macrophages (AMΦ) are submerged in the alveolar surface lining layer (sll)ly lymphatic capillary. *From Weibel ER, Crystal RG: Structural organization of the pulmonary interstitium. New York, Marcel Dekker, 1977, pp 1–81.)*

discussed below in relation to the mechanical properties of the lung.

Interstitial Cells

The resident interstitial cells of the alveolar septum comprise fibroblasts and contractile cells (myofibroblasts, lipofibroblasts, smooth muscle cells, and pericytes) (Fig. 2-28). Free interstitial cells are part of the defense system usually found in the juxta-alveolar connective tissue sleeves (see below) and include interstitial macrophages (histiocytes), mast cells, and under certain conditions, lymphocytes, plasma cells, and granulocytes.

Fibroblasts are a heterogeneous cell population. Many fibroblasts have notable contractile properties; therefore, they been termed myofibroblasts. Myofibroblasts contain bundles of microfilaments anchored in patches beneath the plasma membrane. These filament bundles span the entire width of the cell. At the places where the microfilament bundles are connected to the plasma membrane, attachments to the epithelial and/or endothelial basement membrane exist. Through holes in the basement membranes, myofibroblasts directly link alveolar epithelial and capillary endothelial cells.

Some contractile fibroblasts are equipped with non-membrane–bound lipid bodies, thus termed lipid interstitial cells or lipofibroblasts. These cells are more common in rodent than in human lungs and occur particularly during alveolar development and growth. Lipid bodies consist of an osmiophilic rim of amphipathic phospholipids, glycolipids, sterols and specific proteins, and a hydrophobic core of neutral lipids. In many cell types, lipid bodies represent specialized domains for the synthesis of eicosanoid mediators. Pulmonary lipofibroblasts seem to be related to the lipid-containing perisinusoidal cell (Ito cell) in the liver in that they might serve as a storage depot for retinoids. Under certain conditions, lipofibroblasts might provide fatty acid substrates for surfactant synthesis in type II cells.

The occurence of smooth muscle cells in the alveolar septa is mostly restricted to the free septal edges where they contribute to the network of alveolar entrance rings (Figs. 2-28 and 2-29). Pericytes abut alveolar capillaries (see above).

Structural Aspects of the Defense System of the Lung

The large and delicate alveolar surface is constantly challenged by inhaled microorganisms and particulate matter. Thus, normal lung function critically depends on an efficient defense system. At the alveolar level, the primary defense barrier is the alveolar lining layer. Here, alveolar macrophages are the sentinel phagocytic cells of the innate immune system, as we shall discuss below. In addition, protein components of the innate immune system, including the lung collectins SP-A and SP-D as well as a variety of other antimicrobial peptides (e.g., lysozyme, lactoferrin, defensins, cathelicidins), are present in the alveolar lining layer.

Another set of macrophages forms a second defense line just beneath the alveolar epithelium; i.e., in the interstitial space of the lung parenchyma. In the normal lung, these interstitial macrophages (histiocytes) are not found in alveolar septa; instead, they occur only in the connective tissue sleeves at the periphery and in the center of acini where septal fibers connect to the peripheral fiber system (Fig. 2-30). Thus, they are found in regions where lymphatics begin their course toward the major airways in the hilar region where lymph nodes are found. In these juxta-alveolar regions of connective tissue, we usually find the common elements of the defense system (Figs. 2-30 and 2-31). These include lymphatic vessels and several mobile cells. Interstitial macrophages are constantly being replenished by blood monocytes migrating

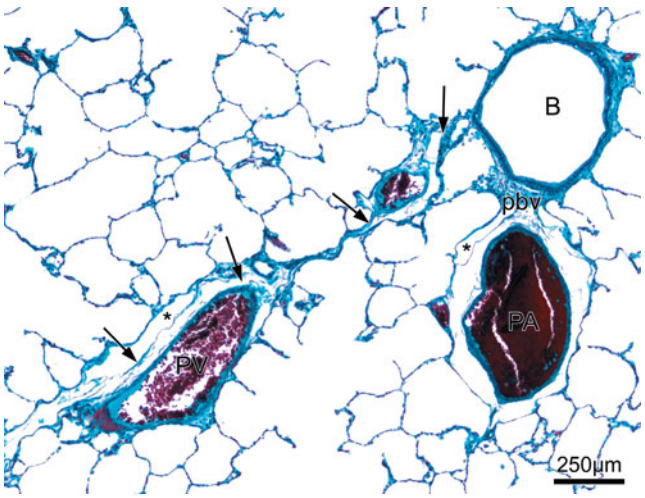

Figure 2-30 Light micrograph of human lung showing connective tissue sleeve *(arrows)* extending from the peribronchovascular space (pbv) around branch of pulmonary artery (PA) and bronchiolus (B) to pulmonary vein branch (PV). Asterisks = lymphatic.

into the interstitial space. Sometimes they become permanent residents in the form of storage cells for "indigestible" foreign matter, such as carbon particles and silicates. Lymphocytes are less common and are mostly present as T cells whereas B cells and natural killer cells are rare in the normal lung. Granulocytes (neutrophils, eosinophils, and basophils) are present in the human lung, but they are also very rare. Mast cells contain granules storing heparin and histamine that, in the human, show a characteristic scroll-like substructure (Fig. 2-32) as well as lipid bodies. Antigen-presenting dendritic cells possess long branched dendritic cell processes (hence, their name) and an irregular, folded nucleus. Phagolysosomes are absent. Once activated, dendritic cells migrate to lymph nodes where they induce the proliferation of antigen-specific T cells; thus, providing a link between innate and adaptive immunity. In addition to their presence within the lung parenchyma, dendritic cells are found within the tracheal and bronchial epithelium where they seem to form a network comparable to the Langerhans' cells in the epidermis. Like Langerhans' cells, airway dendritic cells are characterized by pentalaminar plate-like organelles (Birbeck granules). In the ciliated epithelium of bronchi and bronchioles diapedesis is seen; i.e., lymphocytes and other leukocytes in the process of penetrating the epithelium to reach the mucous blanket. Plasma cells occur in relatively high numbers around the acini of the seromucous glands of bronchi (Fig. 2-7); hence, it is likely that antibodies are being secreted into the mucous blanket by these glands by a process similar to that occurring in the salivary glands or in the glands of the nasal mucosa.

The third defense line is constituted by the lymph nodes, which are arranged along the major bronchi and extend to subsegmental bronchi about 5 mm in diameter (Fig. 2-33). The most peripheral lymph nodes are tiny, a mere 1 to 2 mm in diameter; but closer to the hilum they become larger, reaching 5 to 10 mm in diameter in the region of the tracheal bifurcation and along the trachea. The lymph nodes

Figure 2-32 Mast cell from human lung containing granules (arrows) with scroll-like substructure. *Inset*. from adult human lungs often appear gray or even black because of deposition in the medullary cords of large numbers of macrophages loaded with carbon pigment. This material entered the lung via the airways, primarily as smoke, soot, or coal dust; depending on the size of the particles, they were either deposited on the surface of conducting airways or reached the alveoli. The further down the deposition, the greater the likelihood that this material cannot be eliminated while in the airways, i.e., within the mucous blanket. The only exit from the lung parenchyma then is via the lymphatics, but this exit ultimately leads to the blood, a circumstance that is obviously to be avoided. Filtering the lymph in lymph nodes and providing a depository in the medullary cords protects the blood and hence the entire organism from dissemination of indigestible foreign matter and also, in most instances, of infective agents.

Thus, the lymphatic "circulation" in the lung plays an important defense role. It is unidirectional: It begins as interstitial fluid that seeps from the capillaries and is efficiently drained along the connective tissue fibers toward those connective tissue sleeves in the center and at the periphery of acini where lymph capillaries begin. From there, lymphatic vessels, endowed with valves and an irregular smooth-muscle wall,

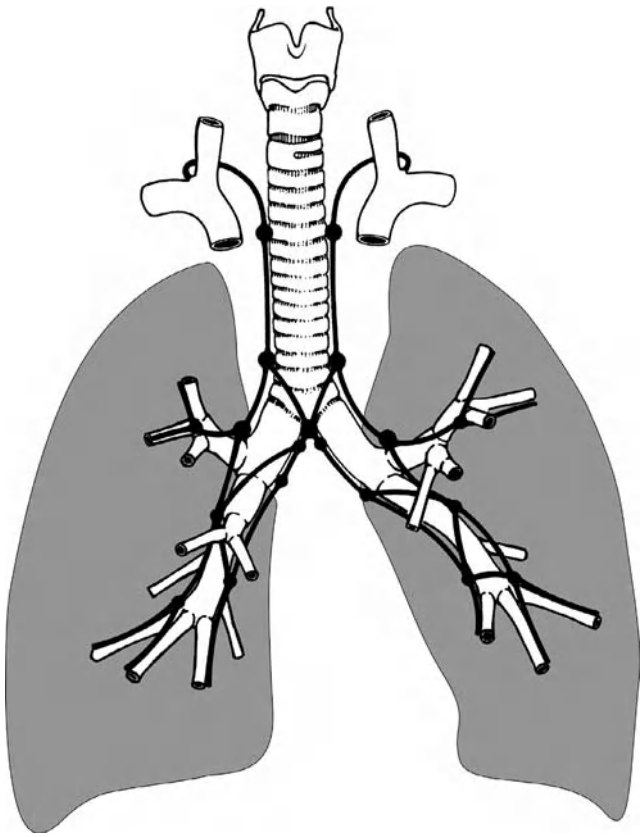

Figure 2-33 Schematic diagram of distribution of lymph nodes and main lymphatic channels along bronchial tree.

course in septal structures, in the pleura, and peribronchial and perivascular sheaths toward the hilar region (Fig. 2-33). Lymph nodes are intercalated in the course of the lymphatics, which lead the lymph toward the tracheal bifurcation and then along the trachea into the right and left mediastinal lymph channels. The right channel drains into the right subclavian vein; the left, together with the thoracic duct, into the left subclavian vein. Because of the many anastomoses connecting parallel lymphatics, a particular lymph node receives lymph from various lung regions, but the closest regions tend to predominate.

Alveolar Macrophages

Lung macrophages can be differentiated into several populations according to the compartment they are found in: intravascular, interstitial, airway, and alveolar macrophages. Of these, the alveolar macrophages, the cell population of the

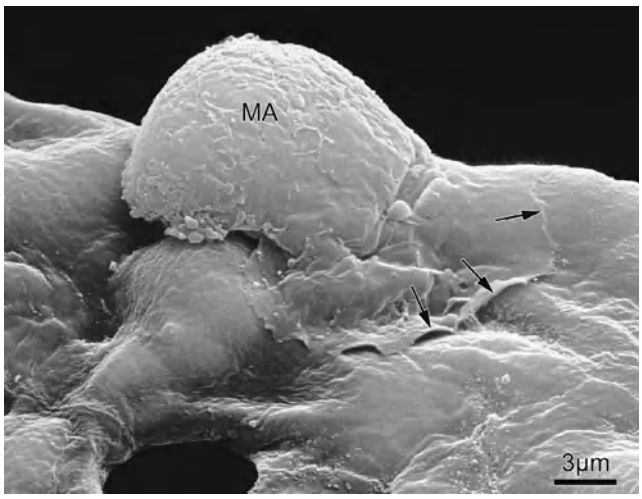

Figure 2-34 Alveolar macrophage (MA) seen sitting on epithelial surface of human lung. Note cytoplasmic lamella *(arrows)* which represents the advancing edge of the cell.

surface lining layer, are of particular importance. They are free cells, endowed with a high phagocytic capacity, which are transiently attached to the surface of the alveolar epithelium by pseudopodia and can crawl over this surface by ameboid movement (Fig. 2-34). Occasionally, alveolar macrophages can be observed during the passage through an interalveolar pore of Kohn. However, they are submerged beneath the surface film of phospholipids (Fig. 2-35) and, therefore, are part of the surface lining layer of alveoli, more specifically of its hypophase. Alveolar macrophages exert their phagocytic activity within the surface lining layer (Fig. 2-25). Hence, it is not surprising that their vacuoles contain large amounts of ingested surfactant material, in part even tubular myelin. The importance of alveolar macrophages for surfactant removal is underscored by the acquired form of pulmonary alveolar proteinosis, where a defect in surfactant catabolism by alveolar macrophages caused by autoantibodies against granulocyte/macrophage colony-stimulating factor (GM-CSF) leads to an accumulation of surfactant material in the alveoli.

Alveolar macrophages are derived from monocytes—indirectly, therefore, from bone marrow cells—and probably reach the alveoli in two steps: first, by settling in the pulmonary interstitial tissue, and second, by migration from the interstitial tissue into the alveoli where they constitute a partly self-reproducing cell population. Their removal seems to involve two different pathways: (1) some of the macrophages undoubtedly move up the bronchial tree in the mucous

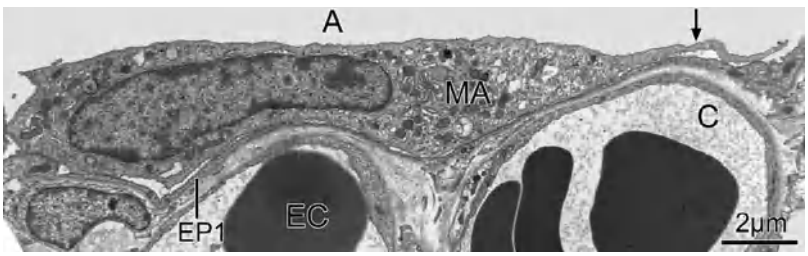

Figure 2-35 Alveolar macrophage (MA) fixed in its natural position of "flat" attachment to the alveolar epithelium. Arrow points to advancing cytoplasmic leaflet.

blanket and eventually appear in the sputum (heart failure cells, dust cells); and (2) others possibly return into the interstitial space. In the normal lung, however, the second path seems to occur exclusively in those alveoli that abut on the connective tissue sleeves around larger vessels and conducting airways or on interacinar septa; i.e., where the lymphatic capillaries are located. A preferred location appears to be in the respiratory bronchioles at the entrance into the acinus or in the center of the acinus, where one often finds congregations of dust-laden macrophages; this may be at the origin of centroacinar damages observed in smokers, which lead to progressive emphysema. In these places, macrophages either settle as carbon pigment-loaded histiocytes, or they leave the lung parenchyma via lymphatics (Fig. 2-31) to settle in the lymph nodes. The way in which macrophages and/or their ingested material are transferred from the alveolar surface to the interstitial space is still unknown.

FUNCTIONAL DESIGN OF THE LUNG

Design of the Branching Airway Tree

The entrance to the lung's airways is the trachea (Fig. 2-3), a single tube; the gas-exchange elements where air and blood are brought into close contact are contained in several million units. Between entrance and periphery lies a meticulously designed system of branching airways that serve to conduct the inspired air into those peripheral channels that carry alveoli in their walls and can thus contribute to the exchange of gases between air and blood (Fig. 2-5).

In the mammalian and human lung the airways are built as dichotomous trees. This is the result of lung morphogenesis where the end bud of each airway tube gives rise to two daughter branches. In the human lung this goes on for 23 generations, on average, and, since the number of branches doubles with each generation, there are 2^{23} or about 8 million end branches, generally called alveolar sacs. This is an average value; in reality the number of branching generations needed to reach the alveolar sacs is quite variable, ranging from about 18 to 30. This variability results from the fact that the airways form a space-filling tree (Fig. 2-3) whose endings must be homogeneously distributed in space and reach into every corner and into every gap in the available space, determined by the form of the chest cavity into which the lung develops. Some spaces are filled rapidly and the airways cannot continue to divide, whereas in other places more branches are needed to fill the space.

This branching process is accompanied by growth in length and diameter of the airway segments, the tubes between the branching nodes. The length of the tubes is adjusted to cover the distances needed to fill the space homogeneously with endings, whereas the diameter is, grossly speaking, made proportional to the volume of peripheral lung that is supplied by this branch.

Fig. 2-36 shows a portion of a cast of the airway tree from a human lung. It is evident that the airways branch

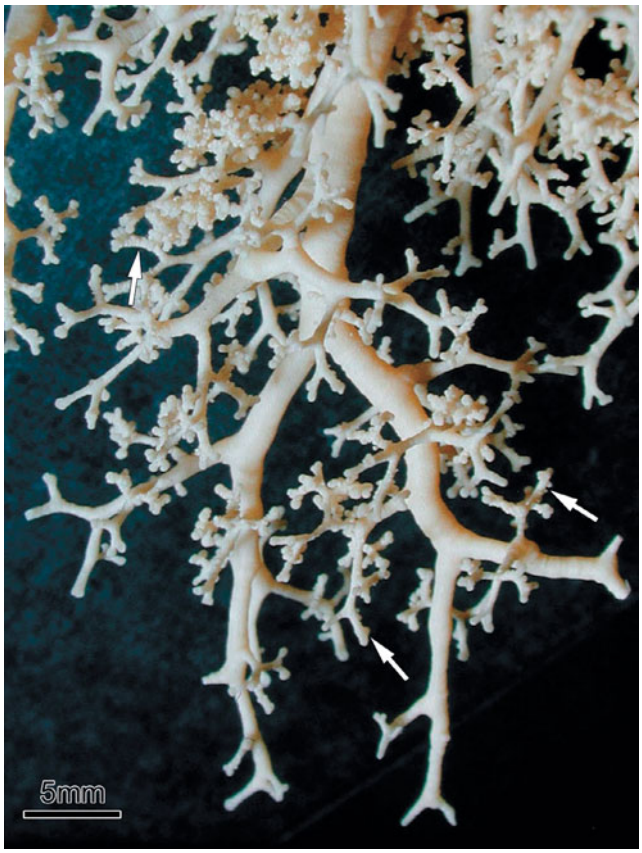

Figure 2-36 Peripheral portion of cast of human airway tree reaching out to the transitional bronchioles and some respiratory bronchioles *(arrows)*.

by dichotomy and that the length and the diameter of the tubes become gradually reduced with each generation. At first sight, the airway branching seems quite regular, but there is a certain degree of asymmetry in the sense that the two daughter branches differ in length and diameter; in animal lungs asymmetry is more pronounced than in human lungs.

Despite asymmetric branching some general rules govern the progression of dimensions along the tree. The diameter of daughter branches is smaller than that of the parent in the sense that the diameter reflects the volume of peripheral lung it supplies with air: larger airways serve larger lung units, smaller airways smaller units. The progression of airway diameters follows the law of Hess (1917) and Murray (1926) that, in a dichotomous tree, the diameters of the daughter branches, d_1 and d_2, are related to the parent branch as:

$$d_0^{\,3} = d_1^{\,3} + d_2^{\,3}$$

a law that predicts optimization of the airway diameters for convective air flow, providing lowest resistance for lowest dead space.

For a symmetric tree in which $d_1 = d_2$ this becomes:

$$d_1 = d_0 \cdot 2^{-1/3}$$

which means that the airway diameter becomes reduced by a factor of cube root of 1/2 or about 0.79 with each

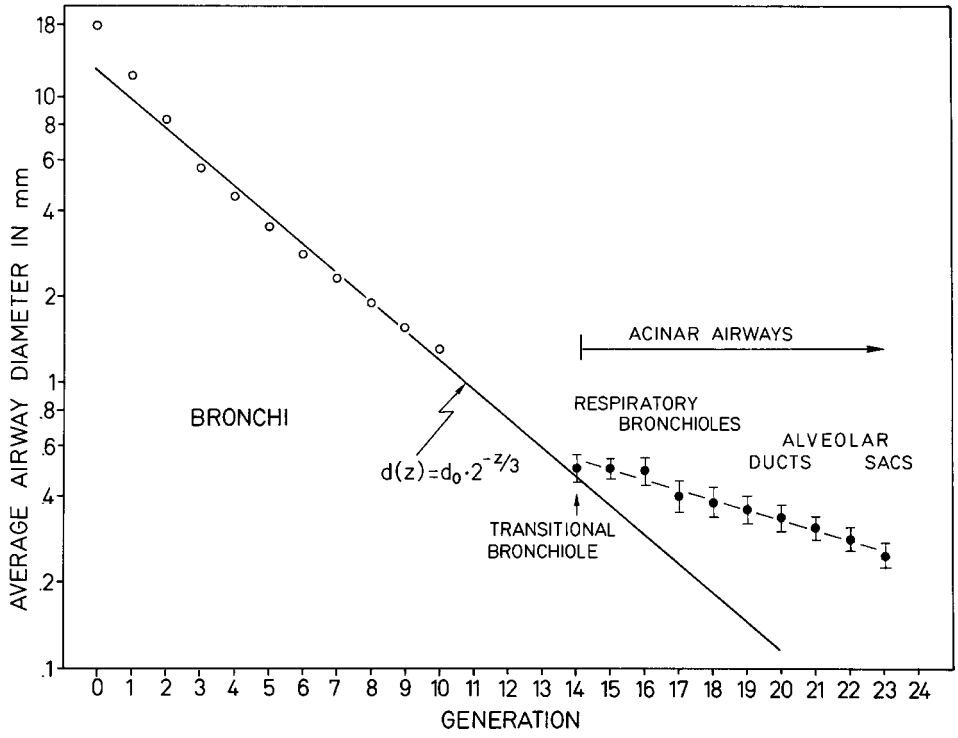

Figure 2-37 Average diameter of airways in human lung plotted by generations of regularized dichotomous branching. *(From Haefeli-Bleuer B, Weibel ER: Morphometry of the human pulmonary acinus. Anat Rec 220:401–414, 1988.)*

generation. Considering the progression of airway dimensions along the tree this law should apply to all successive generations so that we predict the average diameter in generation z to be:

$$d(z) = d_0 \cdot 2^{-z/3}$$

Fig. 2-37 shows that this is approximately the case for the first 14 generations of conducting airways.

However, a closer look at the airways of the human lung shows that this is only approximately correct. It appears that the smaller bronchioles (beyond generation 10) are provided with some safety factor in that the diameter is reduced by a factor of 0.83 rather than the physically optimal 0.79. This allows regulation of airway cross-section by contraction of the bronchiolar muscle sleeve without unduly increasing flow resistance which is very low in small airways (Fig. 2-38). Design optimalization is limited in favor of physiological robustness.

This symmetric airway model reflects the typical pathway along the airway tree. It has been very useful in modeling the basic rules governing the distribution of air flow as well as the deposition of particles entering the lung. However, it disregards the effects of asymmetric branching. It is possible to construct models that take into account irregularities in branching, for example by considering the number of airways of a given diameter, d_μ, that exist in each generation, and the length of the bronchial pathway that intervenes between the larynx and particular airways (Fig. 2-39).

An alternative approach is to regard the airways as a system of tubes converging from the periphery, the acinus,

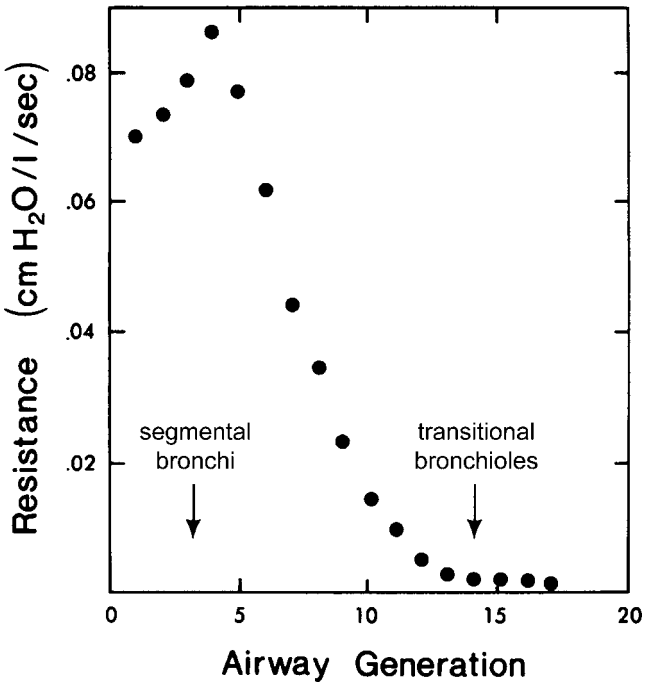

Figure 2-38 Airway resistance to mass air flow is located mostly in the conducting airways and falls rapidly toward the periphery. *(Redrawn after Pedley TJ et al. The prediction of pressure drop and variation of resistance within the human bronchial airways. Respir Physiol 9:387–405, 1970, with permission.)*

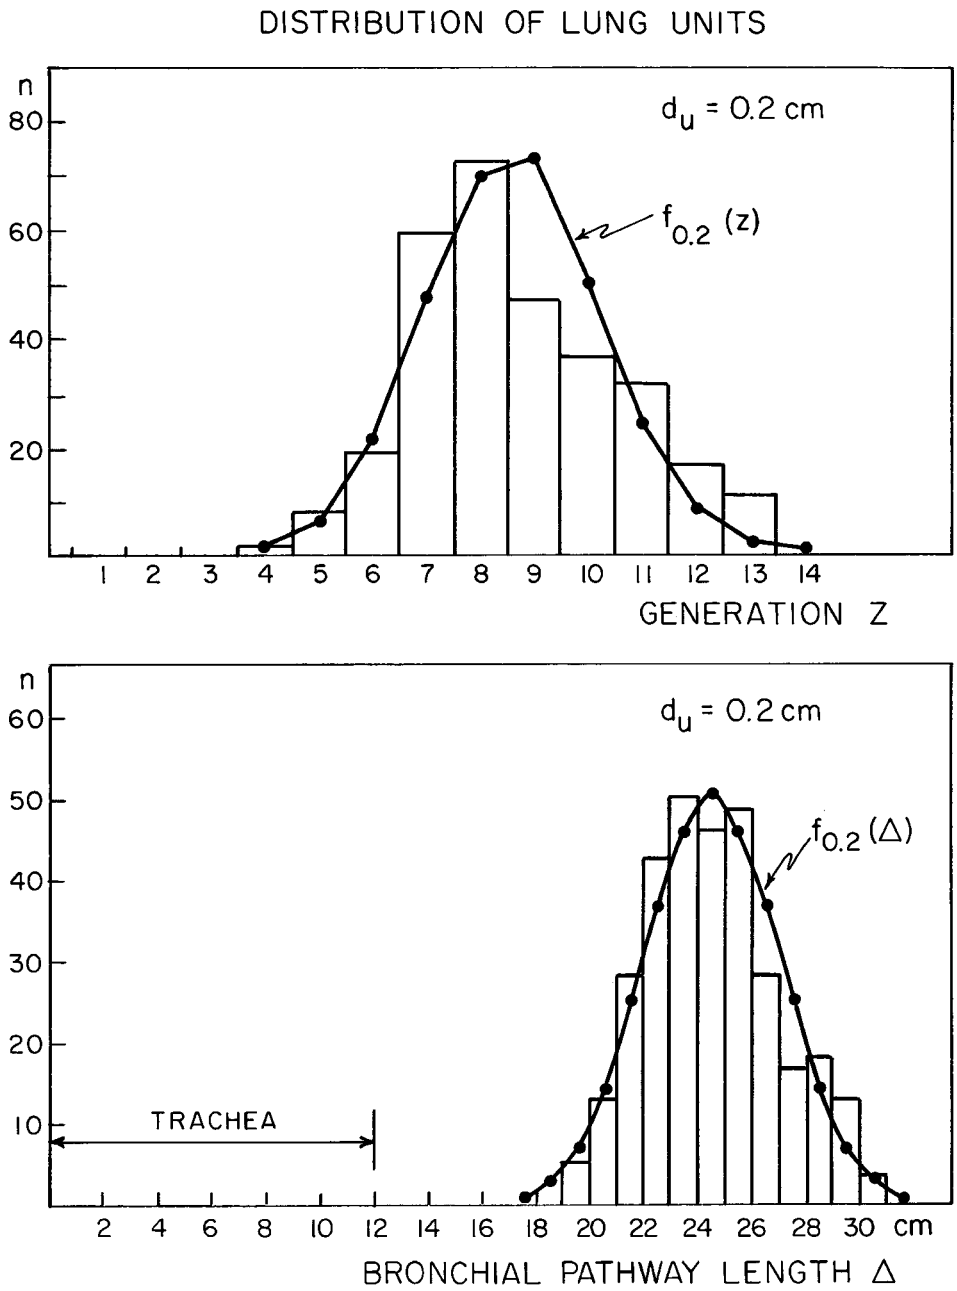

Figure 2-39 Distribution of airways of diameter $d_\mu = 2$ mm with respect to (A) generations of branching and (B) bronchial pathway lengths. *(From Weibel ER: Morphometry of the Human Lung. Heidelberg, Springer-Verlag, 1963.)*

toward the center, the trachea. By using an ascending ordering system that is employed in analyzing rivers (Strahler system), branches are grouped into orders according to the sequence of convergence, beginning with the smallest most peripheral branches, designated as order l. This ordering pattern is particularly well adapted to a system of irregular dichotomy because the size of branches in one order varies less than with the generations-down model. This approach does not really account for the asymmetry of branching, however; it rather represents an attempt at extracting average data with less variability in each order. The degree of asymmetric branching is reflected in the branching ratio determined as the ratio of the number of branches in order μ to that in order $\mu + 1$. Remarkably, the progression of diameters through the various orders is again roughly proportional to the cube root of the branching ratio. Hence, from a functional point of view both models yield comparable results.

The general conclusion drawn from this type of analysis is that the diameters of the conducting airways are such as to assure optimal conditions for airflow but relaxing physical optimality conditions in the interest of physiological robustness; the airways of the lung are thus well designed. The total volume of the conducting airways down to generation 14 (the anatomic dead space) is about 150 mL; it is rapidly flushed by simple gas flow in the course of inhaling 500 mL of fresh air during quiet inspiration. Therefore, for the larger airways,

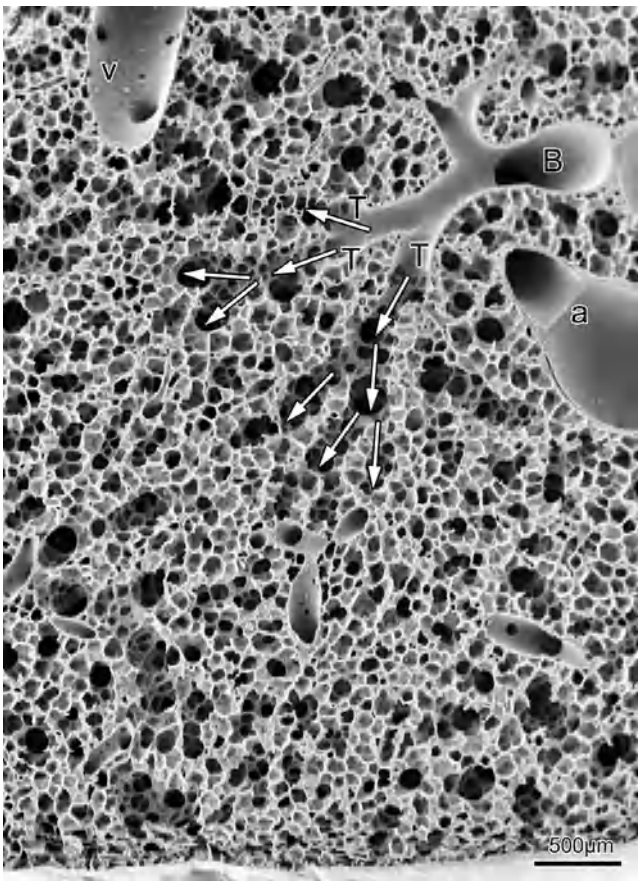

Figure 2-40 Scanning electron micrograph of lung shows branching of small peripheral bronchiole (B) into transitional bronchioles (T), from where the airways continue into respiratory bronchioles and alveolar ducts (arrows). Note the location of the pulmonary artery (a) and vein (v) as well as visceral pleura (bottom).

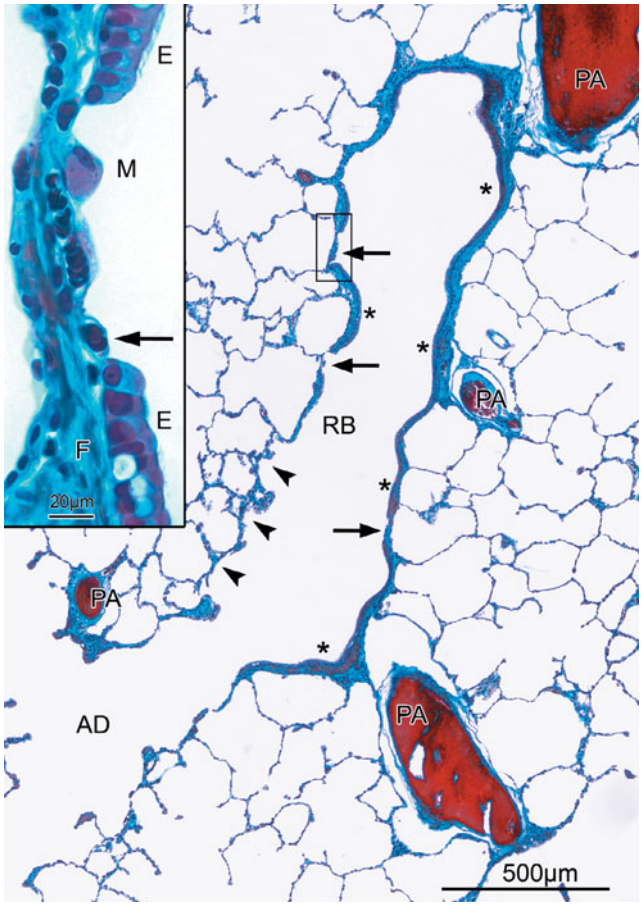

Figure 2-41 Respiratory bronchiole (RB) from human lung cut along its axis toward the transition to alveolar ducts (AD). optimization for flow and its distribution to peripheral units are essential for good design.

These are the characteristics of the proximal airways built as smooth-walled tubes to distribute convective air flow into the lung. This design ends more or less abruptly when the airways reach lung parenchyma, the complex of alveoli that are arranged around peripheral airways (Fig. 2-40). The airway tree is thus subdivided into two major functional zones (Fig. 2-5): the first about 14 to 16 generations, on average, are designed as conducting airways where air flow is by convection; this is followed by about eight generations of acinar airways where an axial channel, called alveolar duct, is enwrapped by a sleeve of alveoli with gas exchange tissue on their surface.

In the human lung the transition is not abrupt. At some point the smooth bronchiolar wall becomes interrupted by one or two alveoli (Fig. 2-41). This so-called transitional bronchiole (Fig. 2-5) marks the entrance into an acinus. It is followed by some three generations of respiratory bronchioles where an increasing fraction of the wall surface is occupied by alveoli, until the alveolar ducts are reached where the central air duct is completely surrounded by alveoli (Fig. 2-42).

These acinar airways continue to branch by dichotomy. Their length and diameter decrease with each generation, but the slope does not follow the law of reduction by the cube root of 1/2; the diameters of respiratory bronchioles and alveolar ducts change very little with each generation. Does this arrangement imply less than an optimal design? On the contrary, the cube-root-of-1/2 law relates to optimizing mass flow of a liquid or air. In the most peripheral airways, mass airflow is only part of the means of transporting O_2 toward the air-blood barrier: Since the airways are blind-ending tubes and since a sizable amount of residual air remains in the lung periphery after expiration, O_2 molecules must move into the residual air by diffusion (Fig. 2-43). However, diffusion of O_2 in the gas phase is best served by establishing as large an interface as possible between residual air and the fresh air that flows in from the trachea. In fact, since the airway diameter remains nearly unchanged, the total airway cross section nearly doubles with each generation beyond generation 14.

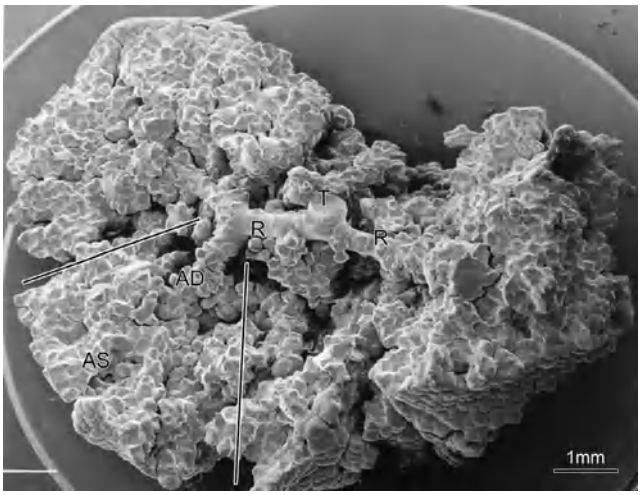

Figure 2-42 Scanning electron micrograph of a complete acinus from a silicon rubber cast of a human lung partly dissected to show transitional (T) and respiratory (R) bronchioles as well as alveolar ducts (AD) and alveolar sacs (AS). Lines mark approximate boundary of 1/8 subacinus. *(From Haefeli-Bleuer B, Weibel ER: Morphometry of the human pulmonary acinus. Anat Rec 220:401–414, 1988.)*

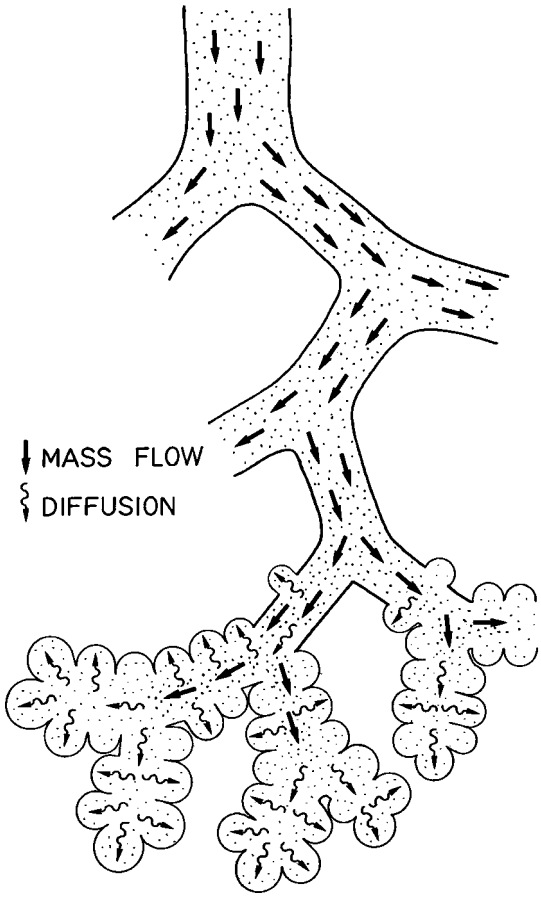

Figure 2-43 Oxygen molecules reach alveoli by combined mass airflow and molecular diffusion, the importance of diffusion increasing toward the periphery.

The dimensions of the airway tree influence the ventilatory flow of air in a number of ways. First of all, airflow velocity falls along the airway tree because the total cross-sectional area of the airways increases with every generation (Fig. 2-44); whereas the cross-sectional area of the trachea is about 2.5 cm^2, that of the 1024 airways in the 10th generation taken together is 13 cm^2, and as we approach the acinar airways, the total cross section reaches 300 cm^2. However, since the same air volume flows through all generations, the flow velocity falls by more than 100-fold from the trachea to the acini: at rest, the mean flow velocity on inspiration is about

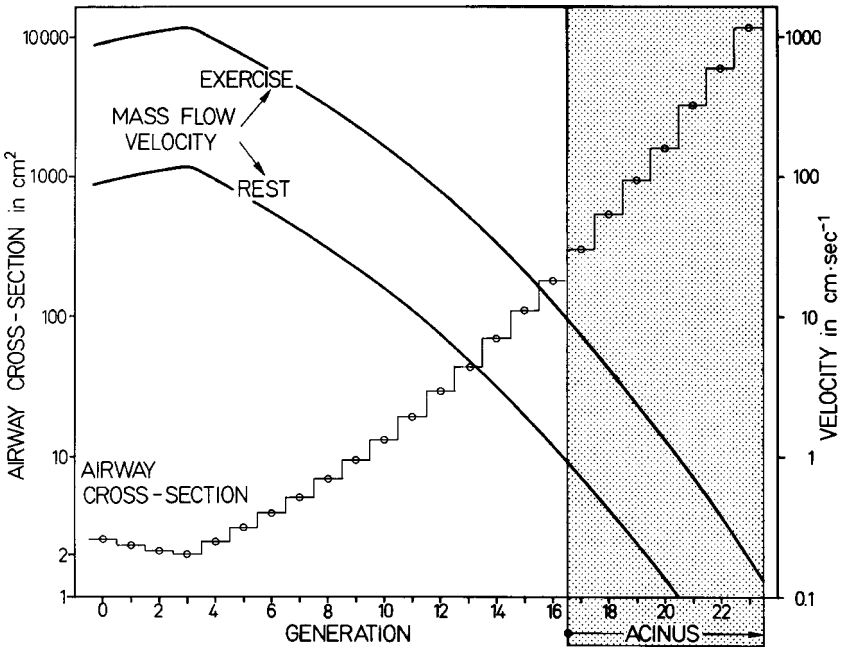

Figure 2-44 As total airway cross-section increases with the generations of airway branching, the mass flow velocity of inspired air decreases rapidly, falling below the molecular velocity of O_2 diffusion in air as we enter the acinus (see Fig. 2-66). *(From Weibel ER: The Pathway for Oxygen. Cambridge, MA, Harvard University Press, 1984.)*

1 m · s^{-1} in the trachea and less than 1 cm · s^{-1} in the first-order respiratory bronchioles. In exercise, the flow velocities are up to 10 times greater, in proportion to the increased ventilation. This is discussed further when considering the relative importance of convection and diffusion in bringing O_2 to the alveolar surface for gas exchange.

The size of airways also determines the resistance to airflow. However, the overall resistance is rather small; it is given by the reciprocal of the ratio of ventilatory airflow to the pressure difference between the mouth and alveoli, which is normally no greater than about 1 cmH_2O (mbar) or less than 1 mmHg. It is large enough, however, to potentially affect the distribution of ventilation to the many gas-exchange units. Because, in laminar flow, the resistance is inversely proportional to d^4 the distribution of air flow depends on a delicate balance of the size of parallel airway tracts. Even a slight narrowing of one of the two daughter branches at a branchpoint will cause disproportionate air flow to the other branch and thus result in ventilation inhomogeneity.

Since the diameter of airways decreases as they branch (Fig. 2-37), one would suspect that their resistance increases toward the periphery. Apparently this is not the case, as the major pressure drop along the airways occurs in medium-sized bronchi; because the airway diameter decreases with a factor larger than the optimal 0.79 resistance becomes very low in the small bronchioles (Fig. 2-38). This is further accentuated by the fact that the thin-walled bronchioles become widened as the lung expands on inspiration because they are subject to the tissue tensions in the coarse fiber system of the lung. Therefore, airway resistance is seen to fall as lung volume increases. When this effect of tissue tension is disturbed, as in emphysema, some small bronchioles may collapse. This causes ventilation of the peripheral lung units to become highly uneven.

This biophysical way of looking at the significance of the progression of airway dimensions has recently been complemented by the alternative notion that the airway and vascular trees could be determined by the laws of fractal geometry. Fractal trees are formed by repeating the branching pattern from one generation to the next: If the proportion between parent and daughter branches remain the same this is called self-similar branching. In a dichotomous tree the diameter is ideally reduced by a factor of $2^{-1/Df}$ where D_f is the fractal dimension. Since the airway tree is nearly space-filling $D_f \sim 3$, which means that the Hess-Murray law also follows from fractal geometry as a rule of optimal design, but because the reduction factor is somewhat larger than $2^{-1/3}$ it follows that the actual fractal dimension of the airway tree is a bit larger than 3; this is possible because the tree is "cut off" at the entrance to the acini and the "space" becomes filled with alveoli.

Design of the Vascular Tree

In many ways, the course and pattern of dimensional changes in the pulmonary blood vessels resemble those of the airways. Fig. 2-3 shows that the pulmonary arteries follow the airways closely, out to the smallest branches; together they form the axis of lung parenchymal units of varying order: acinus, lobule, segment, lobe. As indicated, the veins are differently disposed, lying in the boundary between two or three adjacent units (see Figs 2-30 and 2-45).

The diameter of each pulmonary artery branch also approximates closely that of the accompanying bronchus (Fig. 2-45*A*). Therefore, it is evident that the diameter law presented above for airways must also hold for the first 10 to 16 generations of pulmonary arteries (Fig. 2-37). However, the pulmonary arteries divide more frequently than the airways; very often, small branches leave the artery at right angles and supply blood to the parenchymal units adjacent to the bronchus (Fig. 2-45*B*). From a count of precapillaries, it seems that the pulmonary arteries divide, on the average, over 28 generations, as compared with 23 for the airways. The diameter of these terminal vessels is about 20 to 50 μm; if this range is plotted onto an extension of the graph of Fig. 2-37 to generation 28, it falls on the curve that is obtained by extrapolation from the major branches:

$$d(z) = d_0 \cdot 2^{-z/3}$$

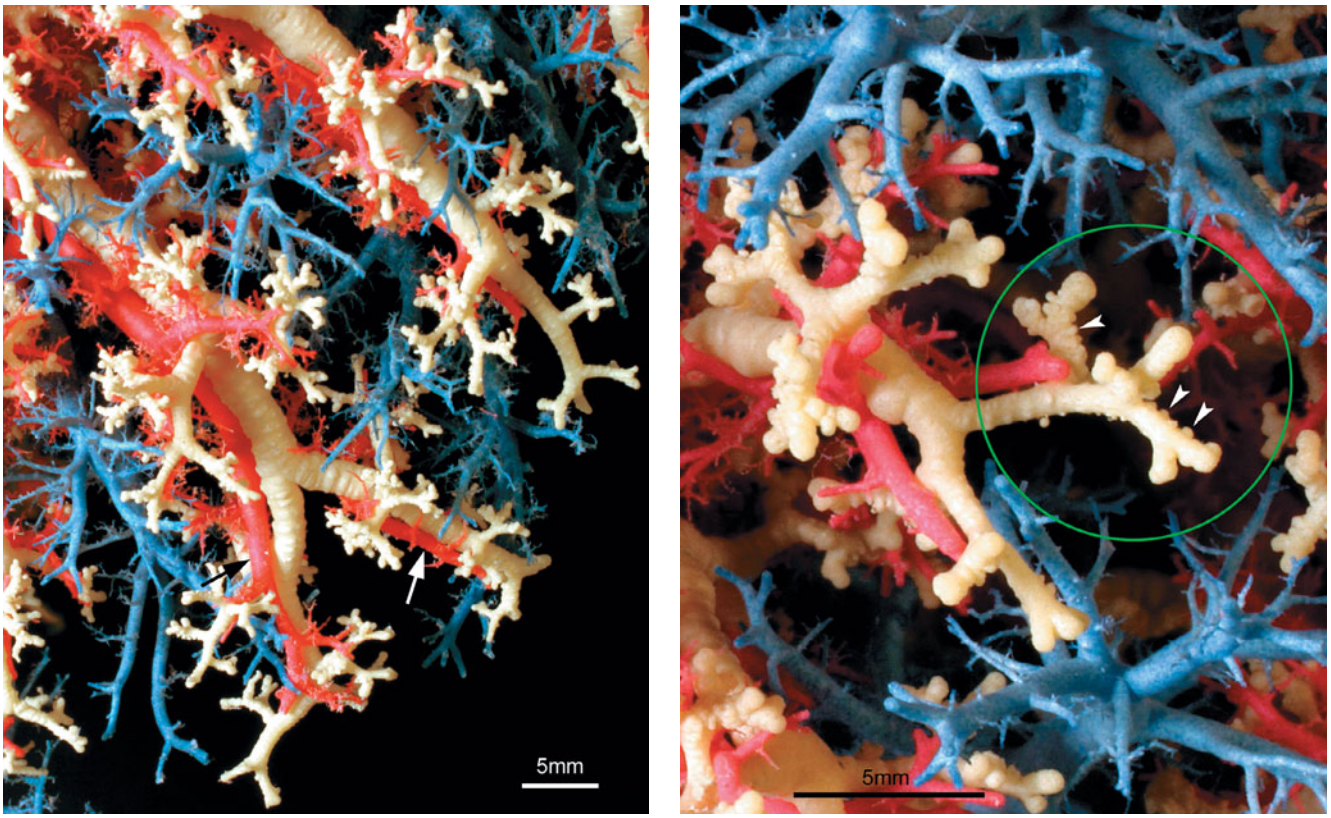
This suggests that the pulmonary arteries abide to the cube-root-of-1/2 law from beginning to end. Evidently, the blood is transported to the capillary bed by mass flow only. Therefore, there is no reason to deviate from this fundamental law of design, which minimizes the loss of energy caused by blood flow.

In a recent thorough analysis of the pulmonary vascular trees conceived as fractal structures it has been shown that the fractal dimension of both arteries and veins is 2.71, thus somewhat less than 3. The diameter reduction factor is therefore slightly smaller than cube-root-of-1/2, and the diameters follow the regression:

$$d(z) = d_0 \cdot 2^{-z/2.71}$$

Therefore, in contrast to the airways, the resistance to blood flow increases along the the pulmonary arteries and is highest in the most peripheral branches or arterioles. The resistance profile of the pulmonary arteries is thus the same as in the systemic circulation.

The alveolar capillary network of the lung is very different from that of the systemic circulation. Whereas in muscle, for example, long capillaries are found to be joined in a loose network, the capillaries of the alveolar walls form dense meshworks made of very short segments (Fig. 2-46). The meshes are so dense that some people believe blood flows through the alveolar walls like a sheet rather than through a system of interconnected tubes. In this sheet-flow concept, the sheet is bounded by two flat membranes, the air-blood barrier, connected by numerous "posts." When blood flows through this sheet, it is not channeled in a given direction but has freedom to move in a tortuous way between the posts. Although this concept oversimplifies the actual structural conditions, it does provide a useful description of the pattern of blood flow through the alveolar walls and explains why blood flow is not interrupted when some parts of the capillary bed become



A *B*

Figure 2-45 Casts of airways and blood vessels of human lung. (*A*) shows how the pulmonary artery *(red)* closely follows the airways *(yellow)* to the periphery, whereas the pulmonary vein branches *(blue)* lie between the units. Note that the diameter of the pulmonary arteries is similar to that of the accompanying airway, but becomes relatively smaller toward the periphery *(arrow);* small supernumerary arteries take off at right angles. (*B*) Higher power view of group of acini (circle), corresponding about to a secondary lobule, shows how artery penetrates into center of gas exchange unit with veins collecting the blood around the periphery. Arrowheads point to alveolar pouches on transitional and respiratory bronchioles.

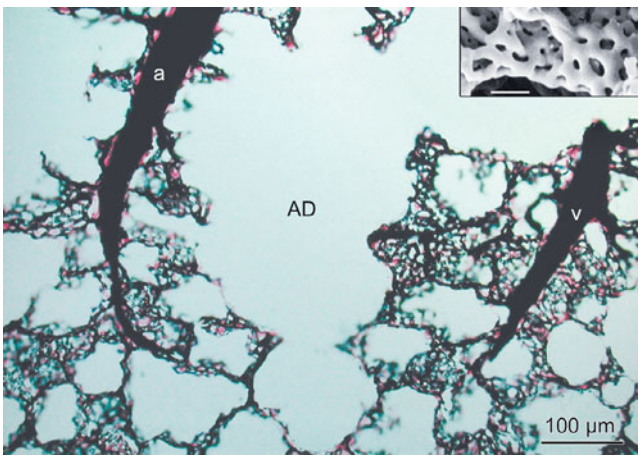


Figure 2-46 Alveolar capillary network demonstrated with gold-labeling of blood plasma in a physiologically perfused preparation of a rabbit lung. The dense capillary network spans between end branches of pulmonary artery (a) and vein (v) and extend through many alveolar septa around alveolar duct (AD). *Inset:* Plastic cast shows the dense meshes of the network. Scale bar = 20 µm. *(Inset courtesy of P. Burri.)*

squashed flat at high inflation levels (see Fig. 2-58); the capillaries that remain open in the corners are simply some channels of this broad sheet. Furthermore, it is important to note that the capillary network or sheet is continuous through many alveolar walls (Fig. 2-46), probably at least throughout the entire acinus, if not for greater distances. Consequently, it is not possible to isolate microvascular units. One finds, rather, that arterial end branches simply feed into this broad sheet at more or less even distances and that the veins drain these sheets in a similar pattern. However, now we must remember that the arteries reach the acinus along the airways, whereas the veins are in a peripheral location (Fig. 2-45). In principle, therefore, blood flows through the acinar capillary sheet from the center to the periphery of the acinar gas exchange unit.

Design of Pulmonary Parenchyma

Alveoli and Capillaries

The airspaces and blood vessels of lung parenchyma are designed to facilitate gas exchange between air and blood. To this end a very large area of contact between air and blood

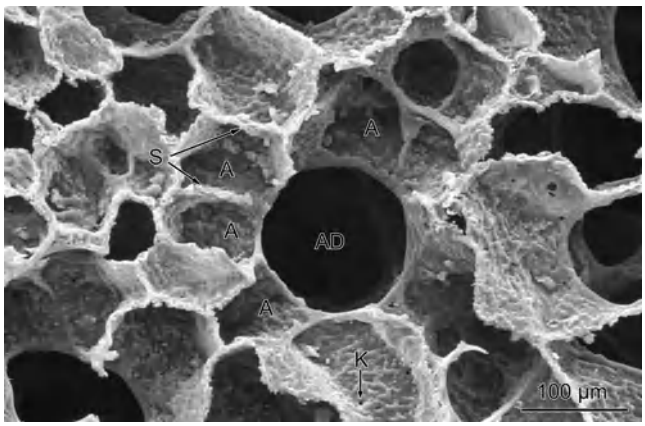

Figure 2-47 Scanning electron micrograph of human lung parenchyma. Alveolar ducts (AD) are surrounded by alveoli (A), which are separated by thin septa (S). K = interalveolar pore of Kohn.

must be established; for the human lung it is sometimes compared with the area of a tennis court in size. Furthermore, the tissue barrier separating air and blood must be kept as thin as possible—it is found to be about 50 times thinner than a sheet of airmail stationery. This is important, because less than 1 s is available for loading O_2 onto the erythrocytes as they flow through the lung's gas exchange region.

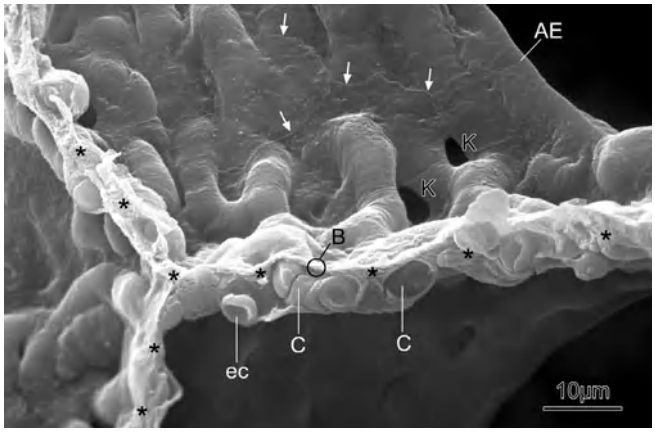
The first design feature to this end is the formation of alveoli in the walls of all airways within the acinus—i.e., in the gas-exchange units beginning with a transitional bronchiole (see above) (Fig. 2-40). In the human lung, one estimates that there are about 30,000 acini and 400 million alveoli, so that each of the gas-exchange units contains some 13,000 alveoli, on average, connected to about seven to nine generations of acinar airways, respiratory bronchioles, and alveolar ducts.

The alveoli are so densely packed that they occupy the entire surface of alveolar ducts; they are separated from each other by delicate alveolar septa that contain the capillary network (Fig. 2-47). About half the space of the septum is taken up by blood, which is thus exposed to the air in two adjacent alveoli (Fig. 2-48*A*). Although the barrier separating air and blood is extremely thin, we find the capillaries to be provided with a complete endothelial lining, as the alveolar surface of the septum is lined by an epithelium. We have seen above that these two cell linings are very much attenuated over the greatest part of the surface.

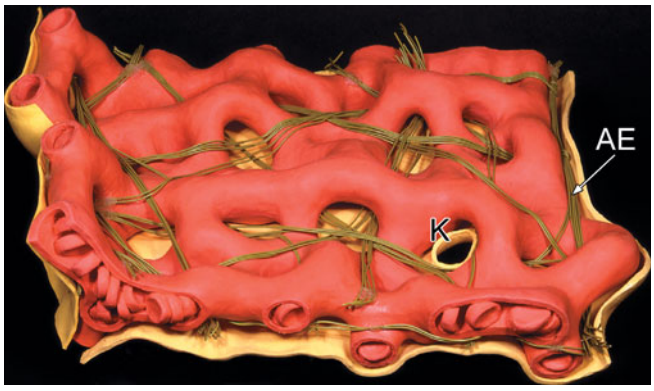
To make the barrier very thin, the interstitial structures must also be reduced to the minimum required (Fig. 2-49). The septal interstitium contains very few cells, mostly slim fibroblast with long extensions; these contain fine bundles of contractile filaments that serve an as yet unknown mechanical function. The septal interstitium usually does not contain cells of the defense system or lymphatics.

Internal Support of Parenchymal Structures: The Pulmonary Fiber Continuum

This extraordinary reduction of the tissue mass in the alveolar septa inevitably introduces a number of major problems. How is it possible to secure the mechanical integrity of the system if we consider that several forces act on the septal tissue with a tendency to disrupt it? The thin barrier must not only withstand the distending pressure of the capillary blood due both to hemodynamic forces and gravity, particularly in the lower lung zones, but must also keep the capillary bed expanded over a very large surface—a task that is made difficult because surface forces that act on the complex alveolar



A



B

Figure 2-48 In the alveolar wall, shown in (*A*) in a scanning electron micrograph from a human lung, the capillary blood (C) with its erythrocytes (ec) is separated from the air by a very thin tissue barrier (*B*). Short arrows mark intercellular junctions of alveolar epithelium that course towards interalveolar pores of Kohn (K). The model (*B*) shows the capillary network *(red)* to be interwoven with the meshwork of septal fibers *(green),* the course of which is marked by asterisks in (*A*). The epithelial lining *(yellow)* that crosses the septum at interalveolar pores (K) is removed on the upper surface of the septum to show the capillary. The septal fibers are anchored on the strong fiber bundle marking the free edge of the septum or the alveolar entrance ring (AE). *(From Weibel ER: The Pathway for Oxygen. Cambridge, MA, Harvard University Press, 1984.)*

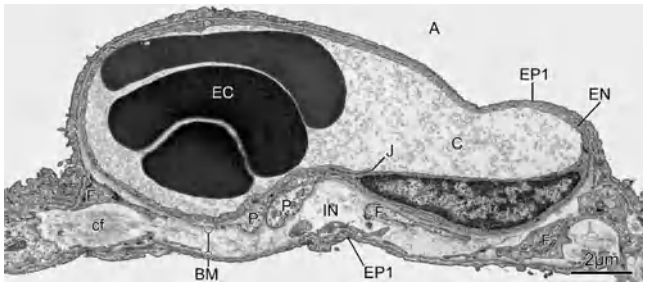


Figure 2-49 Alveolar septum from human lung lined by type I epithelium (EP1) with capillary lined by endothelial cell (EN) that is associated with processes of pericytes (P). Substantial interstitial space (IN) with collagen and elastic fibers (cf) and fibroblasts (F) occurs on one side only, whereas minimal air-blood barrier is formed on other side by fusion of basement membranes (BM) of endothelium and epithelium.

surface would tend to collapse alveoli and capillaries (see the following). This requires a very subtle, economical design of the fibrous support system.

The problem of supporting the capillaries on connective tissue fibers with as little tissue as possible has been solved ingeniously: we find that the fiber network is interlaced with the capillary network. Fig. 2-48*B* shows that when the fibers are taut, the capillaries weave from one side of the septum to the other. This arrangement has a threefold advantage: (1) it allows the capillaries to be supported unit by unit directly on the fiber strands without the need of additional "binders;" (2) it causes the capillaries to become spread out on the alveolar surface when the fibers are stretched; and (3) it optimizes the gas-exchange conditions by limiting the presence of fibers—which must interfere with O_2 flow—to half the capillary surface. The thin section of a capillary shown in Fig. 2-49 reveals that an interstitial space with fibers and fibroblasts exists on only one side of the capillary, whereas on the other the two lining cells, endothelium and epithelium, become closely joined with only a single common basement membrane interposed. Therefore, over half the surface of the capillary blood is separated from the air merely by a minimal tissue barrier made of epithelial and endothelial cytoplasmic sheets with their basement membranes fused leaving no interstitial space that could enlarge with interstitial pulmonary edema (Fig. 2-17).

The principal structural "backbone" of the lung is a continuous system of fibers anchored at the hilum and put under tension by the negative intrapleural pressure that tugs on the visceral pleura. The general construction principle follows from the formation of the mesenchymal sheath of the airway units in the developing lung; as the airway tree grows, its branches remain separated by layers of mesenchyme within which blood vessels form. When fiber networks develop within this mesenchyme, they enwrap all airway units and extend from the hilum right to the visceral pleura. The pulmonary fiber system hence forms a three-dimensional fibrous continuum that is structured by the airway system and is closely related to the blood vessels. By virtue of the design of this fibrous continuum, the lung becomes, in fact, subdivided

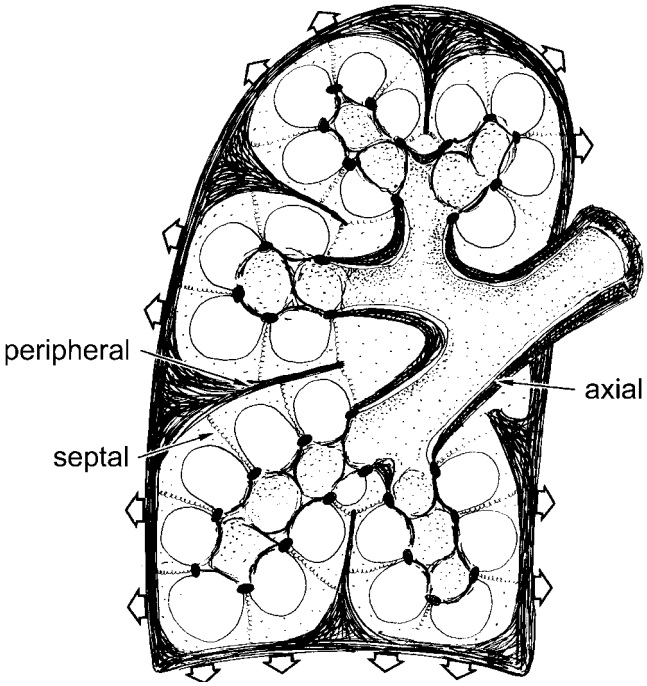

Figure 2-50 The major connective fiber tracts of the lung are divided into axial fibers along the airways and peripheral fibers connected to the pleura. They are connected by septal fibers in the alveolar walls. *(From Weibel ER, Gil J: Structure-function relationships at the alveolar level, in West JB, ed.: Bioengineering Aspects of the Lung. New York, Marcel Dekker, 1977, pp 1–81.)*

into millions of little bellows that are connected to the airway tree, as represented schematically in Fig. 2-50; these structures expand with expansion of the chest because the tension exerted on the visceral pleura by the negative intrapleural pressure becomes transmitted to the bellows' walls through that fiber system.

To try to put some order into this fiber system, we can first single out two major components that can be identified easily (Fig. 2-50). First we find that all airways—from the main-stem bronchus that enters the lung at the hilum out to the terminal bronchioles and beyond—are enwrapped by a strong sheath of fibers. These fibers constitute the axial fiber system; they form the "bark" of the tree whose roots are at the hilum and whose branches penetrate deep into lung parenchyma, following the course of the airways. A second major fiber system is related to the visceral pleura, which is made of strong fiber bags enwrapping all lobes. We then find connective tissue septa penetrating from the visceral pleura into lung parenchyma, separating units of the airway tree. We call these fibers the peripheral fiber system because they mark the boundaries between the units of respiratory lung tissue.

The peripheral fiber system subdivides the lung into a number of units that are not simple to define because they form a continuous hierarchy in accordance with the pattern of airway tree branching. However, as we have seen, two such units appear to be natural: the lobes, which are demarcated by a more or less complete lining by visceral pleura with a serosal

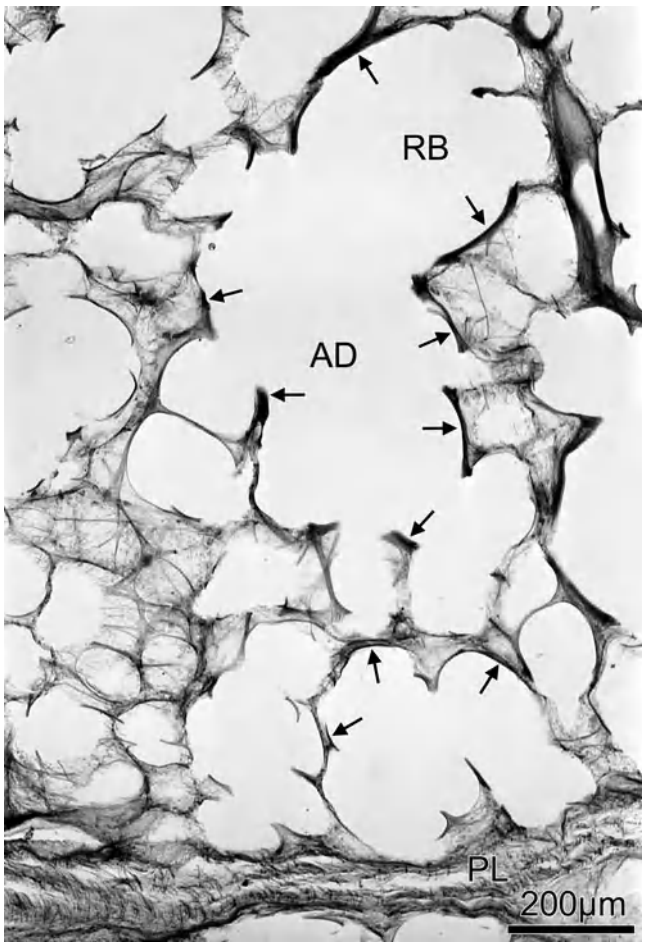

Figure 2-51 Connective tissue stain reveals the strong fiber rings (arrows) that demarcate the alveolar ducts (AD) and respiratory bronchioles (RB). *(From Weibel ER: The Pathway for Oxygen. Cambridge, MA, Harvard University Press, 1984.)*

cleft interposed (Fig. 2-1); and the acinus, the parenchymal unit in which all airways participate in gas exchange.

The acinus is the functional unit of the pulmonary parenchyma. The airway that leads into the acinus, the transitional bronchiole, continues branching within the acinus for about 6 to 10 additional generations (Figs. 2-5 and 2-40). These intra-acinar airways, called respiratory bronchioles and alveolar ducts, also carry in their wall relatively strong fibers of the axial fiber system, which extend to the end of the duct system. However, since the walls of intra-acinar air ducts are densely settled with alveoli, these fibers are reduced to a kind of delicate network whose meshes encircle the alveolar mouths, generally called alveolar entrance rings (Figs. 2-47 and 2-51). These fiber rings are associated with some smooth muscle cells (Fig. 2-29), and they serve as a scaffold for a network of finer fibers that spread within the alveolar septa (Figs. 2-48B and 2-51). However, now we must note that in a fiber system there may be no loose ends. Accordingly, the septal fiber system must be anchored at both ends—on the network of axial fibers around the alveolar ducts, and on extensions of the peripheral fibers that penetrate into the acinus from interlobular septa. Thus, the fiber system of the lung becomes a continuum that spans the entire space of the lung, from the hilus to the visceral pleura (Fig. 2-50). It is put under varying tension as the pleura is expanded by the chest wall and diaphragm.

The continuous nature of a well-ordered fiber system is an essential design feature of the lung. This becomes evident in emphysema. When some fibers are disrupted, they cannot be kept under tension. They retract and larger airspaces form as the fiber system is rearranged near the damage. Small foci of emphysema form in most lungs in the course of time.

The fiber system serves mainly as a mechanical support for the blood vessels, with which it is intimately associated in an orderly fashion. The pulmonary artery branches in parallel with the airway tree, but it is not related to the axial fiber system. Like the pulmonary veins the pulmonary arteries are associated with those parts of the peripheral fiber system that form an adventitial sheath on the larger vessels of both types and also form a boundary sheath on the surface of bronchi where alveolar complexes touch on the bronchial wall. Therefore, it is justified to characterize the connective tissue surrounding bronchi and pulmonary arteries as a peribronchovascular space, which houses the lymphatics as well as the systemic bronchial arteries and their branches. In fact, this space is continuous with the septal connective tissue that enwraps the pulmonary veins (Fig. 2-30) and is continuous with the visceral pleura. However, whereas the arteries penetrate into the acinus, the veins remain at the periphery and are thus located between the airway units (Fig. 2-45). In the alveolar septa, the capillary network spreads out as a broad sheet of vessels whose paths are continuous throughout the system of interconnected alveolar septa (Fig. 2-46). We have seen that these capillaries are intimately related to the septal fiber system (Fig. 2-48*B*).

Parenchymal Mechanics and Tissue Design

As in all connective tissue, the fibers of the lung are composed of collagen and elastic fibers. The collagen fibers are bundles of fibrils bound together by proteoglycans; they are practically inextensible (less than 2 percent) and have a very high tensile strength; they rupture at loads of 50 to 70 dyn/cm^{-2}, which means that a collagen fiber of 1-mm diameter can support a weight of over 500 g. In contrast, elastic fibers have a much lower tensile strength but a high extensibility. They can be stretched to about 130 percent of their relaxed length before rupturing.

In the fiber system of lung parenchyma, collagen and elastic fibers occur in a volume ratio of about 2.5:1, whereas this ratio is 10:1 for the visceral pleura. In a relaxed state, one finds the collagen fibers to be longer than the accompanying elastic fibers, so that they appear wavy. Because of the association between "rubberlike" elastic and "twinelike" collagen fibers, the connective tissue strands behave like an elastic band. They are easy to stretch up to the point where the collagen fibers are taut, but from there on they resist stretching very strongly.

The elastic properties of the lung's fiber system can be studied by filling the airways with fluid so as to eliminate the effects of surface tension. This reveals that the lung's fiber system has a high compliance until high levels of inflation are reached, and that the retractive or recoil force generated by the fiber system amounts to no more than a few millibars at physiological inflation levels. The actual recoil force in the air-filled lung, reflected by the negative pressure in the pleural space, is appreciably higher, but this is caused by surface tension rather than the retractive force of the fibers.

Surface tension arises at any gas-liquid interface because the cohesive forces between the molecules of the liquid are much stronger than those between the liquid and gas. As a result, the liquid surface tends to become as small as possible. A curved surface, such as that of a bubble, generates a pressure that is proportional to the curvature and the surface tension coefficient γ. The general formula of Gibbs relates this pressure, P_s, to the mean curvature $\overline{K}$:

$$P_s = 2\gamma \cdot \overline{K}$$

In a sphere, the curvature is simply the reciprocal of the radius r (Laplace's law):

$$P_s = \frac{2\gamma}{r}$$

The most critical effect of surface tension is that it endangers stability of the air space, because a set of connected "bubbles," the alveoli, is inherently unstable: The small ones should contract and the large ones expand. Since the 400 million alveoli are all connected with each other through the airways, the lung is inherently unstable: Why do the alveoli not all collapse and empty into one large bubble? There are two principal reasons.

The first reason is one of tissue structure. The alveoli are not simply soap bubbles in a froth. Rather, their walls contain an intricate fiber system, as we have seen. Thus, when an alveolus tends to shrink, the fibers in the walls of adjoining alveoli are stretched, and this prevents the alveolus from collapsing altogether. It is said that alveoli are mechanically interdependent and this stabilizes them.

The second reason is related to the fact that the alveolar surface is not simply water exposed to air but is lined by surfactant (Figs. 2-25 and 2-52), which has peculiar properties in that its surface tension coefficient γ is variable. From a large volume of evidence, it is now established that surface tension falls as the alveolar surface becomes smaller, and that it rises when the surface expands. Because of this feature, which is due to the phospholipoprotein nature of alveolar surfactant (see above), alveoli do not behave like soap bubbles whose surface tension remains constant. When an alveolus begins to shrink, the surface tension of its lining layer falls and the retractive force generated at the surface is reduced or even abolished. Combined with interdependence, this property of surfactant allows the complex of alveoli to remain stable.

Which of the two factors for stabilizing lung structure is now the most important: interdependence or surfactant properties? It turns out that both are essential. If one depletes

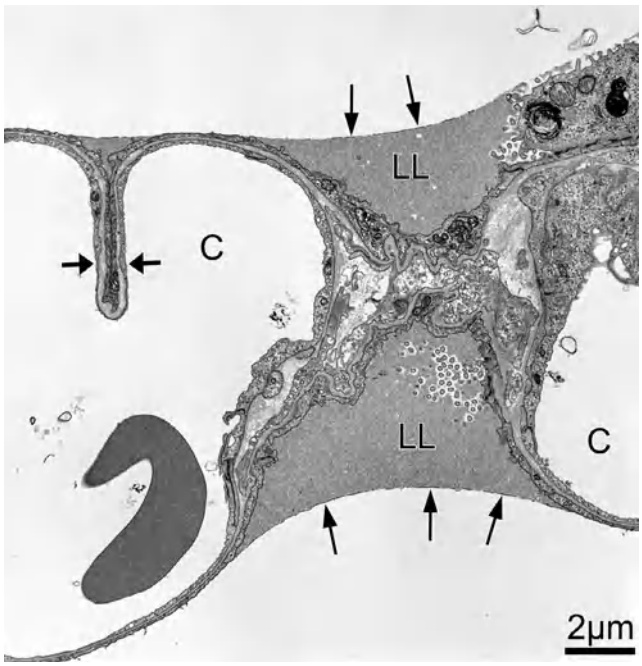

Figure 2-52 Alveolar septum of human lung fixed by perfusion through blood vessels shows alveolar lining layer (LL) in crevices between capillaries (C) topped by surfactant film that appears as a fine black line (arrows). Note the type II cell with lamellar bodies and the fold in thin tissue barrier (bold arrows). *(From Weibel ER: Looking into the lung: What can it tell us? Am J Roentgenol 133:1021–1031, 1979, with permission.)*

the lung of its surfactant lining by washing with a detergent, the pressure-volume curve changes dramatically (Fig. 2-53). On deflation, lung volume falls rapidly. If we look at samples from lungs fixed at the same volume (60 percent total lung capacity) but derived from either normal or detergent-rinsed lungs, we find that surfactant depletion causes the alveoli to collapse (Fig. 2-54). However, this causes the alveolar ducts to enlarge, stretching the strong fiber nets at the mouths of the collapsed alveoli. The ducts do not collapse because of interdependence between adjacent units.

In the normal air-filled lung, surfactant properties and interdependence owing to fiber tension both contribute to stabilizing the complex of alveoli and alveolar ducts. To understand this, let us examine Fig. 2-55, which shows a highly simplified diagram of a parenchymal unit. Interdependence is established by the continuum of axial, septal, and peripheral fibers. Surface tension exerts an inward pull in the hollow alveoli, where curvature is negative. However, over the free edge of the alveolar septa, along the outline of the duct, the surface tension must push outward because there the curvature is positive. The latter force must be rather strong, because the radius of curvature is very small on the septal edge; but this force is counteracted by the strong fiber strands, usually provided with some smooth muscle cells, that we find in the free edge of the alveolar septum (Figs. 2-29, 2-47, and 2-51). Thus, interdependence is an important factor in preventing the complex hollow of the lung, where negative and positive curvatures coexist, from collapsing. However, its capacity to

A *B*

Figure 2-54 Scanning electron micrographs of normal air-filled (*A*) and surfactant-depleted (*B*) rabbit lungs fixed at 60 percent TLC on the deflation curve (Fig. 53) show alveoli to be open (A) in (*A*), collapsed (A') in (*B*). The alveolar duct (AD) is widened in the surfactant depleted lung, resulting in a stretching of the fiber strands around the alveolar mouths *(arrows). (From Wilson TA, Bachofen H: A model for mechanical structure of the alveolar duct. J Appl Physiol 52:1064–1070, 1982.)*

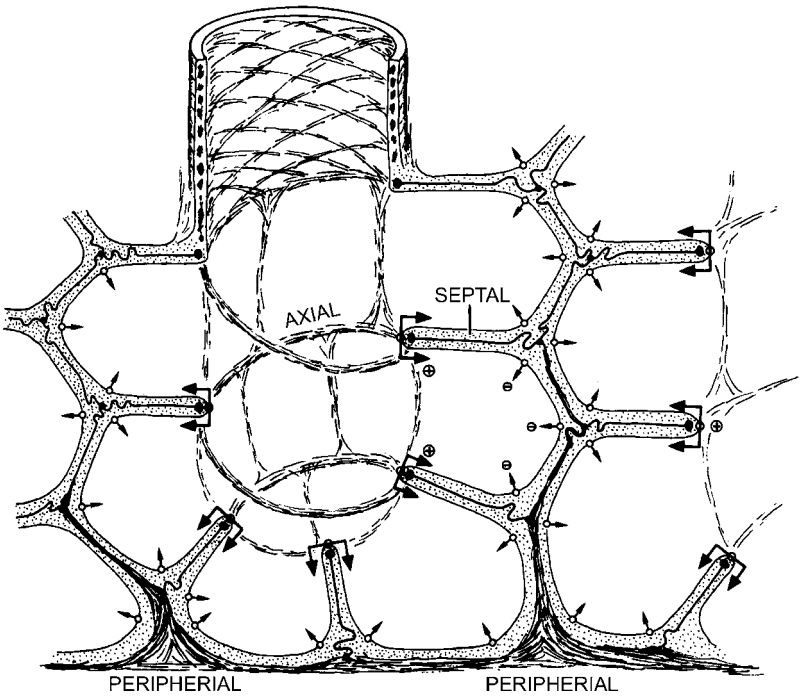

Figure 2-55 Model of the disposition of axial, septal, and peripheral fibers in an acinus showing the effect of surface forces (arrows). *(From Weibel ER: The Pathway for Oxygen. Cambridge, MA, Harvard University Press, 1984.)*

do so is limited and requires low surface tensions, particularly on deflation when the fibers tend to slack. If surface tension becomes too high, the lung's foamlike structure will partly collapse in spite of fiber interdependence (Fig. 2-54).

Micromechanics of the Alveolar Septum

We must finally consider the mechanical factors that shape the alveolar septum in the air-filled lung. As we have seen, the alveolar septum is made of a single capillary network that is interlaced with fibers (Fig. 2-48). When the fibers are stretched, the capillaries bulge alternatingly to one side or the other, and this causes pits and crevices to occur in the meshes of the capillary network.

This irregular surface is to some extent evened out by the presence of an extracellular layer of lining fluid, which is rather thin over the capillaries but forms little pools in the intercapillary pits (Fig. 2-52). This lining consists of an aqueous layer of variable thickness, called the hypophase, and surfactant, which forms a film on the surface of the hypophase. The hypophase seems to contain considerable amounts of reserve surfactant material, which occurs in a characteristic configuration called tubular myelin (Figs. 2-25 and 2-26).

In the alveolar septum, the tissue structures are extremely delicate, as we have seen. Therefore, its configuration is not exclusively determined by structural features but results from the molding effect of various forces that must be kept in balance. Fig. 2-56 shows how the three principal mechanical forces—tissue tension, surface tension, and capillary distending pressure—interact in the septum. The fibers of the alveolar septum are under a tension whose magnitude depends on the level of lung inflation. This tends to straighten out the fibers, so that a force (pressure) normal to the fiber axis results, which is responsible for shifting the capillaries to one side of the septum or the other (Figs. 2-48*B* and 2-56). The walls of the capillaries are exposed to the luminal pressure, which is the result of blood pressure in pulmonary arteries and veins but also depends on gravity, for one finds wider capillaries at the bottom of the lung than at the top. If this distending pressure acts homogeneously over the circumference of the capillary, it will push against the fibers on one side but will cause the thin barrier on the opposite side to bulge outward. This effect is to some extent counteracted by surface tension, which exerts a force normal to the surface (Fig. 2-56). This force depends on two factors: Its direction

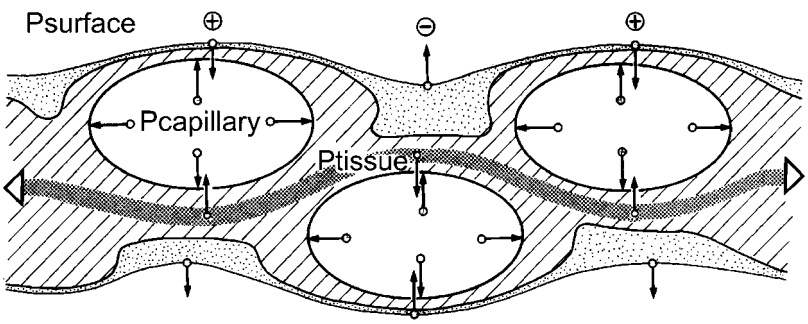

Figure 2-56 Model showing the micromechanical forces of surface tension, tissue tension, and capillary distending pressure that shape the alveolar septum. *(From Weibel ER: The Pathway for Oxygen. Cambridge, MA, Harvard University Press, 1984.)*

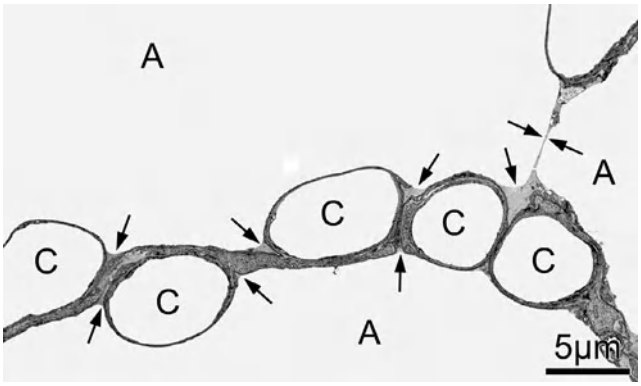

Figure 2-57 Alveolar septum of air-filled rabbit lung perfusion-fixed at 60 percent TLC shows empty capillaries (*C*), which bulge toward the alveolar air space (*A*). Note pools of surface lining layer in the crevices between capillaries *(arrows)* and film spanning across alveolar pore *(double arrows). (From Gil J et al. Alveolar volume-surface area relation in air- and saline-filled lungs fixed by vascular perfusion. J Appl Physiol 52:990-1001, 1979, with permission.)*

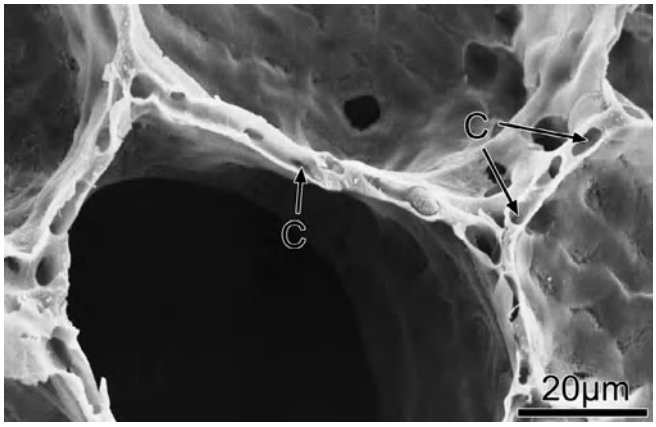
depends on the orientation of curvature, acting toward the alveolar space over concave regions (negative curvature) and toward the tissue over convexities (positive curvature); and its magnitude depends on the degree of curvature and on the value of the surface tension coefficient γ.

The alveolar septum achieves a stable configuration when all these interacting forces are in balance. Combined forces tend to squash the capillary flat; this happens at high levels of lung inflation when the fibers are under high tension and the surface tension coefficient of surfactant reaches its highest value because of expansion of the surface. On deflation, the fibers are relaxed and surface tension falls drastically. The capillary distending pressure now exceeds both the tissue and the surface forces, with the result that the slack fibers are bent, weaving through the capillary network, whereas the capillaries bulge slightly toward the airspace. Surface tension is apparently so low as to permit a considerable degree of surface "crumpling" to persist (Fig. 2-57).

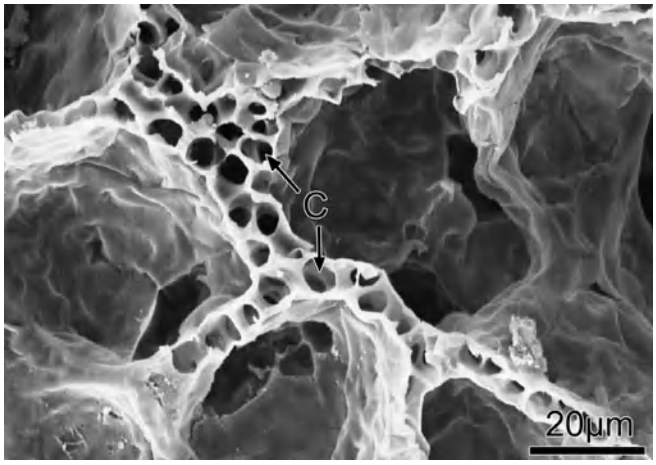
The importance of the balance between the forces that act on the septum is also shown in Fig. 2-58. The specimen of panel B was fixed under zone 3 perfusion conditions and all the capillaries are wide, partly bulging toward the airspace, as in Fig. 2-57. This is different in panel A, which was fixed under zone 2 conditions: In the flat part of the septum, the capillaries are squashed flat, because the surface and tissue forces now exceed the vascular distending pressure. However, it is interesting that the capillaries remain wide in the corners where three septa come together. The distribution of surface forces causes the internal pressure to be lower in the region of these corners, as we can see intuitively from Fig. 2-55.

The Lung as Gas Exchanger

The structures discussed so far are designed to ultimately serve the lung's main function, gas exchange between air and blood, in relation to the body's varying O_2 needs. These are set by the energetic demands of the cells and their mitochondria when these produce ATP by oxidative phosphorylation to allow the cells to do work. This process requires a flow of O_2 to be maintained from the lung to the cells, as will be discussed below. It proceeds along the respiratory system through various steps: into the lung by ventilation, to the blood by diffusion, through the circulation by blood flow, from the blood capillaries by diffusion to the cells and mitochondria, where it disappears in the process of oxidative phosphorylation. A number of basic features characterize this system: (1) under steady-state conditions the O_2 flow rate, $\dot{V}_{O_2}$, is the same at all levels, i.e., O_2 uptake in the lung is equal to O_2 consumption in the tissues; (2) the basic driving force for O_2 flow through the system is a cascade of O_2 partial pressure which falls from



A



B

Figure 2-58 Scanning electron micrographs of alveolar walls of rabbit lungs fixed under (*A*) zone 2 and (*B*) zone 3 conditions of perfusion. Note that capillaries (*C*) are wide in zone 3 and slit-like in zone 2, except for "corner capillaries," which are wide in either case. (*From Bachofen H et al: Morphometric estimates of diffusing capacity in lungs fixed under zone II and zone III conditions. Respir Physiol 52:41–52, 1983, with permission.*)

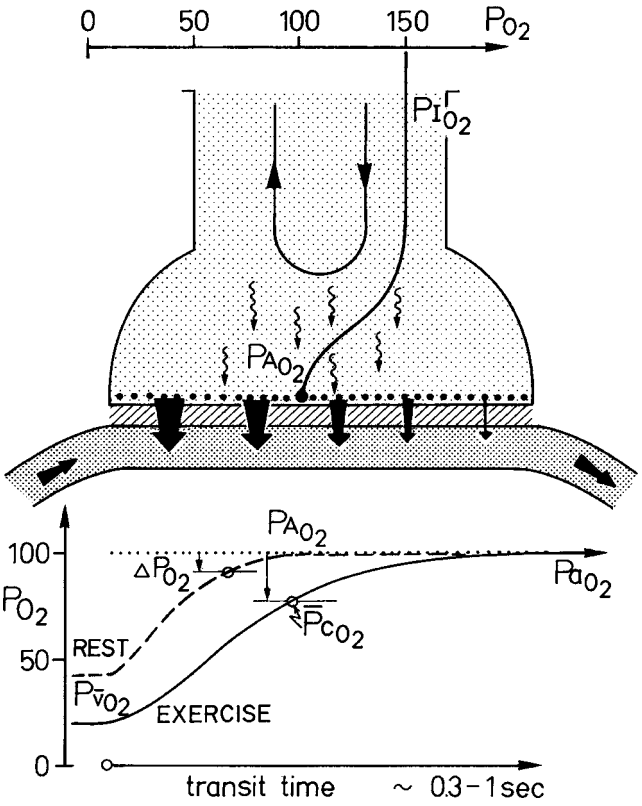


Figure 2-59 Model of gas exchange showing gradual rise of capillary PO_2 (PCO_2) as blood flows through capillary until it approaches alveolar PO_2 (PAO_2). *(From Weibel ER: The Pathway for Oxygen. Cambridge, MA, Harvard University Press, 1984.)*

inspired P_{O_2} down to near zero in the mitochondria; (3) the O_2 flow rate at each step is the product of a partial pressure difference and a conductance which is related to structural and functional properties of the organs participating in O_2 transfer. It can, for example, be shown that the O_2 flow rate into the O_2-consuming step in the cells is directly related to the amount transfer: the lung, the heart, the capillaries, and the mitochondria that perform oxidative phosphorylation.

With respect to gas exchange in the lung (Fig. 2-59), the O_2 flow rate is determined by the Bohr equation:

$$\dot{V}_{O_2} = (P_{A_{O_2}} - P\bar{c}_{O_2}) \cdot D_{L_{O_2}}$$

where

$P_{A_{O_2}} = P_{O_2}$ in alveoli,
$P\bar{c}_{O_2}$ = the mean P_{O_2} in pulmonary capillaries, and
$D_{L_{O_2}}$ = the pulmonary diffusing capacity or the lung's O_2 conductance

The important point is now that all parameters to the right of this equation may be significantly affected by design features. We will see that $D_{L_{O_2}}$ is largely determined by the surface area and the thickness of the air-blood barrier. The O_2 partial pressure difference is established by ventilation and perfusion of the gas exchange units, and this may be affected by the design of the airway and vascular trees, particularly in the acinus.

The Pulmonary Diffusing Capacity

In the above equation, $D_{L_{O_2}}$ is the total conductance of the gas exchanger for O_2 diffusion from the alveolar air into the capillary erythrocytes until it is bound to hemoglobin. It can be estimated physiologically if we can measure O_2 uptake $\dot{V}_{O_2}$ and estimate the effective P_{O_2} difference between alveolar air and capillary blood, not a trivial undertaking as the change in capillary P_{O_2} as O_2 is being taken up must be integrated (Fig. 2-59). On the other hand the conductance is a physical characteristic. Therefore, it should be possible to calculate a theoretical value of $D_{L_{O_2}}$ from the physical properties of the gas exchanger, its dimensions and material properties. In order to do that we must consider the geometry of the structures involved, alveoli, tissue barrier, and capillary blood, in setting up a physical model of $D_{L_{O_2}}$. In a first step, we can break the process into two steps (Fig. 2-60): (1) O_2 flow across the barrier or what has been called the membrane conductance $D_{M_{O_2}}$; and (2) O_2 binding to hemoglobin in the red blood cells or the conductance of capillary blood $D_{e_{O_2}}$. These two conductances are in series. Accordingly their overall effect on O_2 flow is obtained by adding their resistances or the

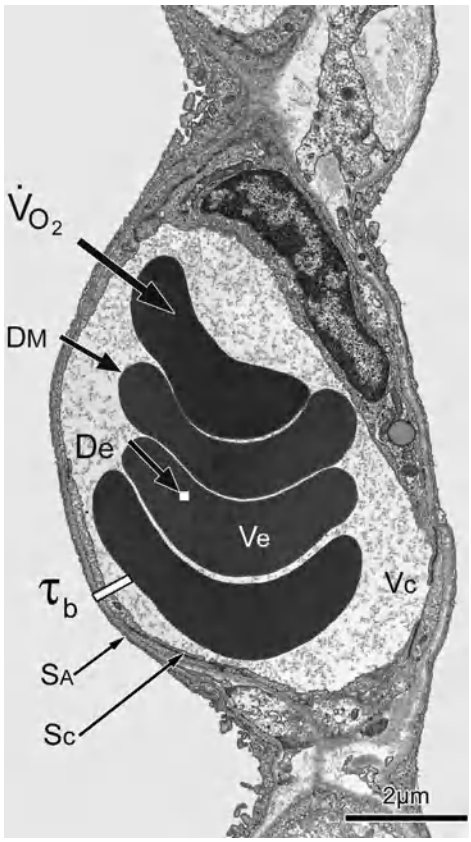

Figure 2-60 Morphometric model for calculating diffusion capacity, DL. Its two components are: (1) the membrane conductance DM, which extends from the alveolar surface (SA) to the nearest erythrocyte membrane traversing the tissue barrier, the capillary surface Sc, and the plasma layer over the distance τ_b; and (2) the conductance of the erythrocyte interior, De, that depends on the capillary and the erythrocyte volume, Vc and Ve. (See text.)

reciprocal of the conductance:

$$1/D_{L_{O_2}} = 1/D_{M_{O_2}} + 1/De_{O_2}$$

The two conductances $D_{M_{O_2}}$ and De_{O_2} are of very different nature. $D_{M_{O_2}}$ is the conductance of a diffusion barrier that offers "passive" resistance to diffusion and thus depends essentially on the material properties of the barrier, estimated by a diffusion coefficient K, and on the dimensions of the barrier: The larger the surface area S and the thinner the barrier thickness τ the greater $D_{M_{O_2}}$, according to the formula $D_{M_{O_2}} = K \cdot S/\tau$. In contrast, De_{O_2} is related to a more complex process that involves, besides diffusion, the binding of O_2 to hemoglobin, which is a non-linear process.

The Membrane Conductance ($D_{M_{O_2}}$)

The structural characteristics of the membrane conductor are seen in Fig. 2-60. It is made of the two layers that separate air in alveoli from the erythrocytes in the capillary: the tissue barrier and the layer of blood plasma. In addition, an alveolar lining layer of varying thickness spreads over the epithelial surface. Even though these layers have distinct characteristics; in effect they act as a single diffusion barrier.

As discussed earlier in this chapter, the tissue barrier is a complex structure. Its two bounding surfaces are formed by independent cell layers, epithelium and endothelium, and they are related to two independent functional spaces, alveoli and capillaries. The two surfaces are not perfectly matched, and the thickness of the barrier varies considerably (Fig. 2-60). Over about half the surface the tissue barrier shows minimal thickness compatible with an intact structure: The thin cytoplasmic leaflets of type I epithelial cells are joined to the thin extensions of endothelial cells by the fused basement membranes leaving no interstitial space. In this region we also find the surface lining layer to be very thin. Over the other half the barrier is thicker because of the occurrence of supporting connective tissue fibers (Fig. 2-49) and the presence of cell bodies of epithelial and endothelial cells as well as fibroblasts, and the lining layer can form deeper pools (Fig. 2-52).

The plasma layer shows even greater variation in its thickness and distribution. Since erythrocytes are of about the same dimension as the capillaries, the plasma layer that separates them from the endothelium can be vanishingly thin where the red cell nearly touches the wall. However, erythrocytes are corpuscular particles and there are "plugs" of plasma of varying size that separate them in the direction of blood flow. Also their distortable disc shape causes the plasma layer between erythrocyte and capillary surface to be quite variable. Furthermore, occasional leukocytes function like plasma plugs in regard to O_2 diffusion to the red cells. Therefore, the diffusion distance from the capillary wall to the red cell membrane can vary from a few nm to several μm.

Strictly speaking, these two layers of the barrier offer O_2 diffusion different resistances so their conductances should be calculated separately. However, this distinction does not appear to be important under normal conditions. Indeed, it is more reasonable to treat them as a single barrier. For one, the flow velocity of the plasma layer is much lower than the diffusion of O_2 so that plasma is quasi-static with respect to diffusion. Furthermore, under normal conditions the surface areas of alveoli, capillaries, and erythrocytes do not differ much, and the diffusion coefficients of tissue and plasma are also quite similar. Therefore, we prefer now to estimate the membrane diffusing capacity by considering O_2 diffusion from the alveolar surface to the erythrocyte membrane as:

$$D_{M_{O_2}} = K_b \cdot S(b)/\tau_{hb} = K_b \cdot (S(A) + S(c))/2 \cdot \tau_{hb}$$

where K_b is Krogh's permeation coefficient estimated at $3.3 \cdot 10^{-8} cm^2 \cdot min^{-1} \cdot mmHg^{-1}$, τ_{hb} is the harmonic mean distance from the alveolar surface to the nearest erythrocyte membrane, and S(b) is the surface area of the barrier that we estimate as the mean of the alveolar and capillary surface areas, S(A) and S(c), respectively, the two most robust measures of the area of air-blood contact. These parameters can be estimated on sections of properly sampled lung tissue by stereological methods.

We should also mention that the presence of a surface lining layer in the living lung may modify the geometry of the barrier as we see it on electron micrographs with the consequence that both the barrier thickness and the alveolar surface are reduced to a similar degree because some thicker parts of the barrier become shifted beneath the surfactant pools (Fig. 2-52). Therefore, the effect on the estimate of $D_{L_{O_2}}$ is negligible.

Erythrocyte Conductance (De_{O_2})

As mentioned, the erythrocyte conductance is of a different nature in that it involves two coupled events: diffusion of molecular oxygen and oxyhemoglobin within the red blood cell as well as the chemical reaction of O_2 with hemoglobin. A way out of this is to obtain an empirical estimate of the rate at which O_2 is bound to whole blood, θ_{O_2}, and to express the erythrocyte conductance De_{O_2} as:

$$De_{O_2} = \theta_{O_2} Vc$$

where Vc is the total capillary blood volume, which can again be estimated on sections by stereologic methods.

The coefficient θ_{O_2} is estimated in vitro on whole blood, but this is difficult because of the effect of variable unstirred layers around the red cells. In addition, θ_{O_2} depends on the hematocrit or hemoglobin concentration, and it is not a constant as it falls with increasing O_2-hemoglobin saturation; recent studies have shown that, as blood moves through alveolar capillaries, θ_{O_2} falls gradually from about 4 to 1 mL O_2 mL^{-1}, $torr^{-1}$ so that the correct value can only be found after Bohr integration of capillary P_{O_2}. For normal human lungs and a hemoglobin content of 15 g/100 ml of blood, a value $\theta_{O_2} = 1.8\,mL\,O_2 \cdot mL^{-1}$, $torr^{-1}$ is a reasonable estimate, but if the actual hemoglobin concentration [Hb] varies a corrected value can be obtained by multiplying this standard value with a factor c = [Hb]/15.

Table 2-4

Morphometric Estimate of $D_{L_{O_2}}$ for Young, Healthy Adult Humans of 70-kg Body Weight, Measuring 175 cm in Height*

Morphometric data (mean ± 1 SE)			
Total lung volume (60% TLC)	4340	±285	ml
Alveolar surface area	130	±12	m^2
Capillary surface area	115	±12	m^2
Capillary volume	194	±30	ml
Air–blood tissue barrier thickness			
Arithmetic mean	2.2	±0.2	μm
Harmonic mean	0.62	±0.04	μm
Total barrier harmonic mean thickness	1.11	±0.1	μm
Diffusing capacity (ml/min/mmHg)			
Membrane	$D_{M_{O_2}}$	350	
Total	$D_{L_{O_2}}$	158

Morphometry of the Human Lung and Diffusing Capacity

With this model in hand, we can now attempt to estimate the diffusing capacity of the human lung on the basis of morphometric data, as listed in Table 2-4. These data, obtained by electron microscopic morphometry on seven young adults, reveal the alveolar surface area to amount to 130 m^2 and the capillary surface to be about 10 percent smaller. These values are higher than those most commonly quoted in textbooks derived from light microscopic studies, which did not adequately resolve the alveolar surface texture. The harmonic mean thickness of the tissue barrier is 0.6 μm, whereas the total barrier, from alveolar to red cell surface (Fig. 2-60) measures 1.11 μm. The capillary volume is estimated at about 200 ml. With these data we calculate $D_{L_{O_2}}$ for the adult human lung to be about 150 to 200 mL $O_2 \cdot min^{-1} \cdot mmHg^{-1}$, the variation depending on the choice of θ_{O_2}.

These data also allow us to ask the question how the resistance to O_2 diffusion is distributed between the diffusion barrier and the red cells. Table 2-4 shows that the diffusion conductance of the "membrane" and that of the red cells are very similar, which means that the resistance to O_2 uptake is nearly equally divided between membrane and red cell.

These morphometric estimates of the diffusing capacity are based on model assumptions that are considered reasonable. The test of their validity must be to compare them with physiological estimates. The standard physiological value of $D_{L_{O_2}}$ of a healthy adult at rest is about 30 ml $O_2 \cdot min^{-1} \cdot mmHg^{-1}$; thus, considerably less than what we find on the basis of morphometric estimates. However, this is not a valid comparison, because, under resting conditions, we take up only one-tenth the amount of O_2 that our lungs are capable of absorbing under conditions of heavy work. There have been a number of estimates of $D_{L_{O_2}}$ in exercising humans, and these have yielded values of the order of 100 ml $O_2 \cdot min^{-1} \cdot mmHg^{-1}$. This estimate should come closer to the "true capacity" of the lung for O_2 transfer to the blood than the value obtained at rest. The fact that this is only about 50 percent lower than the morphometric estimate is not disturbing, for we do not know whether the "true diffusing capacity" is completely exploited even in heavy exercise. Inhomogeneities in the distribution of ventilation and perfusion would, for example, limit the degree to which "true" $D_{L_{O_2}}$ can be exploited. One aspect of this type of limitation is discussed in the following when we consider the effect of the acinus design on gas exchange.

To test whether the morphometric estimate of $D_{L_{O_2}}$ is reasonable we performed, some years ago, a combined physiological and morphometric estimation of pulmonary diffusing capacity on four species of canids ranging from 4 to 30 kg in body mass.

Because it is difficult to estimate mean capillary P_{O_2} reliably, most physiological measurements of the diffusing capacity use carbon monoxide (CO) as a tracer gas; CO binds to hemoglobin so avidly that, for practical purposes, the Pb_{CO} is zero, so that it suffices to measure CO uptake and alveolar CO concentration. It is also possible to revise the morphometric model of diffusing capacity to estimate the conductance for CO instead of O_2 by appropriately changing the permeability coefficients and the rate of CO binding to erythrocytes, θ_{CO}, whereas the morphometric parameters are not changed. In a study on dogs and on other canids, the calculated morphometric value of $D_{L_{CO}}$ was found to be larger than the physiological estimate by less than a factor of 1.5, thus confirming the observation made with respect to human lungs.

Therefore, we conclude that the pulmonary gas exchanger is designed with a certain amount of redundancy or excess capacity, but this is by no means unreasonable from an engineering point of view. Indeed, to design the pulmonary gas exchanger with a certain degree of redundancy may make a lot of sense. The lung forms the interface to the environment and its functional performance will thus depend on environmental conditions, such as the prevailing O_2 partial pressure, which falls as we go from sea level to higher altitudes. It has been shown that goats, whose $D_{L_{O_2}}$ is about twice as large as seemingly required, can maintain their maximal level of exercise-induced $\dot{V}_{O_2}$ even under hypoxic conditions whereas the dogs that have very small excess $D_{L_{O_2}}$ cannot. It has also been suggested that human athletes exercising at high altitude may fully exploit their $D_{L_{O_2}}$. This suggests that the apparent redundancy in $D_{L_{O_2}}$ may be a safety factor to protect the good functioning of the pulmonary gas exchanger even when environmental conditions are not optimal. Recent studies with partial pneumonectomy in dogs have shown that the

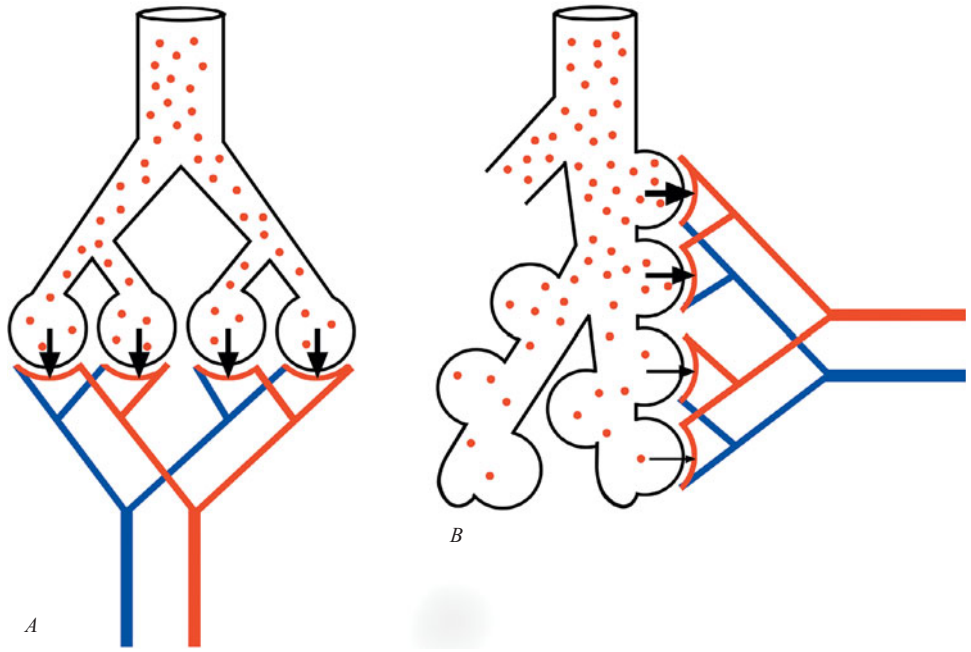

Figure 2-61 Models of ventilation-perfusion relationship in the mammalian pulmonary gas exchanger. *A*. Parallel ventilation/parallel perfusion. *B*. Serial ventilation/parallel perfusion. *(From Sapoval B, Filoche M, Weibel ER: Smaller is better, but not too small: A physical scale for the design of the mammalian pulmonary acinus. Proc Natl Acad Sci USA 99:10411–10416, 2002.)*

lung can achieve 85 percent of its maximal O_2 uptake even when 40 percent of lung tissue is removed after left pneumonectomy, making use of some of this reserve capacity; but when right pneumonectomy removes 60 percent of lung tissue, adequate function can be achieved only after compensatory growth of the residual lung tissue to restore diffusing capacity.

Design of the Acinus and Gas Exchange

The preceding section considered the overall size of the gas exchanger of the entire lung to compare it with the global performance of this organ. In reality, the surface the size of a tennis court is subdivided into some 400 million gas exchange units. These are individually perfused with blood because they correspond to the unit capillary network that spans between pulmonary arteriole and venule (Fig. 2-46). The diameter of such a disk-shaped unit is about 500 μm and has a surface area that corresponds approximately to that of an alveolus, even though alveoli and capillary unit are not congruent as the latter spans over several alveoli and each alveolus is in contact with several capillary units.

These gas exchange units are arranged along the terminal generations of the airway tree that form the pulmonary acinus (Fig. 2-61*B*). Note that this arrangement of gas exchange units to the airway system differs from the common representation of the alveolar-capillary unit as a terminal "bubble" (Fig. 2-61*A*). This has functional consequences because ventilation of alveoli occurs in two steps: (1) upon inspiration oxygen-rich air flows through the airways into the acinus carrying along O_2; (2) in the peripheral airways flow velocity slows down because the airway cross-section increases, and O_2 now moves toward the periphery by diffusion in the air phase, driven by the P_{O_2} gradient that becomes established as O_2 is absorbed at the alveolar surface (Fig. 2-62). Thus, in the peripheral airways diffusion along the airways is combined with diffusive permeation of O_2 into the alveoli and across the tissue barrier to the blood, the actual process of gas exchange. Whereas all capillary network units are individually perfused with venous blood the alveoli are not independent in terms of their O_2 supply, which depends on their location along the airway tree. Therefore, the design of the acinus has significant effects on the gas exchange conditions.

The Acinar Airway System Connected to the Gas Exchanger

In a systematic study of human lungs the mean volume of acini was found to be 187 mm^3 with a standard deviation of 79 mm^3. The branching pattern for an average size human acinus is shown in Fig. 2-63. The segment lengths have been drawn to scale and the terminal clusters of alveoli of the alveolar sacs are marked by a dot. This acinus has been subdivided into eight subacini whose substems are located in the third generation of acinar airways. The acinus shown in Fig. 2-42 in a scanning electron micrograph of a cast is comparable in size and structure. This shows that the transitional bronchiole is followed by two or three generations of respiratory bronchioles, where there are only a few alveoli. In contrast, the alveolar ducts that follow are completely and

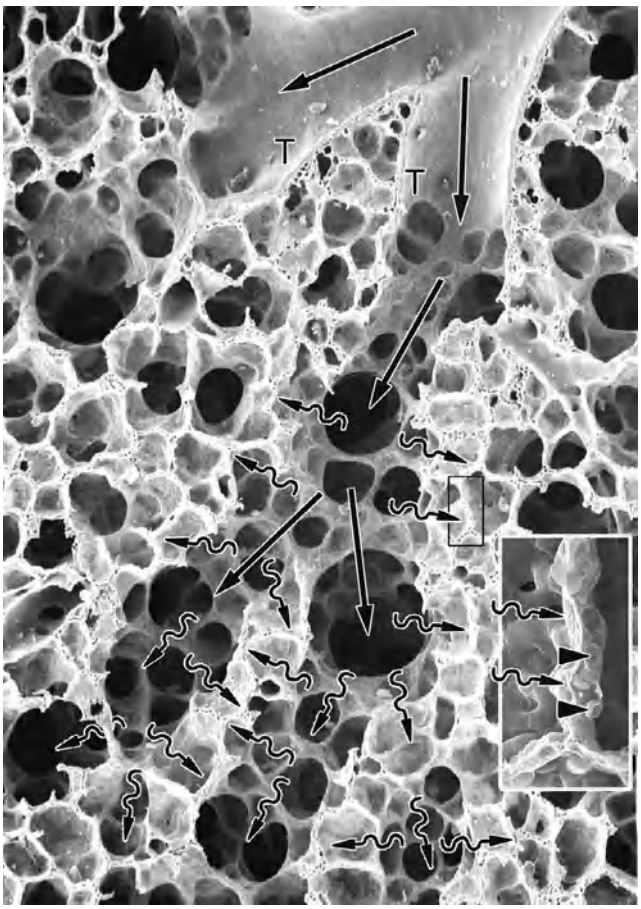

Figure 2-62 Central part of the acinar airways beginning with transitional bronchiole (T) and leading into the branched alveolar ducts. On inspiration air flows in by convection *(straight arrows),* but as flow velocity falls diffusion of O_2 *(wiggly arrows)* becomes the dominant mechanism for bringing O_2 to the gas exchange surface. All along acinar airways O_2 is absorbed by the capillary blood in the septa *(inset, arrowheads).*

densely lined with alveoli (Fig. 2-64). These are the airways of the 1/8 subacinus (Fig. 2-63), a unit that is of functional significance, as we shall see. The intra-acinar airways branch by irregular dichotomy; terminal sacs are located in generations 6 to 11 so that the intraacinar airways branch over an average of 8 generations (Fig. 2-5).

The morphometry of the intra-acinar airways of the human lung shows a number of characteristic traits. The inner diameter (d_{in}) that characterizes the cross section of the duct tube decreases from about 490 μm at the transitional bronchiole to 270 μm in the last generations. When this is plotted onto the graph relating airway diameter to generations of branching (Fig. 2-37), we note that this diameter falls less steeply than the cube-root-of-1/2 law we have observed for conducting airways. This is a significant finding in terms of the ventilation of alveoli by O_2 diffusion.

An important morphometric characteristic of acinar airways is the total path length for O_2 diffusion from the entrance at the transitional bronchiole to the terminal cluster of alveoli at the alveolar sac (Fig. 2-5). This path length is

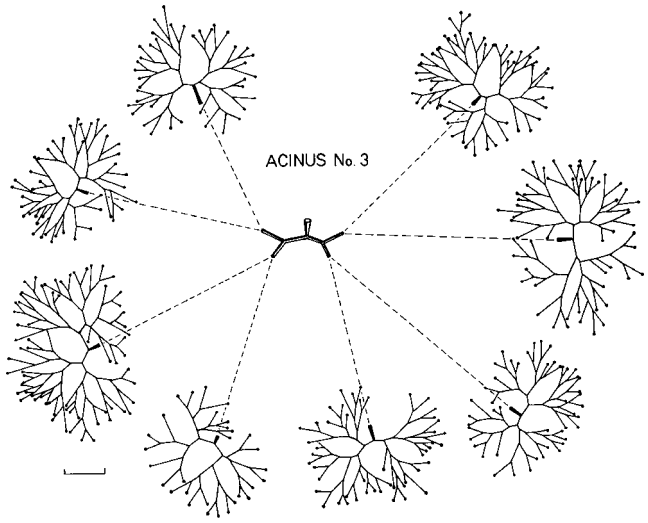

Figure 2-63 Graphic representation of branching pattern of acinar airways in one human acinus of 183 mm^3 volume with the segment lengths drawn to scale. The airways are separated at the third generation thus displaying the branching pattern within each 1/8 subacinus. *(From Haefeli-Bleuer B, Weibel ER: Morphometry of the human pulmonary acinus. Anat Rec 220:401–414, 1988.)*

determined by two factors: the number of generations and the segment length. The length of alveolar ducts gradually decreases from 1330 to 640 μm in the peripheral generations, the alveolar sacs being a little bit longer. Since the number of branching generations varies somewhat, we can expect the path length to vary even within one acinus. In the human lung, the average longitudinal path length measures 8.3 ± 1.4 mm (Fig. 2-65). Because of the decreasing length of acinar ducts 3.4 mm of this total path length are for the first three generations of respiratory bronchioles, whereas the path length of alveolar ducts and sacs comprised in the 1/8 subacinus (Fig. 2-64) averages 4.7 ± 0.88 mm.

Typical Path Model of Human Acinus

In view of assessing the effect of these structural features on the functional performance of the pulmonary gas exchanger we can attempt to develop what we may call a typical path model for an average human acinus (Fig. 2-65; Table 2-5). Such an acinus has a volume of 0.187 cm^3. Its airways branch over an average of eight generations in order to reach the terminal alveolar sacs. With each generation the number of branches doubles to end with some 256 terminal alveolar sacs in each acinus (Fig. 2-63). Locating the transitional bronchiole ($z' = 0$) in generation 14 (Fig. 2-5) the terminal air sacs are in generation 23 of the typical path airway tree. From the estimates of the lengths and inner diameters of the airway segments we can derive overall parameters of functional significance, such as the total airway cross-section per generation, $A_d(z')$, which is a determinant of air flow velocity (Fig. 2-66). Finally, we can also estimate the distribution of alveolar surface area to the different generations in proportion to the duct surface $S_d(z')$, but adjusting for the fact that only

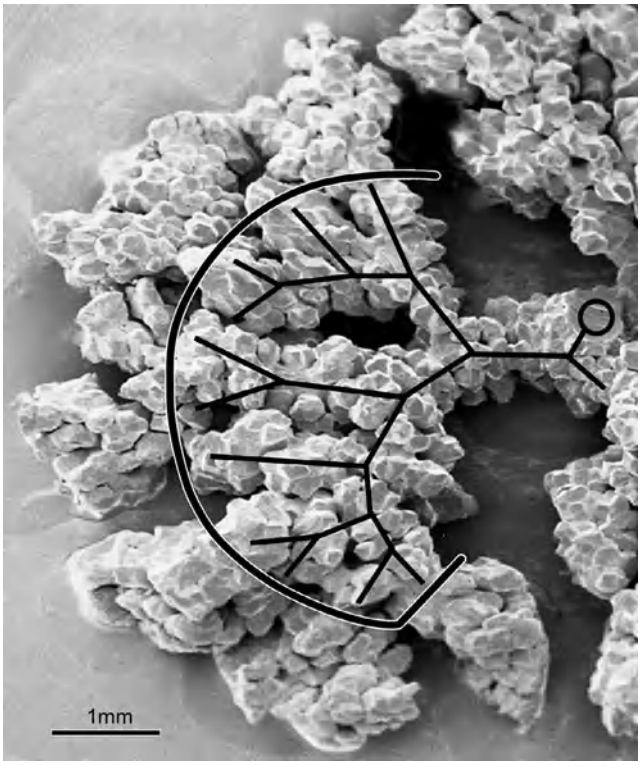

Figure 2-64 Airways of 1/8 subacinus of human lung beginning with generation 18 alveolar duct *(circle)*. The silicon rubber cast has been spread out to show the course of the subsequent branchings. The curved line marks the approximate boundary to the last generation to show that this generation of alveolar sacs (see Fig. 2-5) comprises over half the gas exchange area of the acinus.

part of this surface is associated with alveoli in the respiratory bronchioles (generations $z' = 1–3$). For an estimated alveolar surface of 130 m^2 in the human lung (Table 2-4), there would be about 54 cm^2 of gas exchange surface per average acinus. It is seen that half this gas exchange surface is in the

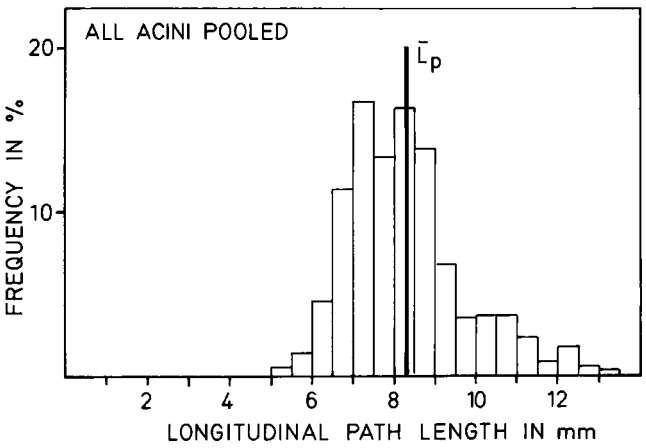

Figure 2-65 Frequency distribution of longitudinal path length from the transitional bronchiole to the alveolar sacs in the human lung. *(From Haefeli-Bleuer B, Weibel ER: Morphometry of the human pulmonary acinus. Anat Rec 220:401–414, 1988.)*

last generation (see also Fig. 2-64). A final check of this model is that the path length from the entrance into the transitional bronchiole to the end of the alveolar sacs is 8.4 mm, which agrees well with the mean path length estimated in the human acini.

Implications of Acinar Design for Gas Exchange Function: The Phenomenon of Diffusion Screening

The gas exchange in the pulmonary acinus involves several physicochemical phenomena that occur within the complex acinar geometry described in the preceding. As mentioned, in the distal regions of the lung, oxygen is transported toward the alveolar membrane both by convection and molecular diffusion. Oxygen then diffuses through the tissue membrane into the blood, where it is bound by hemoglobin. Several physical parameters govern oxygen uptake at the acinar level, such as air flow velocity, diffusion coefficient of oxygen in air, alveolar membrane permeability, blood hemoglobin content, and its reaction rate with oxygen. Conversely, carbon dioxide is discharged from the blood to the alveolar gas through diffusion across the membrane. It then diffuses backwards along the airways to the zone, where convection becomes dominant, and is lastly expelled from the lung. In all these processes, the morphology of the system plays an essential role.

Since oxygen uptake into the blood is driven by the O_2 partial pressure at the alveolar surface we must ask whether this driving force is the same throughout the acinus or whether there could be differences between its central and peripheral parts. Some earlier studies had shown that concentration gradients may exist as a consequence of efficient capture of oxygen by hemoglobin. More recently, we have come to realize that such gradients are strongly influenced by the finite permeability of the membrane that plays a dominant role in the effective properties of the acinus as the gas exchange unit. This is related to a phenomenon known as *diffusional screening*, which means that O_2 molecules entering the diffusion unit have a larger probability to hit the surface of the alveolar membrane near the entrance than in the more distal regions. If the membrane permeability is large, O_2 molecules are absorbed at the very first hits. As a consequence, O_2 is absorbed into the blood in the first parts of the acinar pathway so that the gas exchange units in the deeper part of the acinus would not receive any O_2. These regions would then be of no use: They are *screened*. Blood perfusing these regions would not be oxygenated and would thus appear as a shunt. In contrast, if the permeability is small, molecules will be absorbed only after many collisions with the wall. They then have a fair chance to reach the deeper regions and the entire acinar surface can be effective for gas exchange.

To put this into the perspective of structure-function relations this process is related to the balance between two conductances: a diffusion conductance Y_{cross} for O_2 to *cross* the barrier from alveolar air to capillary blood, and a diffusion conductance Y_{reach} for O_2 to *reach* the surface through

Table 2-5

Typical Path Model of Human Acinus

Generation		Segments			Dimensions per Generation			Path Length
Airways z	Acinus z′	N(z′)	1 mm	d_{in} mm	$A_d(z')$ mm^2	$V_d(z')$ mm^3	$S_{aiv}(z')$ mm^2	$L_p(z')$ mm
15	0	1	1.4	0.50	0.20	0.32	7	1.4
16	1	2	1.33	0.50	0.39	0.52	23	2.73
17	2	4	1.12	0.49	0.75	0.84	67	3.85

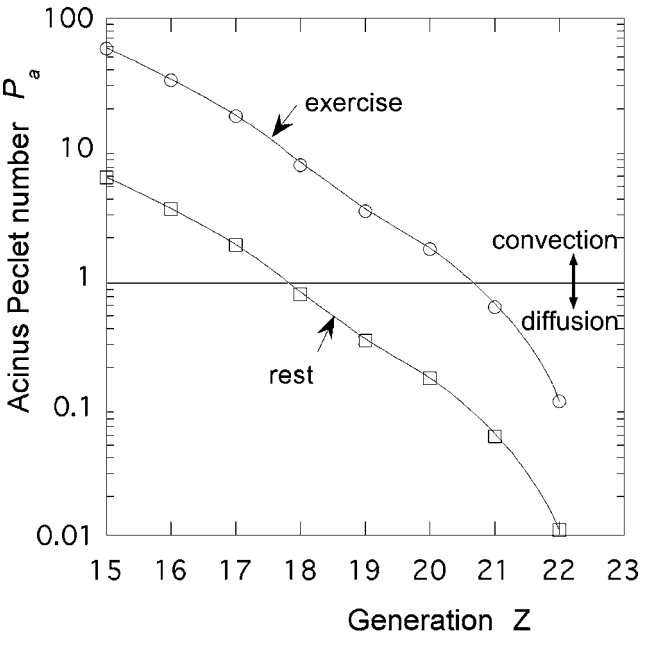

Figure 2-66 In the human acinus the Peclet number, reflecting the relation between convective flow velocity and diffusion velocity of O_2, falls as the airway cross-section increases. Below 1 diffusion becomes the dominant mechanism of alveolar ventilation. This transition point is about in generation 18 at rest and extends out to generation 21 in heavy exercise. *(From Weibel ER, Sapoval B, Filoche M: Design of peripheral airways for efficient gas exchange. Respir Physiol Neurobiol 148:3–21, 2005.)*

the air spaces. Both these conductances are determined by the product of: (a) a physical parameter (the permeability coefficient for O_2 in tissue, and the diffusion coefficient for O_2 in air, respectively); and (b) a morphometric parameter (the gas exchange surface, and the distance along the acinar airways, respectively). The physical coefficients are given quantities, except that the tissue permeability is also affected by the thickness of the tissue barrier, a parameter that varies very little between species. On the other hand, the size and surface of the acinus can be varied during evolution and growth to adjust the two conductances. We can predict that the design of the acinus is optimized if Y_{cross} and Y_{reach} are about equal as this means that both the gas exchange surface and the acinar air volume, or the diffusion distance, are matched. If Y_{cross} were much smaller than Y_{reach} the low permeability of the gas exchanger would need to be compensated by a larger gas exchange surface, and this would inevitably entail a larger volume of the acinus to accommodate the surface and by that a longer diffusion distance.

The morphometric study of acini in various mammalian species revealed that the size of the acini is such that $Y_{cross} \sim Y_{reach}$ so that their morphology seems to be at least partially adapted to minimize the effects of screening. Note that the problem of screening occurs in that part of the acinus where O_2 moves to the surface by diffusion only (Fig. 2-62), in what is called the diffusion cell. The transition between convection and diffusion is determined by the Peclet number (Fig. 2-66), essentially the ratio between air flow and

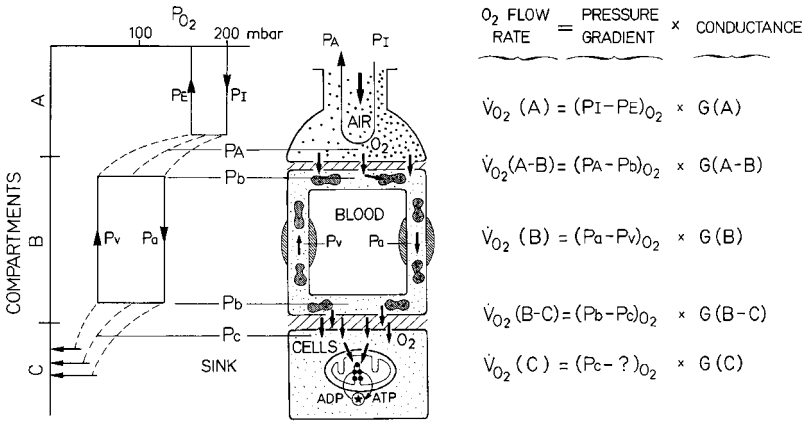

Figure 2-67 Model of the respiratory system from the lung to the cells. Oxygen flow is driven through the system by a cascade of Po_2 ranging from inspired P_{IO_2} to near zero at the mitochondria. At each level the flow rate is determined by a partial pressure difference and a conductance. *(Modified after Weibel ER, Taylor CR: Design of the mammalian respiratory system: I–IX. Respir Physiol 44:1–164, 1981.)*

diffusion velocities: diffusion is more effective than convection when the Peclet number is smaller than 1. In the human lung, under resting conditions, this transition occurs in generation 18 and that is the entrance to the 1/8 subacinus (Fig. 2-63); accordingly the diffusion cell corresponds to the 1/8 subacinus. In exercise, where O_2 consumption as well as ventilation is increased, convective transport of O_2 is effective out to generation 21 (Fig. 2-66). So in exercise there are only two to three generations of acinar airways that act as diffusion cell, but that is still highly significant because these generations accommodate 75 percent of the gas exchange surface (Fig. 2-64 and Table 2-5).

Note that what has been discussed so far relates essentially to about half the respiratory cycle, namely, inspiration when fresh O_2-rich air is actively brought into the acinus. During expiration things are in a way reversed: CO_2 that has diffused from the blood into the acinar air now dilutes O_2 and the convection-diffusion front is moved toward the bronchi. For this reason, the effective duty cycle of the gas exchange system is smaller than 1, particularly under the conditions of high O_2 uptake rate in exercise. This must be considered when modeling gas exchange.

One important aspect of this discussion must also be noted. The fact that the gas exchange units are serially arranged along the acinar airways calls for a modification of the prevailing notion of lung models. In these the gas exchange units are commonly arranged at the end of a system of branched tubes, allowing for ventilation-perfusion variation between the parallel units (Fig. 2-61*A*). That is not a correct representation. We should rather consider a model where the gas exchange units are serially arranged along the ventilation pathway but perfused as parallel units (Fig. 2-61*B*). This has serious consequences because it introduces a degree of inherent ventilation-perfusion inequality that results from the fact that O_2 is absorbed all along the acinar pathway with the result that the P_{O_2} in acinar air is gradually falling along the path. As a consequence, the P_{O_2} is lower in the most peripheral acinar airways so that blood perfusing these peripheral capillaries will be oxygenated to a lower degree than that perfusing more central units. What we measure as arterial P_{O_2} is the average of the P_{O_2} in the blood leaving all the parallel perfusion units.

The Lung as Part of the Pathway for Oxygen

The lung's main function, gas exchange between air and blood, serves the body's varying O_2 needs as they are set by the energetic demands of the cells and their mitochondria when these produce ATP by oxidative phosphorylation to allow the cells to do work. This process requires a flow of O_2 to be maintained from the lung to the cells. It proceeds along the respiratory system through various steps (Fig. 2-67): into the lung by ventilation, to the blood by diffusion, through the circulation by blood flow, and from the blood capillaries by diffusion to the cells and mitochondria, where it disappears in the process of oxidative phosphorylation. A number of basic features characterize this system: (1) under steady-state conditions the O_2 flow rate, $\dot{V}_{O_2}$, is the same at all levels, i.e., O_2 uptake in the lung is equal to O_2 consumption in the tissues; (2) the basic driving force for O_2 flow through the system is a cascade of O_2 partial pressures, which fall from inspired P_{O_2} down to near zero around the mitochondria; (3) the O_2 flow rate at each step is the product of an O_2 partial pressure difference and a conductance G, which is related to structural and functional properties of the organs participating in O_2 transfer. In the preceding section we have seen that the principal design features of the lung that determine one of these conductances, the pulmonary diffusing capacity, are sized to just yield a conductance that allows the O_2 uptake required to satisfy the demands of the whole body cell system at work, with a small margin of safety under normal conditions. Therefore, the lung appears designed to serve the body's needs efficiently and economically. The question we may now ask is whether the other parts of the respiratory system, from the heart to the mitochondria are also designed for economic functional performance.

Let us first look at the overall functional performance of the system. We first note that O_2 consumption is highly variable, increasing by about a factor of 10 between resting conditions and heavy exercise when 90 percent of the O_2 is consumed in the locomotor muscles. Fig. 2-68 shows that the oxygen consumption in muscle is proportional to the energy output, measured for example as running speed, and that it reaches a limit $\dot{V}_{O_2max}$; beyond this the running speed can still be increased, but the additional energy required by the higher

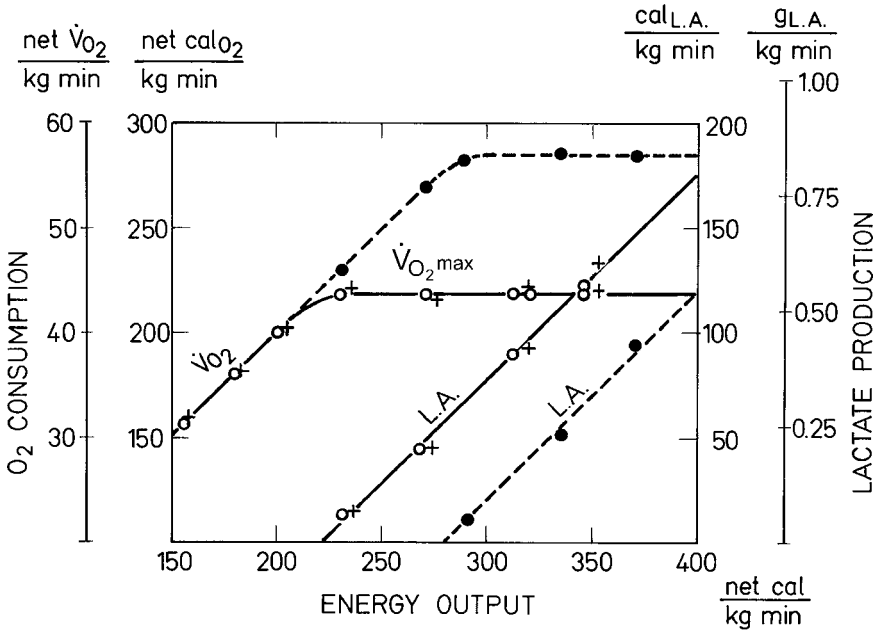

Figure 2-68 Rate of O_2 consumption (left ordinate) and lactic acid production (ordinate at right) in exercise are plotted as a function of the work intensity and, therefore, of the energy requirement (abscissa). Oxygen consumption increases linearly up to a point corresponding to an energy requirement of 220 cal/kg min^{-1}; If work is pushed beyond that there is no further increase in O_2 consumption ($VO_{2\,max}$ is reached) but glycolysis now generates the required energy resulting in an increase in lactic acid production. The broken lines refer to athletes (middle- and long-distance runners) whose maximum oxygen consumption is higher; the line of the lactic acid for these subjects is correspondingly shifted to the right. *(From Margaria R et al: Kinetics and mechanism of oxygen debt contraction in man. J Appl Physiol 18:371–377, 1963.)*

speed is then supplied through glycolysis or anaerobic ATP production with the result that lactic acid concentration in the blood gradually increases. It is now interesting to note that $\dot{V}_{O_2max}$ is a characteristic of the work capacity of an individual: well-trained athletes reach their $\dot{V}_{O_2max}$ at a higher running speed and a higher level of oxygen consumption, and lactic acid concentration in the blood also begins to increases at the higher performance levels corresponding to $\dot{V}_{O_2max}$ (Fig. 2-68).

One may now raise the question whether this variable limitation of oxidative metabolism is a result of variable functional constraints affecting the regulation of metabolic rate and circulatory transport, or whether it could be set by variations in design constraints characterizing the structural components of the pathway, one possible candidate being the pulmonary diffusing capacity. The answer to this question depends on an integrated study of structure and function of the respiratory system. For this we need a quantitative model of the oxygen pathway that identifies all the functional variables and the design parameters at the four levels of the system: the lung, circulation of blood with the heart, capillaries, and mitochondria (Table 2-6). This model is a further development of the one shown in Fig. 2-67 in the sense that, at each level, the equation describing oxygen flow rate sorts out the parameters of functional regulation and those of structural design; these are distinguished in the following sense: Functional variables are regulated according to need with short time constants (seconds), whereas structural design parameters are genetically determined static elements that can be adjusted to a certain extent, for example, by training, but with time constants of weeks to months.

Thus, design variables set the capacity of the system because they are determined by structures whose quantitative properties cannot be adjusted at short notice. If the system were designed according to the principle of symmorphosis we would predict that the design variables are adjusted to $\dot{V}_{O_2max}$ at all levels from the lung to the mitochondria.

The experimental test of this hypothesis requires the integrated measurement of $\dot{V}_{O_2max}$, of the relevant functional parameters, and of all the design parameters, which must then be correlated on the basis of the model of Table 2-6. This cannot be easily done in the human so that is where we can learn from studies in comparative physiology. We know that $\dot{V}_{O_2max}$ is highly variable among mammals. For one, some species such as dogs, horses or pronghorn antelopes have a much higher level of $\dot{V}_{O_2max}$ than "normal" species of the same size such as goats or cows; this is called adaptive variation. On the other hand body size matters so that small animals have a higher metabolic rate per unit body mass than large species, which is called allometric variation. These are genetically determined variations, the result of evolution and selection by fitness, in contrast to the changes in overall work capacity and $\dot{V}_{O_2max}$ induced by exercise training in human athletes, which are epigenetic variations. In all these cases we can ask how and to what extent the structural design parameters are adjusted to meet the different requirements for O_2 to cover the energetic need at the limit of the aerobic work capacity. If there is a bottleneck, then there will be one and only one parameter whose variation is perfectly matched to the variation in the limit of O_2 flow, $\dot{V}_{O_2max}$, whereas all the parameters that are over-designed would appear in haphazard relations to the flow limit. On the other hand, if the limiting resistances are distributed all steps would have to be matched to the varying $\dot{V}_{O_2max}$. If we take the bold view that the organisms are economically designed we would predict that the structural parameters at all levels should be sized to the maximal total O_2 flow requirement with no unnecessary excess capacity because that would be a waste. We have called this design principle symmorphosis, meaning that there should be no more structure built into the system than required to serve the functional needs.

Table 2-6

Model of Structure-Function Relations in Pathway for Oxygen Separating Functional and Structural Parameters in the Equations Defining O_2 Flow Rate through Four Levels

	Function	**Design**	
$\dot{V}_{O_2}$ (lung)	$= (P_{A_{O_2}} - Pb_{O_2})\,\{t_c, \theta_{O_2}\}$	$D_{L_{O_2}}\,\{S(A), S(c), V(c), \tau_{hb}\}$	(1)
$\dot{V}_{O_2}$ (heart)	$= (\sigma_a \cdot Pa_{O_2} - \sigma_{\bar{v}} \cdot P\bar{v}_{O_2}) \cdot f_H$	$Vs\,\{V(LV)\} \cdot V_V(ec)$	(2)
$\dot{V}_{O_2}$ (caps)	$= (Pb_{O_2} - Pc_{O_2})\{t_c, \theta_{O_2}\}$	$D_{T_{O_2}}\{S(c), V(c), V_V(ec), \delta(c,mi)\}$	(3)
$\dot{V}_{O_2}$ (mito)	$= \dot{v}_{O_2}\,\{\dot{m}_{ATP}\}$	$V(mi)\,\{S_V(im,mi)\}$	(4)

The O_2 flow rate $\dot{V}_{O_2}$ is expressed as the product of functional and design parameters; parameters that affect the factors are shown in italics and placed in breaces {.}. The functional parameters include: O_2 partial pressures [P_{O_2}], coefficients of "hematocrit-specific" O_2 capacitance [σ] which depend on O_2-hemoglobin dissociation O_2 binding rate [θ], heart frequency [f_H], capillary transit time [t_c], and mitochondrial O_2 consumption rate as function of ATP flux [$\dot{v}_{O_2}$ {$\dot{m}_{ATP}$}]. Design parameters include: diffusion conductances [D] of lung and tissue gas exchangers that depend on alveolar and capillary exchange surface areas [S(A), S(c)], capillary volumes [V(c)], hematocrit [V_V(ec)], harmonic mean barrier thickness [τ_{hb}], capillary-mitochondrial diffusion distance [δ(c,mi)], and mitochondrial volume [V(mi)] with inner membrane surface density [S_V(im,mi)].

Testing the Hypothesis of Symmorphosis

In order to test such a hypothesis we can first compare mammals that greatly differ in terms of their maximal O_2 consumption. The first type of this variation is found in comparing normal with athletic species, such as dogs with goats or horses with steers. It has been found that such athletic animals can achieve a $\dot{V}_{O_2max}$ that is about 2.5 times higher than that of normal species of the same size. This is much more than what human athletes can achieve. The relevant morphometric data on such species are shown in Table 2-7 for three species pairs. If we go through the respiratory system, beginning at the bottom with the mitochondria, we note that their total volume in the locomotor muscles is also 2.5 times greater in the athletic species with the result that, at $\dot{V}_{O_2max}$, the unit volume of mitochondria consumes the same amount of oxygen in all these six species, namely about 5 ml O_2 per minute and ml mitochonndria. In the next level up, the muscle capillaries, we note that the capillary volume is only 1.7 times greater in the athletic species. However we note that in the athletes the hematocrit, i.e., the concentration of erythrocytes in the blood, is larger so that as a result the capillary erythrocyte volume, the product of capillary volume with hematocrit, is 2.44 times greater, thus well matched to the mitochondrial O_2 demands. Note that this is what counts because oxygen is delivered exclusively from the capillary red blood cells. When we look at the determinants of total blood flow the heart is the central element. We notice that athletic species have larger hearts resulting in a larger stroke volume Vs, but that the maximal heart frequency is not different between the species pairs so that cardiac output is determined by the stroke volume. This is only 1.7 times greater in the athletic species. However, note that, here again, the hematocrit plays an important role as it determines the amount of O_2 that can be transported to the capillaries. If we calculate the cardiac erythrocyte output $\dot{Q}$ (ec) we find that it is again 2.4 times greater in the athletic species. Thus the design parameters of the internal steps of the O_2 transport cascade are quantitatively adjusted to the needs for O_2 flow under limiting conditions. Thus, it appears that the resistance to O_2 flow is distributed to all levels.

When we then consider the design of the pulmonary gas exchanger we note that the O_2 diffusing capacity of the lung of athletic species is only 1.7 times greater than that of normal species. Considering that we found that the human lung may have some excess capacity by about a factor of 1.5, this may signify that normal sedentary species such as goats or cows have a greater excess capacity than athletic species. Indeed, this can be shown to be the case in two ways: (1) when one calculates the progression of O_2 loading on capillary blood (Bohr integration, Fig. 2-59) one finds that dogs reach saturation just before the blood leaves that capillaries into arterial blood, whereas the goats have some 30 percent reserve capacity; (2) when goats are run on a treadmill while breathing hypoxic air one finds that they can maintain their $\dot{V}_{O_2max}$; in contrast, dogs cannot run at their established $\dot{V}_{O_2max}$ under such conditions. We concluded from this observation that athletic species have designed a lung to match the requirements for maximal O_2 uptake with no excess capacity while normal sedentary species apparently allow for a certain safety margin which allows them to perform well also under unfavorable hypoxic conditions. If this is now applied to our observations on the human lung this may mean that the excess capacity of the normal lung may just be sufficient to allow athletes to increase their $\dot{V}_{O_2max}$ by training by a factor 1.5, just about what they can achieve (Fig. 2-67).

One has also found that highly trained athletes do not tolerate heavy exercise at very high altitudes as they cannot achieve O_2 saturation of their arterial blood. Thus, it seems

Table 2-7

that the pulmonary gas exchanger is now the limiting factor for O_2 transfer to the working muscles. The reason for this is that the lung of the adult cannot enlarge its gas exchange surfaces to match the increased demands of trained muscles. So an athlete must make do with the lung she or he has developed during growth. This contrasts with the changes induced by exercise training in muscle with an increase in mitochondria and capillaries, and in the heart by enlargement of the ventricles, all well matched to the maximal O_2 demands. Therefore, it is fortunate—and perhaps a sign of good design—that the lung is designed with some excess diffusing capacity to allow the lower, internal, levels of the respiratory system to exploit their capacity to adapt to increased energetic needs.

The Respiratory Muscles

Marc Decramer

The respiratory muscles constitute a complex pump system. Several muscles comprise this system, represented schematically in Fig. 3-1. Breathing under all circumstances requires a coordinated contraction of different respiratory muscles. The most important inspiratory muscle is the diaphragm. The conditions under which this respiratory muscle system weakens and eventually will fail are addressed in other chapters (see Chapters 93, 94, and 147). This chapter focuses on structural and functional properties of the respiratory muscles, respiratory muscle action, and respiration muscle interaction.

STRUCTURAL AND FUNCTIONAL PROPERTIES OF RESPIRATORY MUSCLES

The respiratory muscles are skeletal muscles, and, in essence, their structural and functional properties are within the range of other skeletal muscles located in the limbs. Adaptations to their specific function, however, make them distinctly different from other skeletal muscles in a number of respects. First, limb muscles are essentially designed to produce movements, and hence, primarily work against inertial loads. Respiratory muscles mainly have to overcome resistive and elastic loads. Second, peripheral muscles contract rhythmically during movements, while respiratory muscles contract rhythmically and continuously, and they are the only skeletal muscles on which life depends. These vital muscles thus have to be well equipped to sustain continuous rhythmic contraction. These adaptations include high fatigue resistance, high oxidative capacity, greater capillary density, and greater maximal blood flow, and they depend upon structural and functional properties of the muscles.

Structural Properties

Structural properties of muscles in general, and respiratory muscles in particular, depend upon fiber types present in the muscle, morphological characteristics of the fibers, and motor unit organization.

Fiber Types

Skeletal muscles are composed of several motor units, each with hundreds of muscle fibers. Three types of muscle fibers are usually present. They are distinguished on the basis of the myofibrillar myosin adenosine triphosphatase (ATPase) activity and its pH dependence. Alternatively, the muscle fibers

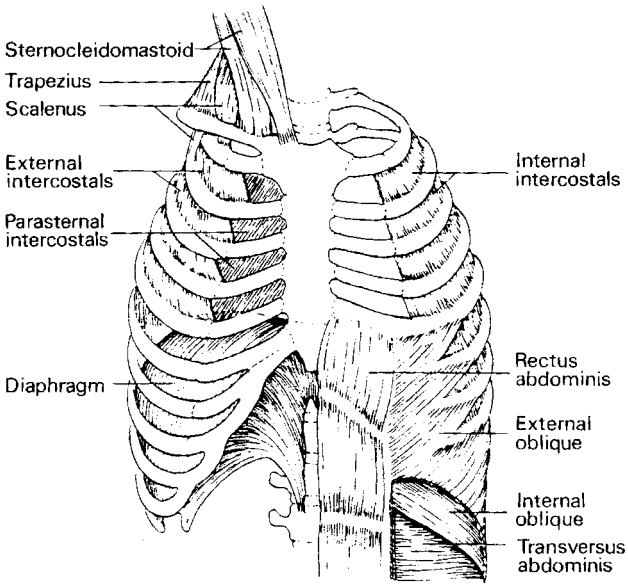

Figure 3-1 Idealized diaphragm of the respiratory muscles.

may be distinguished through myosin heavy chain gene expression. Type I fibers, or slow oxidative fibers, have a slow contraction profile but are high in endurance and rich in oxidative enzymes. Type II fibers are fast-twitch fibers that develop tension rapidly. They either are fatigue resistant or glycolytic oxidative (IIa), or fatigable or glycolytic (IIb). Type II fibers develop greater forces than do type I fibers. Muscles primarily composed of type I fibers have high endurance capacity, whereas those primarily composed of type IIb fibers are designed to develop high forces but have low endurance capacity. Type IIa fibers are intermediate and combine relatively high force development with relatively long endurance. In general, type I fibers have the smallest cross-sectional area, and type IIb fibers tend to have the largest.

Type IIb fibers were further distinguished from the histochemically different type IIx fibers by means of myosin electrophoresis and histochemistry. The respiratory muscles are mixed muscles containing both fast-twitch and slow-twitch fibers. The human diaphragm contains about 55 ± 5 percent type I fibers, 21 ± 6 percent type IIa fibers, and 23 ± 3 percent type IIb fibers. All respiratory muscles (i.e., intercostal muscles, abdominal muscles, sternomastoids, and diaphragm) contain at least 60 percent highly oxidative fibers. No data are available on the scalenes. The respiratory muscles thus seem to be generally well equipped to sustain continuous rhythmic contraction.

Morphological Characteristics of the Fibers

The respiratory muscles consist of muscle bundles oriented in a parallel fashion. These bundles consist of hundreds of muscle fibers, each of which in turn consists of hundreds of myofibrils. These myofibrils are made up of hundreds of sarcomeres arranged in series, each sarcomere consisting of a number of myosin (thick filaments) and twice the number of actin (thin) filaments. The capacity of the muscle to produce forces depends upon the number of myofibrils in parallel, since the forces developed by all these myofibrils are additive, whereas the displacement and velocity of shortening depend upon the number of sarcomeres in series. Indeed, the displacements of these sarcomeres arranged in series are additive.

The density of mitochondria in each of the three fiber types tends to be greater than in the same fiber types in limb muscles. In addition, in humans, the diaphragm is composed of about 80 percent oxidative fibers compared with 36 to 46 percent in the limb muscles of untrained men. As a consequence, the volume density of mitochondria in the diaphragm is twofold greater than in the limb muscles. Therefore, the oxygen uptake capacity of the diaphragm is considerably greater than that of limb muscles because of the high oxidative fiber content and the greater mitochondrial density. Moreover, the maximal blood flow also considerably exceeds that of limb muscles because of the greater capillary density, which is about twice the capillary density in the limb muscle. The diaphragm is thus well equipped to sustain rhythmic contraction at rest through its type I and IIa fibers: the type IIa fibers permit additional recruitment in power and rate during exercise, and the few type IIb fibers permit high power outputs necessary for sneezing and coughing.

Motor Unit Organization

Muscle fibers are organized in motor units. The muscle fibers within a given motor unit are broadly dispersed throughout a region of the diaphragm. Dispersion occurs both horizontally across the surface of the diaphragm and vertically with fibers at different depths. There are three types of motor units in the respiratory muscles: fast-fatiguable (FF), fast-fatigue resistant (FR), and slow (S). Motor units composed of fast fibers are large and develop forces in the range of 110 mN. These, however, are considerably smaller than in limb muscles. Motor units composed of slow fibers are smaller and develop forces in the range of 30 to 60 mN. The recruitment pattern of the diaphragm follows the size principle, the smallest motor units being recruited first.

Functional Properties

Functional properties of muscles are generally described in terms of force-length relationships, time-dependent characteristics of the twitch, force-frequency, force-velocity, and power-frequency relationships.

The force-length characteristics of the diaphragm are in essence similar to other muscles. Maximal tension is generated at the optimal length. Three aspects of the force-length curve of the diaphragm are potentially relevant to clinical medicine. First, with hyperinflation, the diaphragm shortens and its capacity to generate force is concomitantly reduced. Second, when hyperinflation occurs chronically, adaptation occurs in the muscle. This adaptation consists of drop out of sarcomeres such that muscle shortening is then accommodated by a reduced number of sarcomeres rather than

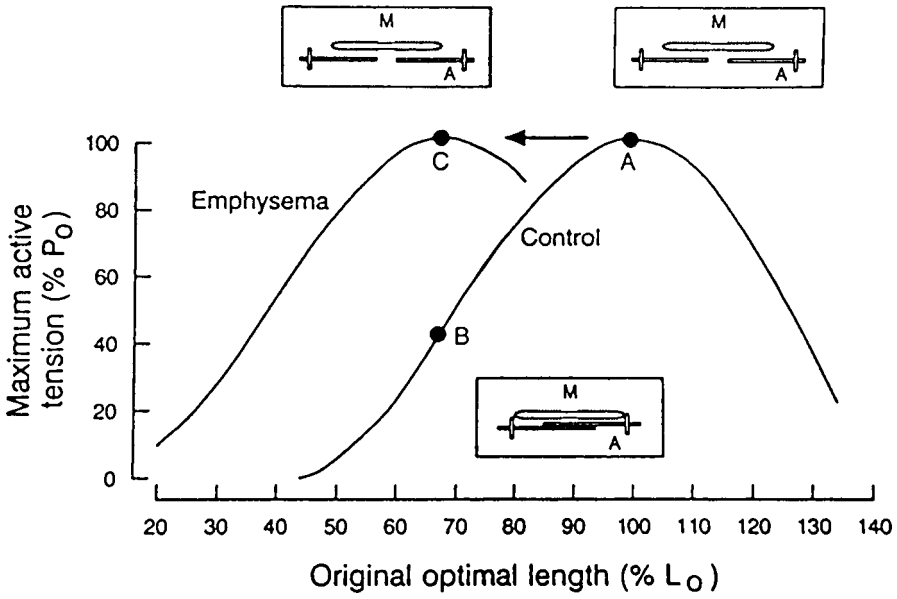

Figure 3-2 Diaphragmatic length–tension curve in normal hamsters and hamsters with elastase-induced emphysema. Tension is expressed as a percentage of maximum tetanic tension, P_O, and length is expressed as a percentage of original optimal length, P_O. The degree of filament overlap among actin (A) and myosin (M) filaments in control (A), acute (B), and chronic hyperinflation (C) is shown. Note that due to sarcomere adaptation in chronic hyperinflation, the degree of filament overlap is the same at a considerably shorter length. *(From Farkas G: Functional characteristics of the respiratory muscles.* Sem Respir Med *12:247–257, 1991, with permission.)*

alterations in filament overlap within the sarcomeres. As a consequence, the force-generating capacity is restored, at least in part, at foreshortened length. This adaptation is summarized in Fig. 3-2. The consequences of this adaptation to patients with hyperinflation are discussed below. Third, although less-than-optimal filament overlap is the primary reason for a reduction in force with muscle shortening, calcium deactivation due to T-tubular failure also plays a role. This is potentially significant for treatment, since inotropic agents restore T-tubular function in foreshortened muscle. Accordingly, inotropic agents exert much greater effects on foreshortened diaphragm than on diaphragm placed at its optimal length. This concept opens up new perspectives for respiratory muscle pharmacotherapy in patients with severe hyperinflation. The length-tension curves of other respiratory muscles and their adaptation to hyperinflation have not been systematically studied.

A particularly interesting question is the relationship between the in situ operational length of the respiratory muscles and the optimal length in vitro. For the diaphragm, the length at functional residual capacity (FRC) comes close to the optimal length. The length changes undergone by the diaphragm over the vital capacity range are large, 30 to 40 percent. These length changes are considerably smaller for the parasternal intercostals, the scalenes, and the sternocleidomastoids. For the parasternal intercostals, the length at FRC is clearly longer than optimal in supine dogs, so that with hyperinflation, the parasternal intercostals move toward their optimal length. Recent experiments, however, indicate that the fall in pleural pressure caused by stimulation of the parasternal intercostals in dogs is reduced with increasing lung volume. This discrepancy was shown to result from changes in orientation and motion of ribs with hyperinflation. The scalenes and sternocleidomastoids appear to operate on the ascending limb of their length-tension curves in supine dogs. How hyperinflation in patients affects the force-generating capacity of these muscles remains unclear. According to a recent analysis, the changes in length during passive inflation are proportional to the mechanical advantage of a particular respiratory muscle. In keeping with this analysis, the mechanical advantage of the diaphragm would be considerably greater than the mechanical advantage of other inspiratory muscles (see below).

The force developed by a muscle increases with increasing frequency of stimulation. The increase in force is considerably steeper for a slow muscle in which fusion occurs at lower frequency because of the longer relaxation time than for a fast muscle. The diaphragm is intermediate, so that at in vivo stimulation frequencies (10 to 30 Hz), a fused tetanic contraction occurs. Particularly interesting is the effect of acute shortening on the force-frequency curve. Since acute shortening is associated with a downward shift of the force-frequency curve, the detrimental effect of acute shortening on the force-generating capacity of the diaphragm appears to be twofold. With muscle shortening there is a clear reduction in maximal tetanic force. However, the decrease in force at submaximal stimulation frequencies is disproportionately greater (Fig. 3-3).

The force-velocity curve of the diaphragm is shown in Fig. 3-4. With increasing loads, the velocity of contraction is reduced. The velocity of contraction is a direct function of myosin ATPase activity, and, hence, the force-velocity curve is primarily determined by the muscle fiber composition. The diaphragm is intermediate between the force-velocity curve of a fast and a slow muscle (Fig. 3-4). The production of airflow into the lungs requires power output by the respiratory muscles. Power may be calculated as the product of the values of velocity and force according to the force-velocity relationship (Fig. 3-4). Instantaneous peak power occurs at 30 percent of maximal force and at 30 percent of maximal velocity. The frequency-isometric force relationship, frequency-shortening force, and frequency-power relationships show a

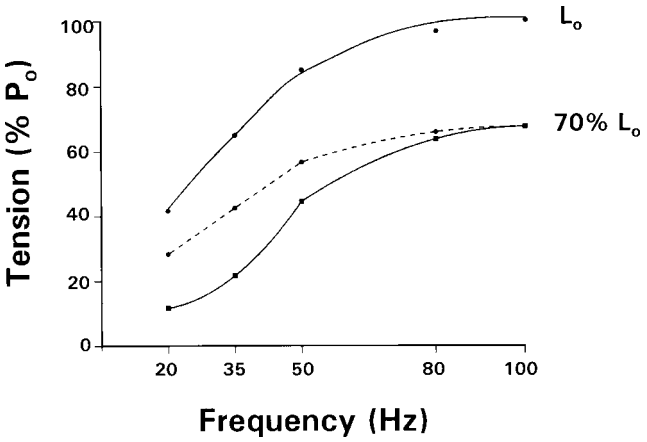

Figure 3-3 Force-frequency curve of human diaphragm at L_O and 70 percent L_O. Force is expressed as a percentage of maximal tetanic tension, P_O, and frequency is expressed in Hz. Dashed line is the predicted line at 70 percent L_O, whereas the solid line is the observed line. The predicted line is based on the assumption that a 30 percent change in length produces a 35 percent drop in force at all stimulation frequencies, as is observed for maximal tetanic force. Note that the decrease in force at lower stimulation frequencies is considerably greater than theoretically predicted. *(Modified from Farkas G: Functional characteristics of the respiratory muscles.* Sem Respir Med *12:247–257, 1991, with permission.)*

similar dependency of force and power upon frequency of stimulation.

Fatigue also affects profoundly the force-length, force-frequency, force-velocity, and power-frequency characteristics of the diaphragm. The effects of fatigue on functional properties of the respiratory muscles are discussed in Chapters 93, 94, and 147. The factors determining the development of respiratory muscle fatigue are also discussed in these chapters.

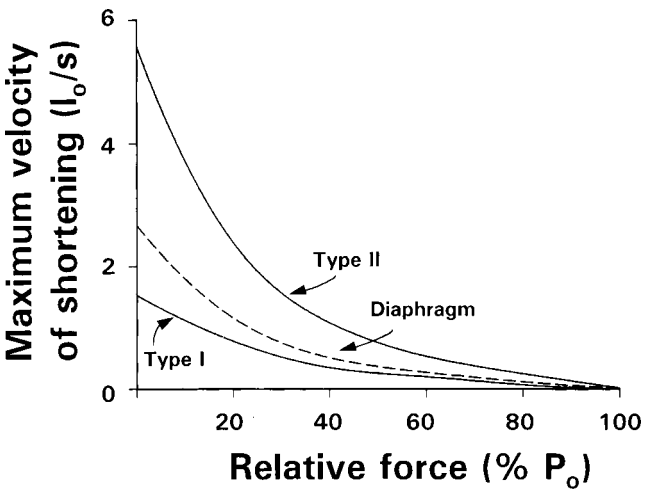

Figure 3-4 Force-velocity curve of human diaphragm (dashed line), which is intermediate between the force-velocity curve of a typical slow muscle (type I) and a typical fast muscle (type II). Maximum velocity is expressed in optimal length, l_O, per second and relative force is expressed as a percentage of maximum tetanic force, P_O.

ACTIONS OF RESPIRATORY MUSCLES

The Diaphragm

The diaphragm is the most important inspiratory muscle. It consists of two distinct parts, the costal and crural parts, which have separate actions on the rib cage, separate segmental motor innervations, and a different embryological origin. In respiratory activities, however, the diaphragm frequently operates as a functional unit, and in the following its action is described as such. Diaphragmatic action is schematically represented in Fig. 3-5. Diaphragmatic contraction increases chest wall dimensions because of three distinct reasons. First, diaphragmatic descent increases the craniocaudal dimensions of the thorax. Diaphragmatic descent is tightly coupled to outward motion of the free abdominal wall.

Second, diaphragmatic contraction increases the dimensions of the lower rib cage because of the increase in abdominal pressure that it causes. This increase in abdominal pressure acts through the zone of apposition (i.e., the zone in which the diaphragm is immediately apposed to the rib cage) to expand the lower rib cage. This action is the appositional component of diaphragmatic action (Fig. 3-5). The magnitude of the appositional component is determined by the magnitude of the zone of apposition, about 25 to 30 percent of the total internal surface area of the rib cage at FRC in standing humans, and by the magnitude of the increase in abdominal pressure caused by diaphragmatic contraction.

Third, diaphragmatic contraction further increases lower rib cage dimensions because of its insertions into the lower rib cage. The diaphragmatic fibers are oriented axially, and their contraction causes pull on the lower rib cage in an axial direction, leading to cephalad motion and outward

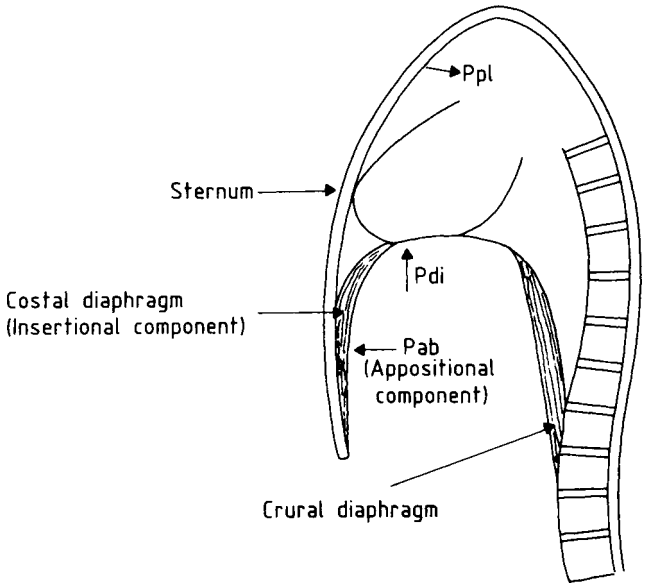

Figure 3-5 Diagram illustrating diaphragmatic action. Lateral view of the thorax. Ppl = pleural pressure, Pab = abdominal pressure. Costal and crural diaphragm are shown. See text for further explanation.

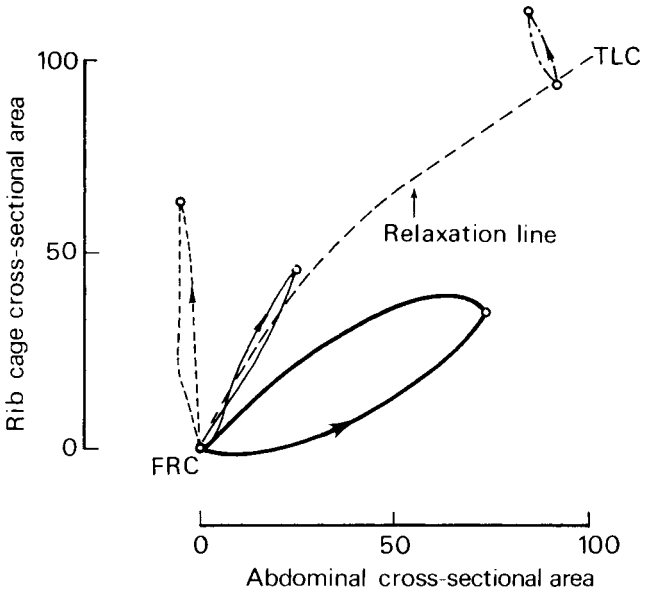

Figure 3-6 Konno-Mead diagram illustrating chest wall motion during quiet breathing (thin loop), diaphragmatic pacing or quiet breathing in tetraplegic patient (thick loop), breathing with diaphragm paralysis (dash loop), and breathing at severely elevated end-expiratory volume (dash-dot loop). Rib cage and abdominal cross-sectional areas are expressed as a percentage of inspiratory capacity. Dashed line is the relaxation line.

rotation of the lower rib and hence, to lower rib cage expansion. This is the *insertional component* of diaphragmatic contraction (Fig. 3-5).

Two points regarding diaphragmatic action are worth further mention. Diaphragmatic contraction also decreases pleural pressure, which causes a reduction in upper rib cage dimensions and hence, an expiratory effect on the lower rib cage. The latter reduction in upper rib cage dimensions is also clearly observed during diaphragmatic contraction or pacing in high quadriplegics, in whom all inspiratory muscles, except for sternocleidomastoids, are paralyzed. The pattern of chest wall motion in quadriplegics is shown in Fig. 3-6. The displacement observed in quadriplegics suggests that diaphragmatic contraction alone cannot be responsible for the pattern of chest wall motion observed during quiet breathing (see below) and, hence, that other muscles assist the diaphragm in moving the chest wall during quiet breathing.

The Intercostal Muscles

The functional anatomy of intercostal muscles is schematically represented in Fig. 3-7. Between the chondral portions of the ribs only one layer of intercostal muscles, the parasternal intercostals, is present. Between the osseous portions of the ribs, two layers are present. The outermost layer runs obliquely downward and forward and is called the *external intercostal*. The innermost layer runs obliquely downward and backward and is called the *internal intercostal* (Fig. 3-7, left panel). Note that the internal intercostals and parasternal intercostals have the same fiber orientation. Dorsally only an external intercostal is present. At its outside runs a fusiform muscle between the transverse processus of the vertebra and the angle of the lower rib. This muscle is called the levator costae (Fig. 3-7, right panel).

The parasternal portion of the intercostal musculature, the "parasternals," is consistently active during quiet breathing both in animal and human subjects, and is the most important inspiratory portion of the intercostal musculature. The parasternal intercostals have the greatest mechanical advantage, and their contraction produces about 60 percent of the cephalad motion of the rib during inspiration. Within the parasternal intercostals, the medial fibers have a greater mechanical advantage and are activated more consistently and before the middle and lateral fibers.

The action as well as the respiratory role of the interosseus intercostals remain the subject of a longstanding debate. The most commonly accepted view on intercostal muscle action is based on a theory of intercostal muscle fiber orientation and rib geometry. This theory states that the external intercostals are inspiratory in action, and the external intercostals are expiratory in action. Numerous experiments do not fit with this theory, although a finite element analysis largely confirmed these actions. It is commonly believed that the interosseus intercostals constitute a reserve system that may be recruited with increased ventilatory load. The external

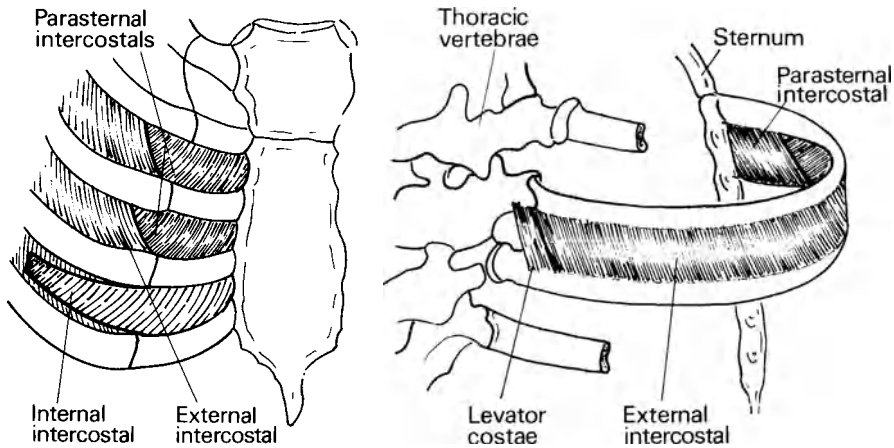

Figure 3-7 Diagram of the functional anatomy of the intercostal muscles, at their anterior (left) and posterior (right) aspects. Notice the parasternal, internal, and external intercostals, and the levator costae.

intercostals are recruited predominantly during inspiration, primarily in the upper interspaces, whereas the internal intercostals are recruited predominantly during expiration primarily in the lower interspaces. In a recent analysis Wilson et al. demonstrated by the application of the reciprocity theorem of Maxwell, that the external intercostals in the dorsal portion of the costal interspaces have a large inspiratory mechanical advantage. This advantage decreases in the ventral and caudal direction such that in the ventral portion of the caudal interspaces it is reversed in an expiratory mechanical advantage. Conversely, the internal intercostals in the caudal interspaces have a large expiratory mechanical advantage, but this advantage decreases in the cranial and ventral direction. Because of this pattern of topographic distribution the pattern of neural activation is crucial for the function of these muscles. This pattern was shown to match the pattern of distribution of mechanical advantage, such that the external intercostals have an inspiratory function and the internal intercostals have an expiratory function.

Without question, the levator costae has an inspiratory action on the rib. It is frequently activated even during quiet inspiration in supine dogs. The levator costae's contribution to inspiratory motion of the ribs during quiet breathing, however, appears substantially smaller than that of the parasternal intercostals. This contribution may further increase when the inspiratory motion of the ribs is appreciably increased.

The Scalenes

The scalenes run between the transverse process of the five lower cervical vertebrae and the upper margin of the first (scalenus anterior) and second (scalenus medius and posterior) ribs. The action of these muscles is to raise the first two ribs. The orientation of their axis in the neck causes upward motion of these ribs ("pump handle" motion). Moreover, the scalenes are consistently active during quiet breathing in normal individuals and contribute to chest wall expansion. They may be very important in the case of spinal cord injury. When the injury is below C_4-C_8, the scalenes' function is entirely or partially preserved, and they contribute importantly to upper rib cage motion in these patients.

The Sternocleidomastoids

The sternocleidomastoids run between the mastoid processes of the temporal bone and the manubrium sterni and medial portion of the clavicle. In humans, these muscles are electrically silent during quiet breathing, but they may be recruited with increased ventilatory load. These muscles are particularly important in high quadriplegics in whom they preserve their function because they are innervated by the 11th cranial nerve and spinal nerves C_1-C_2. Through training the sternocleidomastoids may develop severe hypertrophy and contribute to several hours of ventilator independence in these patients. They also may be recruited in patients with poliomyelitis and diaphragmatic dysfunction. These muscles are thought to be important in moving the upper rib cage in patients with chronic obstructive pulmonary disease (COPD), even though a clinical experimental study failed to demonstrate consistent activity in these muscles in these patients.

The Shoulder Girdle and Neck Muscles

Several shoulder girdle and neck muscles may contribute to inspiration under particular circumstances. Most of these muscles run from the rib cage to an extrathoracic extension. When the rib cage is fixed in the lean-forward position—a position commonly employed by patients with COPD—these muscles contribute to expansion of the rib cage during inspiration. Muscles that may contribute to inspiration include the trapezius, latissimus dorsi, pectoralis major and minor, erector spinae, teres major, serratus anterior, platysma, mylohyoid, and sternohyoid. Since these muscles commonly contribute to inspiration in patients with severe airflow obstruction, using these muscles for other activities, such as hair combing, may considerably increase dyspnea in these patients.

The Clavicular Head of Pectoralis Major

The clavicular head of the pectoralis major runs laterally and caudally from the medial half of the clavicle and manubrium sterni to the humerus. If the arms are fixed and braced, contraction causes downward motion of the ribs and sternum, increase in pleural pressure and, hence, expiration. Simultaneously, the lower rib cage and the abdomen move outward. Tetraplegics use this expiratory action when all other expiratory muscles are paralyzed. Training increases pectoralis strength and increases expiratory reserve volume in these patients.

The Triangularis Sterni

The triangularis sterni is the most important expiratory muscle of the rib cage. The muscle runs at the inside of the thorax between the inner aspect of the sternum and inner aspect of the five lower ribs (Fig. 3-8), and its action is to lower the ribs relative to the sternum and thus to cause expiration. The triangularis sterni is electrically silent in humans breathing quietly, but it is recruited during speech, laughing, or expiration below FRC. Its recruitment threshold is low, lower than the recruitment threshold of most other expiratory muscles.

The Abdominal Muscles

The abdominal muscles are composed of four different muscle layers (Fig. 3-1). Ventrally, a muscular sheet runs between the lower costal cartilages and the sternum and the pubis, the rectus abdominis. This muscle is enclosed in a sheath formed by the aponeuroses of the other three muscles. Laterally, an oblique muscle runs obliquely downward and forward between the lower eight ribs and the iliac crest, inguinal ligament, and linea alba medially, the external oblique. At the inner surface of this muscle lies the internal oblique with a

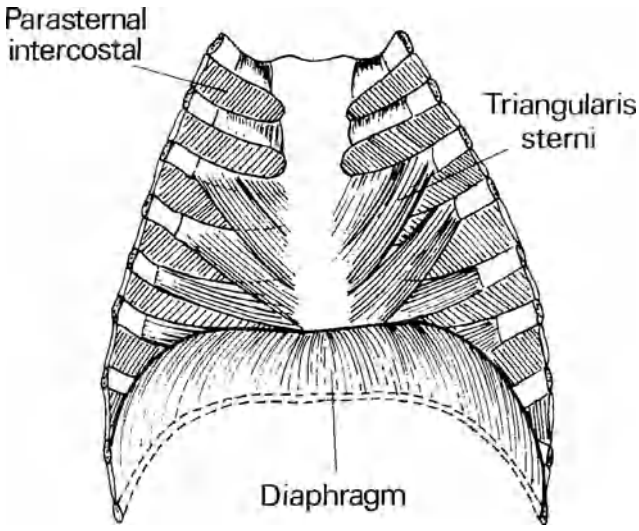

Figure 3-8 Diagram illustrating the functional anatomy of the triangularis sterni. View from inside of the thorax.

fiber orientation, which is 90 degrees perpendicular to the external oblique. These muscles are homologous to the external and internal intercostals. The innermost layer is the transversus abdominis, a circular muscular sheet surrounding the abdomen, with a fiber orientation that is parallel to the ribs. The transversus abdominis originates from the inner surface of the lower six ribs, where it interdigitates with the costal insertions of the diaphragm. It runs from this origin and the lumbar fascia, iliac crest, and inguinal ligament, circumferentially around the abdominal visceral mass to terminate ventrally in the rectus sheet. These muscles all have an expiratory action, by virtue of the inward pull of the abdomen they cause and of the insertions they have in the rib cage. In addition, however, rib cage expansion may occur with contraction of some of these muscles through the increase in abdominal pressure accompanying their contraction.

The abdominal muscles are electrically silent during quiet breathing. Usually, however, tonic activity is present in the abdominal muscles in upright position, particularly in the upper segments. During inspiratory loading, CO_2-induced hyperventilation, exercise, and forced expiration, these muscles are recruited. The transversus abdominis appears to have the lowest recruitment threshold.

RESPIRATORY MUSCLE INTERACTION

Respiratory Muscle Interaction during Quiet Breathing

Respiratory muscle interaction is traditionally studied by means of a Konno-Mead diagram, relating rib cage diameter or cross-sectional area to abdominal diameter or cross-sectional area (Fig. 3-6). First, this relationship is determined in the absence of muscle contraction, during a relaxed expiration, yielding a relaxation line. During quiet breathing in the upright position, the chest wall moves along this relaxation line, which means that proportional expansion of rib cage and abdomen is occurring. In the supine position, abdominal movement is proportionally greater than rib cage movement. Since isolated diaphragmatic contraction in quadriplegics causes abdominal movement without rib cage motion or even inward movement of the upper rib cage (upper rib cage paradox), diaphragmatic contraction alone cannot be responsible for the pattern of motion occurring during quiet breathing (Fig. 3-6). Therefore, this motion requires concomitant contraction of other muscles (i.e., the parasternal intercostals and scalenes). These muscles actively contribute to chest wall motion and cause upper rib cage expansion, whereas diaphragmatic contraction alone would cause upper rib cage paradox. During quiet breathing, the diaphragm probably contributes about 60 to 70 percent of the tidal volume, and the parasternal intercostals and scalenes contribute the rest.

PHYSIOLOGICAL CONDITIONS AFFECTING RESPIRATORY MUSCLE INTERACTION

Respiratory muscle interaction present during quiet breathing and the chest wall motion resulting from it may be altered in a number of circumstances in which ventilatory load is increased. During speech, laughing, and forced expiration, expiratory muscles are recruited. The expiratory muscles with the lowest recruitment threshold appear to be the triangularis sterni, running between the sternum and lower ribs at the inside of the thorax and transversus abdominis, the innermost layer of the abdominal muscles. Recruitment of these expiratory muscles may add significantly to inspiratory work; relaxation of these muscles just prior to the onset of inspiration contributes substantially to inspiration. Major recruitment of expiratory muscles occurs during exercise, inspiratory resistive loading, CO_2-induced hyperventilation, and anesthesia.

PATHOLOGICAL CONDITIONS AFFECTING RESPIRATORY MUSCLE INTERACTION

Respiratory muscle interaction is further profoundly affected by a number of pathological conditions. Hyperinflation is a functional abnormality of lung diseases in which airflow obstruction or loss of elastic recoil are features. Hyperinflation may be particularly severe in patients with COPD, in whom the FRC often exceeds predicted total lung capacity (TLC) (see below).

An overwhelming amount of evidence shows that hyperinflation reduces the diaphragmatic effectiveness as a pressure generator and reduces diaphragm contribution to chest wall motion. The contribution of the intercostal muscles and scalenes is likely to be increased, such that chest wall motion

becomes exclusively or predominantly rib cage motion (Fig. 3-6). The ineffectiveness of the diaphragm may result from diaphragmatic shortening, geometrical alterations, alterations in diaphragm-rib cage interaction, alteration in mechanical arrangements among the costal and crural parts of the diaphragm, reduction in the zone of apposition, and so on. Among these, diaphragmatic shortening appears to be the most important. Indeed, with inflation from FRC to TLC, the diaphragm shortens about 30 to 40 percent, which is expected to reduce significantly its pressure-generating capacity. Several studies indicate that diaphragmatic geometry is not affected significantly by hyperinflation. The appositional component of diaphragmatic action is reduced substantially due to a reduction in the zone of apposition. The insertional component is affected so that diaphragmatic contraction causes inward retraction of the lower rib cage. This may be noticed clinically in patients with severe hyperinflation. The mechanical arrangement between the costal and crural parts of the diaphragm changes from a parallel arrangement at FRC to a series arrangement at TLC. This is likely to further compromise the pressure-generating capacity of the diaphragm independently of its force-length characteristics.

It should be emphasized, however, that the above pertains to acute hyperinflation. In chronic hyperinflation, the diaphragm adapts to the chronically foreshortened state by dropping out of sarcomeres. As a consequence, the filament overlap within each sarcomere is restored toward optimal overlap. This adaptation is shown in Fig. 3-2. It should be noticed, however, that this adaptation only partially restores diaphragmatic function. First, because part of the reduction in force with shortening is due to compression of the T-tubular system, blocking exit-electrolyte flow and impeding excitation-contraction coupling. Whether adaptations in T-tubular function also occur with chronic foreshortening remains to be investigated. Second, sarcomere adaptation adapts only to the loss in diaphragmatic function associated with diaphragmatic shortening and not to the loss in function due to geometrical alterations, alterations in diaphragm-rib cage interaction, changes in mechanical arrangement among different parts of the diaphragm, or loss of zone of apposition. Third, although sarcomere adaptation restores the force-generating capacity of a foreshortened diaphragm, it reduces the number of sarcomeres in series. Consequently, sarcomere adaptation compromises the capacity of the diaphragm to undergo changes in length and, hence, its capacity to produce volume changes, presumably its most important function.

Interventions aimed at reducing hyperinflation such as lung volume reduction surgery (LVRS) and lung transplantation improve diaphragmatic function. The effects of LVRS are primarily due to an increase in the zone of apposition, lengthening of the diaphragm and improved neuromechanical coupling. To what extent complete sarcomere adaptation is present in patients with COPD and extreme hyperinflation is not clear from the clinical studies with LVRS. After lung transplantation the radius of curvature and the zone of apposition of the diaphragm are also restored. This is primarily due to mediastinal displacement toward the graft.

Expiratory muscle recruitment is frequently observed in COPD patients with severe airflow obstruction. The transversus abdominis appears to be frequently recruited. Expiratory muscle recruitment may contribute to the intrinsic positive end-expiratory pressure ($PEEP_i$) that is frequently observed in these patients. $PEEP_i$ is primarily caused by impaired pulmonary mechanics and consequent dynamic hyperinflation. The functional significance of this expiratory muscle activation is poorly understood. Indeed, in severe airflow obstruction, expiratory flow limitation is frequently present. In the presence of expiratory flow limitation, recruitment of expiratory muscles no longer contributes to expiratory flow.

In patients with pulmonary disease in general and COPD in particular, several factors may contribute to generalized muscle weakness, in which the respiratory muscles partake. These include hypoxemia and hypercapnia, malnutrition, cardiac failure, corticosteroid treatment, infection, electrolyte disturbances, and inactivity with consequent disuse atrophy. A recent study demonstrated that COPD exacerbations contributed to the development of this muscle weakness. Of particular importance appears to be treatment with corticosteroids in repetitive bursts, which is often inadvertently administered to COPD patients. Typically this myopathy causes a myopathic pattern on muscle biopsy instead of selective type IIb fiber atrophy as is commonly believed.

ACKNOWLEDGMENTS

The author thanks Mr. Jean Sente for making excellent drawings. He further thanks the Fonds voor Wetenschappelijk Onderzoek-Vlaanderen grants #G.0389.03 and G.0386.05, Research Foundation KU Leuven grant #OT/02/44 and Astra Zeneca Pharmaceuticals for their support of the research mentioned in this chapter.

The Genetic, Molecular, and Cellular Basis of Lung Development

Stijn De Langhe • Pierre Del Moral • Denise Tefft • Saverio Bellusci • David Warburton

The branching pattern in the lung is extremely reproducible from one person to another, suggesting a tight temporal-spatial genetic control of the branching process. This chapter focuses on the growth factors, produced either by the epithelium or the mesenchyme, that play a key role in controlling branch formation, proximal-distal cytodifferentiation as well as folding and expansion of the alveolar gas diffusion surface.

OVERVIEW OF LUNG DEVELOPMENT AND BRANCHING MORPHOGENESIS

The human lung arises at 4 to 5 weeks gestation, while the mouse lung arises at embryonic day E9.5 (Fig. 4-1). In both species the lung arises from the ventral foregut, as the laryngotracheal groove, just anterior to the developing stomach. The primordia of the trachea and the two lung buds consist of an epithelial layer of endoderm surrounded by splanchnic (lateral plate) mesoderm. The trachea is separated from the esophagus by means of lateral, posterior to anterior longitudinal septation of the foregut, while the more distal parts of the lung develop from two lateral bronchial buds that form at the posterior end of the trachea. Initially the primary bronchial buds undergo repetitive outgrowth and branch at invariant positions. However, they develop asymmetrically; therefore, in the mouse the right bud gives rise to four lobes (cranial, medial, caudal, and accessory), whereas the left bud gives rise to only one lobe. In humans, the left lung is trilobed, while the right lung is bilobed. The number of secondary buds on the left and right sides varies among species and is regulated by the pathways that control left-right asymmetry. As lung morphogenesis continues, branching is observed at the tip of each duct, which is driven by reciprocal interactions between the distal mesenchyme and endoderm. Lobation and lobulation of the lungs, as well as the first 16 of 23 airway generations in normal humans, is stereotypic and invariant, which implies the presence of a hard-wired, genetic program that controls early embryonic lung branching morphogenesis. The latter seven generations of lower airway branching and onward into the folding and expansion phase of the alveolar surface are nonstereotypic, but nevertheless follow a recognizable, proximal-distal fractal pattern that is repeated automatically at least 50 million times. The lung morphogenetic program thus drives the formation of an alveolar gas diffusion surface 1 μ thick by 70 m^2 in surface area in humans that is perfectly matched to the alveolar capillary and lymphatic vasculature. This huge gas exchange surface area is packed into the chest in a highly spatially efficient manner, and is supplied by a circulation capable of delivering 25 L/min of blood at maximal exercise.

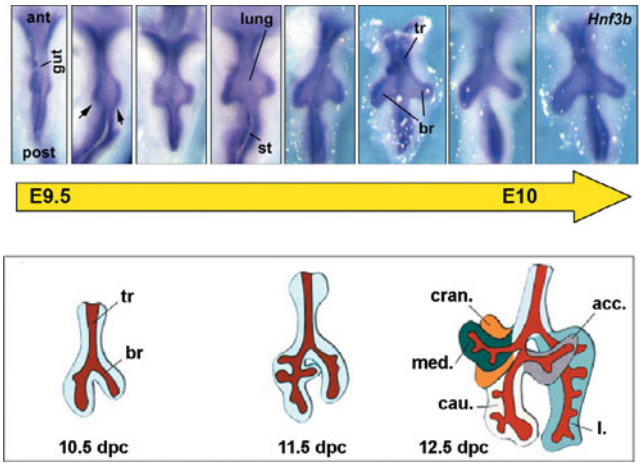

Figure 4-1 Mouse lung branching morphogenesis illustrated by *Hnf3β* expression. Mouse lung development starts at E9.5 with the emergence of two primary buds from the ventral foregut At E10.5, the lung comprises a trachea (tr) and two bronchi (br), arising from the esophagus (oe). Abbreviations; (ant) anterior, (post) posterior, (st) stomach, (cran) carnail lobe, (med) medial lobe, (cau) caudal lobe, (acc) accessory lobe.

Histologically, lung development has been divided into four stages. Following the establishment of the trachea and primary buds, development of the respiratory tree transits through four stages (Fig. 4-2): (1) pseudoglandular stage (E9.5–16.5 in mouse), characterized by the development of the bronchial and respiratory tree and a relatively undifferentiated distal endoderm and vascularization begins; (2) canalicular stage (E16.5–17.5), when the distal endoderm begins to form terminal sacs; (3) saccular stage (E17.5–P5),

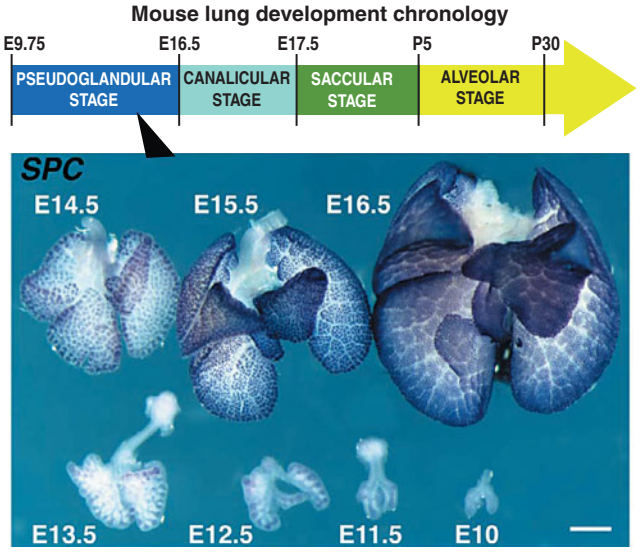

Figure 4-2 Stages of lung development. Histologically, lung development is divided into four stages in mouse; pseudoglandular (E9.5–16.5), canalicular (E16.5–17.5), saccular (E17.5–P5), and alveolar stages (P5–P30). Herein the development of the mouse bronchial and respiratory tree during the pseudoglandular stage is illustrated by *SP-C-lacZ* expression.

characterized by thinning of the mesenchyme, increase in the number of terminal sacs, and vascularization and differentiation of the endoderm into type I and type II cells; (4) alveolar stage (P5–P30), when the terminal sacs develop into mature alveolar ducts and alveoli. Unlike in the mouse, the alveolarization of the human lung begins before birth.

The larynx and trachea are genetically distinguishable from the distal airways. The mechanisms responsible for the initial specification of the lung primordia are not yet fully known. However, several genes have been shown to play a role in the very early development of the trachea and primary lung buds after initial specification.

Null mutation of *Hnf3β* results in failure of closure of the primitive foregut; thus, no laryngotracheal bud can form. Hnf3β functions as a survival factor for the endoderm and regulates *Sp-B* transcription.

Retinoic acid deficiency in mice has long been associated with total agenesis of the lungs, in association with other complex anomalies. Embryos double homozygous for null mutations in the genes encoding RARα and RARα2 are among the few known causes of complete laryngo-tracheo-pulmonary agenesis in mice. RA functions at several stages of lung development. *Raldh2* is a critical enzyme in the RA synthetic pathway that is expressed extensively in the foregut around the time of lung bud formation and subsequently in the lung mesenchyme during the pseudoglandular stage. Moreover, embryos transgenic for a RARE-lacZ reporter gene show that signaling through RA receptors is active in the lung from E10 up to at least E14, with the maximum activity shifting from the mesenchyme and endoderm to the pleura. Exogenous RA added to lung organ cultures results in proximalization of the endoderm. Recently, it has been shown that retinoic acid induces *Fgf10* expression in the mesoderm subjacent to the site of origin of the laryngotracheal groove. Blockade of RAR signaling in E9 foregut cultures not only blocks the local expression of *Fgf10* at this restricted site, but also disrupts expression of *Ttf1* and *Sp-C* in the floor of the primitive pharynx. Thus, retinoic acid signaling may connect formation of the laryngo-tracheal groove with activation of *Fgf10*–dependent bronchial morphogenesis.

Another of the earliest indications of the site of primary bud formation is the expression of *Bmp4* in two patches of the ventral foregut mesoderm.

The gene encoding the homeodomain protein TTF1 (Nkx2.1, c-ebp1) is expressed in the foregut endoderm and is required for the development of the thyroid, thymus, and lung. In $Ttf1^{-/-}$ embryos the trachea and esophagus do not separate and there are only very small or grossly cystic lung buds that do not express *Bmp4* in the endoderm.

The signaling factor Sonic Hedgehog (Shh) is expressed in the ventral foregut endoderm and throughout the endoderm of the primary buds and early respiratory tree, with the highest levels in the most distal tips. By contrast, the gene encoding the patched receptor (*Ptc*) for SHH is expressed in the adjacent mesoderm. In $Shh^{-/-}$ embryos, the trachea and primary buds fail to separate from the esophagus, resulting in a condition similar to the human birth defect

tracheo-esophageal fistula. The primary buds remain as small sacs and do not grow out or branch. Abnormal tracheal and bud morphogenesis is also seen in $Gli2^{-/-}$, $Gli3^{-/-}$, and $Gli2^{-/-}/Gli3^{+/-}$ compound mutants, probably reflecting a function for Gli proteins in the SHH signaling pathway in the foregut mesoderm.

Haploinsufficiency of *Foxf1*, which is itself a SHH target, causes esophageal atresia and tracheo-esophageal fistula. Spatial expression of SHH plays a key role in determining correct patterning of the tracheal cartilages, since peripheral misexpression of *Shh* under the control of the *Sp-C* promoter fails to rescue tracheal cartilage morphogenesis on the *Shh* null background.

FGF 10 signaling is absolutely required for lung morphogenesis distal to the carina. Embryos mutant or defective in signaling for either *Fgf10* or its cognate receptor *Fgfr2IIIb* survive to birth and develop a dysplastic trachea and primary bronchi, but no respiratory tree distal to this. The similarity of these phenotypes reflects the very localized expression of *Fgf10* in the distal mesoderm around the early lung buds and *Fgfr2IIIb* in the endoderm.

Hoxa3 and *5* also play key roles in specifying the larynx and trachea. In *Hoxa-5*$^{-/-}$ mice, tracheal occlusion and respiratory distress are associated with a marked decrease in surfactant protein production, together with altered gene expression in the pulmonary epithelium. Since *Hoxa-5* expression is restricted to the lung mesenchyme, the null mutant phenotype strongly supports the inference that *Hoxa-5* expression is necessary for induction of epithelial gene expression by the underlying mesenchyme.

Gata-6 is required for the differentiation of visceral endoderm. Thereafter, GATA-6 controls the differentiation of the alveolar type II cells and the expression of *Sp-C* and *Sp-A*.

Further evidence for distinctly separate embryonic cell lineages that form the trachea and proximal bronchi versus the peripheral lung was provided by tetracycline-driven *Sp-C-Cre* recombination, which activated lineage marker expression within the peripheral lung but not the trachea, upper bronchi or gastrointestinal tract. Non-overlapping cell lineages of conducting airways (trachea and bronchi), as distinct from those of peripheral airways (bronchioles, acini, and alveoli), were established well before formation of the definitive lung buds at E9–9.5.

GROWTH FACTOR SIGNALING DURING LUNG DEVELOPMENT

Fibroblast growth factor expression and signaling are required for distal lung morphogenesis and instruct directional growth of the epithelial buds.

Many FGFs have been implicated in multiple aspects of vertebrate development. FGF 1, 2, 7, 9, 10 and 18 play overlapping, yet distinct roles in the lung. *Fgfr1, 2,* and *3* encode two receptor isoforms (termed IIIb or IIIc) that are generated by alternative splicing; each binds a specific repertoire of FGF ligands. FGFR2-IIIb (FGFR2b) is found mainly in epithelia and binds four known ligands (FGF1, FGF3, FGF7, and FGF10), which are primarily expressed in mesenchymal cells. The expression of the FGFR2-IIIc (FGFR2c) isoform is restricted to lung mesenchyme and is known to bind to six ligands (FGF1, FGF2, FGF4, FGF6, FGF8, and FGF9).

Overexpression of a dominant negative form of *Fgfr2* in the embryonic lung under the control of the *Sp-C* promoter first clarified the role of Fgfr2-IIIb during embryogenesis. Embryos transgenic for this truncated receptor without a kinase domain, died at birth due to severe pulmonary aplasia. Only the trachea and two elongated primary bronchi developed. Overexpression of a soluble dominant negative receptor, consisting of the extracellular domain of Fgfr2 led to an even more severe reduction in branching morphogenesis and confirmed these results. While mice null for the *Fgfr2* gene die early during embryogenesis, mutant embryos defective in signaling for *Fgfr2IIIB* die at birth of the same severe pulmonary hypoplasia phenotype. They develop a trachea and primary bronchi, but no distal respiratory tree. On the other hand, FGFR3 and FGFR4 rather have a postnatal role, as double mutant mice for $Fgfr3^{-/-}$ and $Fgfr4^{-/-}$ die after birth due to defects in alveogenesis.

The broad domain of expression of Fgfr2-IIIb throughout the epithelium during the early stages of lung development suggests that the ligand controlling branching would be expressed in a more restricted way in the distal mesenchyme. Moreover, the ligand must be expressed in the distal mesenchyme from the start of lung development at E9.5. The FGFR2-IIIb isoform is able to bind several members of the FGF family: FGF1, FGF3, FGF7, and FGF10. However, FGF1, FGF7, and FGF10 are all three expressed in the lung.

FGF10 activity has been associated with instructive mesenchymal-epithelial interactions, such as those that occur during branching morphogenesis. In the developing lung, *Fgf10* is expressed focally in distal mesenchyme adjacent to stereotypically determined branching sites (Fig. 4-3). High levels of *Fgf10* expression are detected in the mesenchymal cells, some distance from the epithelium at the focal sites adjacent to the places where secondary branches later emerge. Moreover, its dynamic pattern of expression and ability to

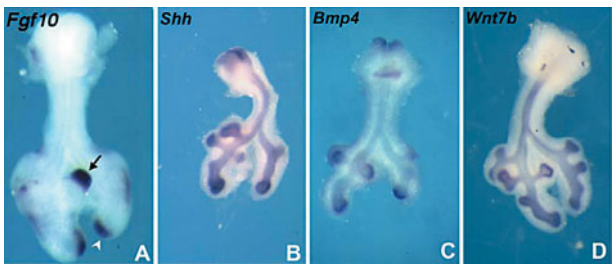

Figure 4-3 Gene expression in early mouse lung between E11.5 and E12. *A. Fgf10* is expressed in the distal mesenchyme at sites of budding (arrows). *B. Shh* is expressed throughout the epithelium. Note that its expression is up-regulated at sites of budding. *C. Bmp4* is expressed at high levels in the distal epithelium. *D.* Lung at E12, *Wnt7b* is expressed in the distal epithelium.

induce epithelial expansion and budding in organ cultures have led to the hypothesis that FGF10 governs the directional outgrowth of lung buds during branching morphogenesis. However, an equally important factor in determining the specificity of the FGF signaling response may be the presence or absence of key downstream intermediate genes. For example, the tyrosine protein phosphatase Shp2 is present in embryonic lung branch tips and plays a key role in determining when and where branching occurs. Shp2 also is essential for FGF signal transduction.

FGF7 is expressed in the mesenchyme surrounding the epithelium from E14 onwards. However, this late and broad expression rules out a role in directing the first round of branching. FGF7 function has been tested in vitro and in vivo. Isolated pulmonary endoderm cultured in Matrigel, in the presence of FGF7, does not form a bud, but a cystlike structure. Moreover, embryos overexpressing *Fgf7* under the control of the *Sp-C* promoter in the distal epithelium present a phenotype resembling pulmonary cystadenoma. This malformation is characterized by expansion of the distal parts of the branches because of the overproliferation of the epithelium and disturbances in the exchange of fluids. FGF7 is regarded to be a growth factor controlling the proliferation and differentiation of the epithelium. However, the function of FGF7 clearly can be compensated for by other factors because the $Fgf7^{-/-}$ mice do not present severe pulmonary defects.

FGF1 is expressed starting from E13.5 in the mesenchyme and the distal epithelium, while afterward its expression is restricted to the epithelium. Like FGF7, FGF18 appears to play a role in mediating postnatal lung. In in vitro culture, isolated endoderm ramifies after treatment with FGF1. Nevertheless, the chemotactic effect of FGF1 on the epithelium is less marked compared to FGF10.

Regulated expression of Heparan sulfate (HS) at sites of budding, with distinct patterns of HS sulfation in the epithelial-associated basement membrane and mesenchyme, influences lung pattern formation by mechanisms that include regulation of FGF10 protein distribution and binding to its epithelial receptor. Decreased HS sulfation results in a reduced binding for FGF10; hence, FGF10 diffuses following a rapidly changing gradient of HS from low O-sulfated HS in the mesenchyme where FGF10 is highly expressed to the epithelium with more highly sulfated HS in its basement membrane. The epithelium functions in this way as an effective FGF10 sink by effectively competing with the weaker binding sites in the mesenchyme. Sulfated domains of HS moieties can dictate specificity of FGF-FGFR binding. Without O-sulfated HS, lung epithelial cultures only survive when treated with FGF7 and not FGF10, both of which are FGFR2B ligands. FGF7 is less sensitive to regulation by HS, and heparan sulfation is suggested as a mechanism that prevents widespread activation of FGFR2B signaling in FGF-dependent branching structures.

Furthermore, FGF10 has been shown to trigger chemotaxis and proliferation on the adjacent epithelium. This results in directional growth of the primary lung buds. The chemotaxis response of the lung endoderm to FGF10 involves the coordinated movement of an entire epithelial tip, containing hundreds of cells, toward an FGF10 source. How this population of cells monitors the FGF gradient and which receptors trigger this effect remains unknown. Consistent with these observations, mice deficient for *Fgf10* show multiple organ defects including lung agenesis.

FGF10 also controls the differentiation of the epithelium by inducing *Surfactant protein C (SP-C)* expression and up-regulating the expression of *Bmp4*, a known regulator of lung epithelial differentiation.

In vitro binding assays have shown that FGF10 acts mostly through FGFR1b and FGFR2b. While there is good evidence that FGF10 acts through FGFR2b in vivo, there are as yet no conclusive data involving FGFR1b (or any other receptor) in vivo. The biologic activities mediated through these two epithelial receptors are likely to be different as FGF7 (acting mostly through FGFR2b) exhibits a different activity compared with FGF10.

FGF10 is the main ligand for FGFRIIIb during the embryonic phase of development, as evidenced by the remarkable similarity of phenotypes exhibited by embryos in which these genes have been inactivated. Mice deficient for *Fgfr2IIIB* or *Fgf10* show agenesis and dysgenesis of multiple organs, including the lungs, indicating that signaling through this receptor is critical for mesenchymal-epithelial interactions during early organogenesis. This idea is supported by the recent finding that prenatally induced misexpression of a dominant negative FGFR2b, to abrogate FGF signaling, results in a hypoplastic, emphysematous lung phenotype. In contrast, induced abrogation of FGF signaling postnatally did not produce any recognizable phenotype.

Another FGF, *Fgf9* is expressed in epithelium and mesothelium until E12.5 but is thereafter restricted to the mesothelium, a thin serous membrane enveloping the lung. The mesothelium is composed of a monolayer of flat cells of mesodermal origin. The *Fgf9* expressed in the mesothelium acts as a proliferative growth factor on the underlying mesenchyme, mostly through the receptor FGFR2-IIIC.

Fgf18 is expressed abundantly in the lung. $Fgf18^{-/-}$ mice show defects in alveogenesis but epithelial differentiation per se appears normal.

POSITIONING AND REGULATION OF FGF10 EXPRESSION IN THE LUNG BUD

Positioning and induction of the lung bud are determined through localized expression and action of FGF10. How the expression domain of *Fgf10* is controlled is still not fully understood. In the chick embryo, *Fgf10* expression in the lung is under the control of TBX4, a transcription factor of the T-box family. Ectopic TBX4 induced ectopic bud formation in the esophagus by activating the expression of *Fgf10*. Ectopic TBX4 or FGF10 then also induced ectopic expression of TTF1 which is a specific marker for the lung endoderm.

Conversely, interference with TBX4 function resulted in repression of *Fgf10* expression and failure of lung bud formation. Hox genes are also involved in defining the *Fgf10* expression domain. *Fgf10* expression is localized around the anterior border of the Hoxb-6 expression domain. *Hoxb-6* and *EphA4* exhibit a mutually exclusive expression profile whose boundaries demarcate the *Fgf10* expression domain at the prospective primary bronchus position.

Sprouty family members function as inducible negative regulators of FGF signaling in lung development. FGF10 induces the expression of its own antagonist, *Sprouty2 (Spry2)*, in the distal epithelium. *mSpry2* is localized to the distal tips of the embryonic lung epithelial branches and is down-regulated at sites of new bud formation.

On the other hand, *mSpry4* is predominantly expressed throughout the distal mesenchyme of the embryonic lung and its expression is induced by FGF acting on the mesenchyme.

Abrogation of *mSpry2* expression in cultured lungs using antisense oligonucleotides stimulates murine lung branching morphogenesis and up-regulated expression of specific lung epithelial maturation/differentiation markers. Conversely, targeted overexpression of *Spry2* in peripheral lung epithelium either under the control of the *SP*-C promoter or by intratracheal microinjection of an adenovirus containing the *mSpry2* cDNA, results in a lower level of branching, smaller lungs with a particular dysplastic appearance along the edges of the lobes and a decrease in epithelial cell proliferation.

In *Drosophila,* in vitro coprecipitation studies show that Spry binds to Gap1 and Drk (a Grb2 ortholog), resulting in inhibition of the Ras-MAPK pathway. Upon further investigation of the mechanism by which mSPRY2 negatively regulates FGF10 in mouse lung epithelial cells (MLE15), it was recently determined that mSPRY2 differentially binds to FGF downstream effector complexes that also contain Shp2, Spry2, Grb2, Sos, and Ras.

Shp2 is essential for FGF signal transduction. Shp2 is spatio-temporally expressed in embryonic lung branch tips and plays a key role in determining when and where branching occurs. Thus, localized expression of Shp2 may play a key role in specifying when and where FGF signals shall be transduced in the lung epithelium and thus may determine the spatio-temporal patterning of airway branches.

Spry is not only found downstream in the FGFR pathway, but also appears to be an inhibitor of other tyrosine kinase signaling pathways such as EGF and Torso. It is also interesting to note that overexpression of *Spry* in chick limb buds results in a reduction in limb bud outgrowth that is consistent with a decrease in FGF signaling. This suggests a possible coregulatory relationship between FGF signaling and Spry during development. In further support of this model, *Spry4* inhibits branching of endothelial cells as well as sprouting of small vessels in cultured mouse embryos. Endothelial cell proliferation and differentiation in response to FGF and VEGF are also inhibited by *mSpry4*, which acts by repressing ERK activation. Thus, *Spry4* may negatively regulate angiogenesis.

Sonic hedgehog (*Shh*) is essential for tracheoesophageal septation as well as distal branching and modulates *Fgf10* expression.

Shh is expressed throughout the endoderm with highest levels at the most distal tips. By contrast, the gene encoding the patched receptor (*Ptc*) for SHH, is expressed mostly in the adjacent mesoderm. In $Shh^{-/-}$ embryos, the trachea and primary buds fail to separate from the esophagus. The primary buds also remain as small sacs and do not grow out or branch. However, proximo-distal differentiation of the endoderm is preserved in the *Shh* null mutant, at least as far as expression of *Sp-C* and *Clara cell protein 10* are concerned.

The expression of the SHH receptor, *Ptc*, is decreased in the absence of *Shh,* as are the *Gli1* and *Gli3* transcriptional factors. *Fgf10* expression, which is highly spatially restricted in wild-type, is up-regulated and widespread in the mesenchyme in contact with the epithelium of the *Shh* null mutant mouse lung. On the other hand, overexpression of *Shh* in the mouse lung epithelium using a transgenic approach results in severe alveolar hypoplasia and a significant increase in interstitial tissue, together with reduced *Fgf10* expression. Thus, *Shh* signaling to the mesenchyme negatively regulates *Fgf10* expression, and the resulting misregulation of *Fgf10* in *Shh* mutant lungs most likely accounts for the observed failure of secondary branching. Conversely, local suppression of SHH signaling by the induction of *Shh*-binding proteins such as *Ptc* and *Hip* in the mesenchyme at branch tips may serve to facilitate FGF signaling locally where branch outgrowth is stereotypically programmed to take place. Thus, temporospatial restriction of *Fgf10* expression by SHH appears to be essential to initiate and maintain branching of lung.

Bone morphogenetic protein 4 (*BMP4*) controls proliferation, branching, and proximal-distal differentiation of the lung epithelium. *Bmp4* expression is first detected in the ventral mesenchyme of the developing lung when the primordial lung buds are emerging from the foregut. This mesenchymal expression is maintained until E13.5. Expression of *Bmp4* is also detected in the distal endoderm of the developing lung bud. Overexpression of *Bmp4*, driven by the Sp-C promoter in the distal endoderm of transgenic mice, causes abnormal lung morphogenesis, with cystic terminal sacs and inhibition of epithelial proliferation. *Bmp4* is induced at the tip of the growing lung buds in response to mesenchymal Fgf10. In isolated E11.5 mouse lung endoderm cultured in Matrigel, addition of exogenous BMP4 prevented further budding, in response to FGF10, therefore ensuring a single extending bud, rather than a cluster of buds.

Based on these results, BMP4 was postulated to mediate localized suppression of epithelial proliferation, thus providing a negative modulatory influence on FGF signaling to mediate arrest of branch extension and hence to set up branch points. However, two groups have now shown that BMP4 added at physiologic concentrations to intact embryonic lung explant cultures, thus in the presence of mesenchyme, is actually a potent stimulator of branching. Moreover, the effects of BMP4 are in turn negatively modulated by the BMP binding proteins Gremlin and Noggin.

Abrogation of Gremlin function results in septation defects of the lung airway epithelium, resulting in decreased numbers of differentiated alveoli in *Grem1*-deficient newborn mice. *Sp-C* promoter-driven over expression of either the BMP antagonist *Xnoggin* or a dominant negative *Alk6* BMP receptor to block BMP signaling, results in severely reduced distal epithelial cell phenotypes and increased proximal cell phenotypes in the lungs of transgenic mice. It thus seems unlikely that BMP4 signaling merely serves to inhibit epithelial proliferation, particularly since BMP4 specific Smads are also expressed in the mesenchyme away from the epithelium at certain developmental stages. However, the exact roles of BMP4 in early mouse lung development remain controversial.

Several additional *Bmps*, including *Bmp3, 5 and 7*, are expressed during embryonic lung development. The expression of *Bmp5* and *Bmp7* has been detected in the mesenchyme and the endoderm of the developing embryonic lung respectively, while *Bmp4* expression is restricted to the distal epithelial cells and adjacent mesenchyme.

Wnt signaling controls epithelial and mesenchymal differentiation and plays an important role in lung branching.

The Wnt growth factor family in the mouse, is comprised of 19 different secreted ligands that interact with 10 known seven transmembrane receptors of the Frizzled (Fz) gene family and either one of two single-span transmembrane proteins, low-density-lipoprotein-receptor–related proteins (LRP-5 and LRP-6). Historically, Wnt proteins have been grouped into two classes, canonical and noncanonical. Canonical Wnts bind to frizzled receptors, inhibiting glycogen-synthase kinase-3β (GSK-3β)–mediated phosphorylation of β-catenin. Hypophosphorylated β-catenin accumulates in the cytoplasm, after which it translocates to the nucleus, where it heterodimerizes with members of the TCF/LEF transcription factor family to activate the transcription of TCF/LEF target genes. Noncanonical Wnts activate other Wnt signaling pathways, such as the planar-cell-polarity (PCP)–like pathway that guides cell movements during gastrulation. Activation of Non-canonical pathway, can antagonize the canonical pathway intracellularly. Secreted Wnt antagonists can be divided into two functional classes, the secreted Frizzled-related protein (sFRP) class and the Dickkopf class. Members of the sFRP class bind directly to Wnts, thereby altering their ability to bind to the Wnt receptor complex, while members of the Dickkopf class inhibit Wnt signaling by binding to the LRP5/LRP6 component of the Wnt receptor complex. In addition to LRP5/6, DKK1 interacts with the high-affinity DKK1 co-receptors Kremen1 (Krm1) or Kremen2 (Krm2), which functionally cooperate with Dkk1 to block Wnt/beta-catenin signaling. DKK1, DKK3, and DKK4 act as inhibitors of canonical Wnt signaling, while DKK2 can function both as an inhibitor in the presence of Kremen2 or as an activator in its absence.

Between E10.5 and 17.5, β-catenin is localized in the cytoplasm and often also in the nucleus of the pulmonary epithelium and adjacent mesenchyme. Wnt ligands, Fz receptors, and the Tcf/Lef1 transcription factors are expressed during early lung development. In the early mouse lung (at E12.5), different Wnts have been reported to be expressed in the developing lung (*Wnt2, Wnt2b, Wnt5a, Wnt7b,* and *Wnt11*). Fully expressed mostly in the distal mesenchyme, *Wnt2b* is expressed in the distal mesenchyme between the epithelial branches, *Wnt7b* is expressed in the lung epithelium with a more intense expression distally, *Wnt2a* is highly expressed in the distal mesenchyme, and *Wnt5a* shows a low expression in the mesenchyme and epithelium and is highest around the trachea and pharynx. *Tcf1* (T-cell factor1), *Lef1* (lymphoid enhancer factor 1), *sFrp1* (secreted Frizzled-related protein 1), and *sFRP2* are highly expressed in the mesenchyme adjacent to the pulmonary epithelium. *Tcf3* is highly expressed at the apical side of the pulmonary epithelium, while *Tcf4* and *sFrp4* are detected in both the epithelium and adjacent mesenchyme. *Fz8* is highly expressed throughout the epithelium, while *Fz2, 3, 6,* and *7* are expressed both in the epithelium and mesenchyme. These expression patterns suggest that Wnt signaling can originate from the epithelium and mesenchyme and can target both tissues in an autocrine and/or paracrine fashion. TOPGAL or BATGAL mice, which harbor a β-*galactosidase* gene under the control of a LEF/TCF and β-catenin–inducible promoter, reveal that from E10.5 until E12.5, canonical Wnt signaling occurs throughout the epithelium and in the mesenchyme adjacent to the proximal airways where the bronchial smooth muscle cells (SMC) arise. From E13.5 TOPGAL activity is no longer present in the mesenchyme and the activity in the epithelium is reduced distally concomitant with the onset of *Dkk1* expression in the distal epithelium.

Conditional inactivation of the β-catenin gene in the epithelium of the developing mouse lung leads to neonatal death resulting from severe lung defects. Branching of secondary bronchi is altered and the number of small peripheral alveolar ducts and terminal saccules is markedly reduced. In addition, the epithelium fails to undergo proper distal differentiation, lacking the expression of pro–*SP-C* protein and vascular endothelial growth factor A *(VegfA)*, the latter correlating with a reduction in alveolar capillaries. So far, inactivation of only two WNT ligands has resulted in lung defects. The inactivation of *Wnt2a* did not show a lung phenotype, probably due to compensatory effects from other Wnts such as *Wnt2b* and *Wnt11* normally expressed in epithelial cells of the lung periphery. $Wnt7b^{-/-}$ mice exhibit perinatal death due to respiratory failure. Defects were observed in proliferation of the lung mesenchyme resulting in lung hypoplasia. In addition, $Wnt7b^{-/-}$ embryos and newborn mice exhibit severe defects in the smooth muscle component of the major pulmonary vessels, with increased apoptosis of the vascular smooth muscle cells (VSMCs), resulting in rupture of the major blood vessels and hemorrhages in the lungs after birth. *Wnt5a* is expressed at high levels in the distal lung mesenchyme. $Wnt5a^{-/-}$ mice die perinatally from lung defects including truncation of the trachea, overexpansion of the peripheral airways, and delayed lung maturation. Absence of WNT5a activity in the mutant lungs leads to increased cell proliferation and up-regulation of the expression

of *Fgf10*, *Bmp4*, *Shh,* and *Ptc*. On the other hand, hyperactive Wnt signaling changes the developmental potential of embryonic lung endoderm to express markers of gut endoderm differentiation.

VEGF isoforms induce vasculogenesis, angiogenesis, and lymphoangiogenesis during lung development. Vascularization must perfectly match epithelial morphogenesis to ensure optimal gas exchange. Several VEGF isoforms are expressed in the developing epithelium, whereas their cognate receptors are expressed in and direct the emergence of developing vascular and lymphatic capillary networks within the mesenchyme. It is possible that VEGF signaling may lie downstream of FGF signaling, since in vivo abrogation of FGF signaling severely affects both epithelial and endothelial morphogenesis. Vasculogenesis is initiated as soon as the lung evaginates from the foregut. VEGF is a critical growth factor during embryonic lung development. The loss of even a single allele of *Vegf* leads to embryonic lethality between days E9.5 and E10.5 in the mouse. VEGF is diffusely distributed in pulmonary epithelial and mesenchymal cells and is involved in controlling endothelial proliferation and the maintenance of vascular structure. VEGF is localized in the basement membrane of epithelial cells.

Both humans and mice have three different VEGF isoforms. VEGF-120, VEGF-164, and VEGF-188 are all expressed in mice during development, but VEGF-164 isoform is the most highly expressed and active during embryogenesis. VEGF signals through the cognate receptors FLK-1 (fetal liver kinase-1 or VEGFR2) and FLT-1 (fetal liver tyrosinase-1 or VEGFR1). VEGF signaling is responsible for the differentiation of embryonic mesenchymal cells into endothelial cells. Interactions between the epithelium and mesenchyme contribute to lung neovascularization, which is crucial in normal lung formation. In fact, epithelial cells of the airways are positive for VEGF, particularly at the budding regions of the distal airway. Also, lung mesenchyme cultured alone in the absence of epithelium degenerates significantly and only a few*Flk-1*–positive cells are maintained. *Vegf* misexpressing transgenic mice, where the *Vegf* transgene is under the control of the *SP-C* promoter, show gross abnormalities in lung morphogenesis that are associated with a decrease in acinar tubules and mesenchyme. VEGF-treated human lung explants show an increase of cellular proliferation in the distal airway epithelial cells with an up-regulation of the mRNA expression of *Sp-A* and *Sp-C* but not *Sp-B*.

VEGF also has been demonstrated to play a role in maintaining alveolar structure. Lungs from newborn mice treated with antibodies to FLT-1 are reduced in size and display significant immaturity with a less complex alveolar pattern. In contrast, the accumulation of VEGF in the alveoli appears to make transgenic VEGF mice more resistant to injury by hyperoxia. VEGF is a target of hypoxia-inducible transcription factor-2α (HIF-2α). *Hif-2α* deficient newborn mice die from respiratory distress syndrome. In *Hif-2α* null mice the expression of VEGF is dramatically reduced in alveolar epithelial type II cells. Additionally we have recently observed that addition of VEGF to early mouse embryonic lung explants markedly stimulates epithelial as well as vascular morphogenesis. Thus we speculate that VEGF signaling plays an important role in matching the epithelial-capillary interface during lung morphogenesis.

VEGF-C and VEGF-D are two additional members of the VEGF family. These factors have a restricted expression pattern, with high levels mainly in lung tissues. VEGF-C and -D stimulate lymphoangiogenesis through their cognate receptor VEGFR-3. Signaling via VEGFR-3 has been shown to be sufficient for lymphoangiogenesis through null mutation. Finally, VEGF-C also interacts with VEGFR-2, and therefore is able to induce angiogenesis in vivo.

PROXIMAL-DISTAL DIFFERENTIATION OF THE LUNG ENDODERM

Epithelial cell lineages are arranged in a distinct proximodistal pattern in the airways. The larynx is lined with squamous epithelium and the upper airways are lined with ciliated columnar cells that express the forkhead gene *Hfh4* and mucus-secreting cells. The lower airways are lined with Clara cells, which secrete a protein called Clara cell 10 kD protein, or CC10. The alveoli are lined with alveolar type I and II epithelial cells (AEC 1 and 2). In the adult lung the type I cells lie in close apposition to the capillaries of the alveoli, whereas the type II cells tend to be positioned in the corners of the alveoli. Type II cells (AEC2) have the potential to transdifferentiate into type I cells (AEC1). AEC2 cells are characterized by their expression of the gene for surfactant protein C (*Sp-C*) and are responsible for the synthesis of the lipoprotein complex termed pulmonary surfactant. AEC1 cells comprise the gas diffusion surface and express a limited number of specific markers, including aquaporin 5 and T1α. Within the AEC2 population lies a specific subpopulation of cells with progenitor characteristics such as relatively high resistance to oxygen, high levels of telomerase expression, and lack of e-cadherin expression. These cells may perform developmental and reparative functions to maintain the alveolar surface. Pulmonary neuroendocrine (PNE) cells are the first airway epithelial cells to form an identifiable subpopulation at around E15 in mouse. PNE cells are situated in small crests or foci and are surrounded by other epithelial cells in the upper airways. PNE cells secrete peptides such as bombesin and calcitonin gene-related peptide, but their precise function is unknown. They also express high levels of *Delta1* (Dlt1), encoding a surface ligand for Notch that may function in determining cell fate. PNE cells are completely lacking in mice null mutant for the forkhead family transcriptional factor *Mash1*. The airway epithelial cells uniformly express *Fgfr2* and *Hnf3*α (*Foxa1*) and β (*Foxa2*). The epithelial and mesenchymal cells at the very tips of the extending branches and buds have a specific pattern of gene transcription, related to intercellular signaling pathways. Genes expressed at high levels in the epithelium at the tips include *Shh, Bmp4, Wnt7b, Fgfr4,* and *c-Fos*. By contrast, the mesenchyme around the tips expresses high levels of *Fgf10, Ptc,* and *Pod1*. Thus, the distal tips are thought to be

organizing centers that contain airway epithelial progenitor cells. These centers also play key roles in regulation of both the epithelial-mesenchymal interactions that drive branching morphogenesis, as well as the proximal-distal patterning of the lung epithelium.

FORMATION OF A FUNCTIONAL RESPIRATORY UNIT (ALVEOLUS)

The alveolar stage involves the formation and maturation of the alveoli. It involves the formation of primary and secondary septa that subdivide the terminal respiratory saccules into multiple alveoli. The interstitial mesenchyme layer of each septum is initially quite substantial and contains a double capillary network that is not in very tight contact with the endodermal cells. As postnatal development in the mouse continues, the number of interstitial cells declines and the AEC 1 cells become very closely apposed to the single capillary endothelial cell network. In the mature lung the tips of the septa contain smooth muscle cells, which produce bundles of elastin fibers that are important for alveogenesis. Several gene knockouts have resulted in failure of alveogenesis. In *Elastin*$^{-/-}$ mice perinatal development of fewer distal air sacs that are dilated, with attenuated tissue septa, resulting in an emphysematous phenotype. In *Pdgfa*$^{-/-}$ mice the smooth muscle cells and elastin fibers are absent and septa fail to form, leading to postnatal death. During the pseudoglandular stage the growth factor, PDGF-A, is expressed by the distal epithelial cells and the receptor, PDGFR-A, by the surrounding mesenchyme cells, from which the smooth muscle cells derive. Finally, inactivation of both *Fgfr3* and *Fgfr4* results in a postnatal lethal pulmonary phenotype in which excess elastin is laid down and alveoli fail to form.

TOWARD AN INTEGRATED MODEL OF LUNG BRANCHING MORPHOGENESIS

As outlined earlier, different growth factors expressed either in the epithelium or mesenchyme are regulating the branching process. These factors are inducing cell proliferation, apoptosis and cell differentiation. The goal of this section is to integrate seemingly disparate data concerning the regulation of the branching process into a coherent overview (Figs. 4-4 and 4-5).

The complete cycle of budding consists of three phases: bud initiation, bud outgrowth, and growth arrest. During the initiation phase, FGF10 is so far the key molecule, and is expressed specifically in the mesenchyme adjacent to the forming epithelial buds. FGF10 expressed in the distal mesenchyme acts on the epithelium mostly through FGFR2-IIIb and promotes cell proliferation. However, in bud initiation, FGF10 also triggers chemotaxis of the epithelium (via a receptor that is not yet characterized) by modulating cell-cell and cell-extracellular matrix interactions to facilitate or

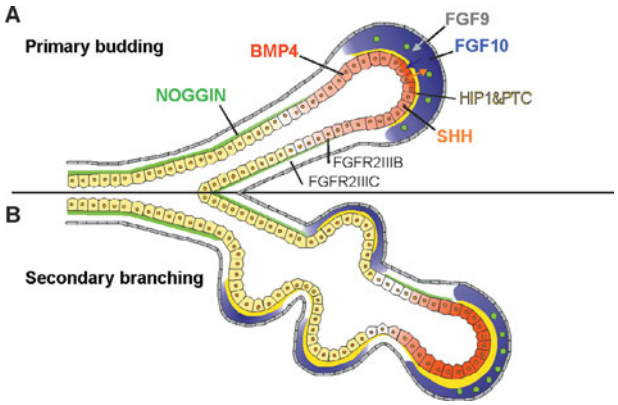

Figure 4-4 Integrated model of budding. *A.* The two primary buds initially elongate. FGF10 (blue), expressed in the distal mesenchyme, acts on the endoderm, through the FGFR2IIIB receptor isoform, to promote its proliferation (blue arrow). SHH (orange dots) is expressed in the epithelium and is up-regulated at the distal tips of the primary buds (darker orange dots). In response to FGF10 signaling, *Bmp4* (red) and *Sprouty2* expression are building up in the endoderm. Because *Fgf10* expression at the sites of future bud formation precedes *Bmp4* up-regulation and *Sprouty2* induction, lung bud outgrowth will occur before *Bmp4* and SPROUTY2 reach a critical concentration sufficient to inhibit FGF10. NOGGIN (a *Bmp4* inhibitor; green dots) is expressed in the distal mesenchyme in response to *Bmp4* signaling and at higher levels in the proximal mesenchyme near the proximal epithelium. The mesothelial layer expresses FGF9 and acts as a proliferative factor on the mesenchyme through receptor FGFR2IIIC (gray arrow). *B.* Secondary bud formation also is induced by localized FGF10 (blue) expression in the mesenchyme corresponding to the future sites of secondary bud formation. Epithelial expression of SHH might be instrumental in restricting *Fgf10* expression to the sites of secondary bud formation by inhibiting *Fgf10* expression. SHH (orange dots) is up-regulated in the epithelium of the secondary buds after the activation of *Fgf10*. However, SHH signaling to the mesenchyme transcriptionally activates *Hedgehog-interacting protein 1* (*Hip1*) and *Patched 1* (*Ptch1*) (yellow), repressors of SHH signaling, to down-regulate the SHH pathway at sites of bud formation. As a result, *Fgf10* expression gets only effectively inhibited at the inter-bud regions. As outgrowth proceeds, the expression of *Bmp4* (red) increases in the distal endoderm, which prevents FGF10 from inducing further budding from the growing lung bud. As a result, a single extending bud, rather than a cluster of buds, is generated. In response to lateral *Fgf10* expression, a new lateral, secondary bud is initiated. The mechanism by which a new *Fgf10* expression domain is initiated is unknown.

promote cell migration. On the other hand, SHH secreted by the distal epithelium induces cell proliferation in the mesenchyme through PTC and GLI. This coordinated process thus allows directional outgrowth of the buds toward the localized domain of *Fgf10* expression, until a negative feedback loop mediated by inducible negative regulators such as Spry blocks FGF signaling and hence bud outgrowth. Interestingly, the positive regulators of *Shh* and *Fgf10* expression are still unknown. For example, factors like the WNTs (*Wnt7b* is expressed in the epithelium), could positively regulate *Fgf10* expression.

During the growth arrest phase, SHH in the epithelium negatively regulates *Fgf10* expression in the mesenchyme. The

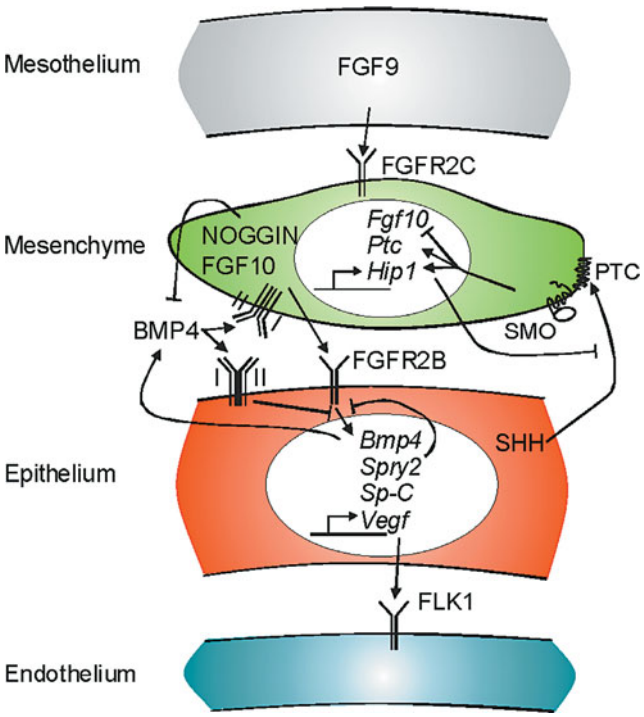

Figure 4-5 Signal integration in lung morphogenesis: mesothelial-mesenchymal-epithelial-endothelial crosstalk within the morphogenetic center at each branch tip. FGF9 is secreted by the mesothelium and activates its cognate receptor FGFR2C in the mesenchyme. Mesenchymal FGFR2C activation in turn modulates expression of *Fgf10, Ptc*, and *Hip1*. FGF10 is in turn secreted by the mesenchyme and activates its cognate receptor FGFR2B on the epithelium. This in turn modulates the epithelial expression of *Bmp4, Spry2, Sp-C,* and *Vegf*. Meanwhile, SHH is secreted by the epithelium and diffuses to the mesenchyme, where it activates its cognate receptor Ptc. SHH signaling through Ptc in turn releases SMO, which translocates to the mesenchymal nucleus, where it negatively modulates *Fgf10* and positively modulates *Ptc* and *Hip1*. HIP1 in turn negatively modulates SHH. NOGGIN is a soluble inhibitor of *Bmp4* activity, which is secreted from the mesenchyme. *Bmp4* is secreted from the epithelium and activates its cognate receptors on both the epithelium and mesenchyme. SP-C is a marker of epithelial cell differentiation down the alveolar epithelial cell lineage. VEGF in turn is secreted by the epithelium and activates cognate receptors on the endothelium of the blood and lymphatic vasculature. The net result of this complex signal integration determines the stereotypy and automaticity of branch events. WNT signaling is not depicted in this diagram, but was recently shown to be negatively modulated by Dickkopf and to determine where fibronectin matrix is laid down. This is important in determining the temporospatial location of branching events.

SHH cognate receptor, patched (PTC), exerts a negative effect on SHH signaling both through the release of the transcriptional repressor Smoothened (SMO) and the induction of the Hedgehog interacting protein (HIP). The precise nature of the inhibition of FGF10 expression is unclear, and more experiments will have to be done to determine if the inhibition is directly promoted by SHH and at what threshold level the effect is elicited. In parallel, FGF10 up-regulates *Bmp4* and *Sprouty2* expression in the epithelium, which in turn can inhibit epithelial cell proliferation and chemotaxis. In general, TGFβ family peptides exert an overriding inhibitory effect on lung epithelial cell proliferation and hence negatively regulate lung morphogenesis. However, *Bmp4* appears to exert a complex negative or positive regulatory influence, depending on whether mesenchymal signaling is intact. Wnt signaling also has emerged as exerting a critical influence on matrix fibronectin deposition and hence the specification of branch points.

Endothelium is present close to the respiratory epithelium from the earliest stage of lung morphogenesis. VEGF signaling arising from the epithelium signals to VEGF receptors on the endothelium so that morphogenesis of the epithelium and endothelium can be finely coordinated.

Development and Growth of the Lung

Johannes C. Schittny • Peter H. Burri

OVERVIEW

The lung is designed to provide a large internal surface area in which the inspired air and capillary blood get in intimate contact to each other and thus allow for an efficient exchange of gases. This goal is achieved by a sequence of distinct but overlapping developmental processes (Fig. 5-1; Table 5-1). Organogenesis (embryonic stage) starts with a ventral outpouching of the foregut giving rise to the left and right lung buds. The following development of the airways and gas exchange structures is based on two different mechanisms. Starting from the lung buds, a continuous process of branching and growth into the surrounding mesenchyme preforms the whole conducting airway tree and probably also parts of the respiratory airways (branching morphogenesis). Most of this process takes place during the pseudoglandular stage. The tremendous increase of the gas exchange surface area in late fetal and postnatal lung development is brought about by a process of repetitive airspace septation leading to the formation of alveoli (stage of alveolarization). The canalicular and saccular stages may be considered as intermediate stages between both developmental principles. In the canalicular stage the first air-blood barriers are formed and surfactant production starts. During the saccular stage the switch from branching to septation occurs.

Following bulk alveolarization, which in humans occurs mainly after birth, the interalveolar septa and their capillary networks are remodeled to optimize gas exchange during the stage of microvascular maturation. At this point lung development is viewed as finished; it is followed by normal growth of the organ. However, we assume today that some form of late alveolarization at a slow rate may exist. Relative to lung development, the time point of birth varies greatly among mammalian species. In humans, birth occurs early in the alveolar stage.

The staging of lung development as described traditionally is highly descriptive. It is based on light microscopical observations of morphologic changes in the developing lung (Figs. 5-1 and 5-2). Large overlaps exist between subsequent stages for two reasons. First, lung development proceeds metachronically from the proximal to the peripheral portions of the airway tree. Second, some developmental steps and maturation processes defining the stages may run in parallel in neighboring areas. The beginning of pulmonary development is relatively well defined by the first appearance of the future trachea and the lung buds in the region of the foregut. There is no such clear limit, however, as to when it ends during childhood. Thus, lung development slowly blends into lung growth and it boils down to a question of sophisticated definitions when development ends and growth starts.

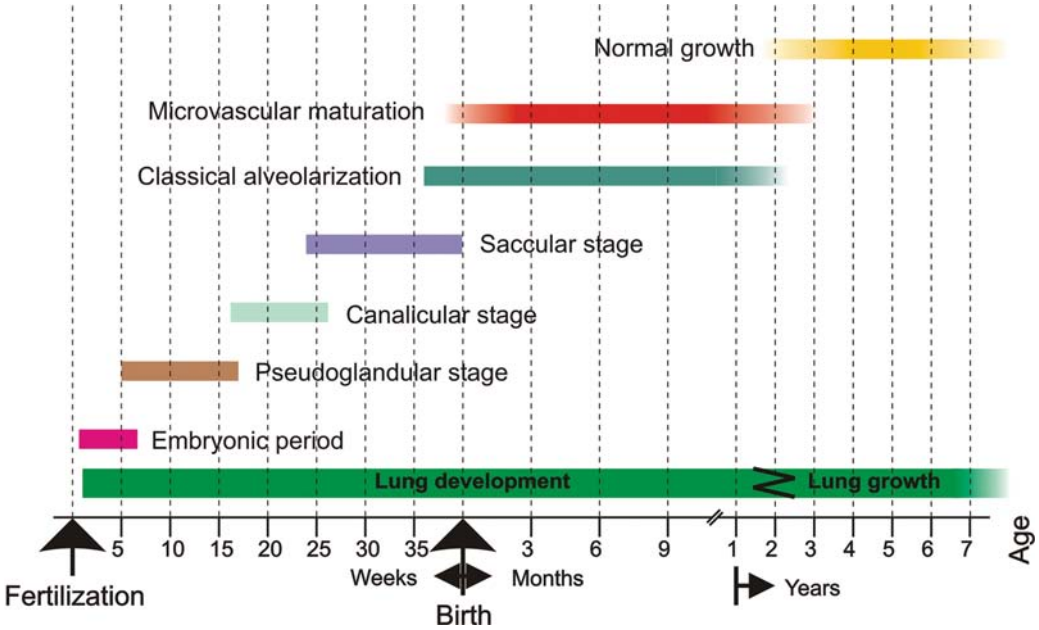

Figure 5-1 Stages of human lung development and their timing. Note overlapping between stages, particularly between the alveolar stage and the stage of microvascular maturation. Open-ended bars indicate uncertainty of the exact timing. The embryonic period is not a period specific for lung development. *(Based on Zeltner TB, Burri PH: The postnatal development and growth of the human lung. II. Morphology.* Respir Physiol *67:269–282, 1987.)*

PRENATAL LUNG DEVELOPMENT—EMBRYONIC PERIOD

Organogenesis (Weeks 4–7)

Following fertilization, the germ cells soon segregate into a cluster of trophoblastic cells to which a few embryoblastic cells adhere. The trophoblastic cells may be viewed as the future placenta, whereas the embryoblastic cells, after differentiation into the three germ layers, will form the human embryo.

Lung Anlage

The organs of the body are laid down by differentiation from the germ layers during the so-called embryonic period, which encompasses the first 7 weeks after fertilization. The lung anlage appears at day 26 as two ventral buds of the foregut at the caudal end of the laryngotracheal sulci (Figs. 5-3 and 5-4; Table 5-1). It will give rise to the left and right lung. Both buds elongate, grow into the surrounding mesenchyme, and form the left and right main bronchi (day 32) (Figs. 5-3 and 5-4). The terminal ends of the growing bronchial tree start a repetitive process of growth and mainly dichotomous branching. By day E37 the future conducting airways are preformed to the lobar, by day E41 to the segmental, and by day E48 to the subsegmental bronchi (Figs. 5-3 and 5-4). An early stage of a budding mouse lung is illustrated in Fig. 5-4.

Epithelial-Mesenchymal Interactions

As is evident from the preceding description, the high columnar epithelium of the tubular sprouts is of endodermal origin, whereas the mesenchyme is derived from the third germ layer, the mesoderm. This double origin of the lung tissues is important: many processes of lung development are dependent on the interaction between epithelium and mesenchyme. Classical transplantation experiments have shown that a cross-talk between the endodermal epithelium and the mesodermal mesenchyme is needed for the control of branching morphogenesis and cytodifferentiation, e.g., after removal of the mesenchyme at the growing tip further branching of the epithelial tubules is prevented. But when the mesenchyme of the growing tip is transplanted next to the prospective trachea, an abnormal outgrowth of bronchial branches is observed in this region.

During the last decade some of the mechanisms involved have been deciphered. Briefly, the epithelium of the growing terminal bud differs from the more proximal epithelium and the epithelium of the forming cleft, which represents the depression between the two buds. The proliferation rate is significantly elevated at the growing tip as compared to the epithelium directly proximal to it and to the one of the cleft. The basement membranes are also different. Although nidogen-1 (also known as entactin-1), collagen IV, and fibronectin are absent in the basement membrane at the growing end buds, tenascin-C is present and the latter takes part in the control of the number of branches.

In addition, a large set of factors which are secreted into the mesenchyme contribute significantly to the epithelial-mesenchymal cross-talk. These factors that are produced in both the epithelium and mesenchyme have a strong influence on the behavior of the epithelium. They include transcription factors like TTF-1, Gli2, and Gli3; as well as growth factors like FGF-10, TGF-β, BMP-4, SHH, EGF, and VEGF. No growth

Table 5-1

Stages of Lung Development and Their Time Scale

Period	Stage	Duration	Characteristics
Embryonic	Embryonic	Rabbit: n.d.–E18 Sheep: E17–E30 **Human: E26–E49 (4–7 Weeks)** Mouse: E9.5–E12 Rat: E11–E13	Start of organogenesis; formation of major airways
Fetal	Pseudoglandular	Rabbit: E18–E24 Sheep: E30–E85 **Human: E35–E119 (5–17 weeks)** Mouse: E12–E16.5 Rat: E13–E18.5	Formation of bronchial tree and large parts of prospective respiratory parenchyma; birth of the acinus
	Canalicular	Rabbit: E23–E27 Sheep: E80–E120 **Human: E112–E182 (16–26 Weeks)** Mouse: E16.5–E17.5 Rat: E18.5–E20	Completion of conducting airways; epithelial differentiation; first airblood barrier; appearance of surfactant
	Saccular or terminal sac	Rabbit: E27–E30 Sheep: E110–E140 **Human: E168–E266 (24 weeks-term)** Mouse: E17.5–P4 Rat: E21–P4	Expansion of airspaces
Postnatal	Alveolar	Rabbit: E30–term (E31) Sheep: E120–term (E145) **Human: E252 (36 weeks preterm): 1–2 years** Mouse: P4–P14 Rat: P4–P14	Alveolarization by formation of secondary septa (septation)
	Microvascular maturation	Rabbit: unknown Sheep: unknown **Human: 0–3 years** Mouse: P14–P21 Rat: P14–P21	Remodeling and maturation of intervaleolar septa and of the capillary bed
	Normal growth	Rabbit: Birth–adulthood Sheep: Birth–adulthood **Human: 2nd year–adulthood** Mouse: 4 weeks–adulthood Rat: 4 weeks–adulthood	Normal growth of the lungs

The described duration of the stages represents the time where the bulk of a particular developmental alteration takes place. Stages are overlapping, in particular the alveolar stage and the stage of microvascular maturation. In addition, regional differences are common, especially between central and peripheral regions. Litter size and nutrition also have an influence on the exact timing of development. E = embryonic day (days post-coitum); n.d. = not determined; P = postnatal day.

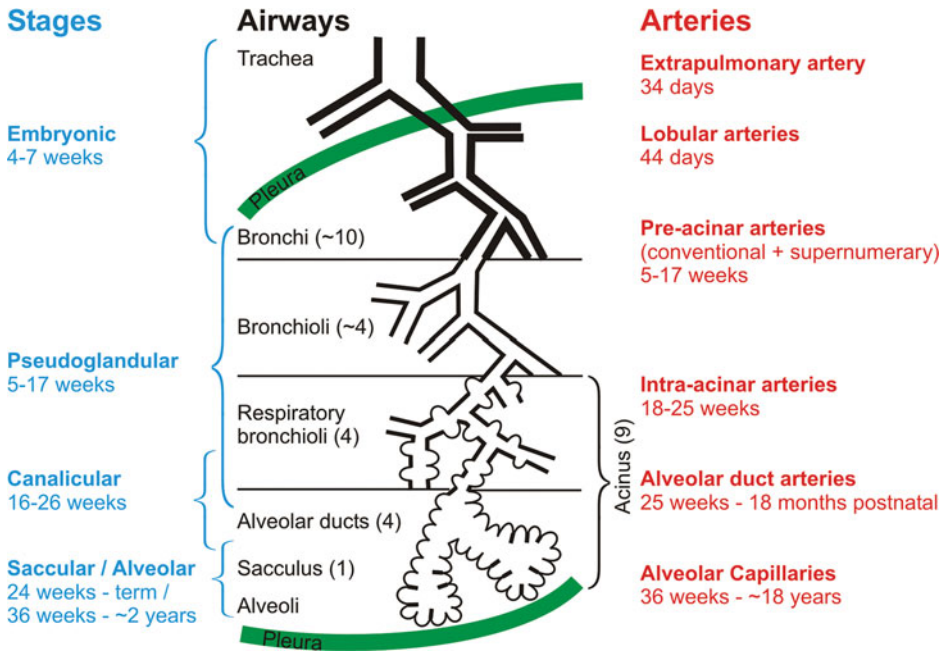

Figure 5-2 Development of the airways and arteries. The stages of lung development (blue) are correlated to the development of the bronchial tree (black) and the arteries (red). An average value of the generations formed by each category of airways is given in parentheses. On average an airway of the human lung ends after 23 generations in an alveolar saccule. In reality this number ranges from about 18 to 30. In the lung pathways are of varying lengths, partly due to space constraints in the thoracic cage. Pre-acinar arteries start as a capillary plexus surrounding the growing lung buds (vasculogenesis). Intra-acinar arteries grow by angiogenesis. *(Based on Hislop A: Developmental biology of the pulmonary circulation. Paediatr Respir Rev 6:35–43, 2005.)*

factor is able to function without its receptor. Therefore, receptors like FGFRs, EGFR, and "patched" are not of minor importance. Also involved are extracellular matrix proteins such as collagens, elastin, fibrillin, laminin-isoforms, nidogen, tenascin-C, as well as their receptors such as dystroglycan and some integrins.

During later stages of prenatal and postnatal lung development, and even in the adult lung, the interplay between differentiating pneumocytes, mesodermally derived interstitial cells, and extracellular matrix continues to be decisive for cell maturation and cell function regulation.

Development of Esophagus and Trachea

The laryngotracheal sulci of the lateral wall of the foregut are deepening and joining in parallel to the appearance of the first airway divisions. As a result the foregut is divided into the prospective trachea and the esophagus by the esophagotracheal septum (Fig. 5-3). The formation of the trachea appears to be independent of the formation of the lung buds. Because FGF10 null mice develop a trachea, but no lung buds, we must assume that trachea formation is independent of the formation of the lung buds. Toward the end of the embryonic period mesenchymal cells surrounding the prospective trachea condense focally and differentiate into cartilage precursors. Proximally, embryonic cartilage is found at the end of week 7. Cartilage formation moves distally along the future airways. Cartilage is commonly found in main bronchi around week 10 and in segmental bronchi in week 12 of gestation. However, cartilage formation continues almost until the end of the canalicular stage until it reaches its completion around the smallest bronchi (week 25). In animal studies and in the human lung, Sparrow and co-workers have demonstrated in beautiful confocal laser scanning microscopic studies that, as the primitive airways and vessels grow and divide,

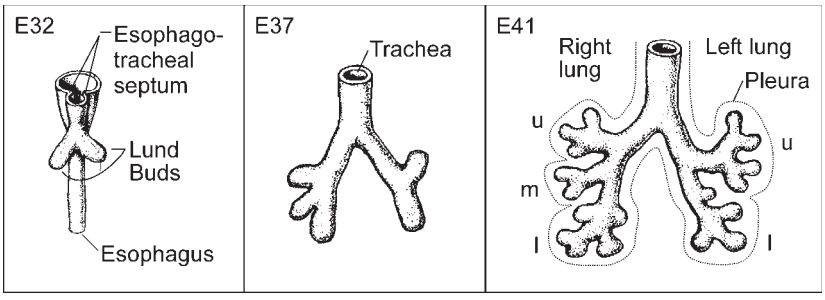

Figure 5-3 Early development of the human lung. Starting at day 26 post-coitum (pc) the anlage of the two lungs is formed by outpouchings of the foregut. The prospective trachea forms by a distal-to-proximal segregation. The lung anlage gives rise to the prospective main bronchi of the lungs at day E32 (*A*). Continuous branching results in the formation of the lobar bronchi at day E37 (*B*) and later at day E41 of the segmental bronchi (*C*). U, upper lobe; m, middle lobe; l, lower lobe. *(Modified from Sadler TW: Langman's Medical Embryology, 6th ed. Baltimore, Williams & Wilkins, 1990.)*

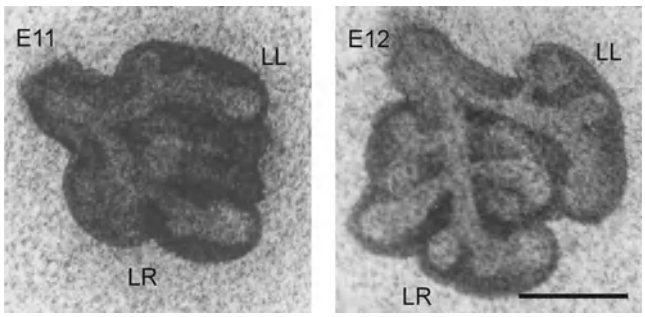

A *B*

Figure 5-4 Lung organogenesis. Freshly explanted mouse lung is shown at days E11.5 (*A*) and E12.5 (*B*) Toward the end of the embryonic period (E11.5/*A*) the visceral pleura and main bronchi of the lung lobes are formed. In mice the right lung consists of four lobes (cranial, middle, caudal, and accessory) and the left lung of only one. At the beginning of the pseudoglandular stage (E12.5/*B*) the lungs are already subdivided into definitive lobes. As seen in both lungs, the branching pattern of the bronchial tree is not dichotomous, but monopodial in mice. LL, left lung; LR, right lung. Bar = 0.5 mm.

they are already accompanied and enwrapped by a network of neural tissue comprising ganglia and nerve fibers.

Pleura and Formation of Lobes

The growing lung buds expand in caudolateral direction into the coelomic cavity. This rather narrow space consists of two canals located at each side of the foregut. They are called pericardioperitoneal canals and will be gradually filled by the growing lungs. During week 5 the pleuropericardial folds separate the pleural cavities from the pericardial cavity. These folds originate along the lateral body wall, elongate into the space between the heart and the developing lungs, and finally meet and fuse with the foregut mesenchyme. Caudally a pair of horizontal pleuroperitoneal membranes starts growing from the posterior body wall. They meet and fuse with the posterior edge of the septum transversum (weeks 5–7) and close the pleural cavities. The visceral pleura has formed by the splanchnic mesoderm, which covers the outside of the lung. The parietal pleura has formed by the somatic mesoderm layer covering the inner surface of the body wall.

As early as the visceral pleura has formed invaginations of the pleura start to separate the lobar bronchi and give rise to the lobar fissure and the lung lobes (Fig. 5-4). Little is known about the mechanisms involved. It appears, however, that the basement membrane of the visceral pleura plays a role, because mice lacking the nidogen-binding domain of the laminin-γ1-chain or the laminin-α5-chain show defective lobar septation and visceral pleura basement membrane formation.

At around 7 weeks, the period of organogenesis can be considered to merge imperceptibly with the period proper of lung development.

Vasculogenesis of the Pulmonary Circulation

In the adult lung, the pulmonary arteries are found in close proximity to the branches of the airways and they distribute

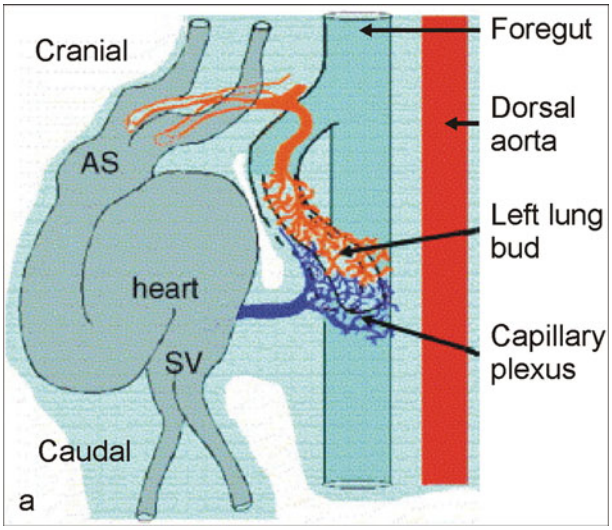

Figure 5-5 Formation of the circulation of the lung buds. *A*. Reconstruction of human embryonic lung at day 34 of gestation with completed circulation between the aortic sac (AS), through a capillary bed surrounding the single left and right lung buds and returning to the sinus venosus (SV). *(Reconstruction by Sue Hall from Hall SM, Hislop AA, Haworth SG: Origin, differentiation, and maturation of human pulmonary veins. Am J Respir Cell Mol Biol 26:333–340, 2002.)*

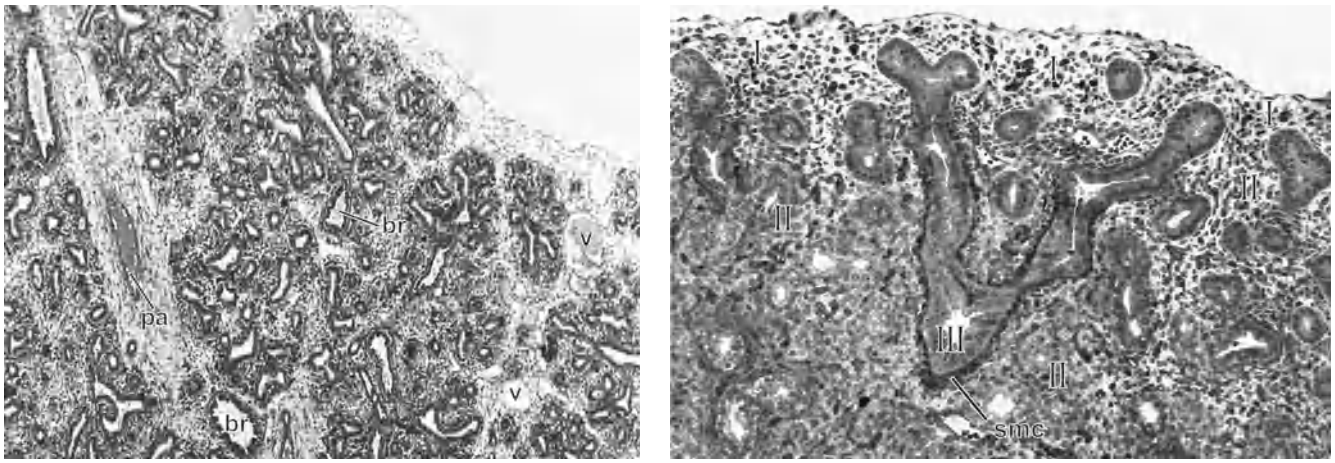
the blood to the alveolar capillary bed. The pulmonary veins are independent of the bronchial tree. They are found roughly in the middle between the pairs of bronchi and arteries. They maintain a similar number of branches and return the blood from the capillary bed to the heart. The close proximity of the circulation and the airways suggests that their development is linked to each other.

The mesenchyme surrounding the lung buds contains a number of cells staining positively for markers of endothelial cells. By day 34 of gestation each prospective main bronchus possesses a capillary network that connects cranially to the aortic sac and caudally to the left atrium (Fig. 5-5). After establishment of these connections there is evidence of circulating blood cells. Apparently, the earliest pulmonary vessels form by vasculogenesis—a process in which vessels form de novo due to a differentiation of mesenchymal cells. The newly formed endothelial cells are connecting to each other to form first capillary tubes. These capillaries coalesce to form small blood vessels alongside the airways. During branching of the future airways a new plexus forms as a halo around each newly formed bud. Each plexus adds to the peripheral circulation and extends the arteries and veins. Thus there is sustained addition of the newly formed tubules to the existing vessels and the airways act as a template for the development of blood vessels.

PRENATAL LUNG DEVELOPMENT—FETAL PERIOD (WEEK 5–TERM)

This period lasts till birth and comprises three phases of development, the names of which are derived from the changing



A *B*

Figure 5-6 Morphology of pseudoglandular stage of lung development in human and rat. *A*. Human fetal lung, gestational age about 15 weeks. Bright bands of loose mesenchyme containing veins (v) indicate subdivision of lung into segments and lobules. Denser mesenchyme surrounds the tubular sprouts. *B*. Subpleural region of rat lung, gestational day 18.5. Zone I (I) is characterized by a loose arrangement of mesenchymal cells immediately below the pleura. In zone II (II) epithelial tubes are enwrapped by a more densely packed network of interstitial cells. The zone I to II boundary is the site of formation, growth, and differentiation of the gas exchange region. The future conducting airways are located in zone III (III), which is characterized by epithelial tubes with an outer layer of smooth muscle cell precursors (smc). Pa, pulmonary artery; br, bronchus; light microscopical image, 65 × (*A*), 150 × (*B*).

morphology of the prospective gas exchange tissue: pseudoglandular, canalicular, and terminal sac (or saccular).

Pseudoglandular Stage (Weeks 5–17)

From the fifth week to the 17th week, the developing lung shows the characteristics of a tubular gland, giving rise to the name for this stage (Fig. 5-6). Until the end of this stage, the tubular tree preforms, through growth and branching, all the conductive airways down to their last generations—i.e., the future terminal bronchioles. Therefore, this stage has often been referred to as the stage of conductive airway formation. Although Boyden claimed that the transition to the next stage was marked by the first appearance of the pulmonary acinus (which means that the prospective lung parenchyma appears at the periphery of the developing lung), the amount of future gas exchange tissue present during and at the end of the pseudoglandular stage has been severely underestimated. Already in the early 1980s, Ten Have–Opbroek had demonstrated by immunohistochemical techniques that epithelial cells at the periphery of the airway tree in the pseudoglandular stage had to be considered precursors of the later alveolar epithelium. In morphologic and morphometric studies of fetal rat lungs, we found that half of the parenchymal epithelial cell mass in the saccular stage before birth was already present in the late pseudoglandular stage. Furthermore, Kitaoka and co-workers concluded from counts of the number of end segments in human lungs in the pseudoglandular and canalicular stages that all the airway divisions down to the level of alveolar ducts were present toward the end of the pseudoglandular stage. For these reasons, the view that the pseudoglandular stage is almost exclusively the stage of conducting airway development can be maintained no longer.

Although the appearance of the acinar structures apparently provides a well-defined morphologic characteristic for the transition to the next stage of development, a precise estimate of gestational age cannot be made from it. Differentiation usually proceeds centrifugally, and the speed of growth varies during a developmental period, with acceleration toward the end of a stage. Furthermore, animal studies have demonstrated that upper lobes develop faster than lower lobes. If the time differences in development observed between lobes in rabbits are transposed to the human lung, the differences in lobar development could amount up to 2 weeks in view of the much longer gestation period. Such differences, however, have never been assessed. Recently it was postulated that human lung development proceeded in a relatively homogeneous manner.

Epithelial and Smooth Muscle Cell Differentiation

During the pseudoglandular stage, the airway tubes are proximally lined by a very high columnar epithelium (Figs. 5-6 and 5-7 *D*). The height of the cells decreases continuously toward the periphery, to reach a cuboidal shape in the terminal branches. The epithelium of the terminal buds maintain their cuboidal undifferentiated state until branching is completed. Mitotic figures are frequent. The cytoplasmic organellar machinery looks relatively simple: mitochondria, many free ribosomes and a little rough endoplasmic reticulum, some lipid droplets, and large patches of glycogen. Remarkably, the epithelial barrier appears to be tight from the early stages of development. In freeze-fracture preparations, the morphology of the junctional complexes does not differ during development to full term; conversely, gap junctions are present early in gestation and disappear during the canalicular stage as the

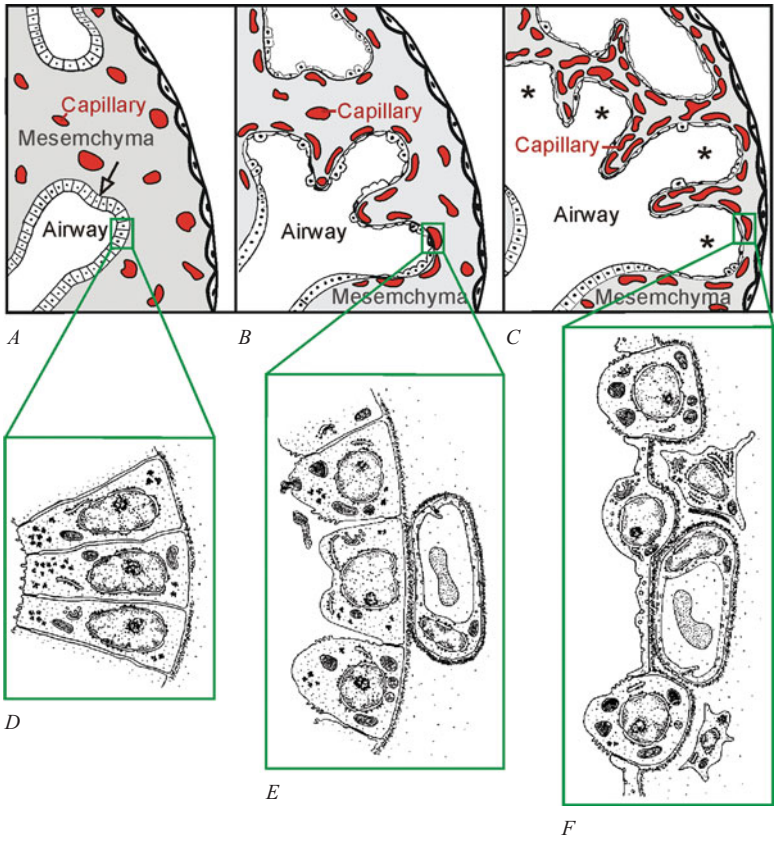


Figure 5-7 Changes in lung parenchymal morphology in the pseudoglandular, canalicular, and saccular stages. *A*. During the pseudoglandular stage, the epithelial tubules branch constantly and penetrate into the surrounding mesenchyme (open arrow, branching point). A loose three-dimensional capillary network is located in the mesenchyme. *B*. The canalicular stage is characterized by: (1) a widening of the future airways; (2) a differentiation of the tall columnar epithelial cells of the pseudoglandular stage (*D*) into prospective lining and secretory cells (type I and II epithelial cells, e + f); (3) a multiplication of the capillaries and their first close contacts to the epithelium; and (4) the formation of first air-blood barriers (e → f). *C*. Throughout the saccular stage the mesenchyme condenses to form thick inter-airway septa that contain a capillary layer on either side of the septum. The widened terminal ends of the bronchial tree are recognized as saccules (asterisks) *(A to C modified from Caduff JH, Fischer LC, Burri PH: Scanning electron microscopic study of the developing microvasculature in the postnatal rat lung. Anat Rec 216:154–164, 1986; D and E from Burri PH, Weibel ER: Ultrastructure and morphometry of the developing lung, in Hodson WA (ed).* Development of the Lung. *New York, Dekker, 215–268, 1977.)*

epithelial cells differentiate. Therefore, it may be that electrical coupling between cells plays a role in cellular differentiation.

The first ciliated, goblet, and basal cells appear in the central airways. Mucous glands and goblet cells appear almost simultaneously in the airway epithelium. They develop from solid epithelial sprouts that invade the mesenchyme underneath the epithelium. At around weeks 12 to 13, mucous glands are found in bronchi; at week 14, mucus formation can be detected in the trachea.

A continuous layer of contractile α-smooth muscle actin positive cells surrounds the larger future airways in the proximal part of the bronchial tree. These cells are defined as smooth muscle cell precursors, because morphologically they are not yet fully differentiated. The layer of smooth muscle cell precursors becomes step by step discontinuous in the more distal parts and ends in front of the terminal buds. Until birth these contractile cells perform spontaneous contractions, which start centrally and travel like a peristaltic wave into the periphery. The resulting wave of intrabronchial liquid pushes liquid into the terminal buds and extends them rhythmically. It was postulated that branching is stimulated by this mechanical signal via mechanical transduction.

Arteries and Veins

During the pseudoglandular stage, the vascular system develops along with the bronchial tree, so that by the end of this stage, all the preacinar vessels, arteries, and veins, are laid down in the characteristic pattern of the adult lung. However, the number of generations in the arterial tree is greater than in the airway system: On average, there are more than 28 generations in the arterial tree versus 23 in the airways. In addition to the conventional arteries that follow the bronchi and bronchioles, there are other branches (i.e., "supernumerary" arteries), which often split off at right angles. Usually these branches are smaller vessels that irrigate the "recurrent" gas exchange tissue adjacent to the conducting airways.

The veins follow different pathways. They run mainly interaxially in mesenchymal septa of the lung segments and subsegments. Verbeken et al. showed that as a general rule venous branches systematically follow the connective tissue septa that extend into the plane between each generation of airway branching. In the central areas the large venous branches join the arteries and airways to reach the hilum.

The generations of the three pulmonary trees—future airways, arteries and veins—develop in parallel. According to current estimations approximately five-sixths of the number of generations is laid down at the end of the pseudoglandular stage. However, due to the exponential growth by mostly dichotomous branching (2^n) the total numbers behave quite differently. In a first approximation the total number of branches, the total length, and the total volume of the airways, arteries, and veins doubles with every additional generation.

Zones of Lung Development

Based on morphologic observation during rat lung development Burri and Moschopulos established a concept of zonal

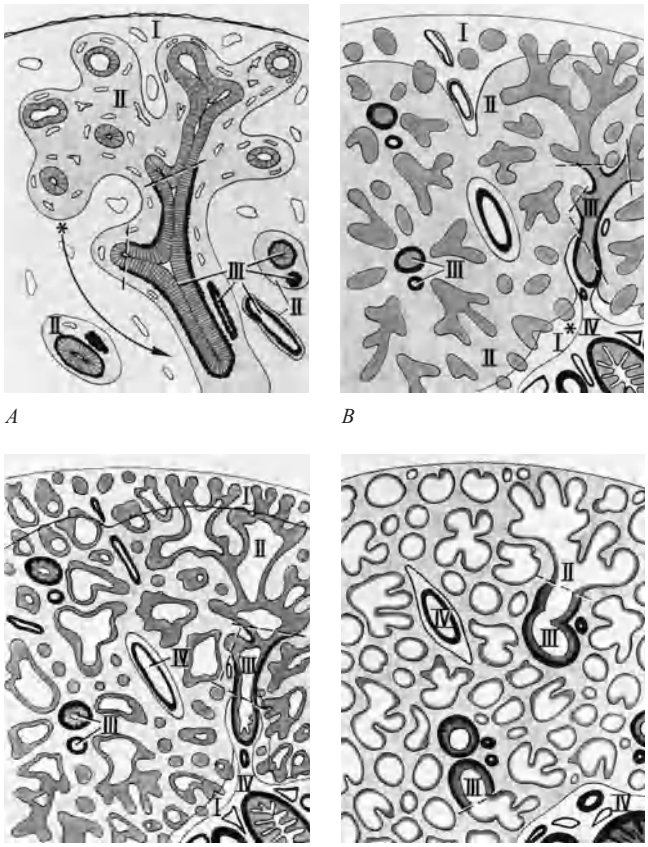

Figure 5-8 Schematic illustration of Zone concept. *A*. Early pseudoglandular stage: Zone I is made from a loose network of mesenchymal cells and capillaries into which the airway tubules of zone II penetrate. Zone III contains the prospective conducting airways and vessels. The conducting structures have no adventitial layer yet. No Zone IV is present. *B*. Late pseudoglandular stage. All four zones have now developed. The peripheral tubules reach into zone I, which represents a layer of almost constant thickness despite lung volume increase. This means that it represents a kind of cambial or germinal layer for airway growth. Due to the recurrent growth of zone II (asterisk and arrow in *A*), zone I areas have reached the cuffs of airways and vessels. Part of airways and vessels of earlier zone III are now enwrapped by an adventitial layer and have therefore muted to zone IV. *C*. Canalicular stage: Airspaces of zones II and III have widened, while the airway buds in zone I retain a cuboidal epithelium. *D*. Saccular stage. Zone I has now disappeared; there is no more budding. The lumina of airspaces and airways are wide. (*From Burri PH, Moschopulos M: Structural analysis of fetal rat lung development.* Anat Rec *1992; 234:399–418.)*

development. Zone I is defined as a superficial mantle around the lobes and the future acini. It consists of primitive mesenchymal cells and represents a zone of growth and branching of the epithelial tubules. Zone I disappears at the beginning of the saccular stage when branching is completed. Zone II is mainly a zone of differentiation. In electron micrographs its interstitium stains intensely due to a dense population of dark cells. Zones III and IV contain the elements of the airway tree and vascular system, zone IV corresponds to the most proximal generations with an adventitial layer. For all differentiation processes a centrifugal directionality is manifested (Figs. 5-6 and 5-8), the most differentiated cells being in the first branching generations, whereas cellular multiplication is at work in the periphery.

Besides helping to understand developmental processes the zone concept is also interesting in terms of molecular aspects, e.g., many factors that are expressed in zone I contribute to the epithelial-mesenchymal interaction during branching (e.g., FGF-10, Gils, Sprouty4). In zone II the expression of hepatocyte nuclear factor/forkhead homologue 4 was observed.

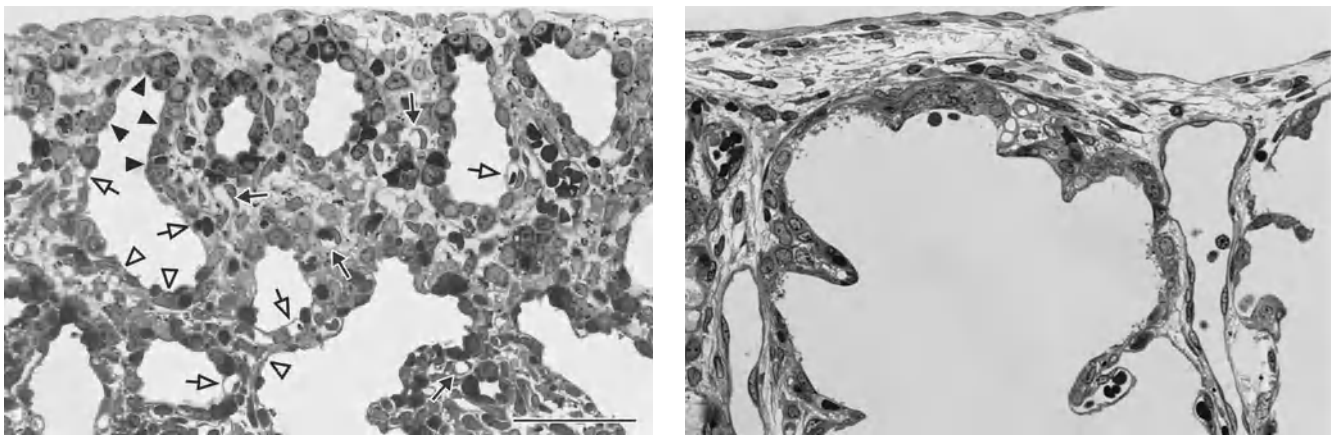
Canalicular Stage (Weeks 16–26)

The canalicular stage comprises important steps in the development of the fetal lung. The lung morphology changes dramatically, owing primarily to: (1) the differentiation of the pulmonary epithelium and formation of the typical air-blood barrier; (2) the beginning of surfactant synthesis and secretion; and (3) the "canalization" of the lung parenchyma by capillaries. The latter process gave this stage its name. These alterations have most important functional consequences: At the end of the canalicular stage, the lung has reached a state of development in which gas exchange is possible in principle. Before these developmental steps, a prematurely born infant has no chance to survive. However, clinical experience unfortunately shows that survival is by no means assured at the end of the canalicular stage.

At the beginning of this stage, the future gas exchange region of the lung can be distinguished from the conductive tubules of the airway tree. Boyden has characterized this step as "birth of the acinus." The early acini are composed of several very short generations of tubules arranged in clusters and taking origin from the actual last segment of the conducting airways, a prospective terminal bronchiole. The acinar borders can be recognized because of rarefaction of the mesenchyme (Figs. 5-6 and 5-8). In subsequent weeks, the distal segments of the airways grow in length and widen at the expense of the mesenchymal mass.

Epithelial Differentiation: Formation of the Air-Blood Barrier

To achieve an operational air-blood barrier, epithelial differentiation and capillary proliferation are needed during this



A *B*

Figure 5-9 Formation of the air-blood barrier. *A*. Early canalicular stage, rat lung. Although the most terminal part of the airway tree still contains a cuboidal, glycogen-rich epithelium (closed arrowhead), the epithelium of the more proximal parts begins to flatten out (open arrowhead) to form thin air-blood barriers. During the latter process capillaries, which are located inside the mesenchyme (closed arrow) "move" toward the epithelium (open arrow). *B*. The periphery of the gas-exchange region in human lung aged 26 days postnatal. There are still remnants of the cuboidal epithelium (closed arrowhead) present at the uttermost periphery at the beginning of alveolarization. It demonstrates the large overlap among the different phases of lung development. Light microscopical image, 175 × (*A*), 320 × (*B*).

stage. The cuboidal glycogen-rich epithelium of the bronchial tree differentiates into two types of epithelial cells: (1) type II epithelial cells, which start to produce surfactant; and (2) type I epithelial cells, which reduce their height and develop sheet-like extensions that cover most of the internal surface of the parenchyma. In addition, the type I cells contribute to the formation of the first thin air-blood barriers (Figs. 5-7*B*, 5-7*E*, and 5-9). The lung parenchyma becomes "canalized" by capillaries, resulting in a dense capillarization of the primitive interstitium. Distal of the conductive zone the future airways not only grow in length, but also widen, causing a reduction of the mesenchymal volume (Fig. 5-7*B*). In rats this reduction includes a peak of programmed cell death (apoptosis). The cellular death indicates that the condensation of the mesenchyme includes a reduction of the number of cells.

During the pseudoglandular stage the capillaries form a loose three-dimensional network inside the mesenchyme (Fig. 5-7*A*). During the canalicular stage a strong angiogenesis of the (micro)-vasculature takes place and the capillaries come into close contact to the epithelial tubules, forming a pericanalicular network (Fig. 5-7*B*). In the regions in which the epithelium has been thinned, the capillaries form the air-blood barrier by an intimate contact to the squamous cells (Figs. 5-7*E* and 5-9*A*). The epithelial and endothelial cells are only separated by one fused basement membrane that possesses one central lamina densa and two laminae lucidae. The mechanism by which the air-blood barrier forms is currently only poorly understood. It is likely that the interaction between the mesodermally derived endothelium and the endodermally derived epithelium takes part in this developmental step. This hypothesis is supported by a transgenic mouse, in which the sequence coding for the nidogen-binding site (γ1III4, within the laminin-γ1-chain) was selectively deleted by gene targeting. In these mice the basement membranes are disrupted or missing in large parts of the air-blood barriers. As a result epithelial and endothelial cells do not form close contacts. The mice die neonatally due to a failure of the gas exchange in the lungs.

During the canalicular stage the type II epithelial cells start to accumulate lamellar bodies containing components of surfactant. Soon afterward the type II cells actively secret surface active material, which appears in the lung liquid. In contrast to most species, in which surfactant appears late in gestation (at about 80–85 percent of total duration of gestation), in the human fetus small amounts are already present at weeks 22 to 24 (approximately 60 percent of gestation). Before the lungs fully mature surfactant appears to be unevenly distributed. The surfactant appears to be more abundant in apical than basal regions. The clinical observation that in some premature born infants the development of hyaline membrane disease is more pronounced in basal than apical parts of the lung may be explained by this uneven appearance of surfactant.

Type II cells are also the progenitor cells of the type I cell population in adult lungs, as could be demonstrated during repair of the damaged alveolar epithelium. Therefore, it is not surprising that a few small lamellated bodies have been found in the cytoplasm of immature epithelial cells *before* they started to differentiate into type I and II cells. In cytokinetic experiments using tritiated thymidine, it has been shown that during lung development, early type II cells (or, more precisely, cells resembling type II cells) also represented the stem cells of the type I and II pulmonary epithelium. Recently, it has been shown in adult mice that circulating bone marrow cells may also be recruited to the lung. At the uttermost periphery of the airspaces, the cuboidal cells of the epithelium remain undifferentiated until after birth (Fig. 5-9*B*).

Saccular (or Terminal Sac) Stage (Weeks 24–38)

This stage lasts from about week 24 almost to term. At the beginning of this stage, the peripheral airways form typical clusters of widened airspaces termed saccules or terminal sacs. By widening and lengthening of all airspace generations distal to the terminal bronchioles, and probably also by the addition of the last generations of airspaces (Fig. 5-2), the future gas exchange region expands massively.

Each new generation of this pathway is originally formed as a blind-ending saccule. As soon as it divides distally, however, it is no longer a saccule, but an open-ended channel. As is discussed in the section on postnatal development, the morphology of all these channels and saccules undergoes change until the formation of the alveoli is completed in the postnatal period. Therefore, these structures have been designated as transitory ducts and transitory saccules or, more generally, as transitory airways or airspaces, because their morphology changes further until alveoli are formed.

Also at this stage, within the mesenchyme, one or two populations of fibroblastic cells have differentiated. Not only are these cells responsible for the deposition of extracellular matrix and fibers but also, by way of interactions with the epithelial cover, they presumably play a role in epithelial differentiation and the control of surfactant secretion. Owing to the expansion of the lumina of the peripheral airspaces in the foregoing and the present stage, the proportion of interstitial tissue within the inter-airspace septa has decreased.

During the canalicular stage the capillary network had formed a capillary layer around each future airway. Due to the expansion of the future airways, the surfaces of the airways approach each other and a capillary double layer is thus formed inside the inter-saccular septa (Fig. 5-7*C*). The inter-saccular and inter-ductular septa are still relatively thick and their interstitium is highly cellular. Because its content in collagen is low, the fetal lung is delicate and fragile: Under mechanical stress it ruptures much more rapidly than the adult organ.

Finally, in anticipation of the next stage, during which the alveoli will be formed, the interstitial cells start to produce elastic fibers along the inter-ductular and inter-saccular walls. Elastin is found first in extracellular bays of large fibroblastic cells rich in organelles. The deposits later extend throughout the septal walls of the parenchyma, from the peribronchial and perivascular sheaths to the pleural sac.

Arteries and Veins

Keeping pace with the intense growth of the gas exchange region during this stage, the vascular tree grows in length and diameter and adds new generations. Measurements on arteriograms by Hislop and Reid have shown that arterial diameter is practically constant at a given distance from the end of the arterial pathway. This is true irrespective of age, either fetal or postnatal. Therefore, for example, a vessel of a given size will supply a large portion of a lobe in an early fetal lung, but only an acinus in a child's lung. In late fetal life, the wall structure of arteries is similar to that of adult lungs. Proximal arteries are elastic, with many elastic lamellae strutted to each other by smooth-muscle cells that are arranged obliquely between the elastic sheets. Smaller arterial vessels show a transitional structure, the muscular component becoming increasingly prominent at the expense of the elastic component. Finally, the muscle layer of the media becomes irregular and assumes a spiral configuration. This configuration explains the "partly muscular" arteries seen in histological sections. Unfortunately, there are no strict relationships between vessel diameter, size of the region supplied, and character of the wall structure; these relationships may differ from one pathway to the other. Intrapulmonary veins are practically devoid of smooth-muscle cells until the end of the canalicular period. In the following weeks, however, a thin muscle layer is formed that, at birth, extends down to vessels of about 100 μm diameter.

Time of Birth

Comparing different species the time point of birth as determined relative to lung development correlates with the activity of the newborn. So far the marsupial quokka wallaby *(Setonix brachyurus)* represents the mammal possessing the most immature lung at birth. These animals are born in the canalicular stage. As insessorial mammals, rats and mice are born during their saccular stage. While human babies are born in the early alveolar stage, precocial mammals such as sheep are born during late alveolar stage (Table 5-1).

POSTNATAL LUNG DEVELOPMENT

At birth the replacement of lung liquid by air and the onset of respiration represents a major caesura in pulmonary development. However, the change from the amniotic into the atmospheric environment is more a functionally than a structurally relevant step. At this time, the complete set of airway generations seems to be present; however, the most peripheral ones are still relatively short. The pulmonary parenchyma consists of several generations of transitory ducts and, as the last generation on each pathway, the transitory saccules. At birth, these structures are on the way to being transformed into alveolar ducts and sacs, respectively, by the process of alveolarization. Although reports indicate that in humans the formation of alveoli starts during late intrauterine life, the alveolar stage of lung development is discussed in this section because most alveoli (more than 85 percent) are formed after birth.

Alveolar Stage (Week 36 to 1–2 Years)

For ethical and technical reasons, many of the general laws and mechanisms involved in the formation of the alveoli and maturation of the alveolar septa have been derived from animal studies. Therefore, the following description of the postnatal lung development is based on experimental findings mainly obtained in the rat lung. Subsequent morphologic and morphometric investigations of human lungs have confirmed

that the postnatal developmental processes do not differ in structural essentials; but, as expected, the timing is different between different species.

At the end of the saccular stage the rat lung goes though a short phase of expansion without any alteration of the parenchymal complexity. The distal airways consist of smooth-walled channels and saccules corresponding to transitory ducts and definitive terminal saccules, respectively. The septa of the saccular parenchyma are thick and contain a double capillary network. They have been called *primary septa* because they represent the basis for the formation of new septa, the secondary septa involved in alveolarization. In many species, among them mice, rats, and humans, alveolarization can be visualized nicely by light and scanning electron microscopy (Fig. 5-10). We have termed this fast and highly visible formation of alveoli during the alveolar stage "bulk alveolarization," to distinguish it from an eventual process of late alveolarization that is much more difficult to detect.

Septation: Alveolarization

The alveoli are formed by lifting off of new tissue ridges from the existing primary septa. In light microscopic sections this process produces a large number of small buds appearing along the primary septa (Figs. 5-10*B* and 5-11*B*). In three dimensions these buds correspond to low ridges representing newly forming septa (Figs. 5-10*D* and 5-12). Soon these low ridges increase in height and subdivide the airspaces into smaller units, the alveoli (Figs. 5-10*D* and 5-11*C*).

It has been proposed that the combination of the three components—myofibroblasts, elastic fibers, and collagen fibrils—provides the critical driving force for septation (Fig. 5-11). Inside to preexisting septa (primary septa) PDGF–receptor-positive smooth muscle cell precursors proliferate and move to the locations in which the new septa will be formed. These cells produce a network of mainly elastic fibers, but also interstitial collagens. During lifting off of the new ridges the contractile cells as well as the fibrous network stay at the tip of the newly forming septa. As indicated by the mechanical stress sensitive expression of tenascin-C at the septal tip this network is supposed to take up mechanical forces.

The alveolar smooth muscle cells or myofibroblasts are required for septation. Alveolarization does not occur in PDGF-A–deficient mice, because these cells do not appear at their normal position and do not deposit the network of elastic fibers. However, it is not known whether these cells are only required for the production of elastic fibers, or whether they exert tractive forces in addition. This question could not be answered by the investigation of elastin null mice, because they do not enter the alveolar stage due to early death.

Folding of Capillary Network

The described network consisting of the smooth muscle cells, elastic fibers, and collagen fibrils is connected to the capillary layer underlying the septal surface. At the locations in which the new ridge will be formed, the capillary layer of the preexisting septum is pulled into the new septum. It gives rise to the double capillary networks within the secondary septa (Fig. 5-11). Wherever lifting off occurs, both types of septa, primary and secondary, now contain two capillary layers, one on each side of a central layer of interstitium. Such thick septa are called "immature" or "primitive" septa to distinguish them from the thin mature septa of adult lungs that contain only a single capillary network. Septation goes along with a tremendous increase in airspace surface area. It is evident that the capillary network has to keep pace with it. If not, septal budding could not occur or forming secondary septa would be devoid of capillaries. This hypothesis was tested by the application of antiangiogenic drugs during the alveolar stage. After a treatment of rats with fumagillin, thalidomide, or Su-5416, respectively, a decrease of the alveolarization by up to 22 percent was observed. In parallel, the pulmonary arterial density decreased by up to 36 percent. This finding emphasizes the importance of vascular growth in the process of alveolarization.

Quantitative Aspects

Morphologic investigations supported by quantitative stereologic analyses have led to the following picture of alveolar formation. Due to the formation of the alveoli, the complexity and also the alveolar surface area are increasing. In simple isotropic growth (expansion of airspaces in proportion to the increase in lung volume), the surface area is expected to increase to the two-thirds power of lung volume. However, in rats the lung volume increases to the power of 1.6. Of interest is that the rapid increase in alveolar surface area is paralleled by changes at the subcellular level in type II cells. The total mass of lamellated bodies is augmented in proportion to the increase in gas exchange surface area; so that lamellar body volume divided by total surface area remains almost unchanged. Interestingly, this means that, if secreted, the lamellar bodies could cover the entire respiratory surface with a film of surfactant that is constant in thickness.

Cell Proliferation

Shortly before and also during the onset of septal formation, DNA synthesis is increased in cells located preferentially in the region of the forming crests. Autoradiographic studies with H_3-thymidine showed that DNA synthesis was high first in the mesodermally derived cells, such as the interstitial and endothelial cells. A few days later (at the age of 1 week), type II cells exhibited the highest activity in DNA synthesis. Within 1 hour after the thymidine injection, not a single type I cell could be labeled, clearly indicating that type I cells are unable to divide. If type I cell labeling could be detected in some experiments, it was always with some delay, which allowed for the differentiation of labeled type II cells into type I cells. At the age of 2 weeks, all labeling indices were back to low levels. Nonetheless, alveolar surface area continued to increase at a high rate during the third week. The morphometric data indicate that this further gain in surface area was obtained by restructuring of the available tissue mass rather than by further proliferative activity.

C *D*

Figure 5-10 Alveolarization of rat lung as seen by light microscopy (a + b) and scanning electron microscopy (c + d). *A*. On postnatal day 1, the terminal bronchioles (tb) open into a smooth walled channel dividing into several saccules(s). *B*. On postnatal day 21, the terminal bronchiole (tb) opens now into several generations of alveolar ducts (ad) surrounded by alveoli. Secondary septa have subdivided the channels and saccules (arrows). *C*. As seen by scanning electron microscopy, the lung parenchyma is made of smoothly lined saccules at postnatal day 1. By the formation of the secondary septa (arrows) the smooth walled channels and saccules of panel a have been transformed into alveolar ducts (ad) and alveolar sacs, respectively (postnatal day 21). Both structures are lined with alveoli (a). Light microscopical images, 32 × (a + b), scanning electron microscopical images 460 × (c + d).

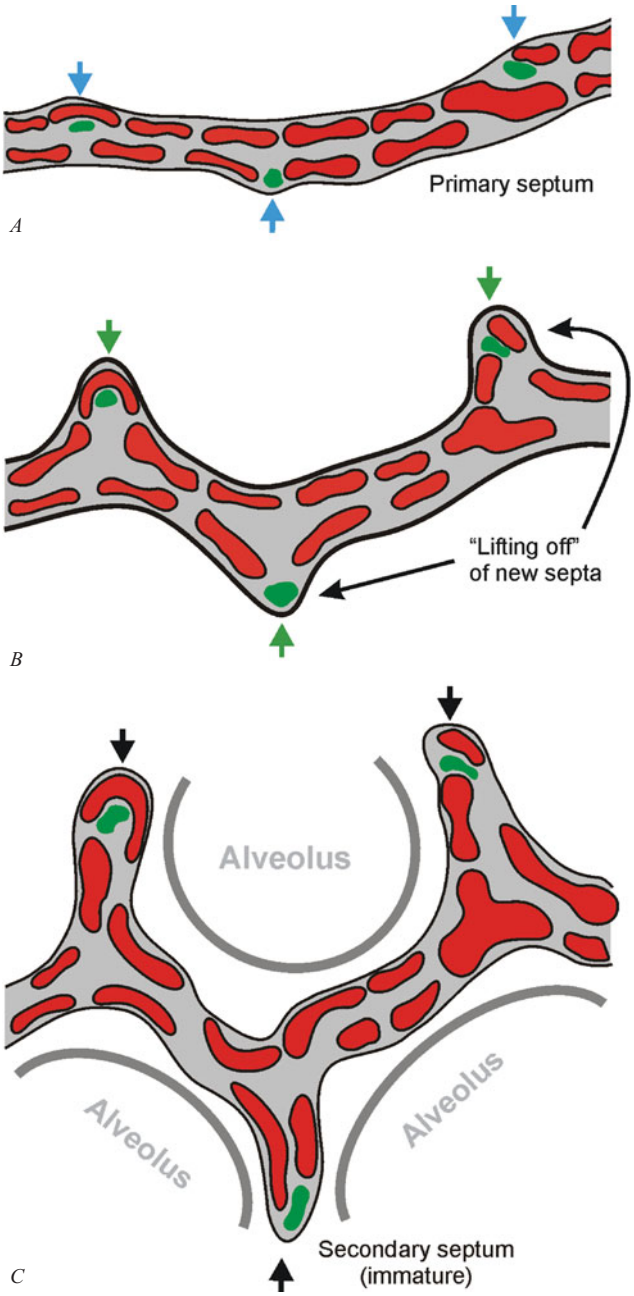

Figure 5-11 Formation of secondary septa/alveolarization. A saccular (or primary) septum contains a double-layered capillary network, where every capillary layer appears as a perforated sheet in sections. Smooth muscle cell precursors, elastic fibers, and collagen fibrils (green spots) accumulate in immature septa at sites where new septa (or secondary septa) will be formed (blue arrows, *A*). Secondary septa are formed by up folding (green arrows) of one of the two capillary layers (red, *B*). As a result, newly formed secondary septa (black arrows) subdivide preexisting airspaces and new alveoli are born (*C*). At this stage, all septa present are immature, showing two capillary layers (= primitive septa). *(Modified from Burri PH: Structural aspects of pre- and postnatal development and growth of the lung, in McDonald J (ed).* Growth and development of the lung. *New York, Dekker, 1997, pp 1–35.)*

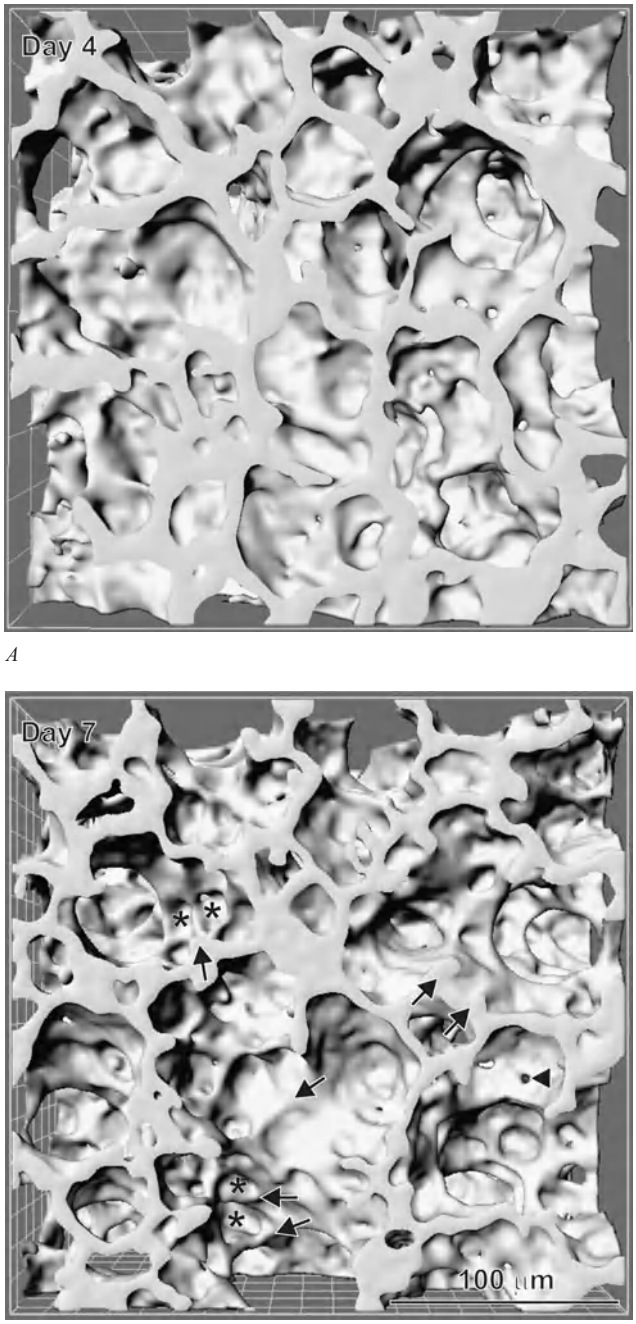

Figure 5-12 Visualization of alveolarization by x-ray tomographic microscopy. Mouse lungs were 3D-visualized by synchrotron radiation x-ray tomographic microscopy just before (postnatal day 4, *A*) and after the beginning of alveolarization (postnatal day 7, *B*). *A*. At the end of the saccular stage large terminal airspaces (saccules) were observed. *B*. Newly formed septa (arrow), which are surrounding newly forming alveoli (asterisk), are visible 3 days later during alveolarization.

Microvascular Maturation Stage (Birth to 2–3 Years)

The essence of this stage is the restructuring of the double capillary networks in the parenchymal septa to the mature aspect with a single capillary system (Figs. 5-13 and 5-14). It is assumed that the latter structure bears functional advantages over the former. Mammalian species with an immature pulmonary microvascular system at birth are mostly of the altricial type, whereas the precocial species such as the sheep are born with mature septa.

The beginning and ending of microvascular maturation are very difficult to access. Septal restructuring is a complex mechanism closely related with growth. In addition, a large overlap with the stage of alveolarization exists. As shown in Fig. 5-15, reporting morphometric measurements of the state of maturity, the rat lung shows already some maturation of the alveolar septa at postnatal day 10, where only one-third of the bulk alveolarization is completed.

Capillary Fusion and Differential Growth

Ultrastructural and morphometric studies in the rat have revealed that the approximation of the two capillary layers was induced by a decrease in the absolute mass of the intercalated septal interstitium. In the third postnatal week the interstitial tissue volume decreased by 27 percent, despite a lung volume increase of 25 percent. The two capillary layers come to lie closer to each other, contact each other, and finally merge their lumina. This happens focally, but in numerous places. However, focal capillary fusions alone would not allow to transform rapidly and extensively the appearance of the interalveolar walls. We proposed that the merged areas were expanded by preferential growth, a process well known in embryology. In summary, microvascular maturation is the result of multiple focal fusions between the two capillary layers combined with preferential growth of the fused areas. By these means large areas of the lung parenchyma can gain the mature aspect within a short period of time.

Programmed Cell Death

In rats the maturation of the alveolar septa does not only lead to a reduction of the absolute mass of the interstitial tissue, but also to a decline of the absolute number of fibroblasts (10–20 percent) and of epithelial cells (greater than 10 percent). We asked how the number of the cells may be reduced and observed that the surplus of fibroblasts is eliminated by classical apoptosis toward the end of microvascular maturation (third postnatal week in rats). Apoptosis is morphologically defined by a typical pattern of structural changes of the dying cells, including the fragmentation of the cell into membrane-enclosed vesicles (apoptotic bodies). Although this happens in the septal myofibroblast population, programmed cell death eliminates the surplus of epithelial cells—mainly type II cells—without the appearance of apoptotic bodies. Most likely alveolar macrophages phagocytose the apoptotic epithelial cells in an early stage of programmed cell death before apoptotic bodies are formed. This peak of cell death disappeared in rats after a short neonatal treatment with glucocorticoids—showing the long-lasting effect of such a treatment.

During microvascular maturation the cell proliferation index stays low. The discrepancy between the rapid growth in surface area and lack of cell proliferation could be explained by an expansion of the type I epithelial cells, meaning that surface area covered by each individual type I epithelial cell enlarges. Because the type II epithelial cells cover only less than 10 percent of the alveolar surface, a reduction of these cells is only important for the production of surfactant and a reduction of the epithelial stem cells. Apparently, a surplus of type II cells exists toward the end of the stage of microvascular maturation. Most likely only type II cells which do not serve as stem cells for the forming of type I cells are removed.

Interalveolar Pores (Pores of Kohn)

Interestingly, the formation of pores of Kohn is closely related to the process of septal thinning. Pores of Kohn represent rounded openings in the interalveolar walls with diameters of a few to several microns. Their frequency varies greatly among species. In the human lung they are not present in the newborn and they appear during postnatal development and growth. Local thinning of the alveolar septa facilitates trans-septal contact of the epithelial cells. The formation of junctional complexes is followed by the reorganization of the cell-cell contacts and retraction of epithelial cells. Finally, the latter leads to the formation of pores. The contacts may be formed by type I-type I and type II-type I cell contacts (for details, see Fig. 5-16). Due to the cuboidal shape of the type II cells the type II-type I contacts contribute more frequently to the formation of a pore than type I-type I cell contacts.

In mice a first peak of pore formation is manifest during the stage of microvascular maturation (third postnatal week). A second peak was observed during the 6th to 10th postnatal week. Because septal thinning continues with further aging of the lung, interalveolar pores may also be formed later, perhaps even up to an older age.

The pores may serve as interalveolar exchange of alveolar liquid, surfactant components, and macrophages. They are filled with surfactant under normal physiological conditions. Tubular myelin may be stored in the pores without increasing the gas diffusion pathway thickness of the active gas exchange surface itself. It is unlikely that interalveolar pores are used for collateral ventilation of alveoli during normal breathing.

In the human lung microvascular maturation starts very early, partly in parallel to alveolarization. At the age of 1 year, large parts of the lung possess already mature septa, but most likely the process goes on till the age of 2 to 3 years. Based on these morphological characteristics we can consider the lung of a 3-year-old child to represent a miniaturized version of the adult one.

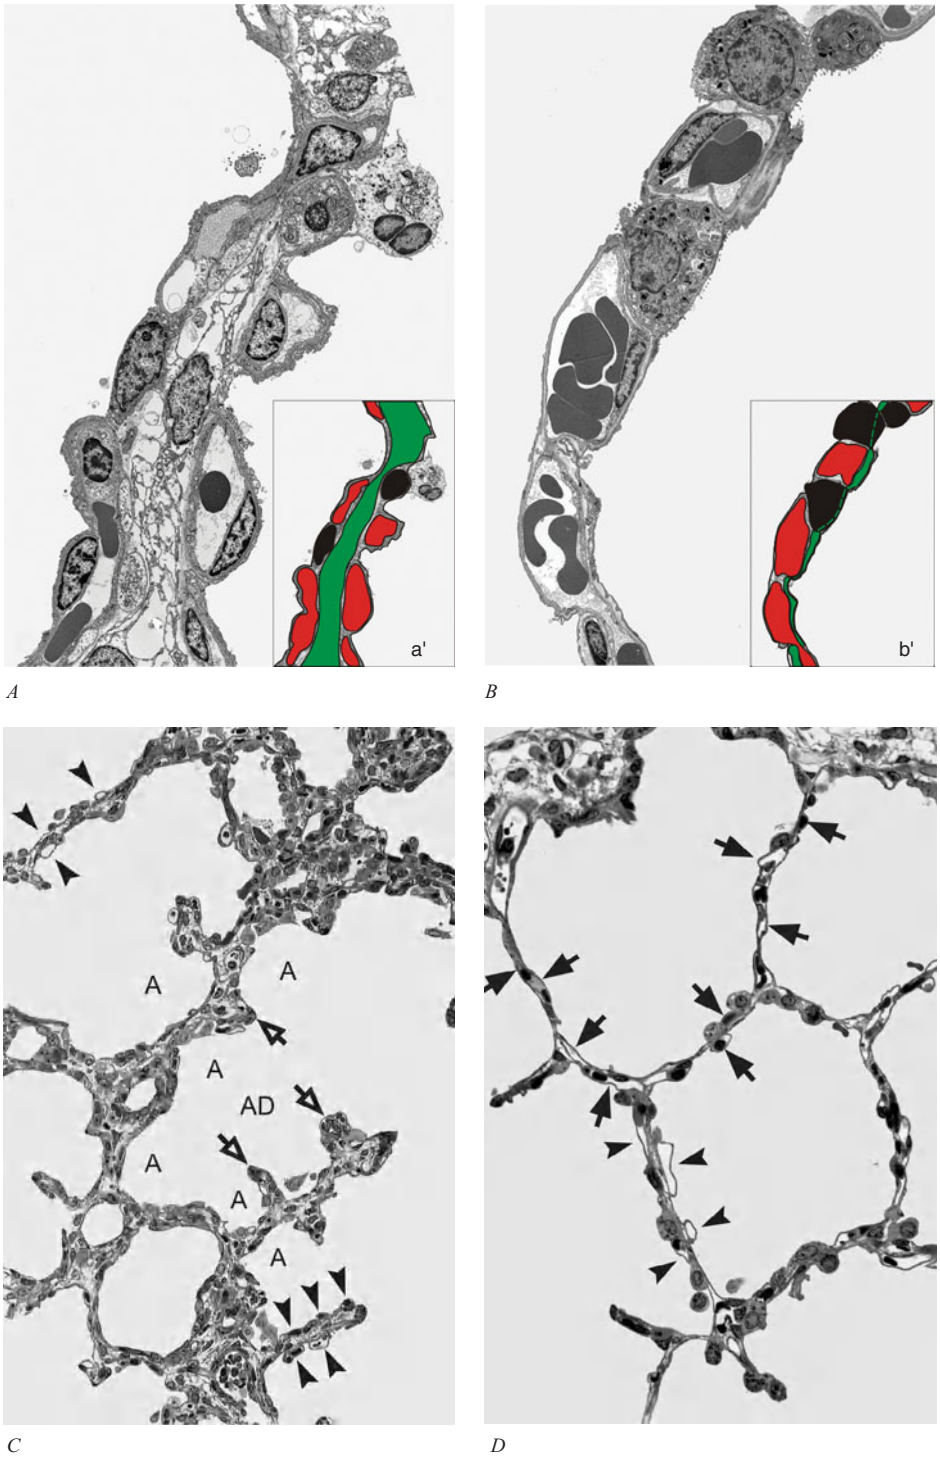

Figure 5-13 Septal maturation during the phase of microvascular maturation. Immature septa contain a double-layered capillary network in which each alveolar surface is served by its own capillary layer. The two capillary layers are separated by a central sheet of interstitial tissue (*A*, electron micrograph of a human lung aged 26 days, 1540×; a′, schematic drawing, capillaries are drawn in red, interstitial tissue in green). Upon maturation the connective tissue layer (green) condenses and thins out so that the two capillary layers merge. The result is a septum where the connective tissue skeleton of the alveolar septum is interwoven with a now single layered capillary network (red/*B*, electron micrograph of an adult human lung, 1540×; b′, schematic drawing). Panels *(C)* and *(D)* show the same development in an overview (light micrographs of human lungs, aged $3^1/_2$ weeks, 250× *(C)* and 5.8 months, 360× *(D)*. *C*. During alveolarization thick immature septa are present that contain a double-layered capillary network (arrowheads) and that are capable to form new secondary septa (open arrows). *D*. During the maturation of the alveolar septa the capillary layers fuse to a single-layered capillary network (closed arrows) that appears alternately on either side of the septum. In some places, immature septa containing a double capillary network are still present (arrowheads).

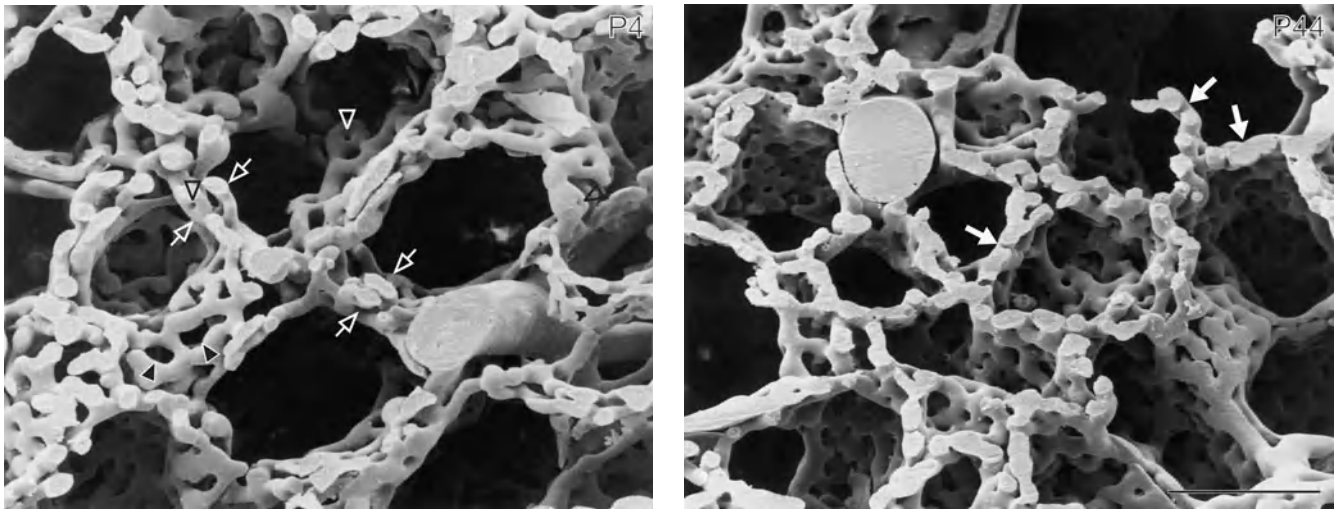

A *B*

Figure 5-14 Microvascular maturation observed in vascular casts of rat lungs. Scanning electron micrographs of vascular casts (Mercox) of rat lungs are shown at postnatal days 4 *(A)* and 44 *(B)*. The immature septa contain a double capillary network (open arrow, *A*). During maturation the capillaries rearrange and form in most parts of the septa one central single layered capillary network (closed arrows, *B*). The lung capillary networks grow mainly by intussusceptive growth. Slender transcapillary posts (holes less than 2 μm in diameter, open arrowhead, *A*) are introduced into the capillaries and grow out to capillary meshes (closed arrowhead, *A*). Bar, 50 μm. *(From Burri PH: Lung development and pulmonary angiogenesis, in Gaultier C, Bourbon J, Post M (eds).* Lung Disease. *New York, Oxford University Press, 1999, pp 122–151.)*

GROWTH OF THE LUNG

Transition from Development to Growth

Morphometric data obtained from the lungs of seven children aged between 26 days and 5 years and complemented with data from eight adult lungs allow us to distinguish two phases of lung growth. The first phase (from birth to about 18 months) corresponds to the period of ongoing lung development (alveolarization and microvascular maturation) and is therefore characterized by major shifts in the quantitative parameters of the parenchymal compartments. The parameters in close relationship with O_2 transport, the airspace and capillary volumes, grow faster than lung volume, mainly at the expense of the parenchymal tissue mass. The fact that capillary blood volume increases massively during the phase of microvascular maturation is an indication that capillary restructuring is associated with intense capillary growth.

In the second phase (from $1^1/_2$ years until body growth stops), the lung grows in a more proportionate fashion. The lung volume increases to the power of 1 to body weight, and the pulmonary compartments augment linearly with lung volume. Most important, the surface area for gas exchange and the morphometrically determined pulmonary diffusion capacity increase both to the power of 1 to body mass.

Lung Parenchyma: Late Alveolarization

As discussed, the stage of alveolarization represents a very distinct and visible period of lung development with its ongoing bulk alveolarization. It corresponds to a period of intense septation accompanied by a marked increase in gas exchange surface area. The question arises whether alveoli are formed once and for ever or further alveoli are added later at a slower pace and in a much less obtrusive manner during the period of so-called normal growth between the age of three and young adult age. This latter assumption implies that growth of existing structures is complemented by the formation of new interalveolar walls. The question can be important, because of some clinical implications. Acute lung injuries and acute respiratory distress syndromes are common causes of morbidity and mortality in intensive care units. Irrespective of the initial cause of the lung injury, both diseases are characterized by a diffuse damage of the lung parenchyma, which includes a reduction of the diffusion capacity and may lead to a loss of alveolar septa. If the lung were able to produce new alveoli all along childhood, this could favor a late recovery from various forms of structural damage. Furthermore, steroids are widely used during the treatment of lung diseases such as asthma and wheezing illnesses or other diseases such as inflammatory bowel diseases. Retinoids are used for the treatment of psoriasis and severe acne. Both drugs are known to alter the lung structure when given neonatally or during the phase of bulk alveolarization. It is evident that these drugs could have negative side effects on the lung in children and adolescents if alveolar formation is still active.

The reports about the end point of alveolarization in humans are conflicting and have been much debated in the past. So far the limitations of alveolar counting techniques,

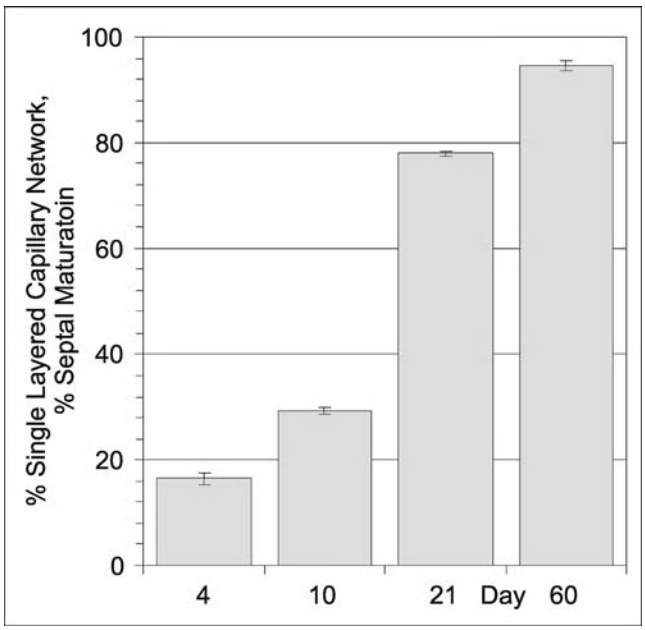

Figure 5-15 Maturation of the alveolar microvasculature. Intersection counting was used to determine the percentage of double- (immature) and single- (mature) layered capillary networks of the inter-airway septa of rat lungs. A basic level of single-layered networks was observed at the end of the saccular stage (day 4). Some maturation of the capillary network is already seen during the phase of alveolarization (day10), which demonstrates the large overlap between alveolarization and microvascular maturation. However, at the end of the phase of microvascular maturation 20 percent of the capillary networks are still immature. Standard deviations are given as error bars. *(From Roth-Kleiner M, Berger TM, Tarek MR, et al: Neonatal dexamethasone induces premature microvascular maturation of the alveolar capfl lary network.* Dev Dyn *233:1261–1271, 2005.)*

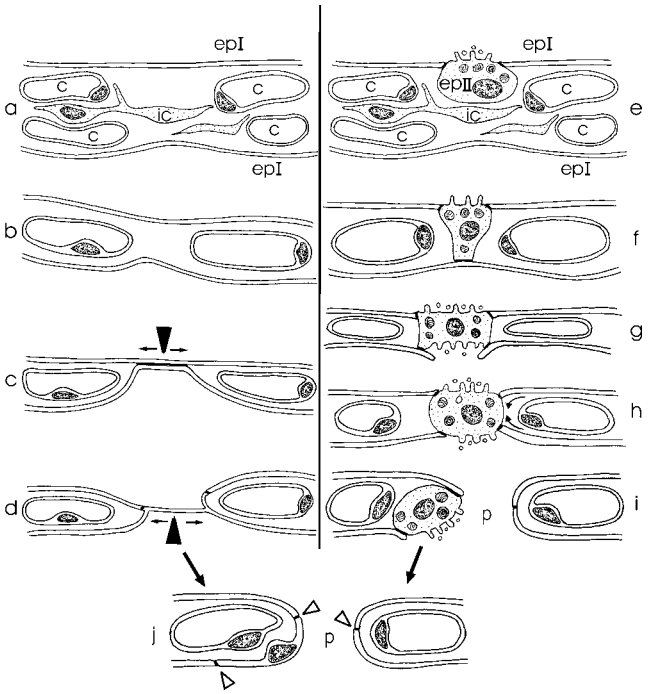

Figure 5-16 Formation of interalveolar pores of Kohn. Interalveolar pores start to form after maturation of the septum (a → b, f). Pores may be formed with (f–i) or without (b–d) the involvement of type II epithelial cells. *A*. Immature interalveolar septum with double capillary network. *B*. Cross section of a part of an interalveolar septum covered by type I epithelial cells (ep I) and containing two capillaries. *C*. Due to a thinning of the septum in the region of a capillary mesh, the connective tissue disappears in a spot like area and permits a contact between the type I cells resting on both surfaces of the septum. After rupture (arrowhead) the cell margins withdraw (arrows) and only one leaflet of one of the type I cells remains. *D*. The same process happens again (arrowhead and arrows) resulting in the formation of an interalveolar pore (i). *E*. Type II epithelial cells may also be involved in the formation of interalveolar pores. In a first step a type II cell makes a contact to a type I cell resting on the opposite side of the septum. *F*. The type II cell becomes also integrated into the epithelium opposite of its original side. *G*. In parallel to the retraction of the type II cell the two leaflets of the type I cells move toward each other. *H*. While forming the type I cell-cell junction the type II cell retracts completely and gives rise to a new pore. *I*. Finally, the type II cell is shifted along the septum and thus leaves the immediate vicinity of the pore. Alternatively, it may stay there or differentiate into a type I cell. Cellular junction running all around the pore (open arrowhead). c, capillary; ep I, type I epithelial cells; ep II, type II epithelial cells; ic, interstitial cell; p, pore. *(Based on Weiss M, Burri PH: Formation of interalveolar pores in the rat lung.* Anat Rec *244:481–489, 1996.)*

genetic and environmental induced variations on lung growth, and statistical constraints have not permitted collection of enough representative age-dependent data. Early studies have postulated an increase in alveolar number up to the age of 20 years. Successively this age has been brought down to about 11 or 8 years and then even to 2 years.

There is evidence that additional alveoli are formed in rats after the early phase of bulk alveolarization is completed. It has been postulated that this kind of later formation of alveoli takes place by means other than septation. Subpleural areas have been found to be preferred sites for the late addition of new alveoli. It was also estimated that in normal growth the number of alveoli increased by a factor of 2 after completion of bulk alveolar formation.

In view of these observations we may question the classical mechanisms of alveolar formation described in the preceding. Does the morphologic concept of alveolarization need to be revised or complemented? Are there other mechanisms of septation, in particular during so-called "late alveolarization"? Can the genetic program of lung development be delayed or even reverted under certain conditions? Or does the original concept of capillary up-folding still hold? Even in late alveolarization?

With the following considerations we would like to shed some light on these questions.

1. Disseminated interalveolar septa with an immature aspect can be found even in adult lungs. They could represent sites of focal alveolar formation (Fig. 5-13 *D*).
2. In a study in which rats were treated neonatally with high doses of glucocorticoids early, the authors observed a focal premature microvascular maturation

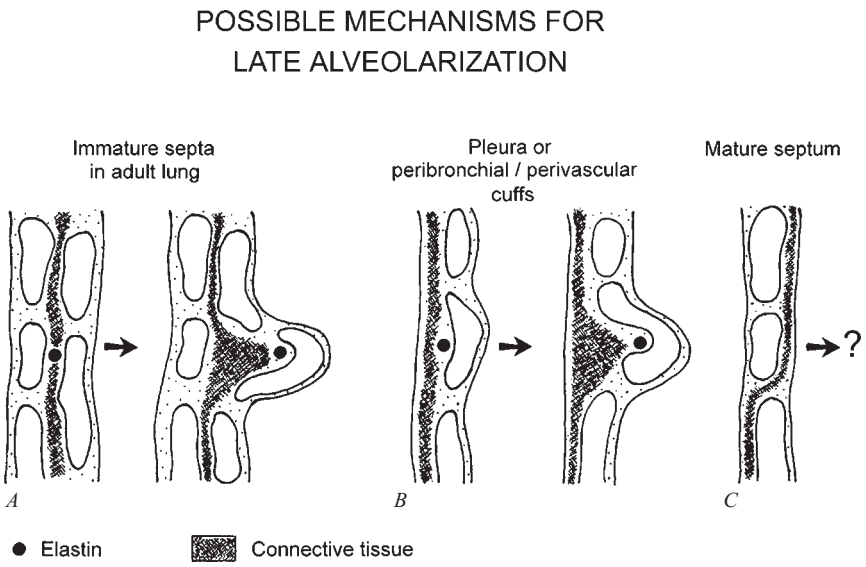

Figure 5-17 Possible mechanisms of late alveolar formation. *A*. Classical mode with lifting off of a capillary network in an immature type septum. Immature septa are still found dispersed in adult lungs. *B*. Classical mode applied in the uttermost lung periphery. *C*. Yet undefined angiogenic mechanism of capillary duplication occurring in mature septa (authors' unpublished observations). *(From Burri PH. Structural aspects of postnatal lung development – alveolar formation and growth*. Biol Neonate *89:313–322, 2006, with permission.)*

(27 percent mature single-layered capillary networks in treated rats versus 16 percent ones in controls), transient septal thinning, and transient inhibition of alveolarization. Following the withdrawal of the drug, the induced structural changes were readily compensated. By postnatal days 36 and 60 the lungs had almost completely recovered from the early insult. This suggests a high plasticity of alveolarization.

3. In the lung periphery, i.e., underneath the pleura and around the adventitial layer of the bronchi and blood vessels, the capillary network involved in gas exchange rests on a sheet of connective tissue. In these regions the capillary layer can be folded up in a manner resembling closely the classical mode of alveolarization (Figs. 5-7*C*, 5-17, and 5-18). For geometrical reasons the lung periphery makes up a high proportion of the total lung volume, especially in smaller lungs. In an adult rat lung a subpleural tissue mantle of 2-mm thickness represents almost 50 percent of the parenchymal lung volume. Therefore, the subdivision of peripheral airspaces can be very effective in increasing alveolar number.
4. There is recent evidence that capillary up-foldings can even be formed in mature rat septa thanks to local duplications of the capillary network at the base of the fold. This has been demonstrated in casts of rat lungs using synchrotron radiation x-ray tomographic microscopy allowing a 360-degree inspection of the critical sites (Schittny, unpublished data).

Conducting Airways

Unlike the lung parenchyma, the structure of the conducting airways is largely mature at birth—except perhaps for the terminal bronchioles, part of which may transform into respiratory bronchioles, as described by Boyden. Whereas the branching pattern does not change with age, it is not clear whether the bronchial tree grows proportionately after birth. In one study, the relationship between diameter and relative distance from the hilum was found to remain almost constant with age. In another analysis, this was true only after the age of 1 year, whereas during the first year of life, the larger bronchi showed a faster growth rate than the smaller conducting airways. Detailed studies of the airway epithelium of hamsters and rhesus monkeys indicate that the airway lining is largely mature at birth. Although there is some postnatal functional maturation, most developmental changes occur before birth.

Arteries and Veins

During fetal life, blood flow through the lung is limited to between 10 and 15 percent of the cardiac output. Clearly, the most important vascular event accompanying the onset of air breathing is the closure of the ductus arteriosus and the shunting of the entire cardiac output through the lung.

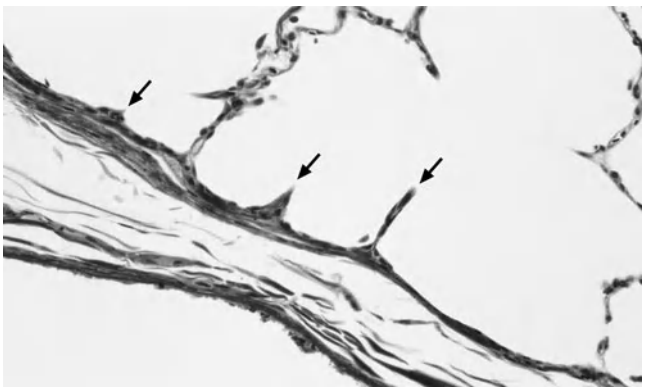

Figure 5-18 Subpleural region of human lung. Pleural interalveolar septa of varying heights. Arrows point to hypothetical sites of late alveolarization. Light micrograph, 320×. (*From Burri PH: Structural aspects of postnatal lung development–-alveolar formation and growth*. Biol Neonate *89:313–322, 2006, with permission.)*

The ductus arteriosus, first obstructed by muscular contraction, is anatomically closed within a few weeks by the fibrotic organization of an intravascular clot. The ligamentum arteriosum represents the tombstone of this important prenatal structure.

After birth, the wall thickness of pulmonary arteries decreases relative to their diameter. In small vessels (up to 200 μm in diameter), this decrease occurs very rapidly. It was assumed that it was due to a fall in smooth muscle tone. A study performed in pigs, however, related the vascular dilatation more to a concurrent extensive rearrangement and shape change of the vascular smooth muscle cells than a change in muscle tone. A similar adaptation has been noted in the small arteries of the human lung, with the structural remodeling being most rapid during the first month of life. In the larger arteries in humans, the thinning of the wall occurs less abruptly: The transformation is achieved by structural adaptations and therefore takes several months. After 1 year of age, the central pulmonary arteries no longer change their relative wall thickness appreciably; instead, they grow more or less proportionally.

Although the central vessels that accompany the conductive airways do not multiply after birth, the situation is completely different for the peripheral vessels. During the first 1 or 2 years of life, intra-acinar arteries undergo intense development and growth as they follow the extension of the peripheral airspaces. The number of small vessels therefore increases both absolutely and relatively. The relative increase

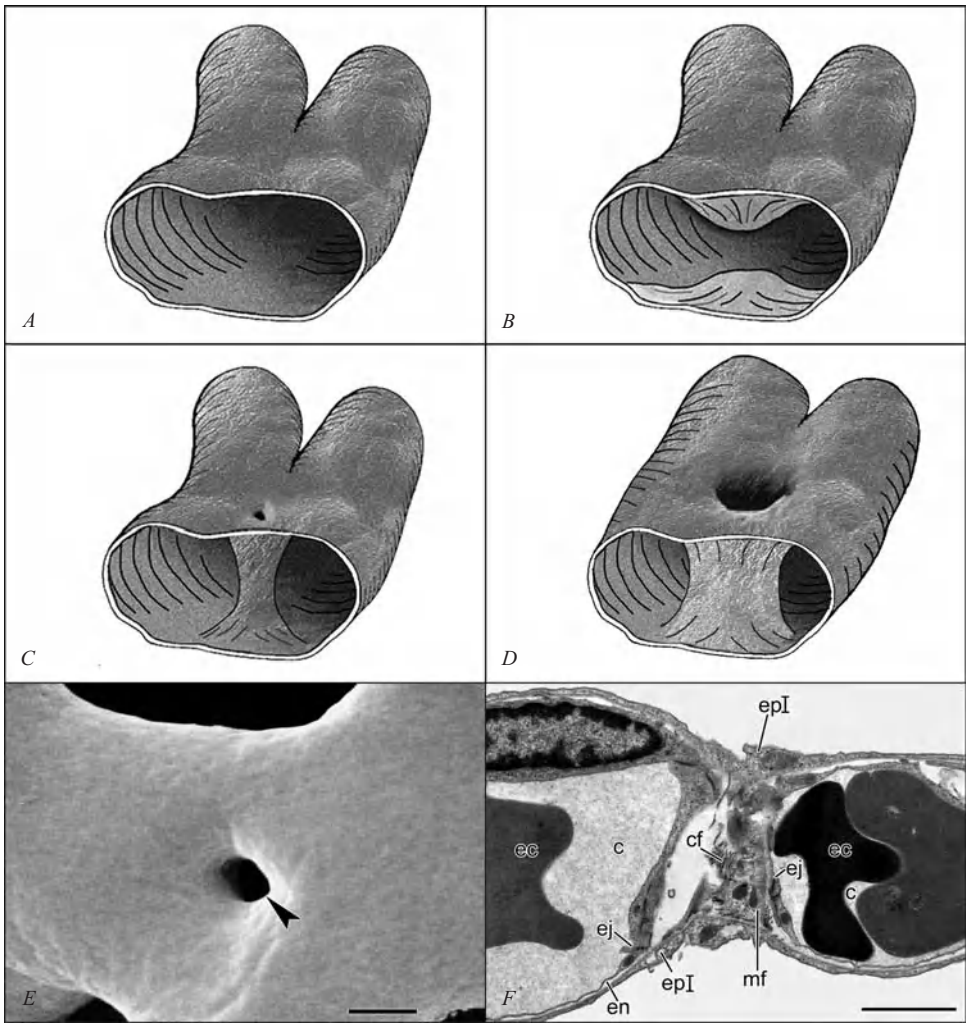

Figure 5-19 Intussusceptive capillary growth. *A–C.* During intussusceptive capillary growth the number of segments, the surface area, and the volume of an existing capillary network increases by the insertion of new transluminal tissue pillars. *D.* After formation, the pillar enlarges to form a new mesh. *E.* A Mercox cast of the alveolar microvasculature. Pillars appear as tiny holes, often in the range of 1.5 μm in diameter (scanning electron micrograph, ×5850, bar 2 μm). *F.* A longitudinal section of a transcapillary tissue pillar. The pillar structure exhibits a central axis formed by the cytoplasmic extension of a myofibroblast (mf) with actin filaments, and some collagen fibrils (cf); c, capillary; ec, erythrocyte; ej, endothelial cell junctions; en, endothelial cell; epI, type I cell (electron micrograph, ×9400, bar 2 μm). *(Panels A–D are based on Kurz H, Burri PH, Djonov VG: Angiogenesis and vascular remodeling by intussusception: From form to function.* News Physiol Sci *18:65–70, 2003.)*

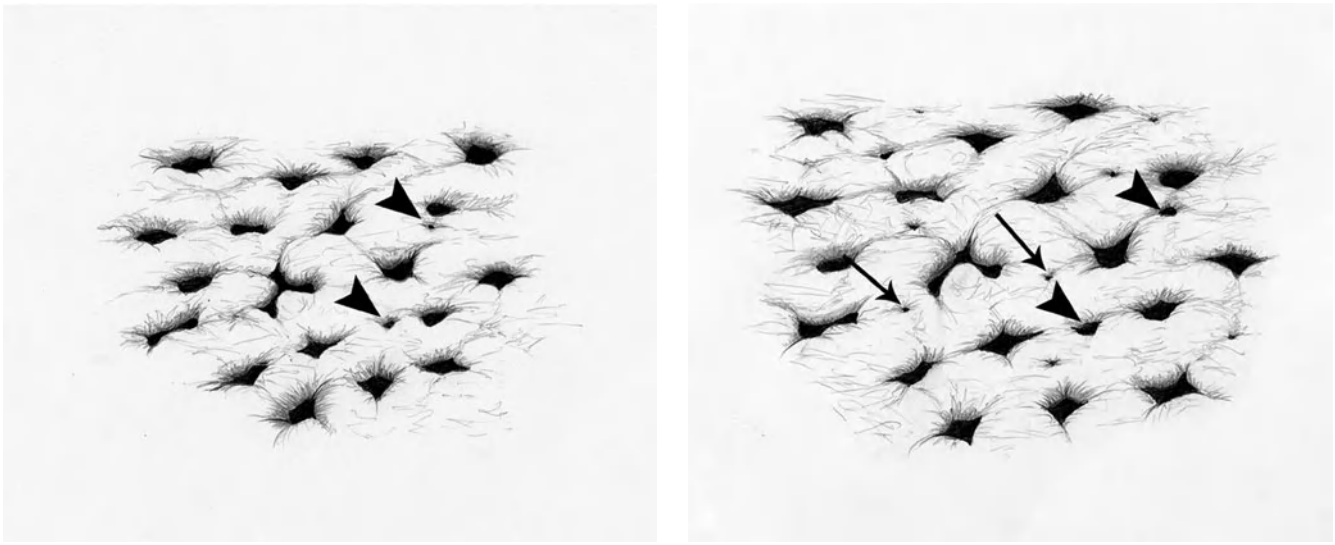
implies that their number augments per unit area of lung section. From the age of 5 years on, the relative number decreases again, reflecting the enlargement of the alveoli. The newly formed vessels are thin walled and are partly muscular or non-muscular, because muscle formation lags behind the increase in diameter. Gradually, muscularization then proceeds toward the periphery, a process that continues into adulthood.

Veins have a smaller amount of smooth muscle than do arteries. However, in principle, the same observations apply to veins as well as arterial development and growth.

Growth of the Lung Microvasculature

Interestingly, both in rats and humans, lung volume was found to increase about 23 times between birth and young adulthood. In both species lung microvasculature grows even more: The capillary volume increases by a factor of 35, whereas the capillary surface area augments about 20 times. Furthermore, scanning electron microscopy of microvascular casts reveals that the capillary meshwork in the interalveolar walls remains at the same high density, which means that all along growth the capillary system expands through the addition of new capillary segments, i.e. by angiogenesis. Angiogenesis is defined as the formation of new vascular segments from preexisting vessels. The classical concept for the expansion of the capillary networks in growing organs was vascular sprouting. Sprouting angiogenesis is characterized by a number of typical steps: local vasodilatation, increased vascular permeability, proteolytic degradation of basal laminas, proliferation and migration of endothelial cells, and formation of a solid sprout, which then is reorganized into a tubule. Finally, the new tubule connects to a neighboring vessel.

While we were investigating the capillary maturation in lung development by studying vascular casts in the scanning electron microscope, one of us (Burri) observed numerous tiny holes sometimes less than 1.5 µm in diameter (Fig. 5-19*E*). We hypothesized that these holes could represent newly formed intercapillary meshes (or "baby meshes"). By repetitive insertion of such tiny meshes, which then would grow and expand to normal-sized capillary meshes, the network would increase in surface area and gain in complexity (Fig. 5-20). Although this concept was first based on observations of casts alone, it was clear that matching structures had to be found in interalveolar walls at the ultrastructural level. The holes in the cast should correspond to some form of tissue pillars traversing the capillary lumina. By electron microscopic investigation of serial sections through the interalveolar septa, we demonstrated indeed the presence of tissue pillars of adequate diameters (Fig. 5-19*F*). The analysis of their ultrastructure allowed us to derive a plausible mechanism for their formation. As depicted in Fig. 19*A–D*, the classical formation of a transcapillary tissue pillar is a four-step process: (1) formation of symmetrical or asymmetrical protrusions from opposite parts of the capillary (Fig. 5-19*B*), which join and create a zone of inter-endothelial cell contact; (2) following reorganization of the inter-endothelial cell junctions the contact zone is centrally perforated: a transcapillary pillar of tissue is formed (Fig. 5-19*C*); (3) invasion of the pillar core by cell processes of pericytes and myofibroblasts, thus stabilizing the pillar structure (Fig. 5-19*F*); (4)



A *B*

Figure 5-20 Drawing of intussusceptive microvascular growth of a capillary layer. While the alveolar capillary networks are growing, the size of the capillary meshes stays quite constant. To achieve this, pillars are inserted into the capillaries (arrows) by intussusceptive angiogenesis. *A–B*. Two schematic drawings of consecutive stages of intussusceptive capillary growth. While newly formed pillars are growing in size (arrowheads in *A* and *B*), additional pillars are inserted into existing capillaries (arrows in *B*). Notice the larger surface covered by the capillary network in *(B)* than in *(A)*. The schematic drawing is based on scanning electron micrographs of vascular casts. *(From Burri PH, Hlushchuk R, Djonov V: Intussusceptive angiogenesis: Its emergence, its characteristics, and its significance.* Dev Dyn *231:474–488, 2004.)*

the pillar grows in diameter (Fig. 5-19 *D*) and finally becomes a normal-sized intercapillary tissue mesh.

We termed this new process of capillary growth intussusceptive microvascular growth (IMG). In histology, the term is commonly used to describe the growth of cartilage, which also grows within itself. Intussusception means "addition of new, but similar elements of formative material among those already present." Since its discovery in 1986, IMG has been well documented in numerous species and various organ systems. In tumor growth, IMG appears to play an important role besides sprouting angiogenesis and may be responsible for the failure of some antiangiogenic treatments targeting sprouting vessels.

This new "non-sprouting" intussusceptive angiogenesis has some advantages over the sprouting form: It is fast (hours versus days); it is not based on cell divisions in a first step; it is less leaky than sprouting; and it is efficient, because it happens while the blood is circulating through the vessel. However, it cannot bridge vascular gaps, such as cuts of the skin or scars.

Recent work has emphasized the significance of the intussusception process in demonstrating that besides capillary growth it was involved in the de novo formation of vascular trees and optimizing vascular branching geometry, and vascular pruning (for review, see Burri and Djonov).

Dimensions of the Adult Lung

Table 5-2 summarizes the relevant data for a "standard" adult human lung. In a direct comparison of quantitative data of adult and newborn lungs, it is manifest that lung structure is far from representing a tissue framework of stable composition. So, with age, the volume density (volume per lung volume) of interalveolar septa decreases, the volume density of the airspace increases, and, within the interalveolar walls, the volume fraction of the blood vessels increases at the expense of the tissue volume. Although the arithmetic mean thickness of the air-blood tissue interface (calculated by dividing total tissue mass by the alveolar surface area) falls from around 5 μm at birth to 2.5 μm in the adult, the functionally more relevant harmonic mean thickness of the air-blood tissue barrier, a measure of the average effective diffusion distance, remains largely unaffected by the structural alterations of postnatal development.

Despite the lung undergoing extensive structural remodeling during development and growth, the gas exchange surface areas of airspaces and capillaries increase linearly with body weight. This fact illustrates that the implemented structural alterations are always well balanced to constantly meet the O_2 needs of the organism throughout lung development.

Table 5-2

Dimensions of the Human Lung Based on Morphometry

Lung volume, l	4.3 ± 0.3
Volume of compartments	
Parenchyma, l	3.9 ± 0.3
Parenchymal tissue, ml	298 ± 36
Parenchymal capillaries, ml	213 ± 31
Surface areas	
Airspace, M2	143 ± 12
Capillary, m2	126 ± 12
Body weight, kg	74 ± 4

Values represent mean values ± standard errors of eight human lungs. Source: Data from Crapo JD, et al: Cell numbers and cell characteristics of the normal human lung. Cellular and Molecular Mechanisms Regulating Airway Smooth Muscle Physiology and Pharmacology

Reynold A. Panettieri, Jr.

Evidence suggests that airway smooth muscle, the most important cell modulating bronchomotor tone, plays an important immunomodulatory role in the orchestration and perpetuation of airway inflammation. The signaling pathways that modulate leukocyte function may be disparate from those found in resident effector cells such as airway smooth muscle, fibroblasts, and epithelial cells. Further investigation and understanding of the pivotal signaling pathways that modulate airway smooth muscle cell shortening, secretion of chemokines/cytokines, and expression of cell adhesion molecules may offer new therapeutic approaches to the treatment of asthma.

Traditionally, airway smooth muscle (ASM) in asthma was perceived as a purely contractile tissue, but new evidence challenges this concept. ASM cells play an important role, not only in regulating bronchomotor tone, but also in the perpetuation of airway inflammation and the remodeling of the airways. This chapter discusses excitation-contraction coupling and the newly identified functions of ASM cells: the synthetic function of ASM cells, defined as the ability to secrete immunomodulatory cytokines and chemokines and express surface receptors that are important for cell adhesion and leukocyte activation as summarized in Fig. 6-1. Pharmacologic approaches to modify the synthetic function of ASM

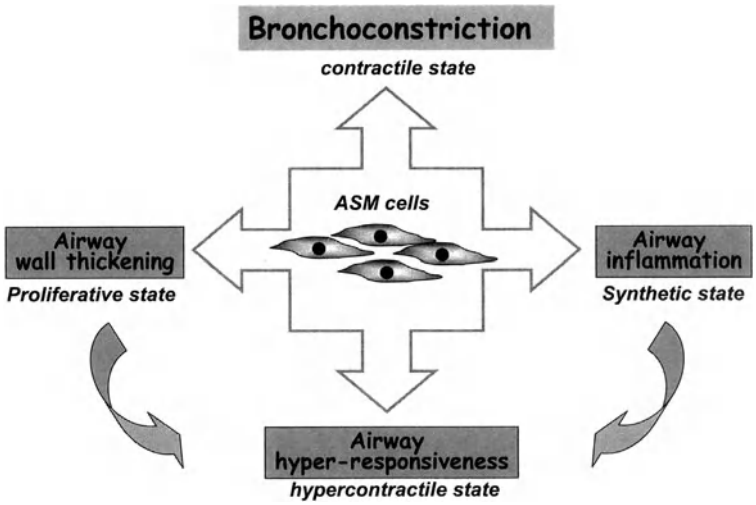

Figure 6-1 Proposed model for the pathological roles of airway smooth muscle (ASM) in lung diseases. The primary function of ASM is to regulate the bronchomotor tone in response to contractile agonists. ASM responsiveness is influenced by a variety of internal factors (contractile proteins, cell hyperplasia) and external stimuli (mechanical forces, extracellular matrix, nerves). In chronic airway diseases where there is an imbalance between these factors, ASM activity will likely be impaired. The degree of bronchoconstriction could be exacerbated by an increase in ASM mass that augments the degree of the airway wall narrowing. Structural changes that alter the forces imposed on ASM or inflammatory agents that alter the intrinsic properties of the ASM may induce airway hyperresponsiveness. By the ability of ASM to secrete a variety of pro-inflammatory mediators, ASM also may regulate airway inflammation, which in turn can affect both contractile and proliferative phenotypes. *(Used with permission from Amrani Y, Panettieri RA: Airway smooth muscle: Contraction and beyond. Int J Biochem Cell Biol 35:272, 2003.)*

cells and how altered synthetic function may contribute to airway remodeling also are discussed.

ASTHMA AND AIRWAY SMOOTH MUSCLE SHORTENING

Asthma is characterized by a nonspecific bronchial hyperresponsiveness (BHR) and is defined as excessive narrowing of airways in response to a variety of contractile agonists. Elucidating the molecular mechanisms that induce and/or maintain BHR will undoubtedly provide insight for the design of new treatments for chronic airway diseases. Evidence suggests that shortening of ASM in response to G protein–coupled receptor (GPCR) stimulation regulates airway caliber and bronchomotor tone. ASM shortening then is initiated by increases in cytosolic Ca^{2+} concentrations and the subsequent activation of the contractile apparatus, including the phosphorylation of myosin light chain (MLC) 20. A variety of stimuli such as inflammatory cytokines, pollutants, mechanical strain, and some therapeutic agents prime the ASM to become "nonspecifically" hyperresponsive to contractile agonists. Allergens and some, but not all, cytokines promote ASM responsiveness to contractile agonists. Tumor necrosis factor α (TNFα) and interleukin (IL)-13 enhance murine ASM contractile responses to carbachol without affecting changes in receptor affinity, suggesting modulation of ASM responsiveness at a site downstream from receptor activation. Repeated allergen challenge also may alter expression of different contractile proteins and increase ASM contractility. Changes in the mechanical properties of ASM (i.e., cytoskeleton reorganization) increase ASM contractile responsiveness by prolonging ASM shortening or inducing sustained mechanical strain. The precise molecular mechanisms defining such augmented ASM contractility remain unknown.

Calcium Signaling: A Potential Target for Modulators of ASM Responsiveness

Because of the central role of Ca^{2+} in regulating ASM contractile function, many investigators have focused on Ca^{2+} regulatory mechanisms in ASM. Using cultured human tracheal or bronchial smooth muscle cells as in vitro models of ASM responsiveness, GPCR-associated signaling in ASM can be modulated by a variety of inflammatory stimuli. Cytokines, such as TNFα, augment agonist-induced ASM contractility by enhancing, in a nonspecific manner, agonist-evoked Ca^{2+} transients to bradykinin and carbachol. Similarly, ASM cells derived from hyperresponsive inbred rats have augmented bradykinin-induced Ca^{2+} responses when compared with ASM cells derived from normoresponsive rats. IL-13, an important mediator in allergic asthma, also nonspecifically increased Ca^{2+} responses to contractile agonists. Together, these data suggest that "pro-asthmatic" cytokines, in a nonspecific manner, modulate GPCR-associated Ca^{2+} responses in ASM—a mechanism likely to affect ASM contractility (Fig. 6-2).

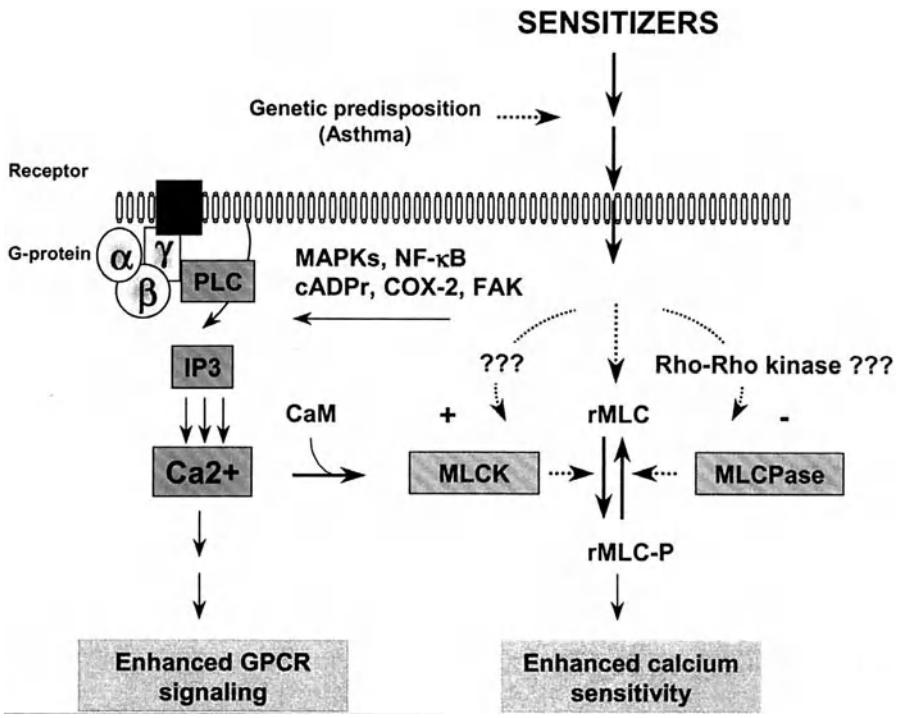

Figure 6-2 Hypothetical model of the potential intracellular mechanisms involved in the modulation of ASM hyperresponsiveness in asthma. In chronic asthma, ASM is exposed to a variety of sensitizers, defined as conditions that increase ASM contractile responses to agonists, such as allergen, inflammatory cytokines and proteins, activated T lymphocytes, therapeutic agents, and pollutants. Based on current evidence, sensitizers may act in concert to modulate ASM reactivity by activating two major intracellular pathways. Some cytokines may increase ASM contraction by enhancing G protein–coupled receptor (GPCR)–associated calcium (Ca^{2+}) responses, an effect that was shown to be regulated by multiple different signaling pathways, such as mitogen-activated protein kinases (MAPKs), nuclear factor-κB (NF-κB), cyclic ADP-ribose (cADPr), and the focal adhesion kinase (FAK). This may occur via the Rho-Rho kinase pathway, which has been shown to enhance the level of myosin light chain (MLC) phosphorylation by inhibiting the activity of MLC phosphatase (MLCPase). Increases in cyclooxygenase (COX)-2 and phospholipase (PL)A_2 expression or activity have also been found to be involved in the modulation of GPCR-associated Ca^{2+} responses. Sensitizers such as other cytokines also may enhance ASM contraction by increasing the sensitivity of the contractile apparatus to Ca^{2+}, which increases the amount of force produced for a given cytosolic concentration of Ca^{2+}. Many studies showed the important role of Rho-Rho kinase pathways, which inhibit the activity of MLCPase and increase MLC phosphorylation. Increases in MLC kinase (MLCK) content or activity, as reported in human sensitized ASM, also may play a potential role in increasing ASM contractile activity; however, the underlying mechanisms are as yet unknown. CaM, calmodulin; IP_3, inositol-1,4,5-trisphosphate; rMLC, regulatory light chains of myosin II. P, phosphorylation. *(Used with permission from Amrani Y, Panettieri RA Jr: Modulation of calcium homeostasis as a mechanism for altering smooth muscle responsiveness in asthma. Curr Opin Allergy Clin Immunol 2:39, 2002.)*

Potential Molecular Mechanisms Underlying ASM Hyperresponsiveness: Increased RhoA/Rho Kinase Pathway Activation

Differences in ASM contractility observed among different mouse strains (e.g., C3H/HeJ, Balb/C, and A/J) may involve mechanisms that are independent of agonist-induced Ca^{2+} responses and, instead, involve modulation of Ca^{2+} sensitivity of the contractile apparatus. A possible mechanism for such effects involves the small monomeric G protein Rho, which can augment ASM contractility by increasing levels of MLC phosphorylation via Rho-activated kinase-dependent suppression of MLC phosphatase as shown in Fig. 6-2. Activation of RhoA and Rho-activated kinase by a variety of stimuli, including cytokines, sphingolipids, and mechanical stress, is associated with the development of BHR. Conceivably, abnormal RhoA activity and/or expression may dramatically alter ASM contractility, not only via Ca^{2+} sensitization but also through increased expression of Rho-dependent contractile proteins.

Persistent Activation of β_2-Adrenergic Receptors

Despite the utility of β-agonists in treating acute bronchoconstriction in asthma, persistent activation of β_2-adrenergic receptors can alter BHR by increasing ASM responsiveness to contractile agonists. Overexpression of β_2-adrenergic receptors in ASM enhances agonist-induced bronchoconstrictive responses both in vivo and in vitro. Conversely, ASM from β_2-adrenoceptor–deficient mice showed reduced

agonist-induced inositol phosphate turnover and isometric force. Together, these data suggest that $G\alpha_q$-coupled receptors and $G\alpha_i$-coupled receptors in ASM are functionally linked, possibly leading to increased expression of phospholipase C-β by β_2-adrenergic receptor activation. Such observations might provide a plausible explanation for the findings that chronic use of β-agonists can worsen asthma control.

Emerging evidence shows that changes in ASM contractile properties play an important role in the development of BHR associated with chronic airway diseases such as asthma. In vitro studies support the concept that a variety of conditions including physical stimuli (e.g., repeated exposure or long-term stimulation) or chemical stimuli (e.g., cytokines) augment the contractile force generated by ASM by acting on multiple key pathways. These pathways include aberrant activation of contractile and relaxant receptors, an altered function of Ca^{2+} regulatory signaling molecules, and a reorganization of the cytoskeletal apparatus. Understanding the signaling pathways involved in excitation-contraction coupling and contractile protein expression and function in ASM therefore may offer potentially new targets for the treatment of bronchial hyperresponsiveness.

AIRWAY SMOOTH MUSCLE HYPERTROPHY AND HYPERPLASIA

Accumulating evidence suggests that asthma may develop into a progressive and irreversible disease. Subjects with asthma have a greater decline in pulmonary function as compared with normal subjects and may manifest persistent airways hyperresponsiveness even after prolonged corticosteroid therapy. Furthermore, morphometric studies in subjects with asthma have revealed structural remodeling in the airways, with reports of airway wall thickening observed at postmortem as compared with that obtained from subjects without asthma. Collectively, the term airway remodeling now refers to increases in ASM mass as well as submucosal fibrosis, airway epithelial desquamation and vascular alterations. Because increased airway wall thickening decreases airway caliber, airway remodeling may enhance airway narrowing seen in asthmatics. Although numerous cell types contribute to airway remodeling, current evidence, using sophisticated modeling techniques, suggests that the increase in ASM mass has the greatest impact on airway narrowing in asthma.

Increases in ASM mass observed in the bronchi of subjects with chronic severe asthma appear to be due to increases in cell number (hyperplasia) and increases in cellular size (hypertrophy). Although hypertrophy of ASM may play an important role in airway remodeling, regulation of ASM hyperplasia is considered an attractive therapeutic target for the potential treatment of airway remodeling and irreversible airflow obstruction in subjects with asthma, as shown in Fig. 6-3.

Despite considerable efforts in the discovery of new anti-inflammatory and bronchodilator agents, the development of anti-remodeling drugs remains in its infancy. Further, specific biomarkers that are readily accessible to investigators that would quantitate ASM hyperplasia remain elusive and, as such, the discovery of drugs to specifically treat airway remodeling remains problematic. Over the past decade, researchers have utilized cell culture techniques to elucidate the cellular and molecular mechanisms underlying ASM cell proliferation and identify the critical cell cycle events that regulate ASM cell growth. Further, new animal models that appear to mimic airway remodeling occurring in human asthma have been used in hopes of designing therapies to prevent or abrogate airway remodeling.

Mediators of Airway Smooth Muscle Proliferation In Vitro

Many inflammatory mediators are found in bronchoalveolar lavage fluid (BALF) from asthmatic airways, and some induce ASM proliferation in vitro. To date, mitogenic or co-mitogenic stimuli include: growth factors, such as epidermal growth factor (EGF), insulin-like growth factors, platelet-derived growth factor (PDGF) isoforms BB and AB and basic fibroblast growth factor; plasma- or inflammatory cell-derived mediators, such as lysosomal hydrolases (β-hexosaminidase and β-glucuronidase), α-thrombin, tryptase, lysophosphatidic acid, and sphingosine 1-phosphate (S1P); and contractile agonists, such as histamine, endothelin-1, substance P, phenylephrine, serotonin, thromboxane A_2, and leukotriene D_4 (LTD_4). Collectively, data suggest that some, but not all, agonists that activate GPCRs alone promote human ASM cell proliferation. However, any contractile agonist that increases cytosolic calcium appears to augment growth factor-induced human ASM mitogenesis.

Although the cytokines interleukin-1β (IL-1β), IL-6, and tumor necrosis factor α (TNFα) are also increased in BALF of subjects with asthma, whether these cytokines stimulate ASM proliferation in vitro remains controversial. IL-1β and IL-6 induced hyperplasia and hypertrophy of cultured guinea pig ASM cells; however, others have shown that IL-1β and IL-6 are not mitogenic for human ASM cells. TNFα has no immediate mitogenic effect on human ASM cells; however, the proliferative effect of TNFα on human ASM cells appears to be biphasic in which low concentrations of TNFα are pro-mitogenic, while at higher concentrations the mitogenic effect is abolished. This biphasic effect of TNFα may be due to cytokine-induced cyclooxygenase 2-dependent prostanoid production or autocrine secretion of interferon β that is growth inhibitory. Cyclooxygenase products, such as prostaglandin E_2, inhibit DNA synthesis. Therefore, cytokine-induced proliferative responses in ASM may be greater under conditions of cyclooxygenase inhibition, in which the expression of growth inhibitory prostanoids, such as prostaglandin E_2, is limited.

ASM proliferation also can be stimulated by mechanisms apart from exposure to soluble mediators. Mechanical stimuli, such as the acute compressive stress of the airway during bronchospasm, induce ASM DNA synthesis. ASM

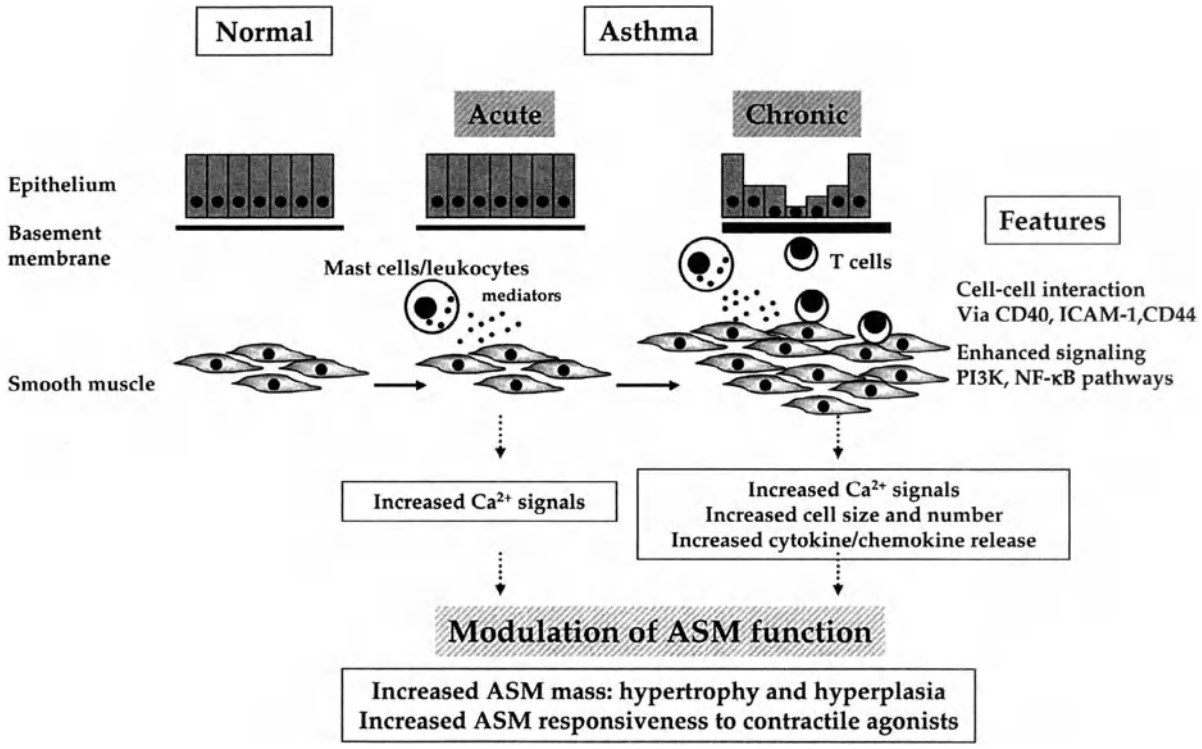

Figure 6-3 Factors affecting ASM function in acute and chronic state of asthma. During acute inflammation, a variety of mediators, such as cytokines, can modulate ASM contractile function by enhancing calcium signaling to agonists. These mediators regulate the recruitment and activation of eosinophils and T lymphocytes in the airway mucosa, a characteristic histopathological feature of the chronic disease. The persistence of airway inflammation via the production of cytokines and chemokines by both inflammatory as well as structural cells has the potential to directly stimulate ASM proliferation or as a result of T cell-ASM interaction mediated by cell surface expression of various CAM proteins such as ICAM-1, CD40 and CD44. Enhanced activation of phosphatidylinositol 3-kinase (PI3K) or the transcription factor NF-κB in ASM also may stimulate mitogenic and synthetic functions. *(Used with permission from Ammit AJ, Panettieri RA Jr: Airway smooth muscle cell hyperplasia: A therapeutic target in airway remodeling in asthma? Prog Cell Cycle Res 5:49, 2003.)*

proliferation also can be regulated by leukocyte-smooth muscle cell interactions, through cell adhesion molecules (CAM), such as ICAM-1 and VCAM-1. Deposition of extracellular matrix (ECM) proteins in the airways, a characteristic feature of airway remodeling in asthma, modulates mitogen-induced ASM growth. ECM proteins collagen I, III, V, fibronectin, tenascin, hyaluronan, versican, and laminin α2/β2 surround ASM and are increased in asthmatic airways as compared with that from healthy subjects. Fibronectin and collagen I increase human ASM cell mitogenesis in response to PDGF-BB or α-thrombin, whereas laminin inhibits proliferation. Furthermore, ECM proteins may be responsible for the low rates of apoptosis observed in ASM cells. The constitutive expression of ECM proteins by human ASM cells can be enhanced by exposure to asthmatic sera. Taken together, these studies suggest an additional cellular source for ECM deposition in asthmatic airways, apart from myofibroblasts, and implicate a novel mechanism in which ASM cells may modulate autocrine proliferative responses.

New evidence suggests that ASM from subjects with asthma may have an intrinsically different pattern of proliferation, compared with that from subjects without asthma. Cultured ASM from subjects with asthma proliferated at a faster rate and in greater numbers than the nonasthmatic controls. This was supported by flow cytometric analysis, whereby the proportion of cells from asthmatics in the G_2 + M phase was approximately twice that observed in the nonasthmatics. Further experiments are warranted to elucidate the underlying mechanism and confirm these observations.

Signal Transduction Pathways That Regulate the Cell Cycle in Airway Smooth Muscle In Vitro

Diverse stimuli, including growth factors, plasma- or inflammatory cell-derived mediators, contractile agonists and cytokines, induce ASM proliferation in vitro. These soluble ASM mitogens act via different receptor-operated mechanisms. While growth factors induce ASM cell mitogenesis by activating receptors with intrinsic protein tyrosine kinase (RTK) activity, contractile agonists released from inflammatory cells mediate their effects via activation of GPCRs. Cytokines signal through cell surface glycoprotein receptors that function as oligomeric complexes consisting of typically two to four receptor chains, coupled to Src family nonreceptor tyrosine kinases, such as lyn.

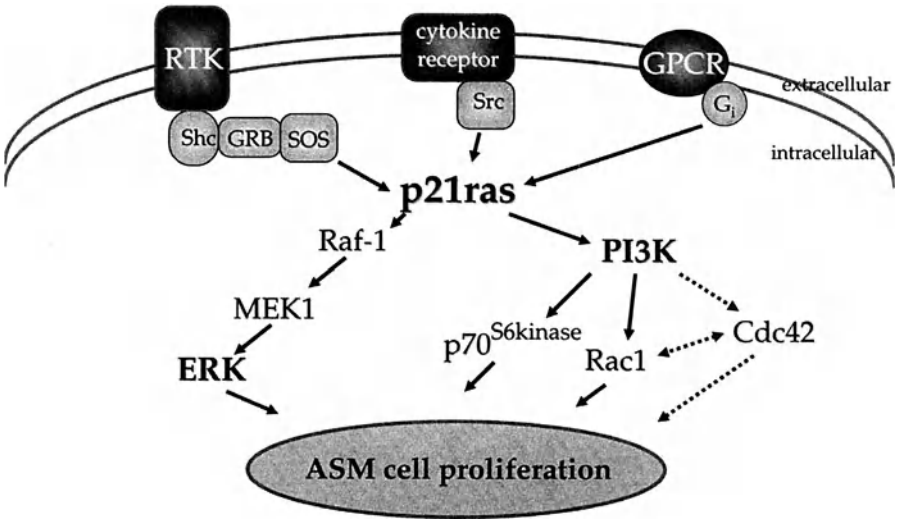

Figure 6-4 Schematic representation of signal transduction mechanisms that regulate ASM proliferation. ASM mitogens act via RTKs, cytokine receptors, or G protein–coupled receptors (GPCRs), to activate the small GTPase p21ras. p21ras Proteins then interact with downstream effectors, Raf-1 and phosphatidylinositol 3-kinase (PI3K). Raf-1 activates MEK1, which then phosphorylates extracellular signal–regulated kinase (ERK). PI3K activates downstream effectors, $p70^{S6k}$ or members of the Rho family GTPases, Rac1, and Cdc42 [although whether Cdc42 acts upstream of Rac1, or cross-talk exists is unknown at present (as indicated by the dashed lines)]. ERK, PI3K, and the downstream effectors of PI3K regulate cell cycle proteins; thus, the ERK and PI3K pathways are considered to be two major independent signaling pathways regulating ASM cell growth. *(Used with permission from Ammit AJ, Panettieri RA Jr: Invited review: the circle of life: cell cycle regulation in airway smooth muscle. J Appl Physiol 91:1431, 2001.)*

Despite disparate receptor-operated mechanisms, recent evidence suggests that the small guanidine triphosphatase (GTPase), p21ras, acts as a point of convergence for diverse extracellular signal-stimulated pathways in ASM cells, as shown in Fig. 6-4. Interestingly, synergy occurs between RTK and GPCRs that promotes human ASM mitogenesis and p21ras activation. In their GTP-bound active state, p21ras proteins interact with downstream effectors, namely, Raf-1 and phosphatidylinositol 3-kinase (PI3K). By recruiting Raf-1, a 74-kD cytoplasmic serine/threonine kinase, to the plasma membrane, GTP-bound p21ras activates the extracellular signal-regulated kinase (ERK) pathway, although Raf-1–independent signaling to ERK also has been described. p21ras Also binds and activates PI3K by using specific regions termed switch I (Asp^{30}–Asp^{38}) and switch II (Gly^{60}–Glu^{76}). Although alternative pathways exist (e.g., protein kinase C–dependent pathways or reactive oxygen–dependent pathways), ERK and PI3K activation appears to be the dominant signal transduction pathway for RTK-, GPCR-, or cytokine-stimulated growth of ASM cells.

Inhibition of Airway Smooth Muscle Proliferation In Vitro

Many of the widely used therapies for the control of asthma symptoms have been examined for their ability to inhibit ASM cell proliferation in vitro. Although a systematic study of the relative efficacies has not been performed, in vitro evidence provides useful data to suggest that anti-asthma drugs may, in part, reduce airway remodeling in vivo. Furthermore, these studies provide useful clues in the design of future therapeutic agents to treat this aspect of asthma.

Corticosteroids are the most widely used therapy for the control of airway inflammation in asthma. In human ASM cells, the corticosteroids dexamethasone and fluticasone propionate arrest ASM cells in the G1 phase of the cell cycle. Corticosteroids reduced thrombin-stimulated increases in cyclin D1 protein and mRNA levels, and attenuated pRb phosphorylation via a pathway either downstream or parallel to the MAPK pathway. Interestingly, corticosteroids may not be effective in inhibiting ASM cell mitogenesis in response to receptor tyrosine kinase–activating mitogens.

β_2-Agonists activate the β_2-adrenergic receptor G_s-adenylyl cyclase pathway to elevate 3′:5′ cyclic adenosine monophosphate (cAMP) in ASM cells. Apart from having potent and rapid effects on the alleviation of bronchospasm, cAMP, presumably through the activation of cAMP-dependent protein kinase, has significant effects on mitogen-induced ASM cell proliferation. Both albuterol and fenoterol inhibit mitogen-induced proliferation of human ASM cells. cAMP can be hydrolyzed within cells by phosphodiesterases (PDEs), a family of enzymes containing at least seven isoenzymes. PDE inhibitors also elevate intracellular cAMP concentration and inhibit cell proliferation. Mitogen-induced ASM cells were attenuated with siguazodan and rolipram, specific inhibitors of type 3 and 4 PDE, the two most important PDE isoenzymes for the control of intracellular cAMP concentration in ASM cells. The effect of cAMP on cell proliferation was via cAMP-mediated transcriptional activation, whereby the effects of forskolin, an

activator of adenylate cyclase, inhibited DNA synthesis and cyclin D1 expression, and induced cAMP response element-binding protein (CREB) phosphorylation and DNA binding in ASM. By increasing cAMP in ASM cells, forskolin suppressed cyclin D1 gene expression via phosphorylation and transactivation of CREB, suggesting that the effect of cAMP on cyclin D1 gene expression is via *cis*-repression of the cyclin D1 promoter. Furthermore, β_2-adrenergic receptor agonists, and other cAMP-elevating agents, also may induce G1 arrest by post-transcriptionally inhibiting cyclin D1 protein levels by action on a proteasome-dependent degradation pathway.

Other approaches aimed at abrogating ASM cell proliferation focus on the inhibition of contractile agonist receptor activation. Cysteinyl leukotrienes (CysLT), such as LTD_4, markedly augment proliferation induced by mitogens, such as EGF and thrombin in human ASM cells. Interestingly, there exists selectivity with regard to the inhibition of the CysLT receptors and the augmentation of ASM mitogenesis. Pranlukast and pobilukast, but not zafirlukast, inhibited LTD_4-augmented EGF-induced human ASM cell mitogenesis. Additional studies are needed to define the precise mechanism by which these antagonists block LTD_4-induced ASM cell growth. Further elucidation of the signaling and transcriptional targets for the inhibition of cell cycle progression by corticosteroids, β_2-agonists, PDE inhibitors, and CysLT receptor antagonists may suggest new uses for traditional asthma therapies. In addition to these existing anti-asthma drugs, heparin, IL-4, nitric oxide, and atrial natriuretic peptide also have been shown to have potent inhibitory effects on mitogen-induced ASM proliferation. Interestingly, inhibiting the secretion of matrix metalloproteinase-2 from ASM cells reduces ASM hyperplasia. Further, the combination of multiple agents may be conducive to limiting airway remodeling in asthma.

CHEMOKINE AND CYTOKINE RELEASE BY AIRWAY SMOOTH MUSCLE CELLS

The production of pro-inflammatory mediators by trafficking leukocytes has a profound influence on ASM cells. Exposure of ASM to cytokines or growth factors alters contractility and calcium homeostasis and induces smooth muscle cell hypertrophy and hyperplasia. New evidence suggests that ASM cells also can secrete a number of cytokines and chemoattractants. In bronchial biopsies of subjects with mild asthma, ASM constitutively expresses RANTES, a C-C chemokine; in vitro, RANTES secretion is induced by TNFα and interferon (IFN) γ. Similarly, the C-X-C chemokine IL-8 also is secreted by ASM in response to TNFα, IL-1β, and bradykinin. Other chemokines that are secreted by ASM cells include eotaxin, an eosinophil chemoattractant, and monocyte chemotactic protein (MCP)-1, MCP-2, MCP-3 as shown in Fig. 6-1.

IL-6, a pleiotropic cytokine, induces smooth muscle cell hyperplasia, but also modulates B- and T-cell proliferation and immunoglobulin secretion. IL-6 secretion by ASM cells is inducible by multiple stimuli, including IL-1β, TNFα, TGF-β, and sphingosine-1-phosphate. Interestingly, transgenic expression of IL-6 in the murine lung evokes a peribronchiolar inflammatory infiltrate but promotes airway *hypo*responsiveness, suggesting an intriguing role for IL-6 in controlling local inflammation and regulating airway reactivity and consistent with the known ability of IL-6 to inhibit TNFα and IL-1β secretion. ASM cells also may play a role in promoting both the recruitment and survival of eosinophils by secretion of GM-CSF and IL-5. Finally, additional cytokines that are secreted by human ASM cells include IL-1β, IFNβ, and other IL-6 family cytokines, such as leukemia inhibitory factor and IL-11, which are secreted following exposure of ASM cells to viral particles.

Receptors Involved in Cell Adhesion and Lymphocyte Activation

Cell adhesion molecules (CAMs) mediate leukocyte-endothelial cell interactions regulating cell recruitment and homing. The expression and activation of a cascade of CAMs that include selectins, integrins, and members of the immunoglobulin superfamily, as well as the local production of chemoattractants, leads to leukocyte adhesion and transmigration into lymph nodes and sites of inflammation involving nonlymphoid tissues. The mechanisms that regulate extravasation of leukocytes from the circulation during the establishment of a local inflammatory response are rapidly being delineated. Less defined are the subsequent interactions of the infiltrating leukocytes with other cell types in the bronchial submucosa or with the ECM, which may be important for sustaining the inflammatory response.

In addition to mediating leukocyte extravasation and transendothelial migration, CAMs promote submucosal or subendothelial contact with cellular and ECM components and serve as co-stimulatory molecules in the activation of leukocytes. New evidence suggests that CAMs mediate inflammatory cell–stromal cell interactions that may contribute to airway inflammation. ASM cells express ICAM-1 and VCAM-1, which are inducible by a wide range of inflammatory mediators. In contrast, contractile agonists such as bradykinin and histamine have little effect on ASM CAM expression. ASM cells also constitutively express CD44, the primary receptor of the matrix protein hyaluronan. Activated T lymphocytes adhere via LFA-1 and VLA-4 to cytokine-induced ICAM-1 and VCAM-1 on cultured human ASM cells. Moreover, an integrin-independent component of lymphocyte-smooth muscle cell adhesion appears to be mediated by CD44-hyaluronan interactions.

CAMs can function as accessory molecules for leukocyte activation. However, whether CAMs expressed on smooth muscle serve this function remains controversial. ASM cells do express major histocompatibility complex (MHC) class II and CD40 following stimulation with IFNγ. Recent studies also suggest that human ASM cells express low levels of CD80 (B7.1) and CD86 (B7.2). The physiological relevance of these findings remains unknown since ASM

cells cannot present alloantigen to CD4 T cells, despite the expression of MHC class II and co-stimulatory molecules.

However, functionally adhesion of stimulated CD4 T cells can induce smooth muscle cell DNA synthesis. This appears to require direct cell-cell contact and is not mimicked by treatment of the cells with T-cell conditioned medium. In addition, ligation of CD40, a co-stimulatory molecule up-regulated by IFNγ, increases intracellular calcium as well as IL-6 secretion; engagement of VCAM-1 on ASM cells activates PI3K and augments growth factor–induced ASM cell proliferation. In addition, ASM cells express Fas in vivo. In vitro, expression of Fas is up-regulated by TNFα and, importantly, crosslinking of Fas induces smooth muscle cell apoptosis. These studies highlight the finding that direct interactions between leukocytes and smooth muscle cells via immune receptors such as CD40 and Fas or adhesion receptors such as ICAM-1 and VCAM-1 contribute to the modulation of the local milieu, resulting in smooth muscle cell activation and growth.

Other Immunomodulatory Proteins

Increased amounts of exhaled nitric oxide (NO) have been detected in subjects with asthma. NO selectively suppresses the Th1 subset of helper T cells, suggesting that increased levels of NO may lead to the predominantly Th2 type response associated with asthma. NO synthase has been demonstrated in cultured ASM, and NO inhibits growth factor–induced ASM cell proliferation. In contrast, there is only indirect evidence that ASM cells produce NO in situ. ASM cells also produce large amounts of prostaglandin (PG) E_2 and, to a lesser extent, other prostanoids, following stimulation with pro-inflammatory cytokines. Although PGE_2 is a potent bronchodilator, it also has significant immunologic effects. For example, PGE_2 can decrease expression of CD23 (FcγRII), which has been shown to be expressed on human ASM cells and may have a role as a negative regulator of airway inflammation and hyperresponsiveness. PGE_2 inhibits cytokine-induced secretion of GM-CSF in vitro and allergen-induced release of PGD_2 in subjects with asthma. In contrast, PGE_2 also primes dendritic cells toward a Th2-promoting capacity and synergizes with IL-4 to induce IgE synthesis. Thus, the roles of ASM-derived NO and PGE_2 need to be further defined, as both molecules may have beneficial and deleterious effects in the airway.

ASM cells express receptors for the cysteinyl leukotrienes, LTC_4, LTD_4, and LTE_4. Expression of the CysLT1 receptor is increased by exposure to IFNγ and increases in LTD_4-mediated force generation in cultured ASM cells. The association between CysLT receptor expression and contractility may explain the increase in airway hyperresponsiveness following viral infection that induces a Th1-predominant environment. This finding suggests that leukotriene receptor antagonists may have a therapeutic role in viral-induced airway inflammation. Finally, receptors for the complement-derived anaphylatoxin peptides C3a and C5a also have been described on ASM cells. These peptides may play an important role in the pathogenesis of asthma by altering airway hyperresponsiveness, rather than airway inflammation.

Table 6-1

Immunomodulatory Proteins Expressed by Human ASM Cells

Cytokines	Chemokines	CAMs	Other
IL-1β	IL-8	ICAM-1	CD40
IL-5	RANTES	VCAM-1	Fas
IL-6	MCP-1,-2,-3	CD44	HLA-DR
IL-8	Eotaxin	LFA-1	FcγRII
IL-11	GM-CSF	$\alpha_9\beta_1$	FcγRIII
LIF		$\alpha_5\beta_1$	NO
IFNβ		α_v, α_6 subunits	PGE_2 CysLT receptors C3a/C5a receptors MMP/TIMP VEGF

ASM cells provide a rich source of cytokines and chemokines, and under certain conditions can express a wide variety of adhesion receptors, co-stimulatory molecules, and other immunomodulatory proteins (Table 6-1). Taken together, these data support the potential role of ASM cells not only in perpetuating airway inflammation, but also in leukocyte activation.

Airway Smooth Muscle as a Target for Anti-Inflammatory Therapy

Given the evidence that ASM cells secrete and express immunomodulatory proteins, investigators are now studying the cellular and molecular processes that regulate ASM synthetic function and examining the role of steroids and β-agonists in modulating cytokine-induced synthetic responses.

One of the most effective medications to date for controlling airway inflammation in asthma has been inhaled corticosteroids. Despite their use for over 25 years, the precise mechanisms by which steroids improve lung function in asthma remain unclear. Current evidence suggests that chemokine and cytokine secretion induced by inflammatory mediators is inhibited by dexamethasone in human ASM cells. Cytokine-induced secretion of RANTES, MCP, eotaxin, GM-CSF, and IL-6 is also abrogated by corticosteroids. Corticosteroid and $[cAMP]_i$ mobilizing agents can act additively to inhibit chemokine and cytokine secretion.

NF-κB is another transcriptional factor mediating chronic inflammatory responses in asthma, rheumatoid

arthritis, psoriasis, and inflammatory bowel disease. Interestingly, dexamethasone had little effect on TNFα- or IL-1β–induced NF-κB activation in human ASM cells. Furthermore, cytokine-induced ICAM-1 expression in ASM cells, which is completely dependent on NF-κB activation, was not affected by dexamethasone, and IL-6 secretion is only partially affected. In contrast, IL-1β–induced cyclooxygenase-2 expression was abrogated. Thus, the anti-inflammatory effects of steroids in asthma may not be due solely to modulation of cytokine-induced NF-κB activation and are likely regulated by myriad pathways such as AP-1 or other transcription factors.

Effects of $[cAMP]_i$ Mobilizing Agents on Cytokine-Induced Synthetic Responses

In asthma, β-agonists such as isoproterenol, albuterol, salmeterol, and formoterol are therapeutic agents that promote bronchodilation by stimulating receptors coupled to Gs, which in turn activates adenylyl cyclase, increases $[cAMP]_i$ and stimulates cAMP-dependent protein kinase (A-kinase) in ASM. $[cAMP]_i$ mobilizing agents in ASM cells also modulate cytokine-induced synthetic function. In TNFα-stimulated ASM cells, both eotaxin and RANTES expression are effectively inhibited by isoproterenol, PGE_2, dibutyl-$[cAMP]_i$, or the PDE inhibitors rolipram and cilomilast. TNFα-induced IL-8 secretion also was inhibited by the combination of $[cAMP]_i$ mobilizing agents and corticosteroids. Similarly, sphingosine-1-phosphate, which activates a Gs protein–coupled receptor and increases $[cAMP]_i$, abrogated TNFα-induced RANTES secretion in ASM cells.

In contrast to the effects of $[cAMP]_i$ on chemokine secretion, pharmacologic agents that increase $[cAMP]_i$ markedly stimulate secretion of IL-6 in human ASM cells. Whether the secreted IL-6 modulates ASM cell function in an autocrine manner or alters leukocyte function in the submucosa remains unknown. However, since the overexpression of IL-6 decreases acetylcholine responsiveness in transgenic mice, the role of IL-6 in asthma may be that of an anti-inflammatory signal in some compartments of the airway. Increases in cAMP also decrease secretion of GM-CSF by ASM cells. Cyclooxygenase inhibitors also reduce PGE_2 and enhance cytokine-induced secretion of GM-CSF, while PDE type IV inhibitors reduce GM-CSF secretion in vitro and antigen-induced BHR in an animal model. Taken together, current evidence suggests that some, but not all, pro-inflammatory functions in ASM cells are inhibited by $[cAMP]_i$ mobilizing agents.

AIRWAY SMOOTH MUSCLE CELLS AND EXTRACELLULAR MATRIX

The importance of airway remodeling in chronic severe asthma has been appreciated only recently. ASM cells, by producing ECM components and matrix-modifying enzymes, may contribute to this process. ASM cells may produce endogenous growth factors that modulate ECM secretion. TGF-β is secreted from ASM cells and inhibits mitogen-induced ASM growth but induces smooth muscle cell synthesis of hyaluronan and collagen. In turn, ECM proteins bind growth factors and may serve as an accessible reservoir of mitogens.

ECM proteins are critical for maintaining the structure and function of the airways. The composition of the ECM is tightly controlled and involves a dynamic process of matrix deposition and degradation. In inflammatory processes such as asthma, this balance is disturbed, resulting not only in an abnormal amount of matrix deposition, but also in an altered composition of matrix components. ASM cells secrete a wide variety of matrix proteins, including fibronectin, collagen, hyaluronan, laminin, and versican. In asthma, there is an increase in hyaluronan, fibronectin, tenascin, versican, laminin, and collagen types 1, 3, and 5. In vitro, serum from asthmatic patients increases smooth muscle cell release of fibronectin, laminin, perlecan, and chondroitin sulfate. In addition, fibronectin and collagen type I enhance smooth muscle cell proliferation in response to PDGF, whereas laminin reduced mitogen-induced proliferation. However, treatment of cells with corticosteroids had no effect on the production of matrix proteins by ASM cells, which is consistent with clinical studies showing that inhaled corticosteroids had minimal effect on altering ECM composition in airways of subjects with asthma. These data support the finding that while corticosteroids are effective at inhibiting inflammation, newer therapies are needed to prevent and/or reverse airway fibrosis seen in asthma.

The derangement in matrix components seen in asthma likely is multifactorial. Not only is there increased matrix deposition, but there is also an imbalance between matrix-degrading enzymes and inhibitors of these proteases. One class of proteins that has been intensively studied is the matrix metalloproteinase (MMP) family. MMP-1 expression is elevated in the smooth muscle cells of subjects with asthma, and LTD_4 increases expression of MMP-1, which acts to degrade insulin-like growth factor binding protein, a growth inhibitor. TNFα induces the release of MMP-9, which can degrade matrix but also plays a critical role in cleaving latent TGF-β to its active form. Progelatinase A (MMP-2) is constitutively released by ASM cells, but remains inactive because of high levels of tissue inhibitor of metalloproteinases (TIMP)-2 on the cell membrane. In contrast, TIMP-1 is secreted in large amounts into the conditioned media of ASM cells. Membrane type 1 MMP is also found on ASM; this proteinase can activate MMP-2 and has been shown to cleave CD44 from the cell surface and promote cell migration. Clearly, ASM cells play an active role in modifying their environment. Further studies will be necessary to understand the interaction among ECM, MMPs, and TIMPs in the development of airway remodeling.

SUMMARY

The biology of ASM is complex and fascinating. The myriad pathways regulating cell shortening, growth, and

proliferation, combined with the emerging role of ASM as a modulator of inflammation, provide a rich area of investigation. Unfortunately, virtually all work in this area has been performed in vitro, and in vivo correlation is needed. Future studies will focus on mechanisms regulating both acute inflammation and the chronic repair processes leading to airway remodeling.

Pulmonary Surfactant System and Alveolar Homeostasis

Jeffrey A. Whitsett • Ann D. Horowitz

Pulmonary surfactant, a complex mixture of phospholipids and proteins, creates a unique interface, separating alveolar gas and liquids at the alveolar cell surface, reducing surface tension, and maintaining lung volumes at end expiration. Reduction of the surface tension at the air-liquid interface is a requirement for respiratory function following birth. Deficiency of pulmonary surfactant causes respiratory failure in premature infants, or infantile respiratory distress syndrome (IRDS). The adequacy of pulmonary surfactant is maintained by unique and highly regulated systems mediating the synthesis, secretion, reuptake, reutilization, and catabolism of surfactant. Loss of pulmonary surfactant later in life occurs in the adult respiratory distress syndrome (ARDS), a significant cause of morbidity and mortality following infection, shock, or trauma. Mutations in genes regulating surfactant homeostasis, including SFTPB, SFTPC, and ABCA3 cause lethal acute and chronic lung disease in newborn infants, children, and adults. This chapter reviews the biology of the surfactant system and its implications for the pathogenesis and treatment of respiratory disease in premature infants and adults. Recent reviews of this topic are suggested.

PHYSICAL FORCES AT THE AIR-LIQUID INTERFACE

In 1929, Van Neergard recognized the critical role of surface tension as a "retractile force" in the lung, observing the marked difference in inflation pressures required to inflate the air- versus water-filled lung. Avery and Mead associated the lack of a lipid-rich material in the lungs of infants dying from IRDS with alveolar collapse and respiratory failure. In the absence of pulmonary surfactant, molecular forces at the air-liquid interface create a region of high surface tension because intermolecular forces between water molecules are unopposed at the air-liquid interface, and an area of high retractile force at the surface is created. Forces of 70 dynes/cm^2 are generated at the air-water interface at 37°C; if unopposed in the alveolus, such forces lead to alveolar collapse and respiratory failure. A surface film composed of multi-layered sheets of phospholipids creates a distinct phase separating air and liquid, reducing surface tension to nearly zero and maintaining residual lung volume at end expiration. Complex

interactions between surfactant phospholipids and proteins are required to maintain surfactant activity throughout life.

COMPOSITION OF PULMONARY SURFACTANT

Pulmonary surfactant isolated by lung lavage consists of highly heterogeneous forms of phospholipid-protein aggregates of distinct sizes, structural characteristics, and composition. Tubular myelin is the most abundant form of alveolar phospholipid and consists of large, relatively dense aggregates (termed large aggregate surfactant) composed of phospholipids and surfactant proteins. Tubular myelin is a highly organized form of surfactant phospholipid, forming square tubular arrays, as in Fig. 7-1. Tubular myelin is surface-active and likely represents an extracellular pool of surfactant lipids that move to the air-liquid interface to form the monolayer or multi-layered sheets that reduce surface tension in the alveolus (Fig. 7-2). Large lamellated structures of composition similar to that of tubular myelin are also seen within the alveolus and likely represent newly secreted lamellar bodies that unravel and form tubular myelin in the airspace. The phospholipid composition of lamellar bodies, the intracellular storage form of surfactant, tubular myelin, and lamellated forms present in the alveolus are virtually identical. Smaller, less dense particles (small aggregates) are also present within the alveolar space, representing remnants or catabolic forms of surfactant that are relatively inactive and destined for uptake, reutilization, or catabolism by type II epithelial cells and catabolism by alveolar macrophages.

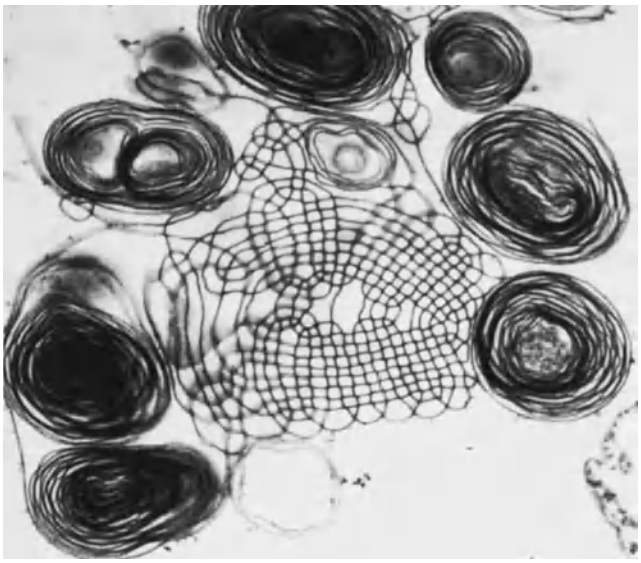

Figure 7-1 Tubular myelin. Tubular myelin is produced after secretion of lamellar bodies into the airspace by a process dependent upon surfactant proteins A and B, phospholipids, and extracellular calcium. Tubular myelin is a relatively dense, highly organized form of phospholipid present in the alveolar subphase. Phospholipid molecules move from the tubular myelin to monolayer and multilayer sheets, reducing surface tension at the air-liquid interface. Tubular myelin is not required for surfactant function or metabolism and may play a role in host defense function against pulmonary pathogens. (Bar = 1 μm.) *(Figure courtesy of Dr. Stephen Young: Randall SH, Young SL: Structure of alveolar epithelial cells and the surface layer during development, in Polin RA, Fox WW, Abman S (eds), Fetal and Neonatal Physiology, 3rd edition. Philadelphia, WB Saunders, 2004, p 1034).*

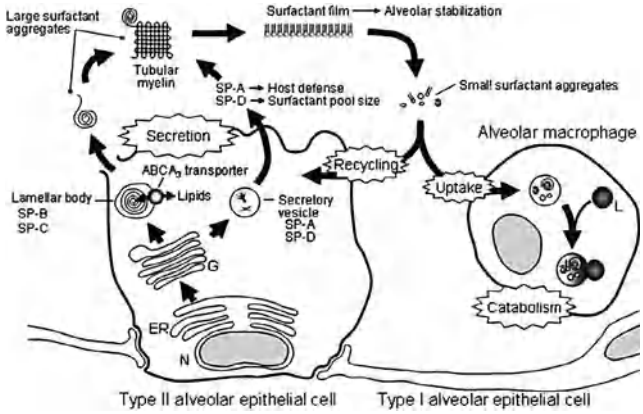

Figure 7-2 Life cycle of pulmonary surfactant. SP-B and SP-C are synthesized, proteolytically processed, and packaged with phospholipids in lamellar bodies and secreted by type II alveolar epithelial cells into the airspace. ABCA3 is present in the limiting membrane of the lamellar bodies, where it is likely to regulate lipid transport from which lipid/protein films are formed at the air-liquid interface. Used surfactant lipids are released from the film as small vesicles, which are taken up and recycled or degraded by type II cells. Alveolar macrophages also take up and degrade surfactant lipids and proteins in a process that requires GM-CSF signaling. *(Figure kindly provided by Dr. Bruce Trapnell: Whitsett JA, Wert SE, Trapnell BC: Genetic disorders influencing lung formation and function at birth. Hum Mol Genet 13:R207, 2004.)*

Surfactant Phospholipids and Proteins

The composition of surfactant phospholipids is similar in all of the structural forms of surfactant isolated from mammalian lung, generally representing 80 to 90 percent of the mass of pulmonary surfactant. In the adult lung, phosphatidylcholine (70 to 80 percent) and phosphatidylglycerol (10 percent) are the most abundant phospholipid constituents. Lesser amounts of phosphatidylserine, phosphatidylethanolamine, sphingomyelin, neutral lipids, and glycolipids are also detected in surfactant. The lung content of surfactant phospholipids increases markedly with advancing gestation. Surfactant is secreted into the amniotic fluid, and total phospholipid, dipalmitoylphosphatidylcholine (DPPC), or increased lecithin to sphingomyelin (L/S) ratio correlate with postnatal respiratory function. These tests are widely used to predict pulmonary maturity prior to the birth of preterm infants. Proteins represent approximately 5 to 15 percent of the mass of pulmonary surfactant and include serum proteins and proteins that are produced by respiratory epithelial cells. Four surfactant proteins—SP-A, SP-B, SP-C, and SP-D—named in the order of discovery, are produced

by respiratory epithelial cells, each playing specific roles in surfactant homeostasis or host defense.

Surfactant is uniquely enriched in disaturated DPPC. The saturated C16 acyl chains pack densely at an air-liquid interface, reducing tension at the surface. However, such dense and stable packing of DPPC occurs at a phase transition of 41°C, far above physiological temperatures. Thus, at 37°C, pure DPPC maintains a semicrystalline or gel phase that is incapable of moving rapidly with the expansion and contraction of the alveolus during the respiratory cycle. The capability of DPPC pulmonary surfactant to move rapidly to the alveolar interface at 37°C and to maintain low surface tension during dynamic compression is conferred by the surfactant-associated proteins SP-B and SP-C.

Structure and Function of Surfactant Proteins

Four distinct proteins have been isolated from surfactant obtained by lung lavage. Their cDNAs, genes, and structures have been identified and are well characterized. These surfactant proteins are expressed in a lung epithelial cell–selective manner and are secreted into the airspace, where they influence the structure, metabolism, and function of surfactant. Two classes of proteins have been distinguished on the basis of their structures. SP-A and SP-D are relatively abundant, hydrophilic, structurally related proteins that are members of the calcium-dependent lectin family of proteins that share collagenous domains (Fig. 7-3). These molecules have little or weak "surfactant"-like qualities, but are able to bind complex carbohydrates, lipids, and glycolipids, including those on the surface of bacteria, viruses, fungi, and other lung pathogens. They act as opsonins, activate alveolar macrophages, and play important roles in host defense in the lung. In contrast, SP-B and SP-C are small, hydrophobic proteins that play critical roles in enhancing the rate of spreading and stability of surfactant phospholipids (Fig. 7-4). SP-B and SP-C are the protein components of the animal-derived surfactant replacement preparations used for the treatment of IRDS.

Surfactant Protein-C

Surfactant protein-C (SP-C) is encoded by a single gene (SFTPC), located on human chromosome 8. SP-C mRNA is expressed exclusively in type II epithelial cells in the lung and is translated to produce a 22-kD precursor that is palmitoylated and proteolytically processed to form the active, hydrophobic peptide of 33 to 35 amino acids. SP-C enhances the surface-active properties of lipid mixtures by lowering surface tension and enhancing adsorption rate of a lipid film at the air-water interface. SP-C and SP-B reduce surface tension of a lipid film to near zero, and they increase lung compliance in premature animals. SP-C is palmitoylated on cysteine residues near the NH_2 terminus. The surface activity of depalmitoylated SP-C is somewhat less than that of palmitoylated SP-C, and the palmitoyl groups may be required for a posttranslational modification of the SP-C precursor. The carboxy-terminal

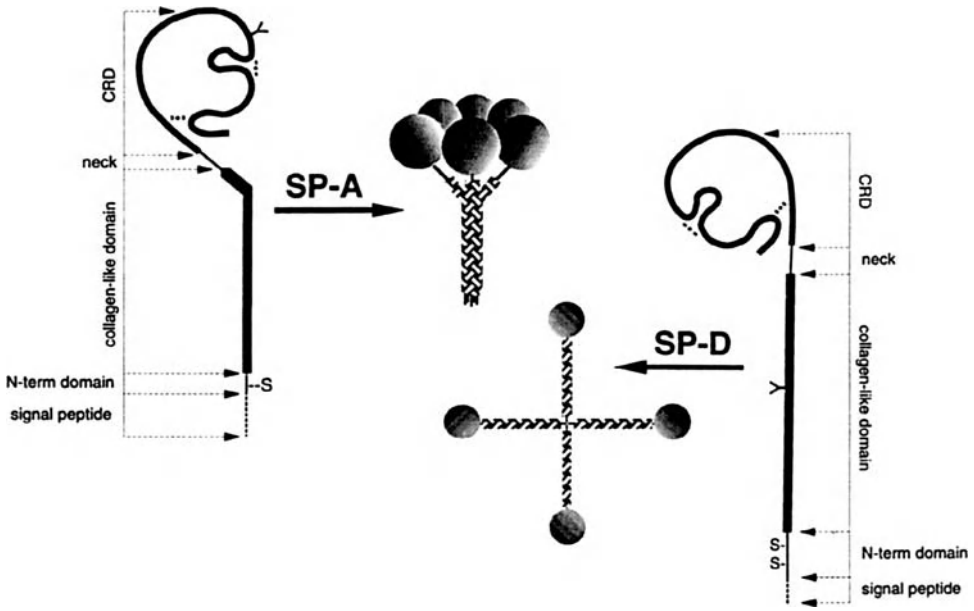

Figure 7-3 Pulmonary collectins: surfactant proteins A and D. Surfactant protein A is produced from a preproprotein that is proteolytically processed by the removal of the signal peptide and glycoslated (Y). SP-A consists of a carboxy-terminal globular, lectin-like domain (CRD) (thin line) and a more rigid, collagen-like domain (dark line) comprising the amino terminal region. Sulfhydryl-dependent interactions between SP-A monomers result in the organization of SP-A into hexamers that further associate to form the larger oligomers present in the alveolar space. SP-D is closely related to SP-A and is also a member of the calcium-dependent family of lectins. SP-D contains a C-terminal globular lectin domain (thin line) that is linked to a larger, NH_2-terminal, collagen-like domain. SP-D forms tetramers and higher-ordered multimers that are relatively weakly associated with surfactant lipids. Human SP-A is encoded by two (*SFTPA*) genes that are located within a single *SFTPD* gene on human chromosome 10.

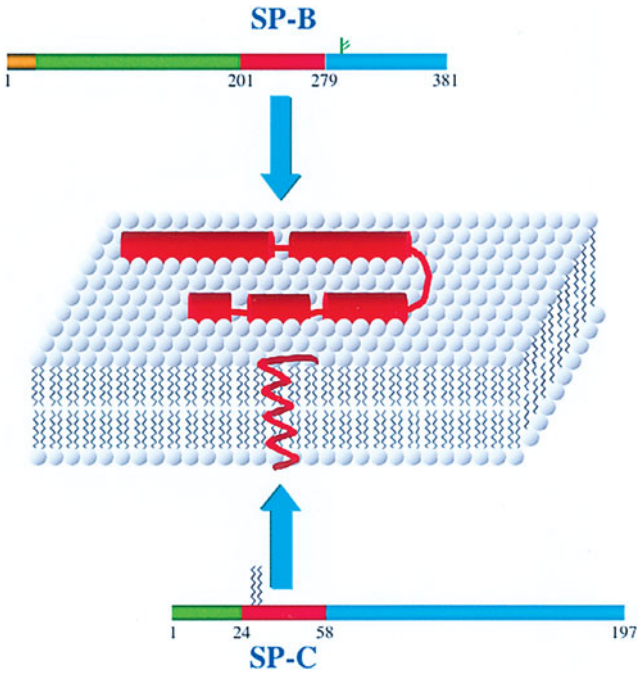

Figure 7-4 Hydrophobic surfactant proteins SP-B and SP-C. The active SP-B peptide is produced by proteolytic processing of pre-proSP-B protein consisting of 381 amino acids. The active 79–amino acid, SP-B peptide interacts with phospholipid head groups, altering the stability of phospholipid films and enhancing their rate of spreading at the air-liquid interface. SP-C is generated by proteolytic processing of a 197–amino acid preproprotein to form the 32– to 34–amino acid active hydrophobic peptide that inserts deeply into the acyl chains of lipid bilayers, disrupting acyl group packing and enhancing mobility of phospholipids at the membrane surface. *(Courtesy of Dr. Timothy Weaver, Cincinnati Children's Hospital Medical Center.)*

two-thirds of SP-C is generally in an α-helical conformation, but depalmitoylation reduces the α-helical content of native SP-C. A form of depalmitoylated SP-C that forms a very stable dimer with a high β-sheet content has also been identified. Although the orientation of the palmitoyl groups in a lipid environment is not currently known, they are likely, due to their hydrophobicity, to hold the amino-terminal region of SP-C in close contact with lipids.

In a lipid bilayer, the orientation of the α-helical segment of SP-C is closely parallel with the lipid acyl chains, implying a transbilayer orientation (Fig. 7-4). In a surface monolayer, SP-C has a preferential orientation parallel to the interface, as observed by circular dichroism of monolayer films. The positive charges near the NH_2 terminus of SP-C may promote in the binding of phospholipid vesicles to the monolayer—a step required for insertion of phospholipids into the monolayer. Blocking of the positively charged residues arginine and lysine with phenylglyoxal produced a modified SP-C, which had lost the ability to enhance binding of lipid vesicles to the monolayer and did not catalyze insertion of lipids into the monolayer. SP-C forms aggregates in DPPC/DPPG (dipalmitoylphosphatidylglycerol) mixtures below the phase transition temperature of the bulk lipid, as observed by fluorescence energy transfer among SP-C molecules labeled with fluorescent probes. SP-C also affects the size and shape of lipid vesicles. It disrupts vesicular structure, causing the formation of larger vesicles and discoid particles.

Function of SP-C In Vivo

Deletion of SP-C in transgenic mice perturbs surfactant function and causes severe interstitial lung disease. While SP-$C^{-/-}$ mice survive after birth, the mice develop airspace abnormalities, pulmonary inflammation, and abnormal lipid accumulations in alveolar macrophages, and epithelial and stromal cells. While surfactant properties are only modestly perturbed, severe and progressive remodeling, emphysema, and fibrosis occur in these mice. Severity of pulmonary disorder related to SP-C deficiency in mice is strongly influenced by genetic strain, age, and injury, indicating that the disorder is influenced by both genetic and environmental factors. The finding that SP-$C^{-/-}$ mice develop an interstitial pulmonary disorder is consistent with findings in humans, wherein SP-C mutations cause severe acute, and chronic lung disease.

Mutations in SFTPC Cause Severe Interstitial Lung Disease in Humans

Mutations in SFTPC represent a rare cause of acute and chronic lung disease in humans. SFTPC mutations are generally inherited as an autosomal-dominant gene that has been causally linked to acute respiratory disease in newborn infants and chronic interstitial lung disease in infants, children, and adults. Most mutations result in the intracellular accumulation of misfolded proSP-C protein, which also results in the lack of synthesis of the active SP-C peptide. Various forms of interstitial lung disease have been associated with the disease, including acute respiratory distress (RDS), chronic pneumonitis of infancy (CPI), non-specific interstitial pneumonitis (NSIP), and other forms of idiopathic pulmonary fibrosis (IPF) (Fig. 7-5). The lung histopathology associated with SFTPC mutations is likely dependent upon age, duration and severity of the disease, treatment, and both genetic and environmental factors. Definitive diagnosis is made by identification of mutations in the SFTPC gene. As seen in the mouse model (SP-$C^{-/-}$ mice), the onset and severity of pulmonary disease in humans is highly variable, even in the same kindreds, indicating that genetic and environmental factors strongly influence the disorder. At present, there is no effective therapy for SP-C–related disease. Lung transplantation has been successfully used to treat hereditary SFTPC deficiency.

In summary, SP-C is likely to be present in both phospholipid monolayers and bilayers. Insertion of SP-C into the phospholipid membranes disrupts acyl group packing; positive charges near the NH_2 terminus and located near the surface of the phospholipids may enhance insertion of phospholipid molecules into surfactant films. Mutations in SFTPC are a rare cause of acute and chronic interstitial lung disease

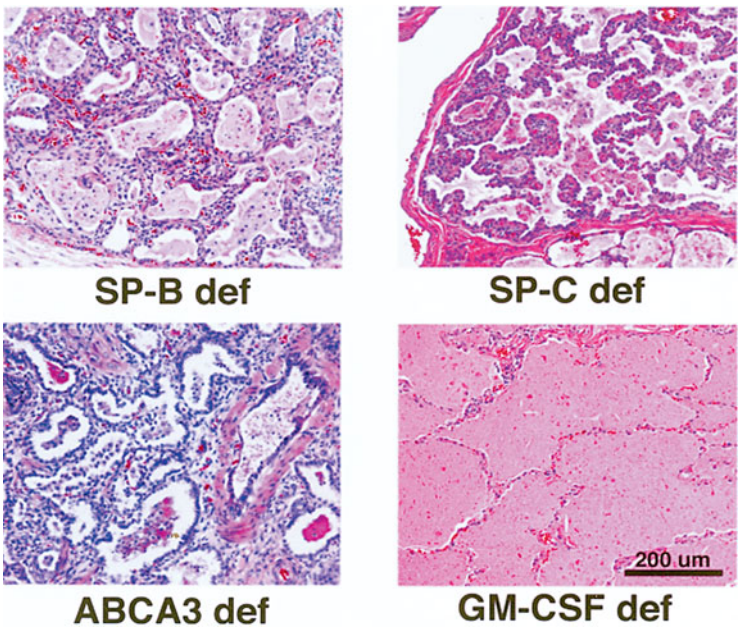

Figure 7-5 Pulmonary histopathology associated with disorders of surfactant homeostasis. Pathologic findings in neonates with mutations in SFTPB, SFTPC, and ABCA3 are consistent with childhood interstitial pneumonitis (CIP) or desquamating interstitial pneumonitis (DIP). Severe alveolar remodeling, alveolar loss, macrophage infiltration, varying degrees of alveolar proteinosis, and stromal thickening are observed. In contrast, autoantibodies against GM-CSF are associated with pulmonary alveolar proteinosis (PAP) in which surfactant lipids and proteins accumulate in the alveolus. Alveolar structure is generally well maintained in PAP. *(Figures courtesy of Dr. Susan Wert: Whitsett JA, Wert SE, Trapnell BC: Genetic disorders influencing lung formation and function at birth. Hum Mol Genet 13:R207, 2004.)*

that are generally inherited as an autosomal dominant mutation, resulting in the production of misfolded mutant proteins that accumulate within type II alveolar cells causing cell and lung injury.

Surfactant Protein-B

Surfactant protein-B (SP-B) is a hydrophobic 8.8-kD protein produced from a single gene (SFTPB) located on human chromosome 2 (Fig. 7-4). The SP-B mRNA is expressed in bronchioles and type II alveolar cells and is translated to produce a 40- to 42-kD precursor that is proteolytically processed to form the active 79-amino acid peptide found in surfactant. In combination with lipids, SP-B reconstitutes most of the surface activity of natural lung surfactant. SP-B contains two regions (Trp_9-Pro_{23}) and (Ile_{56}-Pro_{67}), predicted to form amphipathic α-helices. Almost 50 percent of the protein is in an α-helical conformation, with approximately 20 percent β-sheet and 16 percent turns, as determined by Fourier transform infrared spectroscopy (FTIR). SP-B contains three intramolecular disulfide bonds that confine the amphipathic helices of SP-B in an antiparallel configuration. Cys 48 is free to form an intermolecular disulfide bond, stabilizing the SP-B dimer. Dimers and higher multimers of SP-B, which are probably stabilized by noncovalent interactions, are found in pulmonary surfactant.

SP-B is tightly associated with surfactant phospholipids in the alveolus and lamellar bodies of type II epithelial cells. The positively charged amino acid residues of SP-B selectively interact with the negatively charged phospholipid DPPG, as determined by a variety of physical techniques. In a mixed DPPC/DPPG monolayer, SP-B is believed to purify the DPPC monolayer by removal of DPPG in a complex with SP-B. SP-B increases order in the lipid head group region with little effect on order in the membrane interior. The ability to order the lipid head group region is located in the amino- and carboxy-terminal regions of SP-B (1–20) and (53–78), which contain the predicted amphipathic helices. Synthetic peptides that contain these two regions have surface-tension lowering activity similar to that of native SP-B.

SP-B enhances the insertion of phospholipid vesicles into a preformed DPPC/DPPG monolayer, particularly in the presence of divalent cations. SP-B causes lipids in solution to form discoid particles often appearing as stacks or sheets. Together with SP-A, lipids, and Ca^{2+}, SP-B reconstitutes the characteristic structures of tubular myelin, both multilamellar aggregates and material with a square lattice configuration.

SP-B Is Required for Survival after Birth

Deletion of the gene encoding SP-B in mice causes acute respiratory failure at birth, related to surfactant dysfunction. Likewise, conditional deletion of the gene in adult mice causes acute respiratory distress associated with alveolar capillary leak and surfactant deficiency. SP-B deficiency is associated with failure to form lamellar bodies, accumulation of abnormal multivesicular bodies within the type II cells, and misprocessing of proSP-C by alveolar type II cells. Extracellularly, tubular myelin is absent and surfactant activity is deficient, demonstrating that SP-B plays a critical role in surfactant homeostasis.

Hereditary SP-B Deficiency Causes Respiratory Failure at Birth

Homozygous SP-B–deficient infants and mice die of respiratory failure following birth. While lung morphogenesis proceeds normally in SP-B deficient mice in utero, the lack of SP-B causes atelectasis and respiratory failure in the immediate postnatal period. More than 75 infants with SP-B deficiency have now been identified. SP-B deficiency is inherited as an

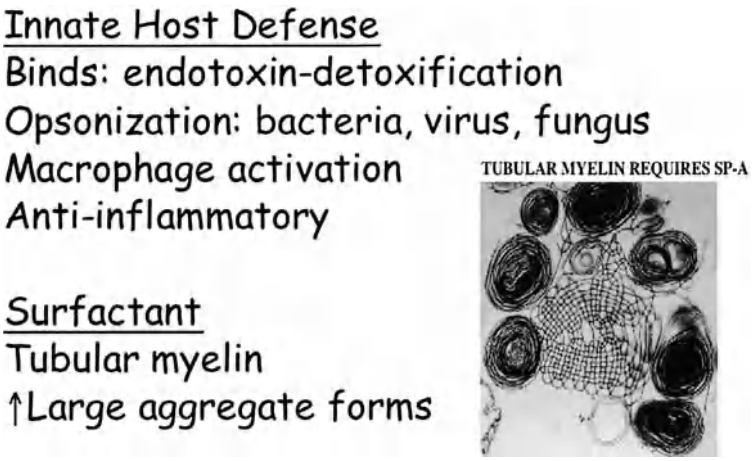

Figure 7-6 Functions of surfactant protein A.

autosomal-recessive mutation in the SFTPB gene, generally presenting in full-term infants with IRDS. The disorder is refractory to surfactant replacement therapy and is generally lethal within the first several months of life. Several infants have undergone lung transplantation. In humans as in mice, SP-B deficiency disrupts the formation of lamellar bodies and tubular myelin, and interferes with the routing of proSP-C. Thus, SP-B–deficient patients and mice lack active SP-B and SP-C proteins in the alveolus; proSP-C accumulates in the airspace, causing a proteinosis-like syndrome. The disorder is generally termed desquamating interstitial pneumonitis depending on age and supportive therapy (Fig. 7-5). The definitive diagnosis is made by identification of the mutations by nucleotide sequence analysis. In most affected infants, SP-B is lacking in bronchoalveolar lavage fluid and the abnormal proSP-C peptide accumulates in the alveoli, findings that can be verified by immunohistochemistry, aiding in the diagnosis of the disorder. Patients with SP-B deficiency do not respond to surfactant replacement and generally succumb from chronic respiratory failure in infancy in spite of intensive care.

ABCA3 Mutations: A Genetic Cause of Respiratory Failure at Birth

ABCA3 is a large, membrane-spanning protein that is present in the limiting membrane of lamellar bodies in type II alveolar epithelial cells. Mutations in the *ABCA3* gene were identified as a cause of severe lung disease in full-term infants. *ABCA3*-related lung disease is inherited as an autosomal recessive gene. A large number of distinct mutations in *ABCA3* have been associated with acute respiratory distress in full-term infants. Generally, affected infants present within the first days of life, and are refractory to conventional therapies, resulting in respiratory failure and death in the first months of life. Pathological findings associated with ABCA3 mutations include proteinosis, cuboidal epithelial cell hyperplasia, interstitial thickening, loss of normal alveolar structure, and features of desquamating interstitial pneumonitis (DIP) (Fig. 7-5). Respiratory failure is not responsive to surfactant replacement, and the only known treatment has been lung transplantation. ABCA3 is a member of the ATP-dependent, Walker domain containing proteins that comprise a family of membrane-associated transport proteins that includes the cystic fibrosis transmembrane conductance regulator (CFTR). ABCA3 homologues mediate lipid transport across membranes. The diagnosis of ABCA3-related lung disease is confirmed by nucleotide sequencing of the gene in infants and children with refractory pulmonary disease. Electronmicroscopy of lung tissue from patients with ABCA3 mutations demonstrates the presence of small, atypical lamellar bodies in alveolar type II epithelial cells and the absence of tubular myelin in the airways, indicating an abnormality in intracellular and extracellular lipid homeostasis.

The Pulmonary Collectins (SP-A and SP-D)

Surfactant Protein A (SP-A)

SP-A is an abundant hydrophilic 26-kD (monomer) glycoprotein that functions in the host defense, and regulation of surfactant lipid structure (Figs. 7-3 and 7-6). SP-A mRNA is expressed in bronchiolar and alveolar type II cells in the lung, being translated from two genes (SFTPA) located on chromosome 10 in the human. In the absence of SP-C and SP-B, SP-A enhances formation of a surface lipid film in the presence of divalent ions, although SP-A is much less effective than the hydrophobic surfactant proteins SP-B and SP-C. SP-A modestly enhances surface activity of lipid films containing SP-C and SP-B. The amino-terminal third of SP-A is arranged in a collagen-like triple helix, while a carboxy-terminal region bears homology to mammalian lectins and serum mannose-binding lectin (MBL). Protein-protein interactions among SP-A molecules mediated by the collagen-like domain and an intermolecular disulfide bond at Cys 9 are necessary for the aggregation of lipids by SP-A. Binding and uptake of SP-A by type II epithelial cells is mediated by a specific, saturable cell-surface receptors; however, the precise nature of SP-A receptors and their intracellular functions remain unclear. The noncollagenous C-terminal domain of SP-A binds to isolated type II cells, suggesting that the receptor-binding site is in the C-terminal region of SP-A. SP-A increases the association of lipids with type II cells but does not appear to increase internalization of lipid, as monitored by uptake of fluorescent

Table 7-1

Surfactant Protein D: Function

Innate host defense	Binds: endotoxin Opsonization: bacteria, virus (RSV, influenza) Macrophage activation Anti-inflammatory
Surfactant	Regulates surfactant lipid pools Influences large/small aggregate surfactant
Regulation of oxidants	SP-D protects from oxidant injury

lipid probes. Deletion of the SP-A gene (Sftpa) in mice does not alter survival or lung function after birth. While tubular myelin is absent, surfactant function, uptake, and secretion are not influenced by deletion of SP-A. SP-A$^{-/-}$ mice are highly susceptible to lung infection by bacterial, viral, and fungal pathogens, indicating that SP-A plays a primary role in innate host defense of the lung.

Surfactant Protein-D

Surfactant protein-D (Table 7-1) is a collagenous Ca^{2+}-dependent carbohydrate-binding protein that is structurally related to SP-A and other C-type lectins (Figs. 7-3). SP-D is encoded by a single gene (SFTPD) located near the SFTPA gene on human chromosome 10. SP-D is synthesized by alveolar type II epithelial cells and is found in the endoplasmic reticulum and Golgi of Clara cells, but it is also expressed in many other tissues. SP-D forms large oligomers that bind carbohydrates and glycolipids on the surface of bacteria, fungi, and viruses. The interaction of SP-D microbial pathogens is Ca^{2+} and carbohydrate dependent. In contrast to surfactant proteins SP-A, SP-B, and SP-C, SP-D is not strongly associated with surfactant lipids in the alveolus but plays an important role in determining surfactant structure and homeostasis.

Function of SP-D In Vivo

Deletion of SP-D in mice has provided insight into its important role in surfactant and alveolar homeostasis. *Sftpd*$^{-/-}$ mice survive after birth, but develop severe pulmonary disease associated with macrophage activation, airspace enlargement, and lipid accumulation. SP-D regulates alveolar pools of large and small aggregate surfactant, influencing surfactant particle size and its uptake by type II epithelial cells. Infiltration with lipid-laden macrophages, and the induction of synthesis of metalloproteinases 2, 9, and 12 by alveolar macrophages, may contribute to the spontaneous airspace remodeling seen in the *Sftpd*$^{-/-}$ mice. *Sftpd*$^{-/-}$ mice are highly susceptible to pulmonary infections and inflammation associated with a viral (respiratory syncytial and influenza virus) and bacterial endotoxin exposure, indicating that SP-D plays a critical role in innate host defense of the lung. SP-D binds bacterial, fungal, and viral pathogens, enhancing their opsonization and their killing by alveolar macrophages. Thus, SP-D plays an important role in the regulation of surfactant lipid homeostasis, innate host defense of the lung, and prevention of inflammation and alveolar remodeling.

RECYCLING AND CATABOLISM OF SURFACTANT LIPIDS AND PROTEINS

Pulmonary surfactant is taken up rapidly in the lung, and much of the lipid is reutilized (Fig. 7-2). Measurements of the efficiency of recycling of phosphatidylcholine (PC) in adult

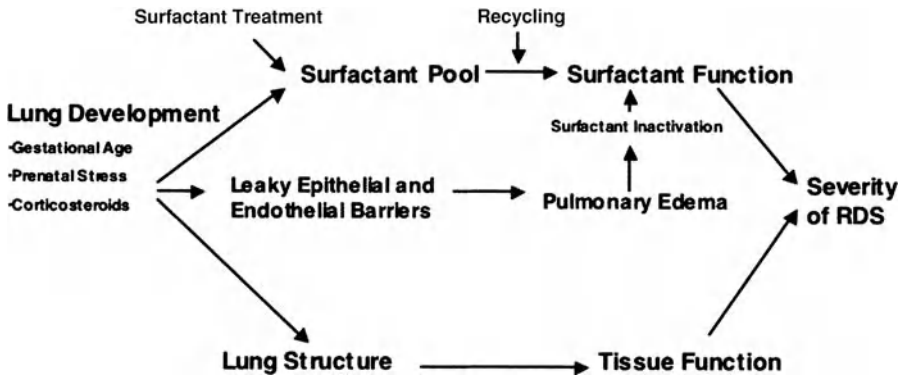

Figure 7-7 Factors influencing the pathogenesis of idiopathic respiratory distress syndrome (IRDS). The pathogenesis of IRDS is multifactional. Immaturity of the alveolar type II cells results in decreased surfactant pools. Lung collapse and injury are caused by surfactant deficiency. Alveolar damage causes leakage of serum proteins and edema, which inactivate surfactant, increasing the severity of respiratory distress. Surfactant treatment reduces surface tension, restores phospholipid pool sizes, and improves alveolar-capillary leak to maintain surfactant function. *(Courtesy of Dr. Alan Jobe).*

rabbit lungs range between 23 and 85 percent, with approximately 10 percent of the alveolar pool of 10 to 15 mg/kg total body weight being recycled every hour. In neonatal rabbits, 94 percent of the PC is reutilized, with a turnover time of the alveolar PC of 10 h. Some 30 to 50 percent of intratracheally injected ^{3}H-PC is sequestered from the alveolar space within a few minutes after instillation and cannot be removed by lavage. After intratracheal administration, labeled lipid appears in type II cells and alveolar macrophages, but is not found in type I cells, indicating that the type II cells actively take up surfactant lipids from the alveolus for recycling or catabolism. Isolated epithelial type II alveolar cells internalize ^{3}H-PC and resecrete the internalized material or degrade it with reincorporation into other lipids. Isolated type II cells endocytose SP-C and SP-B. SP-A also binds to type II cells and is endocytosed by a receptor-mediated mechanism.

Pulmonary surfactant as isolated from lavage fluid exists in several forms that can be fractionated based on density. In vivo labeling indicates that phospholipid is initially secreted in the heaviest forms, followed by conversion into distinct heavy and light forms. The most dense or ultraheavy form contains lamellar bodies and tubular myelin. The heavy forms of tubular myelin are also referred to as large aggregates (LA). A light form, or small aggregates, is comprised of small unilamellar vesicles. Unlike the other two forms, the light form has little surface activity in vitro and is ineffective in enhancing lung compliance in preterm animals. Small aggregate surfactant is inactive, being depleted of SP-A, SP-B, and SP-C, and their lipid composition is similar to that of large aggregates. SP-A and SP-D play important roles in the maintenance of large aggregate surfactant structure. Cycling surfactant by expansion and contraction of surface film in vitro converts lipids from large to small aggregates that are likely remnants destined for catabolism or recycling.

REGULATION OF SURFACTANT PRODUCTION

The synthesis of pulmonary surfactant is subject to precise regulatory controls both during development and postnatally. Surfactant phospholipid synthesis increases markedly in late gestation and is enhanced by a variety of hormones, including glucocorticoids in the fetal lung. Lung phospholipid content increases in the latter two-thirds of gestation in preparation for respiratory adaptation at birth. Prenatal glucocorticoids are routinely used to induce lung maturation and surfactant synthesis in infants at risk for preterm delivery. Glucocorticoids reduce the risk of IRDS and enhance the efficacy of surfactant replacement therapy after birth. Like surfactant phospholipids, the surfactant proteins are highly regulated, increasing in the latter two-thirds of gestation in the mammalian species studied. Expression of surfactant proteins is regulated in complex ways by a variety of hormonal agents. The levels of surfactant protein mRNA increase in the perinatal period in association with increased surfactant synthesis and secretion required for postnatal respiratory adaptation. Expression of the surfactant proteins is regulated at both transcriptional and posttranscriptional levels, maintaining steady-state protein concentrations within tight constraints in the adult lung. Surfactant production is, in general, enhanced by glucocorticoids, epidermal growth factor (EGF), and cyclic adenosine monophosphate (cAMP) but inhibited by tumor necrosis factor-alpha (TNF-α), transforming growth factor-beta (TGF-β) and insulin, depending on experimental conditions. Transcriptional control of the surfactant genes is modulated by interactions with nuclear transcription proteins including thyroid transcription factor-1 (TTF-1), members of the HNF-3 family (Foxa1 and Foxa2), retinoic acid receptors (RARs), and associated co-activators. Surfactant proteins A, B, and D are expressed in bronchiolar and alveolar type II cells, while SP-C is expressed exclusively in type II epithelial cells. Transcriptional and posttranscriptional mechanisms influence the synthesis of surfactant proteins and lipids, regulating surfactant concentrations in the airspace during development and repair.

Critical Role of GM-CSF Signaling in the Catabolism of Surfactant

While less than 10 to 15 percent of surfactant lipids is cleared by catabolism by alveolar macrophages, this pathway is critical in controlling steady-state surfactant concentrations in vivo. Granulocyte-macrophage colony-stimulating factor (GM-CSF) and GM-CSF receptor (common ß-chain) are required for normal surfactant catabolism in the mouse. Surfactant protein and lipid clearance is decreased in GM-CSF$^{-/-}$ and GM-receptor deficient mice in which severe pulmonary alveolar proteinosis is associated with failure to clear surfactant proteins and phospholipids. Therefore, GM-CSF signaling is required for normal clearance and catabolism of surfactant by alveolar macrophages. Recent clinical studies demonstrate that idiopathic pulmonary alveolar proteinosis (PAP) in adults is caused by autoantibodies against GM-CSF. Similar abnormalities in surfactant homeostasis, alveolar macrophage morphology and function are observed in mice lacking GM-CSF signaling and in patients with PAP (see Chapter 79). Administration of GM-CSF, both systemically and intratracheally, has been utilized for connection of the surfactant accumulations in the mouse and in clinical studies in patients with PAP.

SURFACTANT HOMEOSTASIS AND REPLACEMENT IN INFANTILE RESPIRATORY DISTRESS SYNDROME

IRDS is associated with prematurity, the risk increasing as gestational age decreases. In addition to the morphologic immaturity of the respiratory tract, lung phospholipid content and surfactant secretion are decreased in preterm infants. While functional surfactant can be isolated from infants with

IRDS, surfactant pool sizes are markedly decreased in the preterm compared to the term infant, and the surface activity of surfactant from infants with IRDS is decreased. Alveolar-capillary leak of serum proteins, including albumin, causes inactivation of surfactant. Decreased alveolar surfactant activity associated with pulmonary immaturity causes atelectasis, alveolar collapse, and hypoxemia, characteristic of IRDS in the preterm infant. A schematic representing factors influencing the pathogenesis of IRDS is provided by Fig. 7-7.

Supplemental oxygen and ventilatory therapy are used to treat IRDS. However, during the last two decades, widespread use of exogenous surfactant has markedly ameliorated the morbidity and mortality associated with this common disease of preterm infants. Exogenous surfactants—in the form of synthetic mixtures of phospholipids and extracts of lung or surfactant containing surfactant proteins B, C, and phospholipids—have been used extensively for prevention and therapy of RDS in newborn infants. Surfactant replacements with preparations containing surfactant proteins B and C act rapidly, increasing lung volumes and compliance, and decreasing the requirements for positive-pressure ventilation and oxygen. Morbidity and mortality from IRDS have been markedly reduced since the application of surfactant replacement to preterm neonates, decreasing barotrauma, pneumothorax, and mortality from the disorder. Surfactant replacement is given intratracheally, resulting in improved lung function and oxygenation. Synthetic surfactants lacking surfactant proteins improve lung function in a delayed manner, but treatment with both synthetic and protein-containing surfactant has been highly effective in decreasing morbidity and mortality from IRDS in clinical studies and is now standard treatment for IRDS. The effectiveness of surfactant therapy is likely related both to the immediate surface tension–reducing properties and the reuptake and reutilization of the exogenous surfactant particles by the respiratory epithelium. Following preterm birth, production of endogenous surfactant lipids and proteins by the respiratory epithelium is rapidly induced; therefore, surfactant replacement is primarily utilized in the first few days following birth. Surfactant replacement has been used successfully in the treatment of meconium aspiration and pneumonia in neonates.

SURFACTANT IN ADULT RESPIRATORY DISTRESS SYNDROME

Adult respiratory distress syndrome occurs in association with trauma, sepsis, long bone fractures, thermal burns, and injury to the lung from aspiration of gastric contents, pneumonia, and inhalation of toxic gases (see Chapter 59). The prognosis in ARDS patients remains poor, with approximately 30 to 50 percent mortality in most studies. In ARDS, increased permeability of the microvasculature permits leakage of protein and fluid into the lung, inactivating surfactant. Epithelial cell injury may also contribute to surfactant deficiency in ARDS. Various nonsurfactant proteins and lipids present in elevated concentrations in the lung in ARDS have been implicated in reducing surface activity of pulmonary surfactant; these include immunoglobulins, albumin, fibrinogen, fatty acids, lyso-phosphatidylcholine, and C-reactive protein. The mechanisms causing the decrease in surfactant activity in ARDS include competition of the proteins for the air-liquid interface, sequestration and dilution of surfactant in non–surface-active particles, and inhibition of surfactant protein and lipid synthesis and secretion. Alterations in surfactant composition occur during ARDS and may precede the development of respiratory failure. Lavage phospholipid, SP-A, and SP-B are decreased, and the minimum surface tension of surfactant tested in vitro is increased in patients at risk for ARDS. In ARDS, total phospholipid, phosphatidylcholine, phosphatidylglycerol, and surfactant proteins SP-A and SP-B are decreased and the ratio of small to large aggregates is significantly increased compared with that in non-ARDS patients. Thus, ARDS leads to both a deficiency in pulmonary surfactant constituents and inhibition of the activity of the remaining surfactant. ARDS and related syndromes are associated with protein leak into alveolar space and inactivation of surfactant function. While surfactant has been effective in ARDS syndromes in laboratory experiments, to date, clinical studies have not supported the routine use of surfactant replacement for RDS in adult patients.

INHIBITION OF SURFACTANT ACTIVITY

Phospholipases A_2 and C and their products, fatty acids, lysoPC, and dipalmitin inhibit surface activity in vitro. These molecules may be released or produced during lung injury. Inhibitory effects of oleic acid may be related to its miscibility with phospholipids, disrupting the interfacial surfactant film, rather than by competition for the interface. The inhibition by PAF, lysoPC, and oleic acid is not reversible, suggesting that their direct interaction with surfactant lipids disrupts lipid organization at the interface. However, not all fatty acids are inhibitory. Additional palmitic acid improves surfactant function of surfactant preparations used for therapy of IRDS. The surface activity of pulmonary surfactant is readily destroyed by phospholipase A_2 or phospholipase C. In injured lungs, inhibition of surface activity by fatty acids and proteins may be additive, since they appear to inhibit surfactant activity by different mechanisms.

Oxygen therapy, used routinely for ARDS and IRDS, may influence surfactant homeostasis and function in the alveolus. The rate of synthesis of surfactant lipids and clearance of radiolabeled surfactant extracts decreased in rabbits exposed to 100% O_2 for 64 h. In contrast, exposure of adult rats to 85% O_2 increased expression of surfactant proteins SP-A, SP-B, and SP-C, and phospholipids. Oxidants are also released locally in the lung by activated immune cells. Activated alveolar macrophages secrete NO and superoxide, which can then react to form peroxynitrite. Peroxynitrite in combination

with Fe^{3+} EDTA inhibited the surface activity of surfactant by damaging lipids or the surfactant proteins.

Edema fluid leaks into the airspace in both ARDS and IRDS. Edema fluid obtained from hyperoxia-exposed rabbits contains serum proteins capable of inhibiting surface activity of surfactant extracts, as evaluated in the pulsating bubble apparatus. Thus, edema fluid may interfere with surfactant therapy, although the concentration dependence of the inhibition suggests that increased doses of surfactant may aid in overcoming the inhibitory effects of edema fluid.

Plasma Proteins Inactivate Pulmonary Surfactant

Serum albumin, globulin, and fibrinogen reduce the rate of adsorption, increase the minimum surface tension of the surfactant film, and reduce the hysteresis area between compression and expansion curves in vitro. The mechanism by which plasma proteins inhibit the activity of pulmonary surfactant is likely to be one of competition for the interface, because higher surfactant lipid concentrations overcome albumin inhibition even at high albumin concentrations. Inhibition by C-reactive protein, fibrinogen, and other plasma proteins is reversible. Addition of SP-A and organic surfactant extracts reverses inhibition caused by soluble proteins but not by lysoPC. Both SP-C and SP-B increase the ability of a phospholipid mixture to resist inhibition of surface activity by plasma proteins. SP-B is more effective than SP-C at resisting inhibition by fibrinogen. The best resistance to surfactant inhibition by serum protein was observed when both SP-C and SP-B were present.

REDUCTION OF SURFACTANT SYNTHESIS

In addition to the inactivation of pulmonary surfactant by proteins and lipids in edema fluid, a reduction of synthesis of surfactant may contribute to the decreased surfactant activity in ARDS. *Escherichia coli* endotoxin-inhibited surfactant synthesis in lung organ cultures. Synthesis of surfactant proteins is also influenced by inflammatory responses following lung injury or infection. TNF-α decreased de novo synthesis of SP-A, SP-B, and SP-C mRNA, and caused respiratory distress and decreased SP-C mRNA when administered intratracheally to the mouse. TGF-β1, produced during lung injury, decreased the expression of SP-A and SP-C in vitro. Thus, sepsis or lung injury may reduce both the synthesis and functions of surfactant lipids and proteins.

CONCLUSIONS

Pulmonary surfactant is required for airbreathing after birth and for protection of the lung from microbial pathogens. Surfactant homeostasis requires the integrated functions of surfactant proteins and lipids to reduce surface tension in the alveolus. Decreased production or inactivation of pulmonary surfactant has been associated with both IRDS and ARDS. Mutations in genes mediating surfactant protein synthesis (SFTPB and SFTPC) are rare genetic causes of severe acute and chronic lung disease. Likewise, mutations in ABCA3, a lamellar body–associated transport protein, blocks lipid packaging into the lamellar body, and is associated with fatal pulmonary disease in newborn infants and chronic interstitial lung disease in older individuals. Surfactant production and activity are inhibited following injury and alveolar capillary leak. Surfactant function may be further impaired by dilution caused by pulmonary edema and the action of phospholipases. Conversion of active, large aggregate forms of surfactant, to inactive, small aggregate forms that are depleted of the surfactant proteins is accelerated in the injured lung. Surface activity of the remaining surfactant is reduced further by competition with plasma proteins for the air-water interface. Surfactant deficiency and inactivation accompanying RDS in infants can be overcome by treatment with exogenous surfactant. Surfactant therapy for IRDS in premature infants has been highly successful, reducing morbidity and mortality from pulmonary disease. While in early phases of study, therapy with exogenous surfactant preparations containing the surfactant proteins SP-C and SP-B may also be useful in treatment of other lung disorders associated with disruption of surfactant homeostasis.

Transport Function of Airway Epithelia and Submucosal Glands

Paul B. McCray, Jr. • Michael J. Welsh

Secretion and solute transport by epithelial cells that line the airways and comprise the submucosal glands play key roles in the biology of the normal lung. Moreover, abnormalities in airway epithelial and submucosal gland function contribute to the pathogenesis and pathophysiology of several inherited and acquired diseases. Two major functions of these cells are the production and modification of airway surface liquid (ASL) and the secretion of a number of factors that contribute to host defenses. The active transport of electrolytes by surface cells regulates the volume and composition of airway fluid. The specialized cells of submucosal glands also contribute to the secretion of airway surface fluid and are a major producer of macromolecules, including mucins. Together the products and function of these epithelia generate a local host defense system that protects the lungs from inhaled organisms and particulate material.

This chapter describes the function of the surface epithelia and the submucosal glands and their roles in host defense. Despite progress, significant gaps in knowledge persist; these are also noted.

BIOLOGY OF EPITHELIA COVERING THE AIRWAY SURFACE

Morphologic Features Related to Function

Although morphologic aspects of airway epithelia are covered in another chapter, two morphologic features required for transepithelial transport of solute and water are worth considering. First, the epithelial cells are joined at their apical surface by tight junctions. The tight junctions and sheet of epithelial cells form a continuous barrier to solute and water movement. Yet, despite their name, tight junctions do not constitute an impermeable barrier; they have selective permeabilities to ions and other solutes. Thus, solutes can move

across the epithelium through two pathways: between the cells through the tight junctions (the paracellular pathway) or through the epithelial cells (the cellular pathway). Second, epithelial cells are polar; the apical membrane, which faces the mucosal surface, is different from the basolateral membrane, which faces the submucosal or interstitial space. The morphologic differences between the two membranes are paralleled by biochemical and functional differences. Hormone receptors and ion transporters are segregated to one or the other of the two cell membranes. These morphologic features allow the epithelium to serve as a barrier separating the luminal compartment from the interstitial compartment, modify the composition of those compartments by net vectoral transport of electrolytes and macromolecules, and selectively respond to signals from either compartment.

Proximal airway epithelium is a pseudostratified, columnar epithelium composed predominantly of ciliated cells, goblet cells, nonciliated cells, and basal cells. The distal airway epithelia contain mostly ciliated and nonciliated bronchiolar (Clara) cells. In the proximal airway epithelium, studies with intracellular microelectrodes suggest that ciliated surface cells play an important role in both sodium (Na^+) and chloride (Cl^-) transport. Transepithelial electrical resistance (Rt, a measure of the ionic permeability of the epithelium) ranges from 150 to 1000 $\Omega \times cm^2$ in proximal airways and decreases in more distal airways.

In Vivo Studies of Electrolyte Transport

Electrolyte transport by human airway epithelia has been studied in vivo by measuring the voltage across the epithelium (Vt, mucosal surface referenced to interstitial surface). Most frequently this has been done across the nasal epithelium, but qualitatively similar measurements have been made in the large intrapulmonary airways. As shown by the example in Fig. 8-1, Vt across normal human airway epithelia in vivo is in the range of –5 to –20 mV. Because Vt equals the product of Rt and electrical current, knowledge obtained from in vivo Vt measurements is limited in scope; such studies do not assess quantitative aspects of transport, they provide only minimal insight into the cellular and molecular mechanisms involved, and they do not measure electrically silent transport. Nevertheless, important clues have been obtained from measurements of Vt in the presence of various agents perfused onto the epithelial surface. Figure 8-1 shows that when the apical surface is perfused with a solution containing amiloride, which blocks Na^+ channels, Vt decreases. This finding demonstrates the presence of electrogenic Na^+ transport, although it does not determine the magnitude. If the apical surface is then perfused with a solution containing a low Cl^- concentration and an agonist such as terbutaline, which increases cellular levels of adenosine 3′,5′-cyclic phosphate (cAMP), Vt hyperpolarizes. This result, plus the finding that Vt does not hyperpolarize in people with cystic fibrosis (CF) (Fig. 8-1*B*), indicates that the apical membrane contains Cl^- channels, which as described below are CF transmembrane conductance regulator (CFTR) Cl^- channels. Finally, if

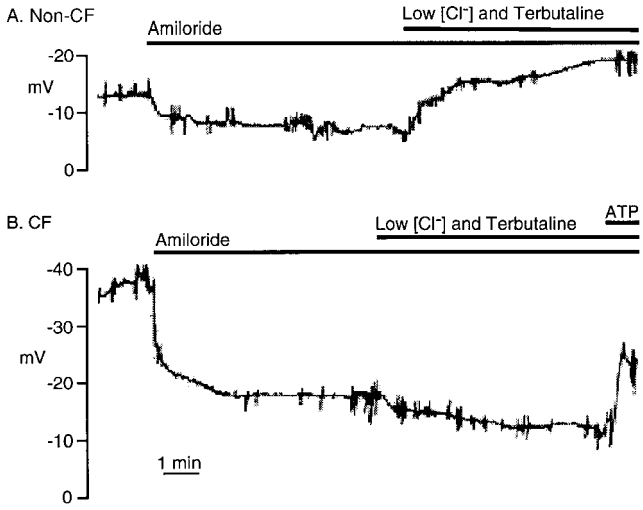

Figure 8-1 Examples of transepithelial voltage (Vt) measured in vivo across the airway epithelium of the nasal mucosa. Amiloride, a solution containing a low Cl^- concentration plus terbutaline, and ATP were present during times indicated by the bars. Top trace *(A)* was from a normal person; bottom trace *(B)* was from a person with cystic fibrosis. (Provided by Dr. Joseph Zabner and Jan Launspach.)

the apical surface is perfused with adenosine 5′-triphosphate (ATP) or another nucleotide in the presence of low Cl^- concentration, Vt transiently hyperpolarizes, indicating the presence of another type of Cl^- channel in the apical membrane. This is particularly prominent in CF epithelia that lack CFTR Cl^- channels.

Thus, measurements of Vt in vivo provide valuable qualitative information about the airways. As a result, they are used frequently to assess airway function in disease states and as an assay to test the effect of potential therapeutic agents.

In Vitro Studies of Airway Epithelia

In vitro studies have increased understanding of mechanisms of electrolyte transport. Although studies from many species have contributed to knowledge of airway biology, here we focus on human airway epithelia. The ability to culture human airway epithelial cells was an important advance for many studies of the airways. Primary cultures of human airway epithelia can be grown on permeable filter supports, often at the air-liquid interface, so that they differentiate, generate a ciliated surface, develop tight junctions, and form distinct apical and basolateral membranes. To study electrolyte transport, cultured epithelia or native epithelia can be mounted in Ussing chambers in which the apical and basolateral compartments are separated. Vt can be measured and controlled (clamped) to desired values. The transepithelial electrical resistance can be determined by measuring the change in Vt that results from an applied current pulse. The short-circuit current (Isc) is measured when Vt is clamped at 0 mV and both sides of the epithelium are bathed with identical solutions. Under these conditions, the Isc is equal to the sum of all active, electrogenic, transepithelial transport.

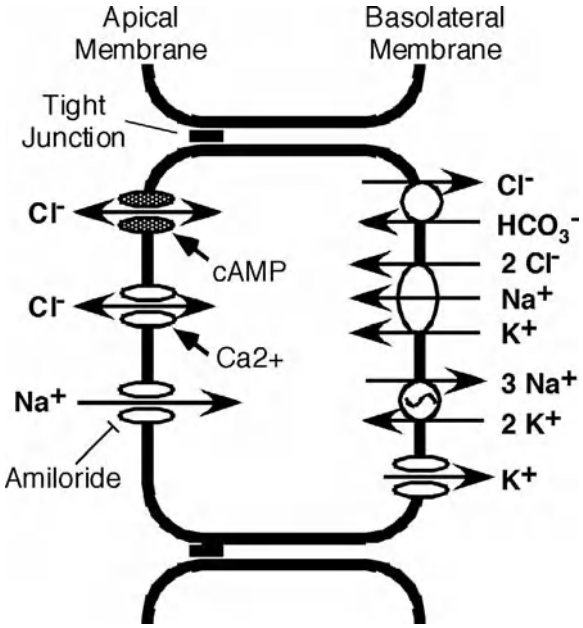

Figure 8-2 Cellular and molecular mechanism of electrolyte transport by airway epithelia. Note that cAMP-dependent and Ca^{2+}-dependent Cl^- secretion and amiloride-sensitive Na^+ absorption appear to occur in the same cell type. The CFTR Cl^- channel, which is defective in cystic fibrosis, is indicated by shading; all other channels, transporters, and pumps are indicated by open symbols.

Cellular and Molecular Mechanisms of Electrolyte Transport

The cellular and molecular mechanisms of transepithelial transport are depicted graphically in Fig. 8-2. Although the magnitude and contribution of specific processes to net transport vary depending on the airway region and experimental conditions, the cellular mechanisms appear similar throughout the airways. As described below, several aspects also apply to the function of submucosal gland epithelia. When the epithelium is studied in vitro, the Isc is accounted for by the absorption of Na^+ from the mucosal to the submucosal surface and anion secretion in the opposite direction. In human epithelia, electrogenic absorption of Na^+ makes a greater contribution to Isc than does anion secretion. In fact, definite identification of Cl^- secretion in human airway epithelia often requires inhibition of Na^+ absorption and opening of Cl^- channels.

The main features of the model for Na^+ transport (Fig. 8-2) include: (1) Na^+ enters the cell through apical membrane epithelial Na^+ channels (ENaC). ENaC channels are inhibited by apical amiloride. Entry is a passive process, with Na^+ flowing down favorable concentration (the intracellular Na^+ concentration is lower than the extracellular concentration) and electrical (intracellular voltage is negative relative to the apical side of the membrane) gradients. (2) Na^+ then exits across the basolateral membrane via the Na^+-K^+-ATPase. This enzyme powers transepithelial transport by using energy from ATP hydrolysis to pump Na^+ out of the cell, thereby maintaining a low intracellular Na^+ concentration. The Na^+-K^+-ATPase also accumulates K^+ inside the cell. (3) K^+ exits passively through basolateral membrane K^+ channels. The basolateral K^+ conductance and the K^+ concentration gradient (high intracellular and low extracellular K^+ concentrations) hyperpolarize the cell, providing part of the driving force for Na^+ entry at the apical membrane.

Under short-circuit conditions in the presence of amiloride, the epithelium can secrete Cl^- or HCO_3^-. The mechanisms for Cl^- secretion (Fig. 8-2) are: (1) Cl^- enters across the basolateral membrane via an electrically neutral cotransport process, coupled to Na^+ and K^+. Entry of Na^+ down its electrochemical gradient provides the driving force for accumulation of Cl^- at a concentration above electrochemical equilibrium. (2) Cl^- exits passively through apical membrane Cl^- channels, moving down a favorable electrochemical gradient. Regulation of the apical Cl^- permeability controls, in part, the rate of transepithelial Cl^- transport. There are at least two types of apical Cl^- channels: CFTR Cl^- channels, which are regulated by phosphorylation by cAMP-dependent protein kinase, and Cl^- channels that are activated by an increase in the cytosolic concentration of free Ca^{2+} $[Ca^{2+}]_c$. The molecular identity of the Cl^- channels controlled by $[Ca^{2+}]_c$ are not yet known. (3) Na^+ that enters the cell at the basolateral membrane coupled to Cl^- exits across the basolateral membrane via the Na^+-K^+-ATPase. (4) K^+ that enters coupled to Cl^- and on the Na^+-K^+-ATPase exits passively through basolateral membrane K^+ channels. When the epithelium is studied in an Ussing chamber under open-circuit conditions (i.e., when Vt is not clamped), often little net Cl^- transport is measured, and Cl^- absorption can occur.

The mechanisms for HCO_3^- and Cl^- secretion are similar except that HCO_3^- enters through a basolateral Cl^-:HCO_3^- exchanger before exiting through CFTR. How epithelia vary and control the proportions of Cl^- and HCO_3^- transport are not well understood. The basolateral membrane also contains a small Cl^- conductance of uncertain molecular identity. These channels may serve as a pathway for anion absorption and may influence the proportion of Cl^- and HCO_3^- secretion.

The CFTR Cl^- Channel

Because the gene for CFTR is mutated in patients with CF, the CFTR Cl^- channel has been studied extensively. CFTR is a member of a protein family named ATP-binding cassette (ABC) transporters. CFTR sits in the apical membrane and within intracellular vesicles beneath the apical membrane. Although epithelia lining the pulmonary airways express little CFTR, the Cl^- channel function (and its absence in CF) is easily measured. This is so because ion channels are very efficient, with an ability to transport 10^6 to 10^7 ions per second. Thus only a relatively few molecules of CFTR are sufficient to support transepithelial Cl^- transport.

As shown in Fig. 8-3, CFTR contains at least five domains: two membrane-spanning domains (MSDs), each composed of six transmembrane segments; an R domain, which contains several consensus phosphorylation

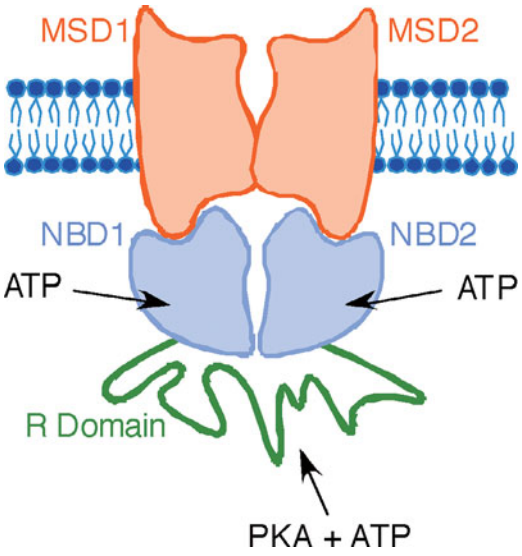

Figure 8-3 Model showing the proposed domain structure of CFTR. *MSD* refers to the membrane spanning domains, *NBD* refers to the nucleotide-binding domains, and *PKA* refers to cAMP-dependent protein kinase. The NBDs and R domain are on the cytosolic side of the membrane.

sequences; and two nucleotide-binding domains (NBDs), which interact with ATP. Each of the different domains contributes to the protein's function. The MSDs combine to form the channel pore and determine anion selectivity. The R domain controls channel activity. The balance of kinase (especially cAMP-dependent protein kinase) and phosphatase activity determines the state of R domain phosphorylation. When the R domain is phosphorylated, the channel can open. Regulation by phosphorylation seems complex because the R domain contains several sites that are phosphorylated, and we do not yet understand how individual phosphorylation sites interact to determine overall activity.

The NBDs also control channel activity. ATP binding and enzymatic activity, either adenylate kinase ($ATP + AMP \leftrightarrows ADP + ADP$) or ATPase ($ATP + H_2O \rightarrow ADP + P_i$), gate the channel. It appears that nucleotide-dependent dimerization of the two NBDs is a central feature of gating. The combination of electrophysiological, biochemical, and structural investigations of the NBDs is providing rapid progress in understanding how this interesting molecule works and how mutations disrupt its function in CF.

Regulation of Electrolyte Transport

A variety of neurohumoral and pharmacologic agents regulate the rate of transepithelial electrolyte transport by the airway epithelia. Extracellular signals regulate two main second messengers: cAMP and $[Ca^{2+}]_c$. An increase in levels of cAMP activates cAMP-dependent protein kinase, which phosphorylates and thereby activates CFTR Cl^- channels, basolateral $Na^+/K^+/Cl^-$ co-transporters, and probably some basolateral K^+ channels. An increase in $[Ca^{2+}]_c$ appears to activate a population of apical Cl^- channels and some basolateral K^+ channels. An increase in $[Ca^{2+}]_c$ and diacylglycerol also may activate protein kinase C, which can modulate the activity of CFTR and several transporters. Most agents that regulate transport tend to stimulate transepithelial Cl^- transport; less is known about how Na^+ transport is regulated. Under some conditions cAMP may stimulate Na^+ absorption, and an increase in $[Ca^{2+}]_c$ may inhibit transport. As in a variety of other Na^+-absorbing epithelia, aldosterone also may regulate Na^+ absorption, although the effect appears to be variable.

A number of hormones, neurotransmitters, and autocoids regulate the intracellular levels of cAMP. The epithelia contain receptors for and respond to β-adrenergic agonists, prostaglandins, adenosine, and vasoactive intestinal peptide. The level of $[Ca^{2+}]_c$ is controlled by bradykinin, substance P, leukotrienes, and nucleotides, such as ATP. Extracellular nucleotides are of particular interest, because they interact with receptors on the apical surface of the epithelium, and by activating Ca^{2+}-activated Cl^- channels they stimulate transepithelial Cl^- transport through a pathway other than the CFTR Cl^- channel.

Effect of Electrolyte Transport on Fluid Transport and Ion Concentrations

Despite much progress in understanding cellular and molecular mechanisms, there is a persistent paucity of knowledge about the integrated physiology of the airways. Liquid transport has been studied in cultured human airway epithelial cells. Active Na^+ absorption drives liquid absorption under baseline conditions. Adding amiloride and agonists that increase cellular levels of cAMP stimulate liquid secretion. The ASL depth is estimated at 5 to 15 μm, thus predicting that 500 to 1500 nl of ASL over each cm^2. While the measured rates of transepithelial liquid transport indicate that the epithelium can secrete or absorb several times this volume over a 24-h period, those studies suffer from the limitation that of necessity they have often been performed with the mucosal surface covered by a comparatively large volume of fluid or following liquid addition. As a result, the effects on net transport of surface forces and the composition of the ASL may not have been apparent.

Current knowledge of the composition and the regulation of ASL is inadequate, and major controversies persist in the literature. Uncertainty and apparently conflicting data result in large part from the small volumes, inaccessibility of the respiratory tract fluid, a variety of model systems, potential species differences, and diverse assay procedures. The uncertainty is compounded by variable results obtained in CF models. Most but not all studies suggest that ASL has a NaCl concentration less than that of serum. However, because the epithelium is very water permeable, the forces that maintain osmotic balance are uncertain. Much more work is needed to learn how fluid composition varies in different airway regions, how it is modified by specific electrolyte transport processes, how liquid flow between airway regions affects volume and composition, and how evaporation changes composition.

BIOLOGY OF AIRWAY SUBMUCOSAL GLANDS

Development

Human submucosal gland development is a prenatal event, beginning at 10 to 12 weeks of gestation. From then until about 25 weeks of gestation, glands appear first in the trachea, then outward to the cartilaginous bronchi. Gland formation is completed before birth and involves budding morphogenesis and migration of surface epithelial cells into the submucosa and formation of a progressively more complex system of branching ducts and tubules. The area and complexity of glands continue to increase postnatally. Recent evidence suggests that more than one surface epithelial cell type serves as a progenitor in the formation of submucosal glands, and expression of the transcription factor Lef1 is required for gland development. Whereas gland hyperplasia may occur with disease states such as chronic bronchitis and CF, the total number of glands appears to be established before birth with little change in number postnatally. It is estimated that 4000 glands are present in the adult human trachea.

Structure and Cell Types

Submucosal glands are complex tubuloacinar structures reflecting the diverse functions of the gland. The cell volume of submucosal glands is approximately 40 times greater than that of the secretory (goblet) cells of the surface epithelium. The glands are predominantly located in the submucosal tissue between cartilage plates in trachea and bronchi and are normally absent from the bronchiolar region. In the adult trachea, submucosal glands occur at a frequency of about $1/mm^2$. As shown in Fig. 8-4, each gland has four anatomic regions. A narrow ciliated duct is lined by ciliated epithelia in continuity with the surface epithelium. The ciliated duct epithelia are morphologically similar to ciliated cells of the surface epithelium. A wider collecting duct is lined by cells containing numerous mitochondria that stain positive with eosin and other poorly characterized cells. Mucous tubules and acini consist of cells rich in acidic glycoconjugates and stain positive with PAS and Alcian blue. Serous tubules and acini are composed of serous cells containing neutral glycoconjugates and are located distal to mucous tubules. Serous cells are also PAS positive but do not stain with Alcian blue. Mucous and serous cells also can be differentiated by specific patterns of staining with several lectins. Multiple branches of mucous and serous tubules occur from each collecting duct, terminating in a variable number of acini. The mucous and serous cells are the main epithelial components of the submucosal gland. In addition to these cells, contractile myoepithelial cells surround the acini and secretory tubules of glands and may be important in the short-term responses of glands, causing the ejection of secreted mucus and fluid from ducts and tubules.

Submucosal Gland Physiology

The functions of submucosal glands appear to be twofold: (1) the secretion of fluid and electrolytes, which contributes to the periciliary fluid layer and hydration of mucus; and (2) the secretion of macromolecules, including mucins and proteins that contribute to host defenses in the airways. The viscous secretions of mucous cells are rich in high-molecular-weight glycoconjugates. In contrast, the secretions of serous cells are less viscous. The thinner secretions of the distally oriented serous cells probably serve to hydrate and mobilize the thicker secretory products of mucous cells. Submucosal glands are richly innervated by postganglionic fibers from both the sympathetic and parasympathetic nervous systems. These fibers release norepinephrine and acetylcholine and produce neuropeptides such as substance P, calcitonin gene-related peptide (CGRP), and vasoactive intestinal peptide (VIP).

Electrolyte Transport in Submucosal Glands

The cellular mechanisms of ion transport in human submucosal glands are under investigation, and some data come from animal studies. Similar to the surface epithelium, the movement of water across submucosal gland epithelia is osmotically coupled to the net direction of active electrolyte transport. Both secretory and absorptive pathways for electrolyte movement are distributed in a polarized fashion in gland epithelia (Fig. 8-2). Serous cells express CFTR at the apical membrane, and the level of expression is greater than the surface epithelium. Submucosal glands also express ENaC in both ductal and acinar epithelia. The Isc of mixed seromucous cell cultures is inhibited by ouabain on the basolateral

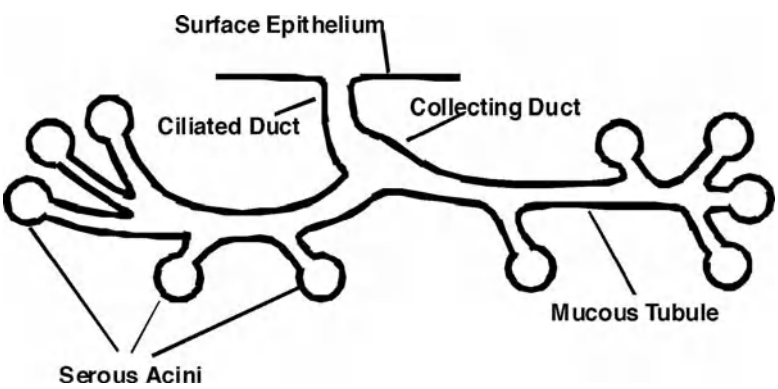

Figure 8-4 Model of submucosal gland from human trachea. The anatomic regions shown include ciliated duct, collecting duct, mucous tubules, and serous acini. See text for details.

membrane, indicating the presence of Na^+/K^+-ATPase. Thus, the pathways for ion movement across gland epithelia bear great similarity to those of the surface cells.

Advances in the isolation and culture of human serous and mucous cells from submucosal glands have brought new insights into submucosal gland physiology. The serous cells of the submucosal gland contribute greatly to the secretion of electrolytes and airway surface fluid. Unlike the surface epithelia, which exhibit absorptive transport properties in the resting state, the serous cells are predominantly Cl^- secretory. Serous gland epithelia exhibit cAMP-activated Cl^- secretion consistent with CFTR function. The Cl^- secretory capacity and CFTR protein expression of serous cells is greater than the mucous cells; thus, the serous cell is probably the predominant source of fluid secreted by submucosal glands. Cl^- secretion is induced by agents that increase $[Ca^{2+}]c$, indicating that, like the surface epithelium, submucosal glands express Ca^{2+}-activated Cl^- channels. When applied to the apical membrane of isolated human submucosal glands, cell preparation amiloride inhibits the Isc, suggesting that in addition to secreting Cl^-, the cells of the gland can modify the volume and composition of secretions by absorbing Na^+.

Electrolyte transport across submucosal gland epithelia is regulated by several secretagogues, including cholinergic agonists, adrenergic agents, bradykinin, and neuropeptides. In contrast to the surface epithelium, cholinergic pathways and agents that increase intracellular Ca^{2+}, rather than β-adrenergic pathways, are the major stimuli for Cl^- secretion in gland epithelia. This information comes from several sources, including receptor autoradiography, receptor binding assays, and in vitro physiology studies. A list of neurohumoral agents regulating Cl^- secretion in submucosal glands is listed in Table 8-1.

Table 8-1

Neurohumoral Regulation of Submucosal Gland Cl^- Secretion

	Target Cell Type	
Agent	**Mucous**	**Serous**
Methacholine	−	++
Histamine	−	+
α Adrenergic	+	+
β Adrenergic	+	++
Bradykinin	+	+
Substance P	+	+

A negative sign (−) indicates no demonstrated effect, and a plus sign (+) indicates stimulation of Cl^- secretion.

Table 8-2

Macromolecular Products of Submucosal Glands

Product	**Cell of Origin**	**Proposed Function**
Mucins	Mucous	Component of mucus blanket
Glycoconjugates	Mucous, serous	Component of mucus blanket
Lysozyme	Serous	Antimicrobial
Lactoferrin	Serous	Antimicrobial
Secretory component	Serous	Antimicrobial
Antileukoproteinase	Serous	Antimicrobial
Peroxidase	Serous	Antimicrobial
Proline-rich proteins	Serous	Antimicrobial
Antimicrobial peptides (β-defensins, LL37)	Mucous, serous	Antimicrobial

Note: The macromolecular products of submucosal glands, the cell of origin (mucous, serous, or both) and proposed function are listed. Note that glycoconjugates are a product of both cell types. Many of the products exhibit antimicrobial properties. See text for details.

Secretion of Macromolecules and Proteins

In addition to the transport of fluid and electrolytes, submucosal glands are the major source of airway mucins and secrete several protein products listed in Table 8-2. Histochemical stains demonstrate that both the serous and mucous cells of the glands produce glycoproteins. Mucous cells contain predominantly acidic glycoconjugates, identified as large, electron neutral granules, whereas serous cells contain neutral, more heavily sulfated glycoconjugates in smaller, electron-dense granules. Although both mucous and serous cells express mRNAs for mucin genes, mucin production is restricted to the mucous cells. The control of secretion by mucous cells is complex. Cholinergic stimuli cause degranulation of both mucous and serous cells. Neuropeptides, including substance P and VIP, also regulate the secretion of macromolecules. In addition to cholinergic, adrenergic, and neuropeptide-mediated secretion, several neural reflexes are associated with mucus secretion. These include cough due to irritation of the airways, hypoxia, and gastric distention.

Inflammatory mediators such as those associated with infections or allergic reactions can stimulate mucus secretion. These include histamine from mast cells, prostaglandins A_2, D_2 and $F_{2\alpha}$, and leukotrienes C_4 and D_4.

Macromolecular Products of Submucosal Glands

Submucosal glands play an important part in lung host defenses by contributing to mucociliary function and secreting products with antimicrobial activity. The fluid and electrolyte secretions produced predominantly by the serous cells of glands are in part responsible for the maintenance of the periciliary fluid layer on airway surface cells. These secretions also hydrate mucins secreted by mucous cells and thus are important for the production of the gel layer. Thus, submucosal gland products are key components of the mucociliary clearance system in the airways and support this first line of defense for handling inhaled infectious and noninfectious particulate matter.

The serous cells of glands elaborate a number of products that constitute additional host defense mechanisms in the airways. These factors act in a broad-spectrum fashion, in some cases exerting antimicrobial effects against bacteria, fungi, and viruses. The cationic, bacteriolytic protein lysozyme is a specific product of the serous cell and is found in measurable quantities in airway secretions. Lactoferrin is found in airway secretions and is distributed in submucosal glands in a pattern similar to lysozyme. It is a cationic, iron-binding protein, which may act by inhibiting growth of iron-requiring bacteria. The serous cells also produce the secretory component of IgA, which is required for the translocation of IgA from the basolateral to apical membrane, where it is released. A low-molecular-weight cationic proteinase inhibitor termed anti-leukoprotease or secretory leukocyte proteinase inhibitor (SLPI) is also produced by serous cells and comprises most of the antineutrophil proteinase activity produced in the airways. Additional products of serous cells with antimicrobial properties include peroxidase and proline-rich proteins. Antimicrobial peptides, including β-defensins and cathelicidins, are also secreted by human submucosal gland cells. It is likely that these multiple components of the nonspecific mucosal immune system act synergistically to prevent infection of the lung from a variety of inhaled or aspirated pathogens.

INTEGRATED PHYSIOLOGY AND HOST DEFENSE FUNCTIONS

Although much has been learned about the specific molecules involved in electrolyte transport and the function of the epithelium on the airway surface and submucosal glands, there is a continuing lack of knowledge about the integrated physiology of the airways. An important function of the airways is in local host defense, protecting the lung from inhaled microorganisms, particulate material, and toxins. Here we describe some aspects of the integrated physiology of the airways, but we also note deficiencies in current knowledge.

Mucociliary Clearance

An important function of airway secretions is in mucociliary clearance. Mucociliary clearance is a pulmonary defense mechanism that serves to remove inhaled particulate material from the lung. Effective clearance requires both ciliary activity and respiratory tract fluid. Cilia cover much of the airway surface, and their coordinated beating provides the mechanical force that propels particulate material toward the larynx. The cilia are immersed in a periciliary fluid layer, or sol phase of the fluid, that is about 5 μm thick. The periciliary fluid is covered by a mucous or gel layer, 5 to 10 μm thick, which exists as a discontinuous blanket, i.e., as islands of mucus. The viscoelastic mucus traps and carries inhaled material, whereas the watery periciliary fluid allows the cilia to move freely, with only the tops of the cilia contacting the overlying mucus and propelling it toward the mouth. The quantity and composition of the periciliary fluid, and perhaps hydration of the mucus, are controlled by the electrolyte transport properties of the cells of the surface and submucosal gland epithelia.

Antibacterial Activity at the Airway Surface

Airway surface liquid contains a rich variety of molecules that kill bacteria. The antimicrobials include lysozyme, lactoferrin, β-defensins, LL-37, SLPI, phospholipase A2, and secreted IgA. These molecules are secreted by the submucosal glands and to a lesser extent by the surface airway epithelium. Airway epithelia also generate nitrous oxide and reactive oxygen species that possess antimicrobial activity. The ASL factors kill bacteria rapidly; they show broad-spectrum activity; they kill some fungi and inactivate some enveloped viruses; and in contrast to pharmaceutical antibiotics, resistance does not develop. Antimicrobial activity in the ASL may be a first line of defense that protects the lung from microorganisms deposited on the airway surface after inhalation and aspiration. This process explains, in part, the ability of the airways to maintain a sterile intrapulmonary environment. Furthermore, the epithelial cells express an array of pattern recognition receptors, including Toll-like receptors that facilitate identification of microbes and elicit responses such as induction of antimicrobials or cytokines. Most endogenous antimicrobials show increased activity when the salt concentration falls, suggesting that interventions that lower ASL salt concentration might enhance host defense against infection. In addition, the beneficial properties of endogenous antimicrobials, especially the lack of resistance, recommend them for development as novel therapeutics.

Phagocytic Cells and Repair

In addition to mucociliary clearance and antibacterial activity, a second line of defense involves the recruitment of

phagocytic cells such as neutrophils and macrophages to the airway surface. By releasing a variety of cytokines and inflammatory molecules, the epithelium mediates the inflammatory response to inhaled bacteria and other pathogens. This topic is covered in depth elsewhere in this book. Airway epithelia also possess the repair mechanisms needed following disruption. These include several growth factors including epithelial growth factor (EGF). In some cases, growth factor ligands are present on the apical surface, physically segregated from their receptors on the basolateral membrane. This arrangement provides a simple system that is primed for activation the instant epithelial integrity is compromised. Such a design could be vital to rapid restoration of barrier function and protection of the organism following a mechanical or toxic wound that disrupts the epithelium. With injury, fibroblasts and interstitial cells also secrete a variety of molecules that remodel the epithelium. Of course, the processes that mediate development and repair also may be important in the pathophysiology of airway diseases involving abnormal proliferation and remodeling, including smoking-associated bronchitis, CF, and asthma.

Insights into Airway Biology from Disease States

Clues about the integrated function and biology of the airways have come from study of several disease states and the development of animal models in which specific genes have been disrupted. We discuss these only briefly here; they are discussed in greater depth in subsequent chapters.

Ciliary activity is disrupted in ciliary dyskinesia syndromes. As a result, mucociliary activity is impaired. Patients often develop chronic infections of the middle ear, sinuses, and airways, which may advance to bronchiectasis. This observation underscores the important role of mucociliary clearance as a defense mechanism in humans.

In CF, the gene encoding CFTR is mutated. The resulting loss of CFTR Cl^- channels leads to chronic respiratory tract infections. This observation supports a central role for electrolyte transport in the normal biology and host defense of the airways. However, the mechanism by which loss of CFTR predisposes to infection remains controversial, and perhaps several factors contribute. Disruption of epithelial salt transport may increase ASL salt concentrations, thereby impairing bacterial killing by ASL antimicrobials. It has been suggested that abnormal amounts or composition of the respiratory tract fluid might make mucociliary clearance less efficient. Disruption of CFTR function in submucosal gland epithelia might increase the viscosity of mucus. Loss of CFTR may reduce HCO_3^- secretion, producing a more acidic ASL. Alterations in the composition of airway surface fluid also may affect the normal hydration of mucus. Loss of CFTR also has been proposed to alter the inflammatory and/or immune response of the airway to bacterial challenge.

Diseases that alter Na^+ absorption also can provide clues about the role of this process in airway biology. In Liddle's syndrome, gain-of-function mutations in the ENaC Na^+ channel increase the rate of amiloride-sensitive Na^+ absorption. In contrast, in pseudohypoaldosteronism, loss-of-function mutations in the ENaC Na^+ channel decrease the rate of Na^+ absorption. Patients with Liddle's syndrome are not reported to have evidence of airway disease, whereas patients with pseudohypoaldosteronism develop airway disease that shows some similarity to CF. If, as expected, the gain or loss of ENaC function in the airways is similar to what has been reported in the kidney of patients with these diseases, then these observations suggest that a reduced capacity for salt absorption would impair airway host defense mechanisms, much as was suggested for the loss of CFTR Cl^- channels in CF. Studies in mice overexpressing ENaC suggest that increased Na^+ absorption may generate changes similar to those observed in CF.

The genes for the CFTR Cl^- channel and the ENaC Na^+ channel also have been disrupted in mice. Unfortunately, these models have not faithfully reproduced the human disease. Mice lacking CFTR do not develop chronic airway disease; it has been speculated that this may be because mice have quantitatively more Ca^{2+}-activated Cl^- current in the airways than humans. Mice lacking subunits of ENaC Na^+ channels die of respiratory distress because of a failure to clear fluid from the lungs after birth. While this established the important role of electrolyte transport in airway function, it did not produce an animal with disease that accurately mimics human disease. Future interventions may be of greater value, and a comparison of disease in mice and humans may yield additional clues as to the biology of the airways.

The appreciation that abnormalities in airway and submucosal gland function play central roles in the pathogenesis and pathophysiology of some inherited and acquired diseases has increased interest and focused research in this area. Future studies in this field should continue to increase our understanding of how airway surface fluid and its secretory products contribute to lung health and are altered in disease states.

CHAPTER 9

Pulmonary Mechanics

Murray D. Altose

For venous blood to be properly arterialized, the distribution of air and blood within the lung is automatically matched in order to ensure effective gas exchange across alveolar-capillary membranes. Arterialization comprises a series of interrelated processes that begin with the mechanical performance of the ventilatory apparatus—i.e., the lungs and chest wall, including the rib cage, diaphragm, and abdominal wall. Although the function of each component of the lung and of the chest bellows can be deranged by injury or disease, the design of the ventilatory apparatus provides for considerable reserve. As a result, mechanical derangements are usually quite severe by the time clinical symptoms appear or arterial blood-gas levels become abnormal.

Depending on the nature of the underlying disorder, assessment of the mechanical properties of the ventilatory apparatus provides several different types of information. In some instances, characterization of the mechanical abnormality provides insight into pathogenesis and affords a quantitative measure of severity. In others, once the nature of the mechanical disorder is understood, the mystery surrounding a life-threatening disorder in gas exchange may be dispelled. Finally, certain breathing patterns make sense only if the mechanical performance of the chest bellows is taken into account.

During breathing, the lungs and chest wall operate in unison. The lungs fill the chest cavity so that the visceral pleura are in contact with the parietal pleura of the chest wall. The two pleural surfaces are separated by only a thin liquid film, which provides the bond holding the lungs and chest wall together.

At the end of a normal exhalation, the respiratory muscles are at rest. The pressure along the entire tracheobronchial

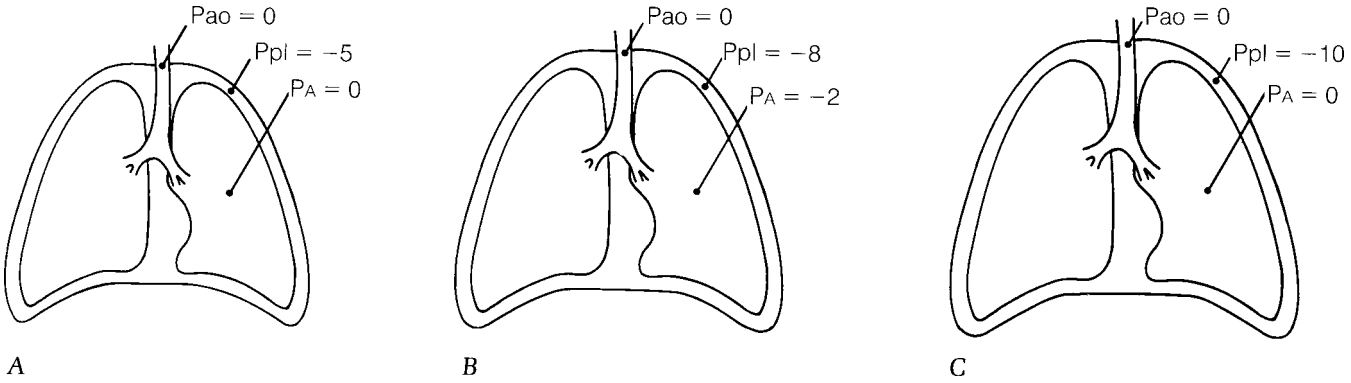

Figure 9-1 Respiratory pressures during a breathing cycle. Ppl = pleural pressure; PA = pressure in the alveoli; Pao = pressure at the airway opening. *A*. End expiration. *B*. During inspiration. *C*. End inspiration.

tree from the airway opening to the alveoli is equal to atmospheric pressure. The tendency of the lung is to deflate, however, and lung elastic recoil is directed centripetally. This is counterbalanced by the elastic recoil of the chest wall, which is directed centrifugally to favor an increase in volume. These opposing forces generate a subatmospheric pleural pressure of about –5 cmH_2O (Fig. 9-1*A*). The tendency for the lung to recoil inward and for the chest wall to recoil outward is illustrated by the observation that when the chest is opened at autopsy, the lungs collapse and the thorax expands.

Although it is conventional to consider pleural pressure as a single, mean value that reflects mechanical events within the entire ventilatory apparatus, this is clearly an oversimplification on several accounts: (1) pleural pressure is not directly determinable because normally there is only a potential space between the visceral and parietal pleura; (2) on conceptual grounds, distinctions exist between surface and liquid pleural pressures; (3) pleural pressures are not uniform over the surface of the lungs, being strongly affected by gravity; and (4) transmission of pleural pressures at the surface to alveoli located at different depths and loci with the lungs depends on the structural interplay among supporting structures in the alveolar walls (interdependence), which resists any inclination of individual alveoli or even a lobule to collapse. Nonetheless, the concept of mean pleural pressure, as generally used in considerations of respiratory system mechanics, has proved to be of great practical value.

The contraction of the muscles of inspiration produces the forces that permit the flow of gas along the tracheobronchial tree and the expansion of the lungs and chest. The movement of air into the lungs requires a pressure difference between the airway opening and the alveoli sufficient to overcome the resistance to airflow of the tracheobronchial tree. Also, a pressure difference across the alveolar walls (between the alveoli and pleural space) must be generated to overcome elastic recoil and inflate the lungs. During spontaneous breathing, the action of the inspiratory muscles causes an increase in the outward recoil of the chest wall. As a result, the pleural pressure becomes more subatmospheric. This pressure change is transmitted to the interior of the lungs, so alveolar pressure also becomes subatmospheric (Fig. 9-1*B*). In contrast, during artificial ventilation with a positive-pressure breathing machine, a supra-atmospheric pressure applied at the inlet to the airways creates the proper pressure gradient between the airway opening and alveoli for airflow.

Expansion of alveoli depends on the achievement of an appropriate distending pressure across alveolar walls. This distending pressure or transpulmonary pressure is the difference between alveolar (PA) and pleural (Ppl) pressures. As shown in Fig. 9-1*A*, the transpulmonary pressure at end-expiration (PA – Ppl) is 5 cmH_2O. At the end of inspiration (Fig. 9-1*C*), *the transpulmonary distending pressure is higher and the lungs contain more air.*

The energy used during inspiration to overcome the elastic resistance of the lungs is stored. Expiration occurs when these forces are released. When the inspiratory muscles relax, the recoil of the lungs causes the alveolar pressure to exceed the pressure at the mouth, and air flows out of the lungs. Although expiration during quiet breathing is passive, the expiratory muscles are engaged at high levels of ventilation to assist the movement of air out of the lungs.

LUNG VOLUMES

The lung volumes and capacities (Table 9-1) are also considered elsewhere in this book (see Appendix B). The end-expiratory position of the lungs, functional residual capacity (FRC), is the major reference point for the volume subdivisions of the lung. This position is set by the opposing recoil forces of the lung and chest wall when the respiratory muscles are at rest.

Total lung capacity (TLC), the total volume of air contained in the lungs after a maximal inhalation, is determined by the balance between the force-generating capacity of the inspiratory muscles and the opposing elastic recoil forces of the lung and chest wall. Weakness of the muscles of inspiration or increased stiffness of the lung reduces TLC. Loss of retractive forces exerted by the lung, as in emphysema, enlarges TLC.

Residual volume (RV), the volume of air remaining in the lungs after a complete exhalation, is set by the balance between the actions of the expiratory muscle and the recoil

Table 9-1

Lung Volumes and Subdivisions

The *functional residual capacity* (FRC) is the volume of air that remains in the lungs at the end of a normal expiration.

The *tidal volume* (TV) is the volume of air that is drawn into the lungs during inspiration from the end-expiratory position (and also leaves the lungs passively during expiration in the course of quiet breathing).

The *expiratory reserve volume* (ERV) is the maximum volume of air that can be forcibly exhaled after a quiet expiration has been completed (i.e., from the end-expiratory position).

The *residual volume* (RV) is the volume of air that remains in the lungs after a maximal expiratory effort.

The *inspiratory capacity* (IC) is the maximum volume of air that can be inhaled from the end-expiratory position. It consists of two subdivisions: tidal volume and the *inspiratory reserve volume* (IRV).

The *total lung capacity* (TLC) is the total volume of air contained in the lungs at the end of a maximum inspiration.

The *vital capacity* (VC) is the volume of air that is exhaled by a maximum expiration after a maximum inspiration.

forces of the lung, which act to decrease lung volume, and the outward recoil forces of the chest wall, which favor lung expansion. In middle-aged and older people, closure of airways at low lung volumes, with air trapping in the lung, is an important determinant of residual volume.

STATIC MECHANICAL PROPERTIES OF THE RESPIRATORY SYSTEM

To assess the elastic properties of the ventilatory apparatus, it is expedient to evaluate the elastic properties of the lungs and chest separately.

ELASTIC PROPERTIES OF THE LUNGS (PULMONARY COMPLIANCE)

The change in transpulmonary pressure required to effect a given change in the volume of air in the lungs is a measure

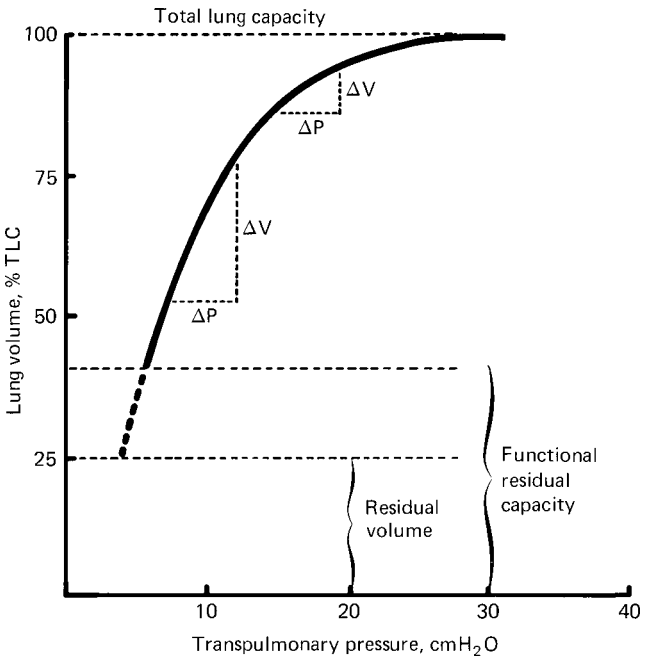

Figure 9-2 Pressure-volume curve of the lung. The static elastic recoil pressure of the lung is approximately 5 cmH_2O at FRC and 30 cmH_2O at TLC. The compliance of the lung ($\Delta V/\Delta P$) is greater at low lung volumes than at high lung volumes.

of the distensibility, or compliance, of the lungs. Pulmonary compliance is calculated as the ratio of the change in lung volume to the change in transpulmonary pressure—i.e.,

$$C = \frac{\Delta V_L}{\Delta(P_A - Pp1)}$$

where

C = lung compliance
$\Delta(P_A - P_P1)$ = change in transpulmonary pressure
ΔV_L = change in lung colume

Compliance denotes distensibility, the ease of stretch or inflation. The inverse of compliance (i.e., elastance) refers to the stiffness or the tendency to resist distortion and to return to the original configuration when the distorting force is removed.

In practice, pulmonary compliance is determined by relating the changes in transpulmonary pressures to the changes in lung volume in the course of an expiration after a maximal inspiration (i.e., starting from total lung capacity).

The pressure-volume characteristics of the lung are nonlinear. As lung volume increases, the elastic elements approach their limits of distensibility, and a given change in transpulmonary pressure produces smaller and smaller increases in lung volume. Thus, the compliance of the lung is least at high lung volumes and greatest as the residual volume is approached (Fig. 9-2). Elastic recoil forces favoring collapse of the lung can be demonstrated throughout the range of the vital capacity, even at low lung volumes approaching the residual volume. If the opposing forces of the chest wall on the lungs are eliminated—for instance, by removing the lungs from the thorax or by opening the chest—the lung collapses

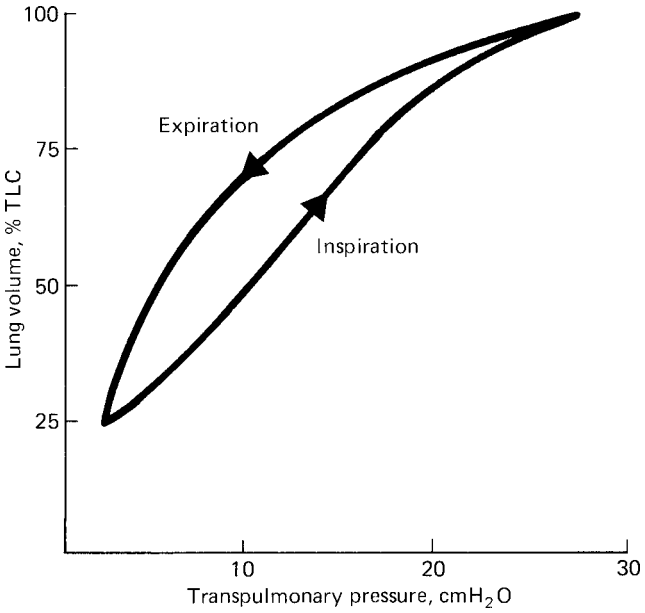

Figure 9-3 Pressure-volume curves of the lung during inspiration and expiration.

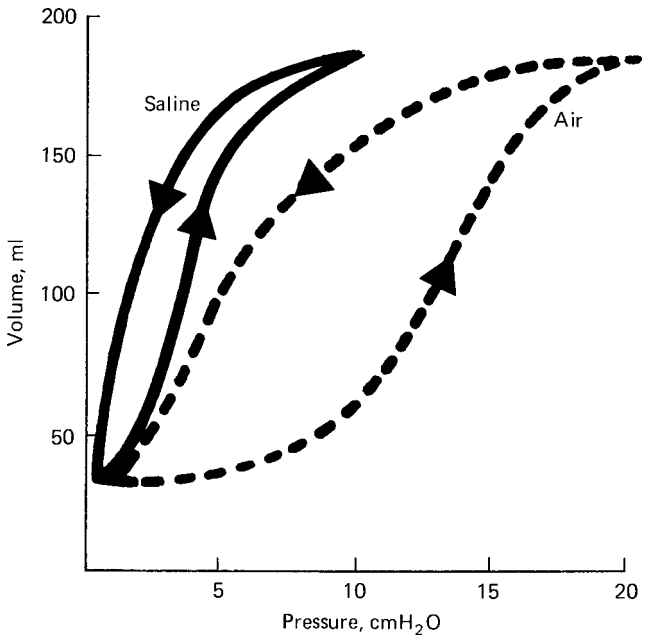

Figure 9-4 Comparison of pressure-volume relationships of air-filled and saline-filled excised lungs. Arrows directed upward indicate inflation; those directed downward indicate deflation. Since saline eliminates surface forces at the liquid-air interface without affecting tissue elasticity, the difference in pressure between the two curves, at any lung volume, is that required to overcome surface forces. To maintain a small lung volume, a large proportion of the pressure is used to overcome surface forces. In contrast, at high lung volumes a greater fraction of the pressure is used to overcome tissue elasticity.

to a near airless state. A minimal volume of air does remain in the lungs because of closure of small airways resulting in the trapping of air in more distal air spaces.

If static measurements of transpulmonary pressure are made during lung inflation rather than deflation, the pressure-volume curve has a different configuration (Fig. 9-3). This indicates that the elastic recoil of the lung depends not only on the lung volume at which the determination is made but also on the "volume history" of the lung.

Hysteresis

Differences in the pathways of the pressure-volume curve during inspiration (when force is applied) and expiration (when force is withdrawn) are designated as hysteresis, which is a property of all elastic structures. In the lungs, it is due to the surface forces and the properties of the surface material lining the alveolar walls and also to the elastic properties of the tissues. An additional factor relates to the closure of small airways at low lung volumes. Once these airways close, the lung units that they serve will not expand during inspiration until a critical opening pressure has been exceeded; only then will the closed units inflate. Recruitment of additional lung units as increasing transpulmonary pressure expands the lungs from low lung volume contributes to the hysteresis of the pressure-volume curve.

The elastic behavior of the lung depends on two factors: the physical properties of the lung tissue, per se, and the surface tension of the film lining of the alveolar walls.

Surface Forces

The interior surfaces of the alveoli are lined by a thin liquid layer of osmophilic material. The surface tension at the air-liquid interface of the alveoli, in addition to the elastic properties of the parenchyma, contributes importantly to the elastic recoil of the lungs and acts to decrease lung compliance. The cohesive forces between the molecules of the liquid lining of the alveoli are stronger than those between the film and alveolar gas, thereby causing the film to shrink to its smallest surface area. The behavior of this surface film has been examined in experimental animals by comparison of pressure-volume relationships of air-filled lungs with those of saline-filled lungs; saline eliminates the liquid-air interface without affecting elastic properties of the tissue. A lung distended with saline requires a lower transpulmonary pressure to maintain a given lung volume than a lung that is inflated with air. Also, hysteresis is less in the saline-filled lung. The greater hysteresis in the air-filled lung is explained by the surface tension of the film lining the alveoli, which is higher during inflation as the film expands than it is during deflation as the film is compressed (Fig. 9-4).

By considering the alveolus to be a sphere, Laplace's law can be applied. Laplace's law states that the pressure inside a spherical structure—e.g., the alveolus—is directly proportional to the tension in the wall and inversely proportional to the radius of curvature:

$$\text{Alveolar pressure} = \frac{2T}{r}$$

where

T = tension (dyn/cm)
r = radius

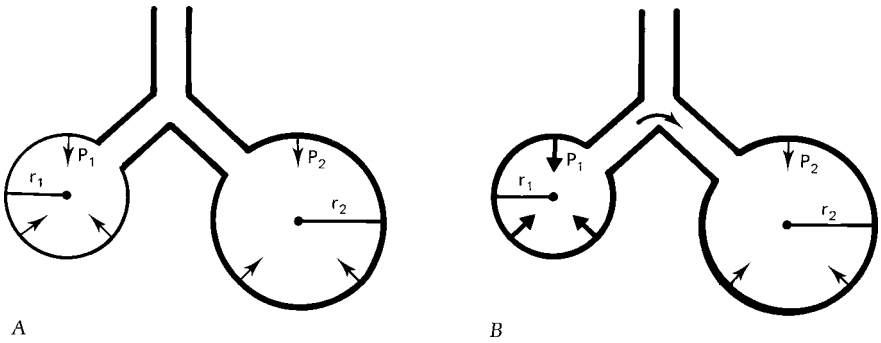

Figure 9-5 The effects of surfactant in maintaining alveolar stability. *A*. Surfactant lowers the tension (T) of the alveolar walls at low lung volumes. Consequently, the transpulmonary pressure (P) of large and small communicating airspaces is the same. $r_1 < r_2, T_1 < T_2, P_1 \leftarrow P_2$. *B*. Without surfactant, the surface tension remains constant as lung volume changes, and the recoil pressure of small airspaces exceeds that of larger ones. As a result, small alveoli tend to empty into larger ones. $r_1 < r_2, T_1 = T_2, P_1 > P_2$.

Abolition of the liquid-air interface by the instillation of saline into the alveolar spaces eliminates surface forces, thereby reducing the transpulmonary pressure required to maintain a given lung volume.

The surface tension of the alveolar walls depends on the lung volume: surface tension is higher at large lung volumes and lower at small lung volumes. These variations in surface tension with lung volume are due to the surface film, surfactant. The superficial layer of the film facing the alveolar air is made up of surface-active phospholipids, notably dipalmitoyl lecithin. The deeper layer termed the hypophase consists of surface-active phospholipids linked to protein. Surfactant is generated by type II alveolar cells and undergoes a continuous cycle of formation, removal, and replenishment.

Surfactant serves several important functions. The surface tension of surfactant is inherently low and decreases even further at low lung volumes when the surface area of the film is reduced. The minimization of surface forces, particularly at low lung volumes, minimizes the adherence of the walls of distal airways that tend to close at low lung volumes and increases the compliance of the lung and decreases the work required to inflate the lungs during the next breath. The automatic adjustment of surface tension as lung volume changes also promotes stability of alveoli at low lung volumes; if the surface tension were to remain constant instead of changing with lung volume, the transpulmonary pressure required to keep an alveolus open would increase as the radius of curvature diminished with decreasing lung volume. Therefore, small alveoli would empty into the larger ones with which they communicate, and atelectasis would be a regular occurrence (Fig. 9-5).

Interdependence and Collateral Ventilation

The low surface tension of surfactant is not the most important determinant of alveolar stability. In reality, the alveoli form a froth rather than individual bubbles. The walls of each alveolus are shared in common with those of adjacent alveoli so that contiguous air spaces attached by their connective tissue framework are tethered to one another and are not free to move independently. The tendency of any one alveolus to collapse is opposed by the traction exerted by the surrounding alveoli. This mechanical interdependence of adjacent air spaces resists the collapse of individual alveoli and serves as a stabilizing influence and ensures uniform inflation.

Even when a distal airway is completely obstructed, the alveoli served by the airway can still be ventilated through collateral channels between alveoli (pores of Kohn) and from bronchioles to alveoli (canals of Lambert). This collateral ventilation also prevents alveolar collapse and enhances the uniformity of ventilation, particularly in patients with lung disease.

Physical Properties of Lung Tissue

A number of different tissue components contribute to lung elasticity. The pleura, the intralobular septa, peripheral airway smooth-muscle tone, and pulmonary vasomotor tone, as well as the tissues of the alveolar walls, play a role in shaping lung elastic recoil.

The major connective-tissue elements of the alveolar walls are the collagen and elastin fibers. Elastin fibers in the alveolar walls and surrounding the bronchioles and pulmonary capillaries have a low tensile strength but can be stretched to over twice their resting length. Elastin fibers are thought to bear most of the stress in the lung at low volumes. Collagen fibers have high tensile strength but are poorly extensible and probably act to limit expansion at high lung volumes. Like a stretched nylon stocking, expansion of the lungs appears to entail an unfolding and geometric rearrangement of the fibers and only slight elongation of individual fibers.

As a result of alterations in the elastin and collagen fibers in the lung, the distensibility of the lungs (measured as compliance) increases with age. This is part of the normal aging process. Pulmonary compliance is also increased by the destruction of alveolar walls and the enlargement of alveolar spaces that characterize pulmonary emphysema. In contrast, the distensibility of the lungs is reduced by pulmonary fibrosis, which stiffens its interstitial tissues.

Elastic Properties of the Thorax

The elastic recoil of the chest wall is such that if it were unopposed by the lungs, the chest would enlarge to approximately 70 percent of total lung capacity. This position represents its equilibrium or resting position. In this position (when the respiratory muscles are completely relaxed), the pressure difference across the chest wall—i.e., the difference between pleural pressure and the pressure at the surface of the chest—is zero. If the chest were forced to enlarge further by an increasingly positive pleural pressure or by the application of subatmospheric pressure at the body surface, it would, like the

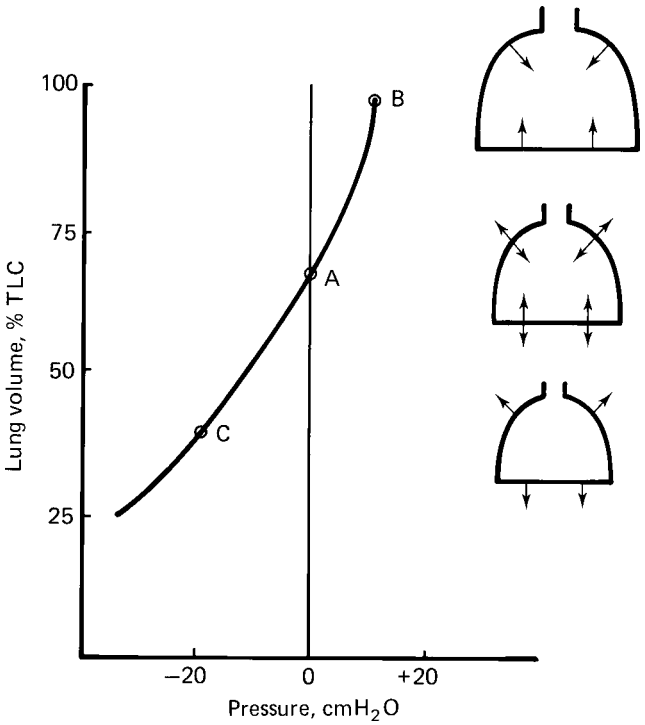

Figure 9-6 Pressure-volume relationships of the isolated chest wall. The equilibrium position of the chest wall (*A*), unopposed by the lungs, is approximately 70 percent of the total lung capacity. In this position, the pressure difference across the chest wall is zero. At larger volumes (*B*), there is inward recoil of the chest wall; at volumes below the equilibrium position (*C*), the recoil of the chest wall is directed outward, favoring expansion.

lung, recoil inward, resisting expansion and favoring return to its equilibrium position. Conversely, at volumes less than 70 percent of total lung capacity, the recoil of the chest is opposite that of the lung and is directed outward (Fig. 9-6). The chest wall can also be represented as a two-compartment system consisting of the rib cage and the abdomen, and volume changes can be partitioned between the two compartments. Changing from the upright to the supine position at a constant overall lung volume produces a shift in volume from the abdominal to the rib cage compartment. The compliance of the rib cage is similar in the supine and upright positions, but the compliance of the abdominal compartment—particularly at high volumes—is greater in the supine position.

The elastic recoil properties of the chest wall play an important role in determining the subdivisions of lung volume. They may be seriously deranged by disorders affecting the chest wall, such as marked obesity, kyphoscoliosis, and ankylosing spondylitis.

Elastic Properties of the Respiratory System as a Whole

If we consider the lung and the chest wall to operate mechanically in series, the elastic recoil pressure of the total respiratory system (Prs) can be calculated as the algebraic sum of the pressures exerted by the elastic recoil of the lung (transpulmonary pressure) and the elastic recoil of the chest wall.

Since the elastic recoil of the lung is determined (under static conditions of arrested airflow) as the difference between alveolar pressure (P_A) and pleural pressure (Ppl)—i.e., P_A – Ppl—and the elastic recoil of the chest wall is determined (while the respiratory muscles are completely at rest) as the difference between pleural pressure and the pressure at the external surface of the chest (Pbs)—i.e., Ppl – Pbs, the elastic recoil of the entire respiratory system can be expressed as the sum of the two:

$$Prs = (P_A - Ppl) + (Ppl - Pbs) = P_A - Pbs$$

Thus, a measure of the elastic recoil of the respiratory system is supplied by the alveolar pressure, provided that the respiratory muscles are completely at rest and the pressure of the body surface is at atmospheric levels. In the absence of airflow into or out of the lung and when the glottis is open, alveolar pressure corresponds to the pressure at the mouth.

Relaxation Pressure-Volume Curve

The elastic properties of the entire respiratory system can be determined from the relaxation pressure-volume curve (Fig. 9-7). Functional residual capacity represents the equilibrium position of the lung-chest wall system while the

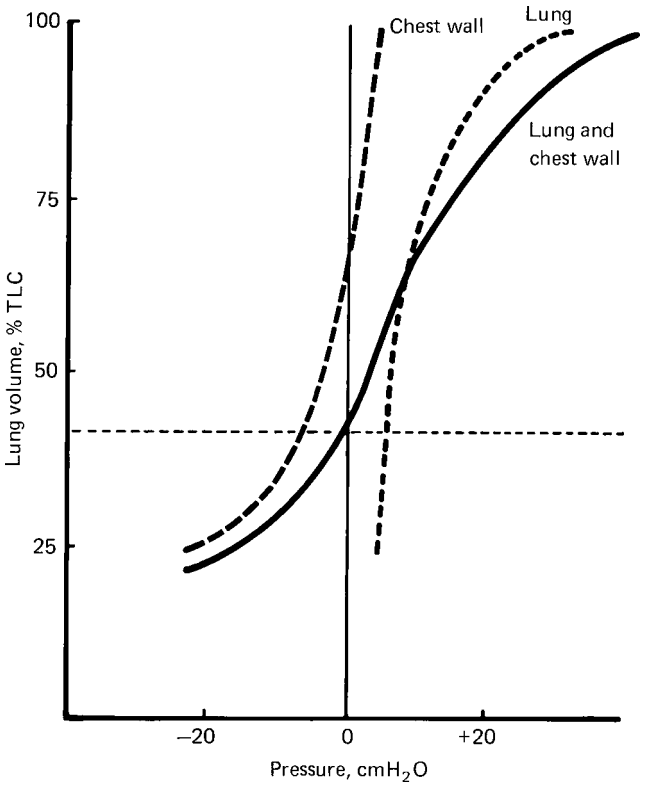

Figure 9-7 Relaxation pressure-volume curves. The elastic recoil pressures of the total respiratory system in the algebraic sum of the recoil pressures of the lung and chest wall are equal but opposite. Since the net recoil pressure is zero, the respiratory system is in a position of equilibrium.

respiratory muscles are relaxed. At this point, the opposing recoils of the lung and chest wall are of equal magnitude, and the recoil pressure of the entire respiratory system is zero. With increases in lung volume above functional residual capacity, the recoil pressure of the entire system becomes positive, owing to the combination of an increase in centripetal elastic recoil of the lungs and a decrease in the centrifugal recoil of the chest wall. The net effect favors a decrease in lung volume, and lung volume can be maintained with the airway open to the atmosphere only by the action of the inspiratory muscles. As lung volume exceeds 75 percent of total lung capacity, the recoil of the chest wall also becomes centripetal and the recoil pressure of the chest wall adds to the inward forces acting to diminish lung volume. Total lung capacity represents the lung volume at which the inward passive elastic recoil pressure of the respiratory system reaches the maximum force that can be generated by the inspiratory muscles.

At lung volumes below functional residual capacity, when the centrifugal recoil of the chest wall exceeds the reduced centripetal recoil of the lungs, the relaxation pressure is negative and this net effect favors an increase in lung volume. Lung volumes below functional residual capacity are achieved and maintained by the muscles of expiration.

A switch from the sitting to the supine position decreases functional residual capacity because of the effects of gravity. In the upright position, gravity pulls the abdominal contents away from the chest wall. In contrast, in the supine position, the push of the abdominal contents against the diaphragm decreases the centrifugal recoil of the chest wall. The chest wall pressure-volume curve—and, consequently, the pressure-volume curve of the entire respiratory system—is displaced to the right.

DYNAMIC MECHANICAL PROPERTIES OF THE RESPIRATORY SYSTEM

The total nonelastic resistance of the lungs consists of the resistance of the airways to airflow (airway resistance), defined in terms of the driving pressure and the resulting rate of airflow, and the frictional resistance of the lung tissues to displacement during breathing (tissue resistance). Normally, tissue resistance makes up only 10 to 20 percent of the total pulmonary nonelastic resistance, but in diseases of the pulmonary parenchyma, it may increase considerably.

Airway Resistance

A large fraction of the resistance to airflow is in the upper respiratory tract, including the nose, mouth, pharynx, larynx, and trachea. During nasal breathing, the nose constitutes up to 50 percent of total airway resistance. During quiet mouth breathing, the mouth, pharynx, larynx, and trachea constitute 20 to 30 percent of the airway resistance; but they account for up to 50 percent of the total airway resistance when minute ventilation increases—during vigorous exercise, for example. Most of the remainder of airway resistance is in medium-sized lobar, segmental, and subsegmental bronchi up to about the seventh generation of airways. Additional branching distally causes a progressive increase in the number of airways in any generation. While the caliber of individual airways in daughter branches compared to the parent branch is reduced, the total cross-sectional area of all of the airways in a given generation increases tremendously with successive generation along the tracheobronchial tree. Consequently, in the normal lung, the small peripheral airways, particularly those less than 2 mm in diameter, constitute only about 10 to 20 percent of the total airway resistance.

Airway Caliber

The airways, like the pulmonary parenchyma, exhibit elasticity and can be compressed or distended. Therefore, the diameter of an airway varies with the transmural pressure applied to that airway—i.e., the difference between the pressure within the airway and the pressure surrounding the airway. The pressure surrounding intrathoracic airways approximates pleural pressure, since these airways are tethered to the parenchymal tissue and are exposed to the expansive forces that are active in overcoming the elastic recoil of the lung.

As the lung volume increases, the elastic recoil forces of the lung increase; the traction applied to the walls of the intrathoracic airways also increases, widening the airways and decreasing their resistance to airflow. Conversely, at low lung volumes, the transmural airway pressure is lower and airway resistance increases. If the elastic recoil of the lung is reduced—by destruction of alveolar walls in pulmonary emphysema, for instance—the transmural airway pressure at any given lung volume decreases correspondingly; the airways are narrower and airway resistance is greater even though there is no disease of the airways per se.

The effects of a change in transmural pressure on airway caliber depend on the compliance of the airways—which, in turn, is determined by their structural support. The trachea, for example, is almost completely surrounded by cartilaginous rings, which tend to prevent complete collapse even when the transmural pressure is negative. The bronchi are less well supported by incomplete cartilaginous rings and plates, whereas the bronchioles lack cartilaginous support. All airways can be stiffened, albeit to different degrees, by contraction of smooth muscle in their walls.

In patients with airway disease, mucosal edema, hypertrophy and hyperplasia of mucous glands, increased elaboration of mucus, and hypertrophy of smooth muscle further compromise airway caliber and increase airway resistance.

The innervation of airway smooth muscle also has an important effect on airway caliber. Parasympathetic stimulation originating from the vagus nerve causes airway smooth muscle contraction and airway narrowing. Conversely, sympathetic stimulation with the release of the post-ganglionic neurotransmitter, norepinephrine, results in airway smooth muscle relaxation and airway dilatation.

Pressure-Flow Relationships: Theoretical Considerations

In the lungs, pressure-flow relationships are extremely complicated because the airways consist of a system of irregular branching tubes that are neither rigid nor perfectly circular. For purposes of simplification, pressure-flow relationships in rigid tubes are generally regarded as a model for those in the airways.

The driving pressure that produces flow of air into and out of the lung must suffice to overcome friction and to accelerate the air. Acceleration in the lungs is of two types: local (i.e., changes in the rate of airflow with time when flow is initiated) and convective (i.e., acceleration of molecules of air over distance while flow is constant). The driving pressure required for convective acceleration is proportional to the gas density and to the square of the flow rate. It is important during expiration because, as air moves downstream from the alveoli toward the airway opening, the total cross-sectional airway diameter decreases; therefore, molecules of air must accelerate through the converging channels even though the overall flow rate remains unchanged. Also, the driving pressure that produces high expiratory flow rates at large lung volume serves for convective acceleration rather than for overcoming friction.

The driving pressure required to overcome friction depends on the rate and the pattern of airflow. Two major patterns of airflow warrant special consideration: laminar and turbulent. Laminar flow is characterized by streamlines that parallel the sides of the tube and are capable of sliding over one another. Also, because the streamlines at the center of the tube move faster than those closest to the walls, the flow profile is parabolic (Fig. 9-8). The pressure-flow characteristics of laminar flow depend on the length (l) and the radius (r) of the tube and the viscosity of the gas (n) according to Poiseuille's equation:

$$\Delta P = \frac{\dot{V} 8 n l}{\pi r^4}$$

where

ΔP = the driving pressure (pressure drop between the beginning and the end of the tube)
$\dot{V}$ = the flow rate that the driving pressure produces
r = the radius of the tube

The critical importance of tube radius in determining the driving pressure for a given flow is apparent in the above equation. If the radius of the tube is halved, the pressure that is required to maintain a given flow rate must be increased 16-fold. Laminar flow patterns occur only in small peripheral airways, where, because of the enormous overall cross-sectional area, flow through the individual airways is exceedingly slow.

Turbulent flow occurs at high flow rates and is characterized by a complete disorganization of streamlines, so that the molecules of gas move laterally, collide with each other, and change velocities. Under these circumstances, pressure-flow relationships change. In contrast to laminar flow, the rate

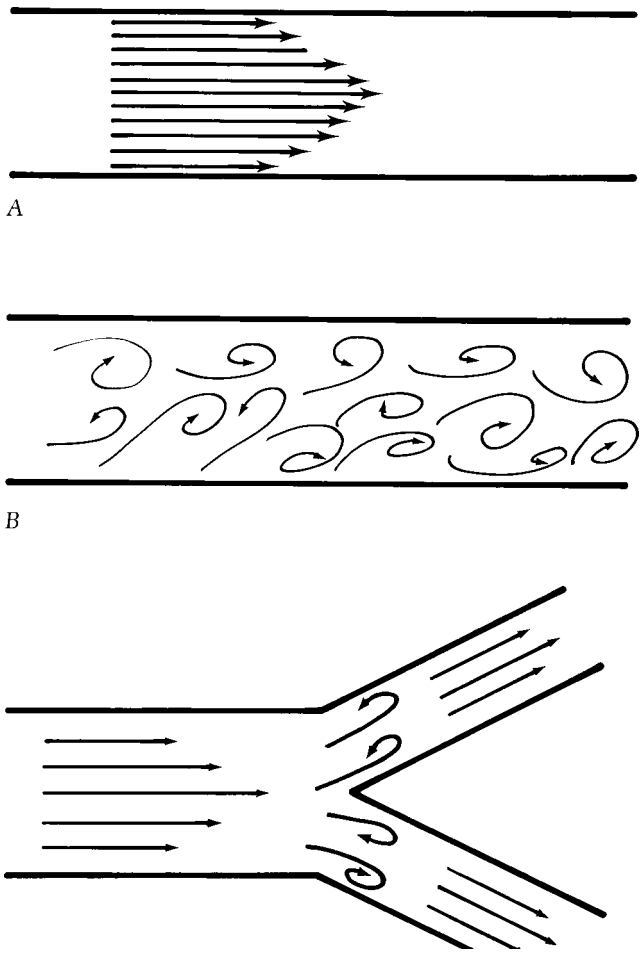

Figure 9-8 Patterns of airflow. *A*. Laminar flow. *B*. Turbulent flow. *C*. Transition flow.

of turbulent airflow is no longer proportional to the driving pressure. Instead, the driving pressure to produce a given rate of airflow is proportional to the square of flow and is dependent on gas density. Turbulent flow occurs regularly in the trachea.

At lower flow rates during expiration—particularly at branches in the tracheobronchial tree, where flow in two separate tubes comes together into a single channel—the parabolic profile of laminar flow becomes blunted, the streamlines separate from the walls of the tube, and minor eddy formation develops. This is referred to as a mixed, or transitional, flow pattern. In a mixed pattern of airflow, the driving pressure for a given flow depends on both the viscosity and the density of the gas.

Whether airflow is laminar or turbulent is predictable from the Reynolds number (Re), a dimensionless number that depends on the average velocity ($\bar{v}$), the density of the gas (ρ), the viscosity of the gas (η), and the diameter of the tube (D), so that

$$Re = \frac{\bar{v} D \rho}{\eta}$$

In straight, smooth, rigid tubes, turbulence occurs when the Reynolds number exceeds 2000. Therefore, turbulence is most apt to occur when the average velocity is high, gas density is high, gas viscosity is low, and the tube diameter is large. Since most of the resistance to airflow in the normal lung is in large airways, where resistance is density dependent, breathing a mixture of 80 percent helium and 20 percent oxygen (a mixture that is 64 percent less dense than air) increases airflow at a given driving pressure and substantially decreases airway resistance.

Calculation of Airflow Resistance

The driving pressure along the tracheobronchial tree—i.e., the difference between alveolar pressure and the pressure at the airway opening (mouth) that is required to produce a given rate of airflow into the lungs—provides a measure of the flow resistance of the airways, according to the equation

$$\text{Raw} = \frac{P_A - \text{Pao}}{\dot{V}}$$

where

$\dot{V}$ = airflow (L/s)
P_A = alveolar pressure (cmH_2O)
Pao = airway-opening pressure (cmH_2O)
Raw = airway resistance (cmH_2O/L/s)

Flow-Volume Relationships

Considerable insight into the flow-resistive properties of the airways can be obtained from the relationship between airflow and lung volume during maximal expiratory and inspiratory maneuvers. In practice, a person inhales maximally to total lung capacity; then exhales as forcefully, rapidly, and completely as possible to residual volume; and then returns to total lung capacity by a rapid, forceful inhalation (Fig. 9-9). During the maximal expiration, the rate of airflow peaks at a lung volume that is close to the total lung capacity; as the lung volume decreases and intrathoracic airways narrow, airway resistance increases, and the rate of airflow decreases progressively.

During the maximal inspiration, the pattern of airflow is different: Because of the markedly negative pleural pressure and large transmural airway pressure, the bronchi are wide, and their calibers increase further as lung volume increases. Consequently, inspiratory flow becomes high while the lung volume is still low and remains high over much of the vital capacity, even though the force generated by the inspiratory muscles decreases as they shorten.

A family of flow-volume loops is produced by repeating full expiratory and inspiratory maneuvers over the entire range of the vital capacity using different levels of effort (Fig. 9-10). The greater the effort exerted during inspiration, the greater is the rate of airflow over the entire range—i.e., from residual volume to total lung capacity. Similarly, during expiration, the rate of airflow increases progressively with increasing effort at large lung volumes close to total lung capacity. At intermediate and low lung volumes, the rate of expiratory airflow reaches a maximum while the effort expended is only moderate; thereafter, airflow does not increase further despite increasing expiratory efforts.

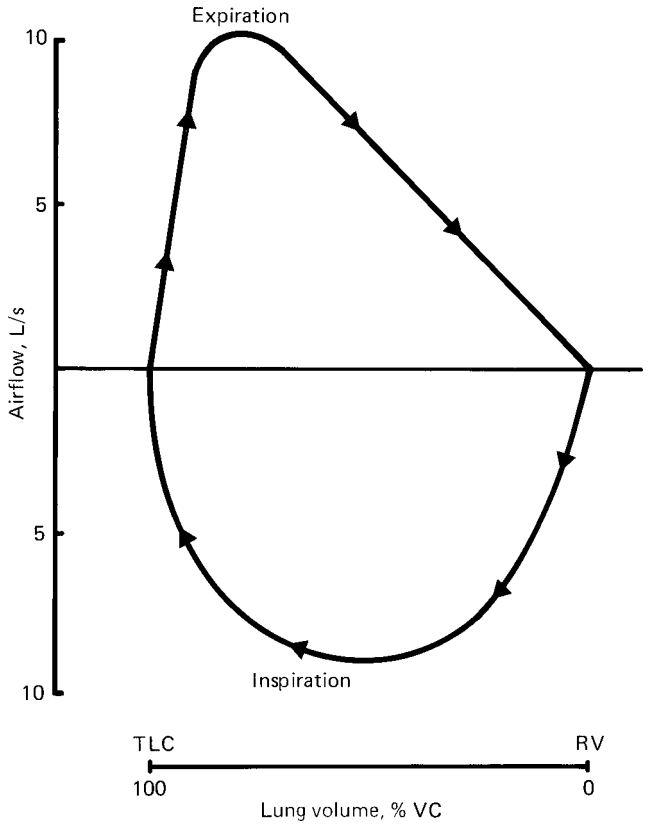

Figure 9-9 Maximal expiratory and inspiratory flow-volume loop.

Isovolume Pressure-Flow Curves

Separation of the effects of increasing effort from those of changes in lung volume on the rate of airflow during expiration can be accomplished by using isovolume pressure-flow curves (Fig. 9-11). During repeated expiratory maneuvers performed with varying degrees of effort, simultaneous measurements are made of airflow rate, lung volumes, and pleural pressure. For each lung volume the rate of airflow is plotted against the pleural pressure, an index of the degree of effort.

As expiratory effort is increased at any given lung volume, the pleural pressure increases toward, and then exceeds, atmospheric pressure; correspondingly, the rate of airflow increases. At lung volumes greater than 75 percent of the vital capacity, airflow increases progressively as pleural pressure increases; it is considered to be effort dependent. In contrast, at lung volumes below 75 percent of the vital capacity, the rate of airflow levels off as the pleural pressure exceeds atmospheric pressure and becomes fixed at a maximum level. Thereafter, further increases in effort, and in pleural pressure, effect no further increase in the rate of airflow; at these lower

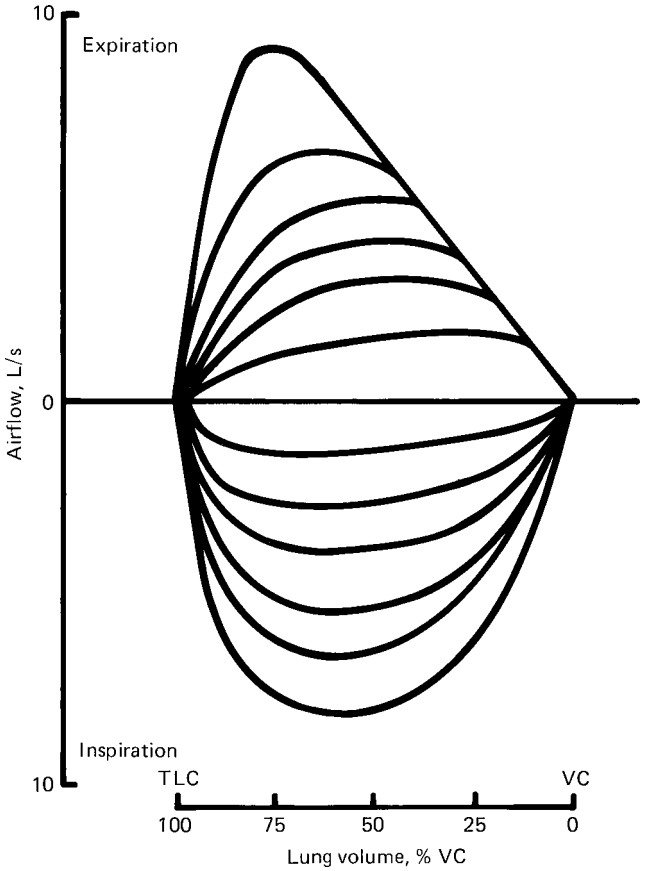

Figure 9-10 Series of flow-volume loops constructed from complete inspiratory and expiratory maneuvers repeated at different levels of effort.

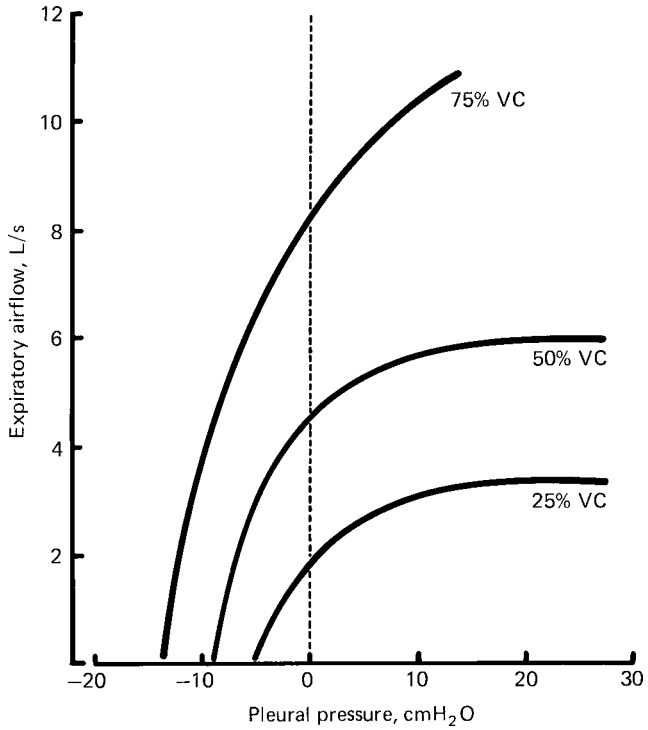

Figure 9-11 Isovolumetric pressure-flow curves. At lung volumes greater than 75 percent of the vital capacity, airflow is effort dependent; i.e., airflow increases progressively with increasing effort. At lower lung volumes, airflow is effort independent; i.e., airflow becomes fixed at a maximum level and does not increase despite further increases in effort.

lung volumes, airflow is considered to be effort independent. Since the rate of airflow remains constant despite increasing driving pressure, it follows that the resistance to airflow must be increasing in direct proportion to the increase in driving pressure. This increase in resistance is attributed to compression and narrowing of large intrathoracic airways.

Equal Pressure Point Theory: Dynamic Compression of Airways

To illustrate the mechanisms that normally limit airflow during a maximal expiratory maneuver, it is useful to consider a model of the lung where the alveoli are represented by an elastic sac and the intrathoracic airways by a compressible tube, both enclosed within a pleural space (Fig. 9-12).

At a given lung volume, when there is no airflow (as during breath holding with the glottis open), pleural pressure is subatmospheric, counterbalancing the elastic recoil pressure of the lung. The alveolar pressure (PA), which is the sum of the recoil pressure of the lung and pleural pressure (Ppl), is zero (Fig. 9-12*A*). Since airflow has ceased, the pressure along the entire airway is also atmospheric.

At the same lung volume during a quiet expiration, pleural pressure is less subatmospheric. Since lung volume and the elastic recoil pressure of the lung are unchanged, alveolar pressure is now positive with respect to atmospheric pressure; airflow occurs. The alveolar pressure is gradually dissipated along the airway in overcoming resistance so that the pressure at the airway opening (Pao) is zero. All along the airway, however, the airway pressure exceeds pleural pressure and the transmural pressure is positive; the airways remain open, and flow continues (Fig. 9-12*B*).

A forceful expiration raises pleural pressure above atmospheric pressure and further increases alveolar pressure (Fig. 9-12*C*). Airway pressure again falls progressively from the alveolus toward the airway opening. But at some point along the airway—the equal pressure point—the drop in airway pressure is equal to the recoil pressure of the lung; intraluminal pressure and the pressure surrounding the airways are equal and the same as pleural pressure. Downstream (i.e., toward the airway opening) the transmural pressure is negative, because the intraluminal airway pressure is less than pleural pressure; the airways are subjected to dynamic compression.

The equal pressure point divides the airways into two components arranged in series: an upstream segment, from the alveoli to the equal pressure point, and a downstream segment, from the equal pressure point to the airway opening. With increasing expiratory effort as the pleural pressure becomes more and more positive with respect to atmospheric pressure, the equal pressure point moves upstream. Once maximum expiratory flow is achieved, the position of the

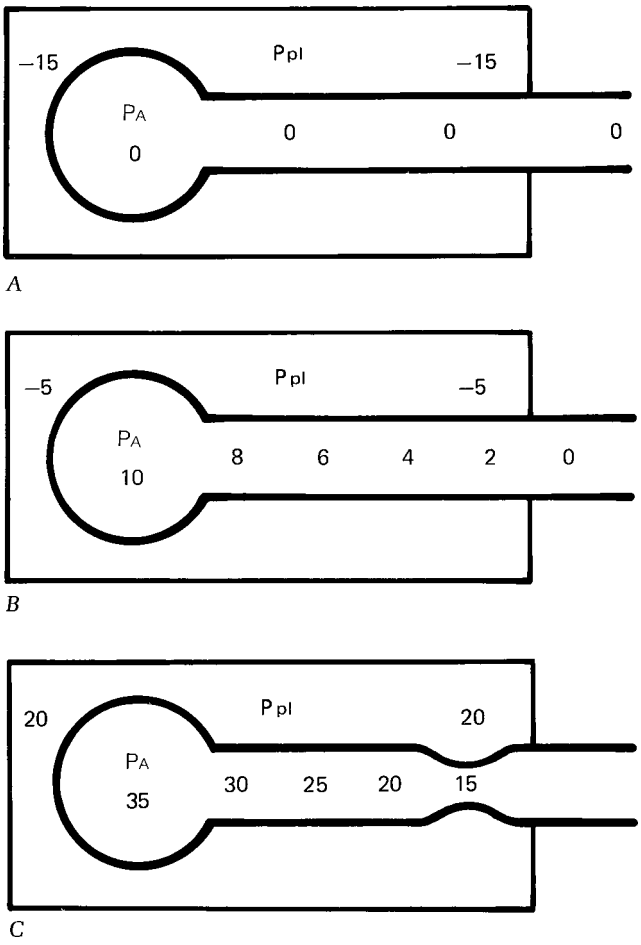

Figure 9-12 Schema of the distribution of pleural, alveolar, and airway pressures at rest and during expiration, illustrating the equal pressure point concept. *A*. End-expiration. *B*. Quiet expiration. *C*. Forced expiration.

equal pressure point becomes fixed in the region of the lobar or segmental bronchi. Further increase in pleural pressure by increasing expiratory force simply produces more compression of the downstream segment without affecting airflow through the upstream segment.

The driving pressure of the upstream segment—i.e., the pressure drop along the airways of that segment—is equal to the elastic recoil of the lung. The maximum rate of airflow during forced expiration ($\dot{V}max$) can be expressed in terms of the elastic recoil pressure of the lung (P_L) and the resistance of the upstream segment (Rus), as follows:

$$\dot{V}\,\text{max} = \frac{P_L}{\text{Rus}}$$

Measurements of the rate of airflow during force expiration form the basis of many tests used to assess the flow-resistive properties of the lung. It is evident, however, that the maximum rate of expiratory airflow depends on many factors: The lung volume at which airflow is determined, the force of expiration (particularly at high lung volumes—i.e., above 75 percent of vital capacity), the elastic recoil pressure of the lung, the cross-sectional area of large airways, the collapsibility of large intrathoracic airways, and the resistance of small peripheral airways.

Wave Speed Limitation Theory

An alternative explanation for airflow limitation during forced expiration is based on principles of wave speed theory. The wave speed theory proposes that flow is limited by the velocity of propagation of pressure waves along the wall of the tube. The velocity of propagation (v) varies proportionally with the cross-sectional area of the tube (A) and the elastance of the tube walls (dP/dA). At a site where the linear velocity of gas molecules equals the velocity of propagation of pressure waves, a choke point develops, preventing further increases in flow rate. Where choke points occur in the tracheobronchial tree depends on the lung volume: at large lung volumes, a choke point is situated in the vicinity of the lower trachea; at lower lung volumes, choke points develop more upstream along the bronchial tree. Extension of the neck exerts longitudinal tension and stiffens the trachea, increases wave velocity, and increases maximum expiratory flow rates at large lung volumes.

MECHANICAL DETERMINANTS OF REGIONAL VENTILATION

The lung is not homogeneous, and the mechanical properties of all airways in a given generation and of all alveoli are not the same. This results in important nonuniformities of regional ventilation.

Pleural pressure in the upright person is more subatmospheric at the apex than at the base of the lung, because of the effects of gravity and the weight of the lung. Pleural pressure topography and regional lung expansion are also determined by the shape of the chest wall and by the forces required for the lung to conform to the thoracic gravity shape. The rate of increase in pleural pressure from top to bottom is approximately 0.25 cmH_2O per centimeter of vertical distance. Consequently, the transpulmonary pressure—i.e., alveolar pressure minus pleural pressure—is greater at the top than at the bottom of the lung. Therefore, at most lung volumes, the alveoli at the lung apexes are larger (more expanded) than those at the lung bases (Fig. 9-13).

Because of regional variations in lung compliance, ventilation is not uniform, even in the normal lung. With the use of external scanners after the inhalation of a radioactive gas, such as ^{133}Xe, it has been demonstrated that within the range of normal tidal volume, lung units are better ventilated, and ventilation per alveolus is greater, at the bottom than at the top of the lung.

At low lung volumes (i.e., near the residual volume), pleural pressure at the bottom of the lung actually exceeds airway pressure and leads to closure of peripheral airways (Fig. 9-13). During a breath taken from residual volume, air

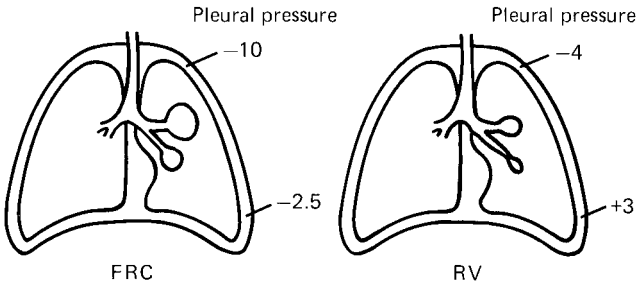

Figure 9-13 Pleural pressure gradients in the upright lung at FRC *(left)* and at RV *(right)*. The effect of the gradient on alveolar volumes is shown for each case.

that enters the lungs first is preferentially distributed to the lung apexes.

The distribution of ventilation within the lungs and the volume at which airways at the lung bases begin to close can be assessed by the single-breath N_2 washout test. This test requires a maximum expiration into an N_2 meter after a maximal inspiration of pure O_2 from residual volume; the changing concentration of nitrogen is plotted against expired lung volume (Fig. 9-14). Because the inspiration starts at the residual volume, the initial portion of the breath containing dead-space gas, rich in nitrogen, is distributed to alveoli in the upper lung zones. The rest of the breath, which contains only O_2, goes preferentially to lower lung zones. Consequently, the concentration of nitrogen is lower in the alveoli at the lung bases than in the alveoli at the apexes of the lungs.

During expiration, the initial portion of the breath consists of O_2 remaining in the large airways; it contains no N_2 (phase I). As alveolar gas containing N_2 begins to be washed out, the concentration of N_2 in the expired air rises to reach a plateau. The portion of the curve where the concentration of N_2 rises steeply is phase II. The plateau is phase III. Phase III depends on the uniformity of the distribution of ventilation in the lung. If gas enters and leaves alveoli throughout the lung

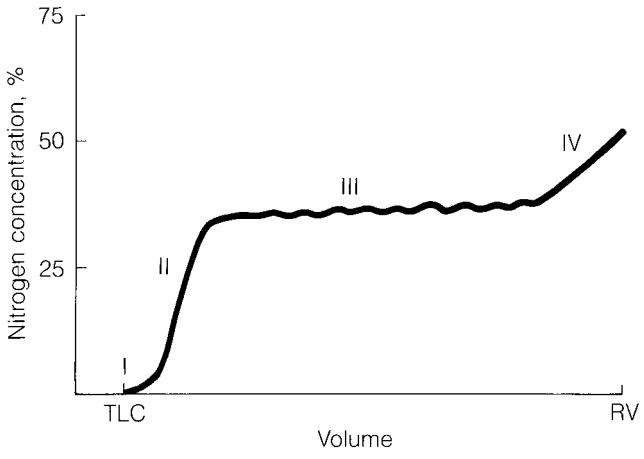

Figure 9-14 Tracing of expired nitrogen concentration during a slow expiration from TLC to RV after a full inspiration of pure O_2. The four phases are indicated.

synchronously and equally, phase III is flat. But when the distribution of ventilation is nonuniform, so that gases coming from different alveoli have different N_2 concentration, phase III slopes upward.

At low lung volumes, airways at the lung bases close; only alveoli at the top of the lung continue to empty. Since the concentration of N_2 in the alveoli of upper lung zones is higher than in the alveoli at the lung bases, the slope of the N_2-volume curve increases abruptly, marking the start of phase IV. The volume, above residual volume, at which phase IV begins is the closing volume.

Dynamic Compliance of the Lungs

The relationship between changes in volume and changes in pleural pressure during a normal breathing cycle is shown in Fig. 9-15. Airflow momentarily ceases at the end of expiration (A) and at the end of inspiration (C); the change in pleural pressure between these two points reflects the increasing elastic recoil of the lung as the volume of air in the lungs increases. The slope of the line connecting the end-expiratory and end-inspiratory points (AEC in the figure) on a pressure-volume loop provides a measure of the dynamic compliance of the lungs.

In normal persons, dynamic compliance closely approximates inspiratory static lung compliance and remains essentially unchanged even when breathing frequency is

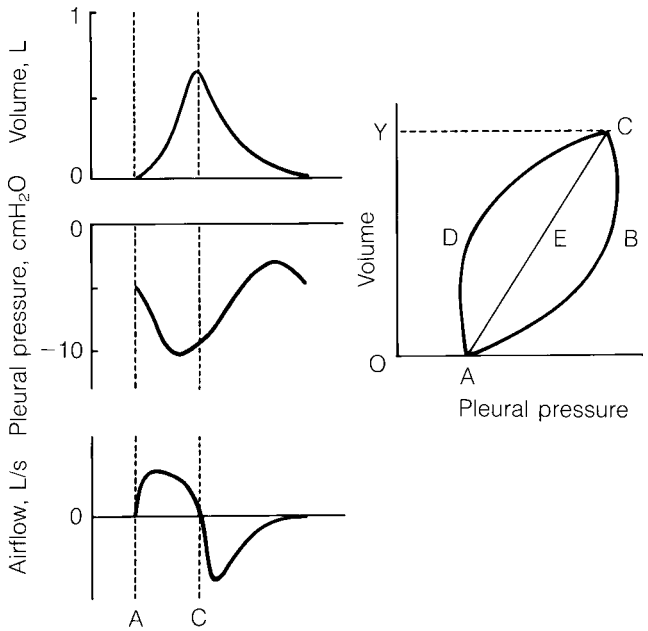

Figure 9-15 Individual tracings of tidal volume, pleural pressure, and airflow, taken simultaneously during a single complete breath, are shown on the left. The relationship between volume and pleural pressure is illustrated by the dynamic pressure-volume loop on the right. Dynamic compliance is determined as the slope of the line AEC. The work of breathing during inspiration to overcome the elastic forces of the lung is represented by the area of the trapezoid OAECY, and the work required to overcome nonelastic forces is represented by the area of the loop ABCEA.

increased up to 60 breaths per min. This indicates that lung units that are parallel with each other normally fill and empty uniformly and synchronously, even when airflow is high and the change in lung volume is rapid. The rate of filling and emptying of a lung unit depends on its time constant—i.e., the product of its resistance and compliance. In order for the distribution of ventilation in parallel lung units to be independent of the rate of airflow, the resistance and compliance of these units must be matched so that the time constants of individual units throughout the lungs are approximately the same. The time constants of lung units distal to airways 2 mm in diameter are approximately 0.01 s, and fourfold differences in time constants are necessary to cause dynamic compliance to become frequency dependent.

Patchy narrowing of small peripheral airways produces regional differences in time constants. At low breathing frequencies, when the rate of airflow is low, ventilation is fairly evenly distributed. As the breathing frequency increases, however, ventilation tends to be distributed to areas that offer the least resistance to airflow. Therefore, lung units fed by narrowed airways receive proportionally less ventilation than do areas of the lung where the airways remain normal; the change in pleural pressure required to effect the same change in overall lung volume increases. As a result, the dynamic compliance falls.

Measurements of frequency dependence of dynamic compliance are time-consuming and technically difficult, but this test has proved useful in the diagnosis of obstruction in small peripheral airways when results of other conventional tests of lung mechanics are still within normal limits.

WORK AND ENERGY COST OF BREATHING

During breathing, the respiratory muscles work to overcome the elastic, flow-resistive, and inertial forces of the lungs and chest wall. The elastic work of breathing is done to overcome the elastic recoil of the lungs and chest wall; the resistive work is done in overcoming the resistance of airways and tissues. The mechanical work of breathing can be determined by relating the pressure exerted across the respiratory system to the resulting change in volume, since the product of pressure (P) and volume (V) has the dimension of work, according to the equation

$$\text{work} = \int P\,dV$$

Records of pleural pressure and lung volume changes during spontaneous breathing can be used to measure the work of breathing; the work of breathing performed on the lungs can be determined from the area of dynamic pressure-volume loop (Fig. 9-15) and fractionated into its elastic and resistive components. During inspiration, the work done to overcome the elastic forces of the lung is determined from the area of the trapezoid OAECY (Fig. 9-15). The area of the loop ABCEA is the work in overcoming nonelastic forces during inspiration, and the area of the loop OABCY is the total work of breathing during inspiration.

Expiration during quiet breathing is passive, since the elastic recoil of the lung suffices to overcome the expiratory airflow resistance. Some of the stored elastic energy is also used to overcome inspiratory muscle activity that persists into the expiratory phase of breathing. At high levels of ventilation and when airway resistance is increased, additional mechanical work during expiration is required to overcome nonelastic forces. Under these circumstances, the pleural pressure exceeds atmospheric pressure, and the loop AECDA extends beyond the confines of the trapezoid OAECY.

Work of Breathing

The work of breathing at any given level of ventilation depends on the pattern of breathing. Large tidal volumes increase the elastic work of breathing, whereas rapid breathing frequencies increase the work against flow-resistive forces. During quiet breathing and during exercise, people tend to adjust tidal volume and breathing frequency at values that minimize the force and the work of breathing. Similar adjustments are also seen in patients with pulmonary disorders: Patients with pulmonary fibrosis, which is characterized by an increased elastic work of breathing, tend to breathe shallowly and rapidly; those with airway obstruction and increased nonelastic work of breathing usually breathe more deeply and slowly.

The work done on the chest wall during breathing is calculated by subtracting the work performed on the lung from the total mechanical work of breathing. The total mechanical work of breathing cannot be readily measured during spontaneous breathing because the respiratory muscles that perform the work also make up part of the resistance offered by the chest wall. But the total mechanical work can be determined during artificial ventilation by using either intermittent positive airway pressure or negative pressure applied to the chest, provided that the respiratory muscles are completely at rest. For this determination, the change in lung volume is related to the pressure difference across the respiratory system—i.e., differential pressure between the mouth and the body surface. Disturbances of the chest wall, such as kyphoscoliosis and obesity, usually increase the work of breathing severalfold.

Oxygen Cost of Breathing

In order to perform their work, the respiratory muscles require O_2. The O_2 cost of breathing, which reflects the energy requirements of the respiratory muscles, provides an indirect measure of the work of breathing. The O_2 cost of breathing is assessed by determining the total O_2 consumption of the body at rest and at an increased level of ventilation produced by voluntary hyperventilation or CO_2 breathing. Provided there are no other factors acting to increase O_2 consumption, the added O_2 uptake is attributed to the metabolism of the respiratory muscles.

The O_2 cost of breathing in normal subjects is approximately 1 ml/L of ventilation and constitutes less than 5 percent of the total O_2 consumption. At high levels of ventilation, however, the O_2 cost of breathing becomes progressively greater. There is a dramatic increase in the O_2 cost of breathing at high levels of ventilation in some diseases of the lung, such as pneumonia, pulmonary fibrosis, and emphysema, and in disorders of the chest wall, such as obesity and kyphoscoliosis. The increase in the energy requirement of the respiratory muscles during increased ventilation, concomitant with a decrease in O_2 supply secondary to arterial hypoxemia, probably produces muscle fatigue, thereby limiting the amount of exertion that these patients can sustain.

Control of Ventilation

Neil S. Cherniack

We breathe by the coordinated action of thoracic and upper airway muscles. Principal among these is the diaphragm, which generates negative pressure in the chest, inflating the lung. Expiration in quiet breathing occurs passively by relaxation of the inspiratory muscles except during its first portion where the diaphragm, by briefly continuing its activity, brakes the release of air from the lungs. In deep or rapid breathing the abdominal and other expiratory muscles augment the expulsion of air.

To regulate the action of these muscles, the respiratory control system uses signals from chemical sensors that measure P_{O_2} and P_{CO_2} and mechanoreceptors, which monitor lung and respiratory muscle movements to match the level of ventilation to the metabolic demand. These signals are fed back to rhythm generators, neurons located in the rostral medulla that cause the respiratory muscles to contract, setting the tidal volume and frequency of breathing.

A number of other factors influence the level and pattern of breathing besides oxygen and carbon dioxide (Fig. 10-1). Of major importance is the sleep-wake cycle. In conscious humans, cortical projections to the rhythm generators and, more directly, to the respiratory motor neurons cannot only override automatic control for short periods of time but even more important provide the mechanism that allows excitatory stimuli from within and without the body to maintain ventilation even at very low levels of P_{CO_2}. This drive, known as the wakefulness drive, adds to the chemical drive arising from increases in carbon dioxide and by hypoxia (Fig. 10-2).

The breathing pattern is also affected by afferent information provided principally by receptors in the lung monitoring its deformation. In addition, movement of each of the respiratory muscles is monitored by mechanoreceptors to ensure that central commands to the muscle are executed.

MAJOR AFFERENT SYSTEMS

Peripheral Chemoreceptors

The carotid bodies are the major peripheral chemoreceptors. The aortic bodies are less important. Indeed in humans ventilation does not increase with hypoxia when carotid bodies

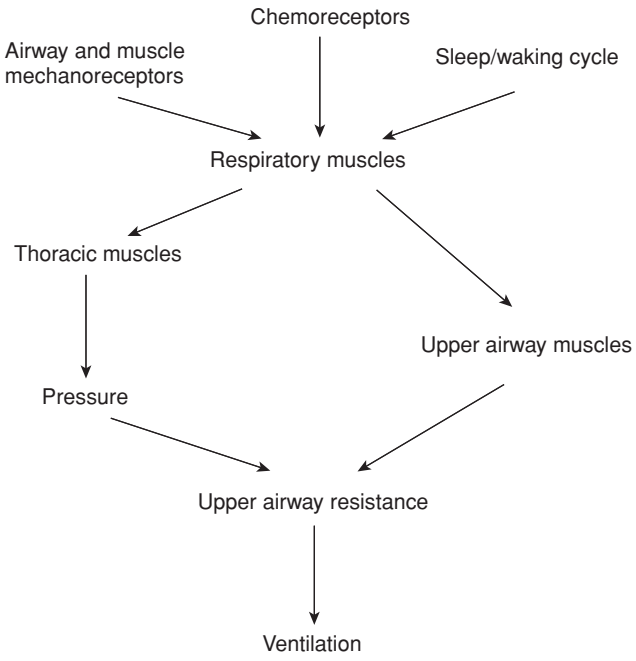

Figure 10-1 Factors controlling airway and thoracic muscles.

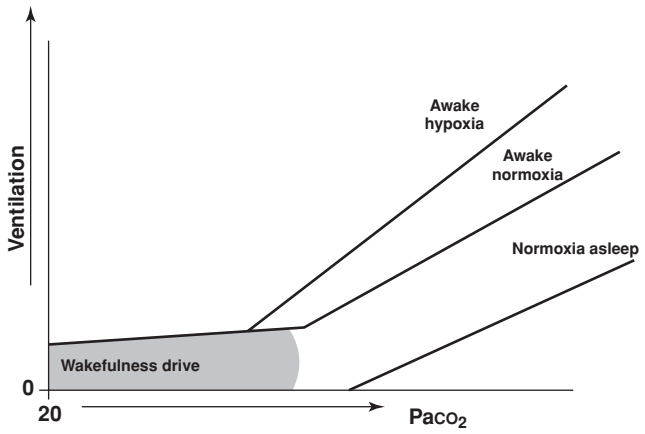

Figure 10-2 Ventilation response to hypercapnia while awake under normoxic and under constant hypoxic conditions. Not shown when the response to CO_2 is examined under more severe hypoxia the slope of the response line becomes steeper. The effect of sleep on normoxic CO_2 response is shown. Shaded area indicates approximate level of wakefulness drive. Note that apnea readily occurs with hyperventilation during sleep but is more difficult awake because of wakefulness drive.

are nonfunctioning. During normal quiet breathing of ambient air the carotid bodies contribute about 15 percent of the ventilatory drive. They also account for about 30 percent of the ventilatory response to hypercapnia. The carotid bodies are located at the bifurcations of the common carotid arteries in the neck. They are supplied by blood from a branch of the external carotid artery, while their venous drainage is to the internal jugular. They have an enormous blood flow for their small mass (of the order of 10 mg in humans). Because of the large blood flow, the arteriovenous difference for oxygen is extremely small (0.2 to 0.5 ml per 100 ml). This large blood flow, coupled with the low extraction of oxygen, makes the carotid body relatively insensitive to variations in oxygen delivery (O_2 content times blood flow). Instead, carotid bodies respond primarily to changes in oxygen tension.

At a constant P_{CO_2}, a hyperbolic relationship exists between carotid body discharge and P_{O_2}, whereas at a constant P_{O_2}, the relationship between activity and P_{CO_2} is linear (Fig. 10-3). The interaction of the two signals is such that the carotid body becomes more sensitive to P_{CO_2}, as hypoxia becomes more severe (see Fig. 10-3). Most, but not all, studies indicate that the receptors are sensitive to the rate of change of P_{CO_2}. The rate sensitivity of the receptors, and their rapid

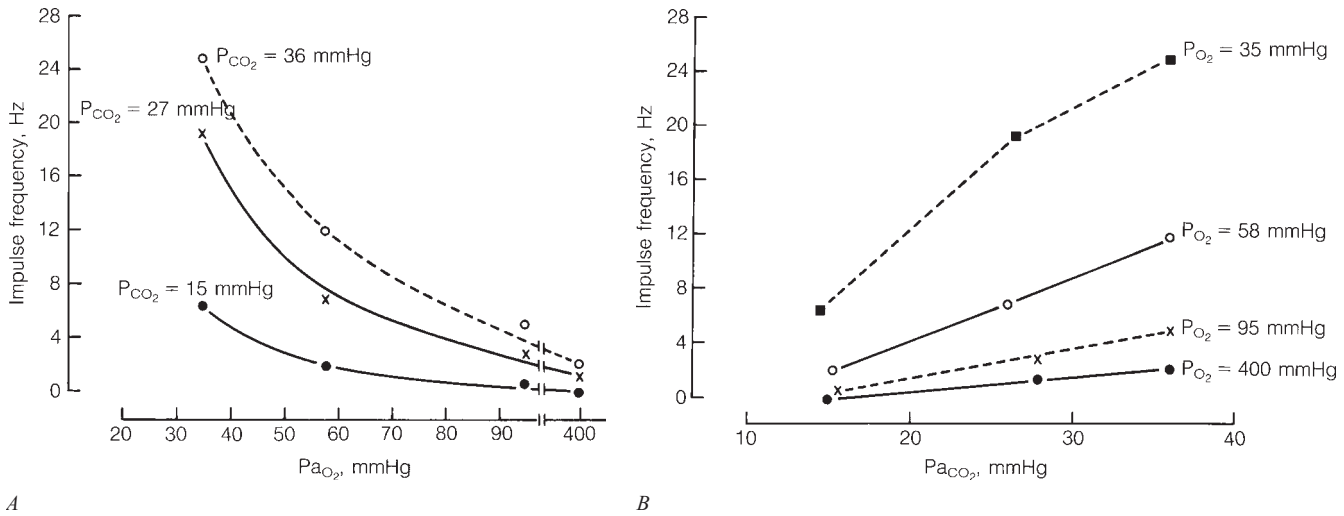

Figure 10-3 *A.* Relationship between carotid body afferent activity (single fiber) and P_{O_2} (at different levels of P_{CO_2}). *B.* Relationship between single-fiber carotid body afferent activity and P_{CO_2} at different levels of P_{O_2}. *(These data are redrawn from Lahiri S, deLaney RG:* Respir Physiol *24:249–266, 1975.)*

response to changes in P_{CO_2} and P_{O_2}, enable the carotid body to follow respiratory-related oscillations in arterial blood-gas tensions.

The afferent signals from the carotid body are relayed in fibers in the glossopharyngeal nerve to the nucleus tractus solitarius. There is also efferent innervation via sympathetic nerves and via the glossopharyngeal nerve. Stimulation of the sympathetic nervous system leads to an increase in carotid body discharge, an effect that is probably due to local changes in blood flow within the organ. In contrast, increased activity of the efferent glossopharyngeal pathway through the release of nitric oxide inhibits chemoreceptor discharge. Thus, the system allows adjustment of the sensitivity (gain) of the carotid body and the range of carotid body operations.

The majority of the afferent fibers terminate on glomus cells (i.e., the type I cells that constitute 60 to 80 percent of the specific cell types of the carotid body). The type I cells contain rough endoplasmic reticulum, aggregates of ribosomes, a well-developed Golgi apparatus, and dense core vesicles. The glomus cells are arranged in groups (glomerules), and each group is surrounded by the second main cell type of the carotid body (i.e., the sheath, or type II cell). Type II cells do not appear to be innervated, nor do they contain the dense core vesicles of the type I glomus cell.

Type I cells contain catecholamines (dopamine, norepinephrine, and epinephrine) in their dense core vesicles. Of these, dopamine is the principal one (60 to 90 percent of the total catecholamine present). The carotid bodies can take up circulating catecholamines and their precursors and can synthesize catecholamines from tyrosine. Hypoxia increases the levels of dopamine, but we do not know if dopamine is an essential neurotransmitter or, as seems more likely, it modulates the chemoreceptor process. Exogenously administered dopamine depresses chemoreceptor discharge. Other potential neurotransmitters such as 5-hydroxy-tryptamine (serotonin), acetylcholine, and neuropeptide such as substance P, vasoactive intestinal polypeptide (VIP), met- and leuenkephalin are present in the carotid body. The role of these substances in the transduction process is also unknown. Recent data indicate that both carbon monoxide (CO) and nitric oxide (NO) inhibit carotid body activity. NO formation from arginine is catalyzed by the enzyme nitric oxide synthesis, which is found in the carotid body, mainly in nerve fibers. Inhibition of NO synthase increases carotid body activity both in vivo and in vitro. Because NO synthase, which forms NO in vivo, is itself inhibited by hypoxia, the decrease in NO formation may contribute to hypoxic stimulation of the carotid body. Heme-oxygenase 2 (HO-2), which catalyzes CO production, is also found in type I cells. Metalloprotoporphyrins that inhibit HO-2 enhance carotid body discharge.

It is agreed that the type I cells contain the O_2 sensing mechanism. There are two not necessarily conflicting ideas on how hypoxia excites type I cells: One idea is that hypoxia acts at the cell membrane, decreasing the conductance in oxygen sensitive potassium channels, thus leading to cell depolarization. This in turn leads to a calcium influx and the release of neurotransmitters. The other, the so-called metabolic hypothesis, is that hypoxia interferes with respiratory energy production in type I cells, and that in turn triggers increased chemoreceptor discharge. Cytochrome A_3 according to this idea is the biochemical substance responsible for O_2 sensitivity. Reactive oxygen species that vary with oxygen level seem to be involved in oxygen sensing process.

Other tissues and organs besides the carotid body respond to long-term hypoxia with increases in the formation of enzymes that participate in anaerobic metabolism and the formation of substances such as erythropoietin, which enlarges red cell mass through the action of the transcription factor, hypoxia-inducible factor (HIF1-alpha). This is constantly produced normally but degraded by the enzyme proline hydroxylase. It accumulates during hypoxia, which inhibits proline hydroxylase.

Neurons near the ventral surface of the medulla containing the enzyme HO-2 that breaks down hemoglobin to biliverdin and CO may also be involved in hypoxic sensing and when stimulated, lead to increases in blood pressure. The importance of these central hypoxia receptors is unclear.

Central Chemoreceptors for Carbon Dioxide and Hydrogen Ion

Central chemoreceptors in the brain stem account for 70 percent of the response to hypercapnia. There is appreciable evidence that chemosensitive cells near the rostral ventral medullary surface play a significant role in mediating this response. Using tissue slices and cell cultures it has been demonstrated that neurons at other sites also respond to local changes in acidity or CO_2 by depolarization and increased activity. The current view is that neurons, which respond to acidity include besides the ventral medullary surface, rostral aspects of the ventral respiratory group, dorsal motor nucleus of the vagus, nucleus of the respiratory tract, locus ceruleus, medial raphe, pre-Boetzinger complex, and fastigial nucleus of the cerebellum. In addition, cells that respond to increases in CO_2 by increasing respiratory frequency have been observed in spinal cord and in a brain stem spinal cord preparation isolated from newborn rats.

Chemoreceptors in any single location are reported to account for only 20 to 25 percent of the total ventilatory response to breathing 7 percent CO_2 with the contribution depending on sleep-wake state. Interpretation of these results is complicated because even well-defined interventions can produce reactions in distant areas that are indirectly excitatory or inhibitory to breathing. Also CO_2, and the changes in hydrogen ion it produces, have diverse effects on many systems besides respiration as, for example, the autonomic nervous system, sleep-wake processes and metabolism.

The specific stimulus for the central chemoreceptors continues to be a subject of debate. The prevailing theory is that the stimulus is uniquely related to hydrogen ion concentration at the receptor site. However, a given decrease in pH produced by CO_2 inhalation has more marked effects on respiration than does the same decrease produced by

metabolic acidosis, suggesting that CO_2 may, per se, have an additional stimulatory action.

Cells that respond to CO_2 or acidity have no special morphological features. And several different neurotransmitters such as acetylcholine, glutamate, and serotonin may participate in central chemoreception.

A number of different molecular mechanisms have been considered to account for central chemosensitivity. It may be that chemosensitive cells, unlike nonchemosensitive cells, cannot rapidly restore internal pH after being challenged by changes in CO_2. On the other hand, many nonchemosensitive cells can. Another idea is that central chemoreceptors contain pH sensitive potassium channels that are inhibited by acidosis leading to depolarization.

Pulmonary Mechanoreceptors

Complementing the information from the chemoreceptors are afferent systems that provide information via mechanoreceptors about the state of the lungs and the respiratory muscles. There are several receptor types within the lung: stretch receptors, rapidly adapting (irritant) receptors both in the airways *(juxtacapillary*, or *J receptors)* in pulmonary interstitium and *bronchial C receptors* but the respiratory muscles are provided by muscle spindles and tendon organs, which will be discussed later. The intercostals and abdominal muscles are relatively richly innervated with both muscle spindles and tendon organs, whereas the diaphragm is relatively poor in muscle spindles.

The *pulmonary stretch receptors* are situated within the smooth muscle of the airways, mainly in the more proximal ones. They show a slowly adapting response to inflation of the lung (Fig. 10-4A). The rate of inflation (dynamic response) also affects firing rate.

The *rapidly adapting receptors* (also called, *irritant receptors* and *deflation* or *collapse receptors*) are also found mainly in the larger airways; indirect evidence indicates that they are situated in the epithelium and submucosa. The firing rate of these receptors depends strongly on the rate of airflow and occurs mainly during inflation (Fig. 10-4B); also, decreases in compliance during inflation lead to increased firing of the receptor. The rapidly adapting receptor may also be responsible for the generation of intermittent sighs without which pulmonary compliance decreases progressively.

Originally identified by their rapidly adapting response to lung inflation (see Fig. 10-4B), these receptors have since become known as irritant receptors since they respond to a variety of chemical irritants (e.g., ammonia, cigarette smoke, ether vapor, and inert dust particles). This was thought to elicit a defense reflex; i.e., coughing, laryngeal constriction, airway narrowing, and increased production of respiratory tract mucus.

Both the rapidly adapting receptors, since they are quite sensitive to histamine, which is secreted in asthmatic attacks, and a group of nonmyelinated afferent endings in the bronchi, the bronchial C receptors, may be important mediators of reflex bronchoconstriction in asthma. The latter are also stimulated by phenyldiguanide and capsaicin; as well as by a variety of pulmonary autocoids released in asthma and inflammatory disease [i.e., bradykinin, serotonin, prostaglandins (PGF_{2a}, PGE_2, PGI_2), prostacyclin] and inhaled irritants such as sulfur dioxide. Activation of these receptors produces reflex tachypnea, increased tracheobronchial secretion, and bronchoconstriction. The low baseline firing of the receptors may contribute to normal bronchomotor tone.

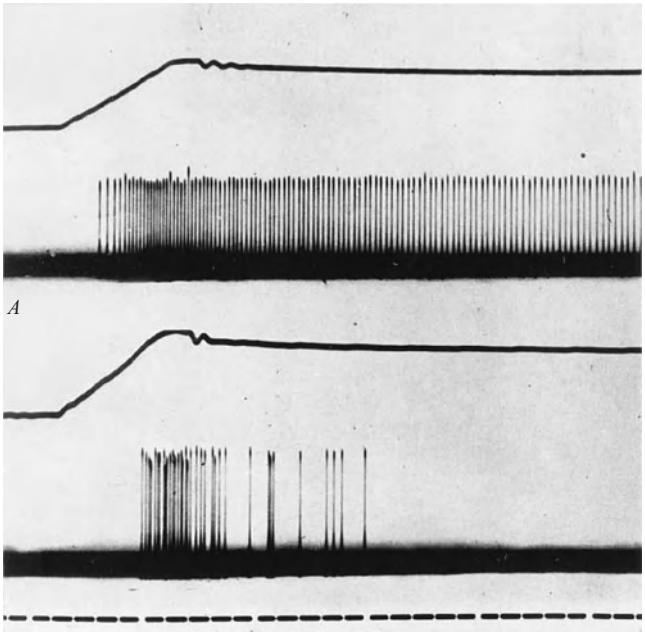

Figure 10-4 Response characteristics of the two major mechanoreceptors in the airways. *A*. A response of pulmonary stretch receptor. This shows the slowly adapting nature of the response and the continued discharge of the receptor during maintained inflation of the lung. *B*. Response of the rapidly adapting ("irritant") receptor, which fires largely during the period while the lung is being inflated and then adapts. *(Reproduced with permission from Knowlton GC, Larabee MG:* Am J Physiol *147:100–114, 1946.)*

Nonmyelinated afferent endings in the pulmonary interstitium (i.e., the juxtacapillary or J receptors) also respond to chemicals such as phenyldiguanide and capsaicin but show only weak stimulation in response to histamine and virtually no response to bradykinin. The reflex effects of stimulation of J receptors are different from those of bronchial C fibers. Stimulation of J receptors produces the pulmonary chemoreflex, a triad of apnea, bradycardia, and hypotension. Less intense but more sustained stimulation elicits tachypnea rather than apnea. The cardiac depressor effects are due to both cardiac slowing and a fall in right ventricular stroke volume. Although some cardiac depression also occurs after stimulation of bronchial C receptors, the depression is modest compared with that for J receptors.

Stimulation of J receptors additionally inhibits motor neurons of the spinal cord by a central reflex mechanism; the motoneurons that innervate the respiratory muscles and those involved in monosynaptic and polysynaptic spinal

reflexes are affected by this inhibition. This component of the reflex response, which has been called the *J reflex*, suggested that these receptors function to limit exercise by inhibiting motor neuron discharge whenever alveolar-capillary interstitial pressure increases as the result of interstitial deformation (e.g., by an increase in interstitial water). At present, the role of the J receptors in exercise can only be regarded as unsettled.

CENTRAL NEURAL MECHANISMS

Of the various ideas of the neural mechanisms that might produce rhythmic behavior, the most widely held is that respiratory rhythmicity is a property of the synaptic interactions between the various types of inspiratory and expiratory neurons in the brain stem. The central pattern generator is believed to be located in the ventral medulla. A three-part rhythm is produced consisting of: inspiration, postinspiration (phase 1, expiration), and late expiration (phase 2, expiration). Identification of these phases is based on the different mechanical effects of each (lung inflation, passive expiration with braking of expiratory air flow, and active expiration, respectively).

During inspiration, inspiratory neurons in the medulla that are premotor to the phrenic and intercostal motor nuclei display an augmenting discharge. Intracellular recordings from such neurons reveal that they receive increasing excitatory postsynaptic activity throughout inspiration. This activity is due, in part, to these neurons re-exciting each other but more than that, to an excitatory input, that they receive from an unidentified source.

At the end of inspiration, discharge from these inspiratory neurons is extinguished by an inhibitory activity from other neurons. Certain afferent inputs, such as the pulmonary stretch receptor, affect the duration of the respiratory phases. Increased activity of pulmonary stretch receptors shortens inspiratory duration. As a result, the larger the tidal volume, the shorter the duration of inspiration.

The end of inspiration is followed by a period of postinspiratory activity on the part of certain inspiratory neurons. During this period of declining activity, the inspiratory neurons receive both excitatory and inhibitory postsynaptic potentials. This neural activity is associated with active braking of airflow at the beginning of expiration. The duration of this postinspiratory phase of the respiratory cycle seems to be an important determinant of total duration of expiration.

Succeeding the postinspiratory phase of the respiratory cycle is a period during which the expiratory muscles may undergo active contraction. In this phase of the cycle, inspiratory bulbospinal neurons receive inhibitory postsynaptic potentials in an augmenting pattern.

Although the duration of expiration, like inspiration, can be set by intrinsic brain stem mechanisms, normally it is modulated by afferent inputs. Throughout expiration, there is a decreasing inhibition of the following inspiration. Thus, early in expiration larger stimuli (e.g., pulmonary deflations) are needed to trigger the onset of inspiration than later in expiration. Activity of the pulmonary stretch receptors prolongs expiration (i.e., the Hering-Breuer expiratory promoting reflex).

For many years the respiratory pattern generator has been studied in vivo in adult and neonatal animals relying mainly on electrophysiological techniques of intracellular and extracellular recordings. These studies failed to localize the pattern generator but revealed an array of neurons with differing activity patterns in relation to the respiratory cycle. In reduced preparations as in slices of neonatal rodent medulla, the respiratory pattern generator has been localized anatomically to the pre-Boetzinger complex in the rostral ventral medulla. The pattern generator seems to have a similar location in the adult animal as shown by the interruption of the respiratory pattern in studies in which this complex is ablated.

In immature beings pacemakers rather than mutually inhibiting circuits seem to produce the respiratory rhythm but their importance in the adult is questionable. Both inspiratory and expiratory pacemakers have been identified. Some believe that even in adults there are conditional pacemaker neurons imbedded within the oscillating network that produces the rhythm. Pacemaker neurons may depend on persistent sodium current or calcium-dependent currents for their spontaneous bursts of activity. The respiratory rhythm generated, whether or not it is produced by pacemaker neurons, is formed and shaped through the interactions of groups of premotor, motor, and sensory neurons.

COORDINATION OF THE ACTIVITY OF THE RESPIRATORY MUSCLES

The coordinated activity of the muscles that insert upon the thoracic cage not only brings air to the alveoli but also prevents the waste of energy that could be caused by chest wall distortion during breathing.

The pharyngeal channels, which air must traverse before arriving at the lungs, have flexible walls and contain valve-like mobile structures that can be displaced to obstruct the airways by the negative and positive swings in pressure that occur during normal breathing. The rigidity and configuration of these channels and their patency depend on the activity of the laryngeal and pharyngeal muscles, which have a respiratory modulation that increases as breathing is stimulated.

Thoracic Muscles

During quiet breathing the diaphragm is the muscle mainly responsible for the tidal excursions of air. As the diaphragm contracts, it presses on the abdominal contents, which are primarily fluid, to push the abdominal wall outward. At the same time, through its insertions on the lower ribs, the diaphragm elevates the costal margins and expands the chest cavity. Even the small transthoracic pressure changes that occur during

breathing are sufficient to distort the chest wall. Acting alone, the diaphragm would use energy not only to overcome the resistance of the airways and the stiffness of the chest wall, but also to distort the ribs. Contraction of the parasternal intercostal muscles, and perhaps the scalene muscles, prevents this distortion.

The postinspiratory activity of the inspiratory muscles may help to improve the efficiency of gas exchange and, in infants (in whom the chest wall is extremely pliable), may help to preserve the functional residual capacity by preventing too much air from leaving the lungs during the expiratory period.

The diaphragm itself does not behave as if it were a single muscle. The costal portion of the diaphragm is supplied mainly by the upper cervical roots, which make up the phrenic nerve, whereas the crural portion of the diaphragm receives its innervation mainly through the lower phrenic roots. Isolated contraction of the crural diaphragm causes primarily expansion of the abdomen, whereas contraction of the costal portion, in addition to causing movement of the abdominal wall, enlarges the rib cage. The crural diaphragm may also act as a part of the sphincter mechanism for the lower esophagus; its contraction compresses the sphincter.

The phrenic motor neurons themselves have been divided into early firing units, the activity of which begins at the very onset of inspiration, and late firing units, which commence their activity much later in inspiration. As respiration increases, the frequency of firing of both the early and late units increases; in addition, more and larger motor units are recruited according to a "size principle." Phrenic neurons supplying larger motor units (which contain more fibers) are recruited later than are neurons that innervate smaller units. Also, as ventilation increases, the intercostal muscles come into play, the upper intercostals becoming active first and then the lower intercostals. The expiratory muscles begin to contract at higher levels of ventilation. At high levels of ventilation, the "accessory" muscles of respiration, such as the sternocleidomastoid, the hyoid muscle, and muscles attaching to the spine, also contribute to breathing.

Spindles, length/tension receptors in the muscles, increase the strength of muscular contraction via a spinal reflex when their movement is hindered. Spindles however are scarce in the diaphragm. Tendon organs in the diaphragm and intercostals prevent excessively powerful contractions.

The diaphragm, like other skeletal muscles, has less ability to produce force as the velocity of contraction and the degree of shortening increase. The ability of the respiratory system to increase tidal volume is preserved by at least three mechanisms: (1) Motor output to the diaphragm grows greater; (2) as air flow accelerates, reflex mechanisms (possibly from rapidly adapting receptors) further increase motor output; and (3) the recruitment of more muscles helps curtail the load on the diaphragm.

When skeletal muscles are made to contract forcibly over long periods, they tire (i.e., are unable to generate as much pressure). The diaphragm can also become fatigued when it is obliged to develop large pressure changes because of either sustained respiratory stimulation or chronic mechanical impairment of the lungs. Fatigue leads to decreasing tidal volume and, ultimately, to CO_2 retention. Diaphragm fatigue can result from interference with cellular contractile mechanisms but can also be central in origin. Afferent signals from the diaphragm, originating from unspecified receptors that project to the brain via the phrenic nerves, may signal impending fatigue and enable motor output to diminish, thereby preventing irreversible damage to the muscle itself.

Upper Airway Muscles

The muscles of the upper airways also serve an important respiratory function. Contraction of the posterior cricoarytenoid muscle during inspiration to open the laryngeal aperture, an important site of airway resistance, increases the efficiency of energy used by the thoracic muscles during breathing. Changes in the laryngeal aperture are thus synchronized with breathing. When respiratory drive is increased, as during exercise or acute hypercapnia, the magnitude of this effect increases.

In addition to the larynx, activity of the cranial nerves that innervate muscles of the upper airways, such as the alae nasi (nasal dilator), genioglossus (protrussor muscle of the tongue), and muscles inserting on the hyoid, varies with the breathing cycle. During inspiration these muscles contract, dilating the upper airway passages and overcoming the negative intraluminal pressures produced by shortening of the thoracic muscles. This inspiratory activity may be of particular importance during sleep when the alignment of gravitational forces favors occlusion of the upper airways. Inspiratory activity of the upper airways also begins slightly before the onset of activity of the chest wall muscles. This difference in time of onset within a breath may also help to prevent airway obstruction.

The upper airway muscles seem to be more susceptible to the inspiratory inhibiting action of pulmonary stretch receptor input than are the muscles of the chest wall. The reduction in stretch receptor stimulation that occurs during airway occlusion increases the inspiratory activity of the upper airway muscles far more than that of either diaphragm or intercostal muscles. This heightening of discharge helps to dilate the upper airways and prevent obstruction during breathing.

INTEGRATED RESPONSES OF THE CONTROL SYSTEM

Response to Exercise

There are several phases to the exercise response: an initial rapid response, believed to be neurally mediated; followed by a slower exponential response that plateaus; and in severe exercise by a further increase due to the accumulation of lactic acid when oxygen consumption exceeds the anaerobic threshold and lactic acid accumulates in the blood. During exercise

there appears to be an additional stimulus to breathing which increases ventilation sufficiently so that there is little change in P_{CO_2} despite the rise in metabolic rate. The origins of this stimulus remain unclear. Proposed sources have included signals arising from the cortex (so-called feed forward control), temperature increases, afferent signals arising as a result of muscle contraction, accumulation of catecholamines, and increases in potassium in the venous blood.

The importance of the carotid body in the ventilatory response to exercise is disputed. Most but not all, studies indicate that the carotid body is sensitive to the rate of change of P_{CO_2}. The rate sensitivity of the receptors, and their rapid response to changes in P_{CO_2} and P_{O_2}, enable the carotid body to follow respiratory-related oscillations in arterial blood-gas tensions. Since the magnitude of oscillations in arterial P_{CO_2} is directly related to metabolic CO_2 production, it has been proposed that this oscillatory signal helps in the coupling of metabolic production of CO_2 and ventilation that occurs during exercise. This postulate has been the subject of much study, but experimental results have been conflicting.

Chemoreceptors in the mixed venous blood where oxygen levels decrease with increases in metabolic rate would allow measurement of changes in metabolism; but there has been little experimental support for this idea. However, recent studies in mutant mice with hemoglobin that has subnormal affinity for oxygen, has suggested that tissue levels of P_{O_2} might be sensed and initiate systemic responses.

Adaptations to Altitude and Chronic Continuous and Intermittent Hypoxia

Acute exposure to decreased barometric pressure with a resulting reduction in the partial pressure of oxygen produces an immediate boost in ventilation mediated through the peripheral chemoreceptors. With continued exposure, ventilation, in humans, continues to increase for several days resulting in a gradual decrease in arterial P_{CO_2}. There is also an increase in CO_2 sensitivity. This process, called acclimatization, is followed by the slow return of ventilation when the acclimatized individual returns to sea level. These slow processes occur mainly via changes in peripheral chemoreceptor activity rather than from the central effects of hypoxia. Similar changes in response occur with exposure to chronic hypoxia at sea level even if the exposure is intermittent rather than continuous.

Brief but repeated episodes of hypoxia for an hour or more produces augmented ventilation even when normoxia is restored, a phenomenon called long-term facilitation. This does not occur after sustained hypoxia of equal duration. This enhancement occurs in animals lacking intact carotid bodies and seems to depend largely on changes in serotonin and on brain-derived growth factors within the central nervous system. However, the carotid body when intact may contribute to the increase.

Sustained hypoxia after about 6 min has a depressive effect on the brain, limiting its response to further hypoxia. This is caused by increases in cerebral blood flow, which lower levels of brain P_{CO_2}, and by a direct depressive effect on the brain. This hypoxic depression spreads rostrally to caudally in the brain. Hypoxic depression may be the result of slowed removal of inhibitory neurotransmitters like GABA during hypoxia caused perhaps by the buildup of lactic acid in the brain.

The actions of hypoxia on the systemic circulation may also modify breathing. While the direct effect of hypoxia on the systemic blood vessels is dilating, hypoxia activates the sympathetic nervous system and produces a compensatory vasoconstriction. The inability of children with familial dysautonomia to tolerate hypoxia seems to be caused by failure of systemic blood vessels to constrict and maintain blood pressure.

Adaptation to Metabolic Acid-Base Disturbances

Lowered blood bicarbonate levels, which reduce arterial pH, increase ventilation and cause hypocapnia. For example, hyperventilation is a feature of diabetic ketoacidosis and renal failure. Conversely, repeated vomiting elevates blood bicarbonate levels and raises arterial pH, frequently causes hypoventilation and hypercapnia helping to restore pH.

Although reductions in P_{CO_2} invariably accompany metabolic acidosis, P_{CO_2} does not always rise in response to metabolic alkalosis. For example, it is widely held that blood alkalosis produced by K depletion does not elicit hypoventilation, presumably as a result of the intracellular acidosis that seems to accompany K loss. Also, in hypoxic, hypercapnic patients, complete compensation for metabolic alkalosis is limited by the hypoxia that accompanies hypoventilation.

Like the ventilatory response to altitude, the compensatory responses to chronic metabolic disturbance occur over hours and days rather than immediately. Because of this time course, it seems likely that central, as well as peripheral, chemoreceptors contribute to the ventilatory compensation, though the relative role of each remains to be determined. Acidosis either leaves ventilatory responses to inhaled CO_2 unaltered or causes them to increase; ventilatory responses tend to decrease with metabolic alkalosis.

Responses to External Mechanical Loads and Bronchoconstriction

The respiratory control system can also adjust so as to maintain ventilation in the face of mechanical impediments to breathing such as bronchoconstriction.

Several factors act to maintain ventilation. First are factors intrinsic to the respiratory muscles. The force that the muscle develops for a fixed electrical input depends on the length of the muscle (the force-length relationship). As the muscle shortens, less force is developed. The force also depends on the velocity of shortening (force-velocity relationship), with less force being developed as the velocity of shortening increases. With mechanical impediments (loading),

both the magnitude and the velocity of shortening tend to decrease.

In addition, there are reflex effects. At the spinal level, less shortening of the inspiratory muscles increases the signal from muscle spindles that, in turn, augments contraction of these muscles. During loading, afferent information from pulmonary mechanoreceptors also changes. Since tidal volume is depressed, inspiratory duration tends to be prolonged (Hering-Breuer inspiratory terminating reflex). In humans this mechanism is of little importance in compensating for mechanical loads.

Loads elicit a conscious response that increases neuromuscular output even in the face of a constant chemical drive. The magnitude of the increase is related to the severity of the mechanical load. This aspect of load compensation is abolished by anesthesia. The intensity of this load-compensating mechanism is variable. It is reduced in patients with chronic obstructive lung disease.

When loads are so severe that hypoventilation ensues, the resulting changes in arterial blood-gas tensions (increase in P_{CO_2}, reduction in P_{O_2}) act to sustain ventilation. The magnitude of this component of the response depends on the sensitivity of the peripheral and central chemoreflexes.

Major differences exist between the neural responses to bronchoconstriction and external loading. In particular, inspiratory muscle activity increases during bronchoconstriction even in anesthetized animals. During bronchoconstriction, rapidly adapting receptors can be stimulated by the mechanical changes in the airways and by substances such as histamine and bradykinin that are released in the lungs in asthma-induced bronchoconstriction.

Bronchoconstriction causes reflex changes in respiratory timing so that breathing frequency increases. Expiratory duration shortens more than inspiratory duration; within expiration, larger changes take place in the second phase of the expiratory part of the cycle.

Sleep

On the basis of EEG criteria, sleep has been divided into rapid eye movement (REM) and non-REM (NREM) sleep. REM sleep (the stage in which dreaming tends to occur) usually follows NREM (quiet sleep) states in which EEG frequencies are slower. REM sleep is characterized by the occurrence of a desynchronized EEG and periods of rapid eye movements. It is also accompanied by inhibition of motor neurons, which leads to a profound loss of muscle tone that affects the diaphragm less than other respiratory muscles. Even healthy people have occasional periods of apnea during sleep usually in the lighter forms of NREM sleep and in REM sleep.

In both REM and NREM sleep, ventilatory responses to hypoxia and hypercapnia are reduced. The normoxic and hypoxic CO_2 response curves are shifted to the right (see Fig. 10-2). Changes in lung mechanics occurring during sleep (increased upper airway resistance and decreased compliance) may contribute to depressed ventilatory responses.

Responses to mechanoreceptor stimulation are also altered by sleep. For example, the compensatory response in motor activity, which occurs during wakefulness when the airway is obstructed, is reduced or eliminated during sleep.

Airway obstruction during sleep usually terminates with arousal. Arousability varies during sleep with periods of increased arousability occurring particularly during NREM sleep.

PATHOPHYSIOLOGY: DISORDERS OF THE REGULATION OF BREATHING

Reduced Chemoreceptor Function

The importance of chemoreceptors stimulation in wakefulness and sleep may differ. Individuals with no apparent response to carbon dioxide or hypoxia may have normal blood gases while awake at rest and even during exercise. However, ventilation above the anaerobic threshold in intense exercise is subnormal in individuals lacking CO_2 sensitivity. Inadequate carotid body function in the newborn or decreased central chemosensitivity may contribute to the sudden infant death syndrome. Depressed responses to carbon dioxide may lead to persistent carbon dioxide retention in patients with thoracic diseases.

Persons who congenitally lack or have poor chemosensitivity to both hypercapnia and hypoxia (so-called Ondine's curse) suffer from inadequate ventilation during sleep. The hypoventilation is believed to be caused by maldevelopment of neural crest cells and is often associated with Hirschsprung's disease in which varying lengths of the colon are aganglionic. Patients may have a family history of the disorder that is associated with several different gene mutations especially of the PHOX2B gene, the receptor tyrosine kinase, the RET gene and endothelin1 and 3 genes, and brain derived neurotrophic factor.

Abnormalities of Respiratory Rhythm

Rapid breathing without an increase in tidal volume, i.e., tachypnea, occurs with temperature elevations and pulmonary fibrosis. Apneustic breathing occurs with lesions of the pons and is characterized by prolonged inspiratory duration.

Apnea is probably the most frequent and striking abnormality in respiratory rhythm. In Biot's breathing, a rare form of respiratory rhythm abnormality, tidal volumes of fixed amplitude are separated by periods of apnea. Apneas are observed most often in premature infants but can occur in healthy adults, especially during sleep, and can be isolated events or can be recurrent. Apneas sometimes produce severe hypoxia and hypercapnia; they may cause clinically significant cardiac arrhythmias; or have long-lasting effects such as pulmonary hypertension.

Several different mechanisms can potentially produce random central apneas. These include: (1) reduced excitation of chemoreceptors as a consequence of hypocapnia and hyperoxia; (2) loss of nonspecific respiratory excitatory stimulation (noise, light, tactile stimuli in the absence of adequate

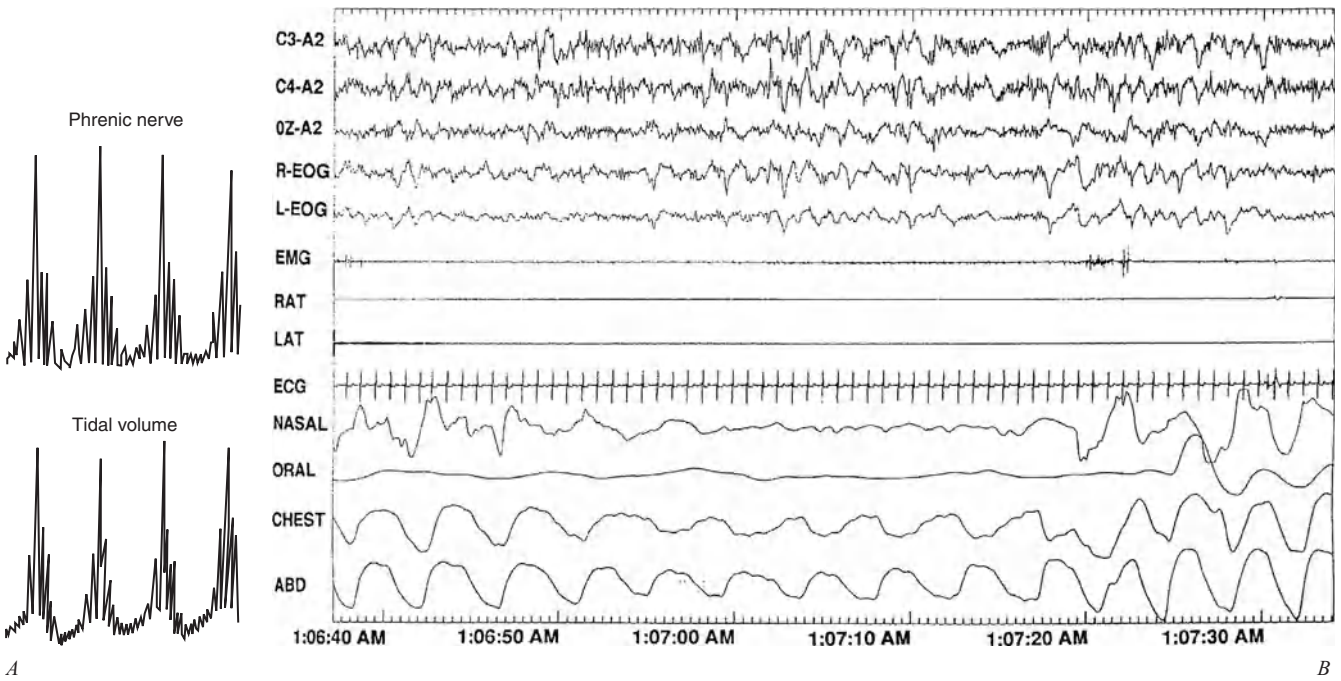

Figure 10-5 *A*. Shows Cheyne-Stokes respiration produced experimentally in a cat by increasing controller gain through a servo-respirator. Note the oscillating pattern of both tidal volume and phrenic nerve activity. *B*. Example of obstructive apnea. The top three tracings (C3-A2, C4-A2, 0Z-A2) are EEG, the next two (R-EOG, L-EOG) for eye movements, then chin EMG, right and left anterior tibialis EMG (RAT, LAT) ECG, nasal and oral airflow and finally chest and abdominal motion. The tracing shows a long episode of no airflow (apnea) but continued movement of chest and abdomen. During the apnea, chest and abdominal motion is paradoxical due to the obstruction; i.e., abdomen moves out while chest wall moves in). The apnea is terminated by an arousal with a burst of EMG activity and sudden increase in airflow as the upper airway is suddenly opened.

chemical drives); and (3) active suppression of breathing by respiratory inhibitory reflexes arising from the cardiovascular system, the lung and chest wall, or via somatic and visceral afferents. For example, excitation of receptors located in the upper airway can, via the superior laryngeal nerve, trigger an apnea. Stimulation of J receptors in the lungs by inhaled irritants may produce temporary apnea.

Recurrent apneas may appear as part of a pattern of grossly irregular ataxic breathing. Patients with this kind of breathing usually have functional or actual structural medullary damage. The breathing disturbance results from a kind of sputtering of damaged respiratory neuronal circuits. Breathing responds poorly to stimulants, and patients with this disorder tend to hypoventilate.

In other types of abnormalities, such as Cheyne-Stokes breathing and many sleep apneas, apneas occur more predictably. Apneas may be separated by periods of gradually increasing and decreasing breathing, as in Cheyne-Stokes breathing.

Sleep Apnea

Apneas occur occasionally during sleep in healthy humans; but in those who have the sleep apnea syndrome, apneas or near-apneas (hypopneas) are frequent and prolonged, so that much of the night is spent hypoxemic. They are often sleepy during the day and may have elevated levels of arterial P_{CO_2} and pulmonary artery pressure. Sleep apnea occurs most frequently in premature infants, adult males, and postmenopausal women.

Apneas can be central (absent respiratory movements) or obstructive (due to blockage of the upper airway). Heightened CO_2 sensitivity and hypocapnia during sleep have been implicated in the induction of recurrent central apneas during sleep. Sometimes these occur with a regular waxing and waning of ventilation resembling Cheyne-Stokes respiration.

Obstructive apneas are associated with obesity, snoring, and anatomical narrowing of the upper airway passages. Arousal terminates the periods of obstructive apnea, which occur more frequently in individuals with narrowed airway passages. Poor response of the upper airway muscles to carbon dioxide and or hypoxia in addition to the anatomic factors that narrow the upper airway predispose to the occurrence of obstructive apneas during sleep.

Cheyne-Stokes Respiration

Cheyne-Stokes breathing is one form of periodic breathing characterized by a cyclic rise and fall in ventilation with recurrent periods of apnea or near apnea. It was first observed in patients with cardiac or central nervous system disease, but it has since been reported in seemingly normal humans. The appearance of Cheyne-Stokes breathing can be triggered by the administration of sedatives and opiates and is more common during sleep. The period of the oscillations in ventilation in Cheyne-Stokes breathing is related to the circulation time

measured from the lung to a systemic artery. Cycle length increases when circulation time is prolonged. Arterial blood P_{CO_2} is highest during the phase of rapid breathing and arterial P_{O_2} is then at its minimum, but alveolar gas tensions cycle in the opposite way. Changes in the level of alertness occur coincidentally with the respiratory oscillations. Arousal tends to occur during the hyperpneic phase along with an increase in cerebral blood flow. The EEG shows greater fast-wave activity. The pupils dilate, and muscle tone is increased. The sensorium seems more depressed during apnea, the pupils are constricted, and muscle tone is diminished. Cerebral blood flow is often less during apnea, and there is a higher percentage of slow-wave activity in the EEG.

Cheyne-Stokes breathing has not been consistently produced in animals by lesions in the central nervous system, but it has been shown to follow manipulations that are likely to produce unstable feedback control of breathing.

Instability in the Feedback Control of Breathing as a Cause of Recurrent Apneas

Instability in feedback control can affect the regularity of breathing and produce a periodic increase and decrease in ventilation with apneas as in Cheyne-Stokes respiration. Although biologic control systems are much more complex than physical ones, design principles are similar, and some abnormalities in breathing resemble disturbances occurring in systems used to control machines. Ideally, biological control systems minimize the effects of disturbances and rapidly restore steady-state conditions to prevent wide swings in the internal conditions and to operate with minimal use of energy, but it may not be possible to meet these objectives simultaneously. Fluctuations in arterial blood-gas tensions can arise if the system is excessively stressed or from destruction of key components in the control system, which render it insensitive; less obviously, they may also occur if control is too rigorous.

Like physical control systems, the feedback system that regulates P_{O_2} and P_{CO_2} can be considered to consist of a controller and controlled elements linked by feedback loops as shown diagrammatically in Fig. 10-6. In this system the controller consists of the mechanoreceptors as well as the chemoreceptors and neurons in the brain. The mechanoreceptors and chemoreceptors communicate with the respiratory pattern generator, which produces the signal that drives the respiratory muscles and allows the lungs to be ventilated. The controlled system consists of these respiratory muscles, the lungs and the O_2 and CO_2 chemically bound and physically dissolve in the body (the gas stores). Changes in ventilation alter the amount of CO_2 and O_2 stored in the lung, blood, and tissues and so adjust the level of P_{CO_2} and O_2. Information on gas tension is transmitted to the sensors by the circulation. The bulbopontine neurons sense the difference between the input from the chemosensors and desired reference value levels and readjust the output to the respiratory muscles to reduce the discrepancy. State of alertness and sleep alter reference values.

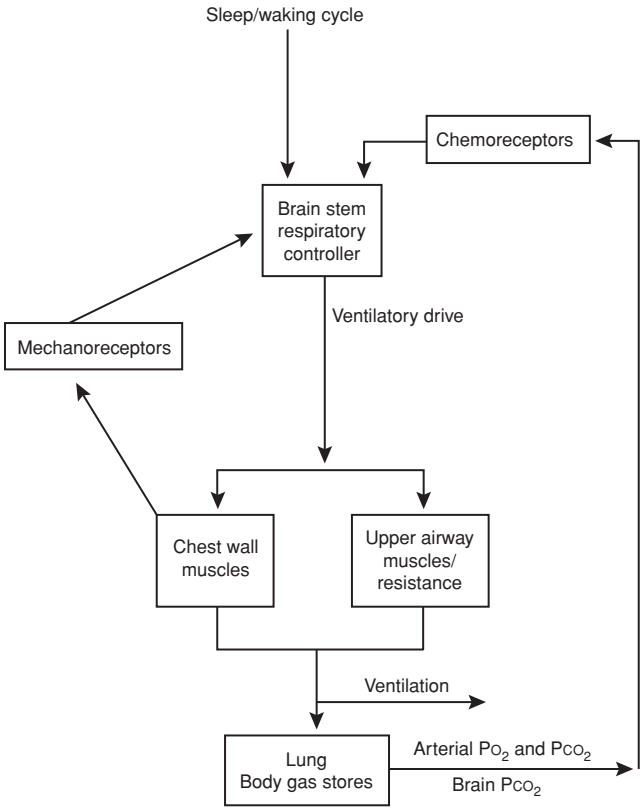

Figure 10-6 Diagram of respiratory control system showing feedback from chemo- and mechanoreceptors. See text.

Cyclic changes in both the rate of breathing and tidal volume can be produced by instability in the respiratory control system operation. Common mechanisms that produce instability include transport delays (increased circulation time such as occurs in heart failure) and increased loop gain (caused by greater controller sensitivity or changes in the operating point that allow the controller to exert a larger effect of the controlled system). This might occur in patients with a stroke.

In linear control systems, the occurrence of instability and the characteristics of the cyclic changes can be predicted by graphical techniques, for example, by the Bode and Nyquist diagrams. However, the respiratory control system behaves nonlinearly, and the prediction of the effects of specific alterations in system components usually requires the use of mathematical models. Although they differ somewhat in details, models of the respiratory system show that unstable operations can occur with alterations in the activity of the components of the system or can be triggered by disturbances that are well within the range of physiological possibility.

Dyspnea (Shortness of Breath)

Normally breathing is not noticeable, but respiratory movements and forces are perceptible and when sufficiently intense, result in symptoms of shortness of breath. Patients with lung disease may complain of dyspnea even at rest. Since

dyspnea itself can become an incapacitating symptom, considerable attention has been given to its etiology.

Earlier experiments used breathholding as a model for the investigation of dyspnea. These studies showed that hypercapnia and hypoxia decrease breath-holding times, supporting the idea that increased levels of chemical drive promote dyspnea; conversely, increased lung volume lengthened breath-holding time because it slows these chemical changes.

Combined blockade of the phrenic and vagus nerves extends the time apnea can be voluntarily maintained, leading to the idea that signals from respiratory muscles are an important contributor to the sense of dyspnea.

Dyspnea also seems to be related to the effort (motor command) used during breathing, expressed as a percentage of its maximum. Thus, dyspnea increases as the pressures required for tidal breathing grow greater or the maximal inspiratory pressure decreases (e.g., as by paresis, disease, or respiratory muscle fatigue).

Recent studies suggest that there may be two forms of dyspnea; one a sense of air hunger as occurs in breathholding and the second a sense of excessive effort as occurs during breathing against a resistance. It has been proposed that the two types are produced by different mechanisms with different anatomical pathways and this idea is supported by PET scanning studies in humans. Cognitive factors, and probably affective factors which determine the relative pleasantness of a sensation as well as sensory intensity, affect the level of dyspnea. The dyspnea experienced during CO_2 breathing may be mediated through the limbic system.

It is of interest in connection with dyspnea that subjects who fail to increase their ventilation with CO_2 inhalation also have long breath-holding times and fail to experience dyspnea, but do feel dyspneic during exercise. This is one argument for there being two types of dyspnea.

Dyspnea may have a useful purpose as a warning device. Patients who have experienced a nearly fatal asthmatic attack requiring mechanical ventilation often have depressed sensations of dyspnea when exercising or when breathing on resistive loads.

Ventilation, Pulmonary Blood Flow, and Ventilation-Perfusion Relationships

Peter D. Wagner

This chapter and that succeeding it together share responsibility for presenting the physiological basis of normal pulmonary gas exchange. Gas exchange occurs by an integrated series of gas transport steps between the environmental air we breathe and the Hb molecule of the red cells passing through the pulmonary capillaries. These transport steps are of two types—diffusive and convective, and a number of conceptually separate diffusive as well as convective processes interact to accomplish the gas exchange mission. This is true both for gases that are taken up from the environment into the blood (i.e., O_2 and occasional toxic gases or volatile anesthetics) and for gases that are eliminated from the body (i.e., CO_2 and volatile anesthetic agents).

This chapter deals principally with the convective processes and the following chapter with those involving diffusion. However, since the two types of process occur simultaneously they are closely linked.

BASIC OUTLINE OF THE GAS EXCHANGE PATHWAY

This section dwells on O_2, being the gas of principal physiological interest. However, the pathway components are of course identical for all gases and furthermore do not depend on whether the gas is being taken up (O_2) or eliminated (CO_2). On the other hand, distinct quantitative differences in the uptake or elimination patterns of different gases exist, but those are readily explained by differences in their fundamental physical or chemical properties, and not by transport pathway differences.

To understand the gas transport pathway, one must first appreciate the anatomy of the lungs, laid out in detail in Chapter 2. The salient functional features are presented in Fig. 11-1.

The chest wall (rib cage and diaphragm) contain muscles that on contraction expand the volume of the chest cavity and thus reduce the intrathoracic pressure of the pleural space, expanding the lungs with air drawn in via the mouth and nose. Although there is but a single air passage in the neck (i.e., the trachea), this soon branches into right and left main bronchi. These also divide many times, essentially dichotomously. There are some 16 such orders of branching of these bronchi, resulting in a structure that resembles an inverted deciduous tree without its leaves in winter. With each successive branch the airways become shorter and narrower, but ever greater in number, usually doubling at each branching. Thus, although the cross-sectional area of any one airway becomes smaller with each branching, the greater number of airways more than makes up for loss of individual cross sectional area such that the sum of cross-sectional areas of all airways of a given generation rises essentially exponentially with each branching (Fig. 11-2). The total volume of gas in these 16 conducting airway generations is called the

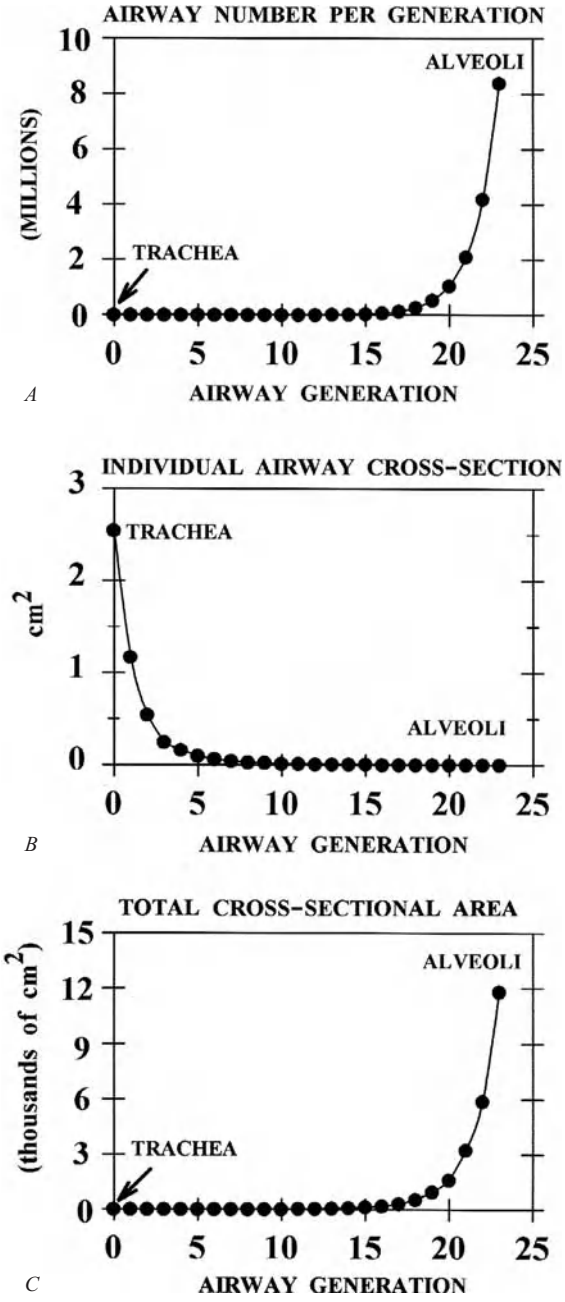

Figure 11-2 Relationship between number (*A*) and cross-sectional area (*B*) of the airways at a given generation. Note that total airway cross-sectional area (*C*) increases extremely rapidly beyond approximate airway generation 15, which is the beginning of the respiratory zone for gas exchange.

anatomic or conducting airway dead space, and approximates 1 ml per pound of body weight. After these 16 or so successive branches, the tubular, purely conducting airways begin to show alveolar units in their wall (generation 17 to 19 or so) and these finally give way to fully alveolated structures (in succession: alveolar ducts, alveolar sacs, and alveoli). There are some 300 million alveoli, each about 300 μm in diameter. They are blind structures so that ventilation has to be accomplished by a tidal, in-and-out process (rather than a flow-through process as for pulmonary blood flow). The alveoli can be seen in Fig. 11-1 from a different perspective. For gas exchange to occur, O_2 must be moved from the mouth all the way to the alveoli—it is only within alveoli that gas exchange occurs.

Each alveolus is densely covered in a capillary network, seen from various perspectives in Fig. 11-1. This network is closely applied to the alveolar gas space as Fig. 11-1 shows, with on average only about 1/2 μm of cellular and interstitial tissue between the blood inside the capillary and the alveolar gas outside. The capillary network is fed by the pulmonary arterial tree, which branches alongside the airways in a very similar pattern as the airways. The capillaries then drain into venules that join to form larger and larger vessels, eventually becoming the pulmonary veins that drain oxygenated blood into the left atrium. This coalescence of venous vessels forms a similar branching tree to the pulmonary arteries and airways, but in reverse. The right ventricle is responsible for unidirectional pumping of blood through this vascular system.

The gas exchange pathway from the lips to the left atrium is highly complex structurally, and understanding how gases pass along the pathway requires following the events an O_2 molecule must participate in between the lips and the left atrium.

1. The first step is inspiration of air into the trachea via mouth and nose. Accomplished by inspiratory chest wall muscle contraction, which reduces intrathoracic pressure, this step is convective (like water flowing from a region of high to low pressure along a garden hose). All the respired air must pass the trachea, but at the first branch point some air goes to the right lung, the rest to the left. At each successive branch point, similar mass-conserving distribution of air must occur between the daughter branches of each parent pathway. Remembering that there are some 23 total branchings from the mouth to the 300 million alveoli, there is a very real risk of quite uneven distribution of that inspired air among those alveoli. The principal determinants of how air is distributed at branch points (i.e., between daughter branches) are the mechanical properties of the respiratory system: the compliance (elastic properties), the resistance, and the inertial properties. These concepts are more fully treated in Chapter 9.
2. During normal resting inspiration, flow is laminar in most of the airways. Thus inspired gas develops a parabolic profile due to higher molecular velocities in the center than periphery of the airway (Fig. 11-3). The parabolic "tongue" of inspired gas in Fig. 11-3 moves down an airway, while around the tongue is gas remaining from the previous expiration. The tongue therefore has O_2 at a concentration of 21 percent and essentially no CO_2. The gas around the tongue, having undergone gas exchange during the preceding breath, has about 14 percent O_2 and 5 percent CO_2. Consequently, during forward motion of this tongue toward the alveoli, O_2 will diffuse from

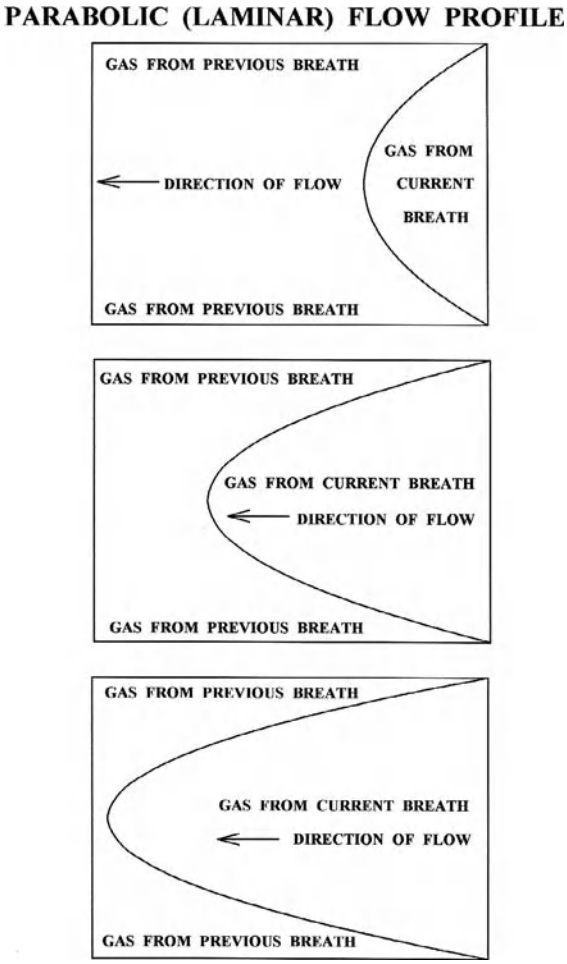

Figure 11-3 The parabolic profile of laminar flow. The three panels indicate sequential points in time during a single inspiration proceeding from right to left. Because the gas remaining from the previous breath has a low oxygen concentration and high CO_2 concentration relative to that of the inspired gas in the current breath, there is diffusive exchange between the parabolic tongue and surrounding gas (Taylor dispersion).

the tongue to its surrounding gas while CO_2 will diffuse in the opposite direction. This is called *Taylor dispersion*, and it reduces the forward transport of O_2 produced by the onward convective movement of the tongue. This effect however is considered quite small and is generally not of significance to overall gas exchange.

Note that if inspiration occurs at high rates as in exercise, such laminar flow may not occur in the larger airways—it may be turbulent and then Taylor dispersion is essentially noncontributory, as the turbulent mixing evens gas concentrations across the airway lumen.

3. Figure 11-2C shows the exponential increase in airway cross-sectional surface area as one proceeds deeper and deeper into the lungs. The significance of this curve is that since the mass flow rate of inspired gas is the same at every generation (because the airways are simply a conducting system), the forward velocity of O_2 molecules falls (since flow rate is the product of velocity and cross-sectional area). As it happens, by about generations 17 to 19, where the alveoli are just beginning to appear, this forward velocity has become so low that passage of O_2 from here on out to the alveoli is heavily dependent on simple gaseous diffusion, not just on continuing convective flow.
4. If alveoli are not equally ventilated with gas (and equally perfused with blood), their alveolar O_2 concentration will differ, as explained later in this chapter. Because adjacent alveoli are so physically close, there can be considerable diffusion of O_2 between such alveoli when their O_2 levels are different. This passive process tends to reduce concentration differences between these alveoli. However, although it can be detected experimentally, it is of probably minor clinical significance. Step 3 (and to some extent step 4) are responsible for most of the alveolar gas mixing that must occur for gas exchange to take place; that is, the mixing of each breath of newly inspired gas with alveolar gas still present from prior breaths.
5. The heart acts as a massaging pump to further enhance gas mixing into the alveolar gas spaces. Alternate filling and emptying of the cardiac chambers, respectively, facilitates exhaling and inhaling of airway gas into those alveoli physically close to the heart, but has little effect on more distant alveoli. Although a well-known and easily demonstrated phenomenon, this so-called cardiogenic mixing is probably also of minimal physiological impact for gas exchange.
6. Once the dominant convective and diffusive gas transport steps have brought O_2 from the lips to the alveolar gas spaces, O_2 physically dissolves in the tissues separating alveolar gas from capillary blood, the blood-gas barrier (see Fig. 11-1). O_2 then moves by diffusion through the blood-gas barrier and into the plasma. Over 98 percent of these O_2 molecules diffuse further, i.e., into the red cell interior, and then bind rapidly to hemoglobin. The remaining 2 percent or so remain physically dissolved in the plasma and red cell water.

   This transport process from alveolar gas to hemoglobin is accomplished passively by simple diffusion. No convective forces or active transport processes are involved. The diffusion process is discussed more fully in the next chapter. In normal lungs at rest, this process is very rapid and causes no O_2 transport limitation.
7. Finally, the red cells are transported convectively by cardiac pumping action out of the pulmonary capillaries and into the pulmonary veins and then to the left atrium, and left ventricle, finally reaching the various body tissues.

POTENTIAL DISRUPTION OF THE GAS TRANSPORT PATHWAY

If all the above elements of the transport pathway were functionally perfect, the partial pressure of O_2 (and other gases) would be identical in the gas of all 300 million alveoli and equal to that in systemic arterial blood. The system comes close to perfection in health, but there is never complete equivalence of alveolar and arterial pressures, even in healthy young, normal people. Aging further leads to a progressive impairment of the pathway with arterial P_{O_2} falling from 95 to 100 mmHg at age 20, to 75 to 80 mmHg at approximately age 80. However, alveolar P_{O_2} tends to be invariant with age. Thus, the difference between alveolar and arterial P_{O_2} steadily increases from about 5 to 10 mmHg to about 20 to 25 mmHg over this age range. Pulmonary diseases such as asthma, emphysema, bronchitis, fibrosis, pneumonia, and many others can greatly disrupt gas transport to the point of causing death from insufficient tissue O_2 supply.

Consequently, it is essential to have a good understanding of the O_2 transport pathway and what may affect it even in health, in order to appreciate the problems seen in pulmonary diseases.

A traditional view of how to consider abnormalities of the transport pathway has evolved over the years and is very useful as a framework for discussion. It is based upon the end result of gas exchange—the arterial P_{O_2}—and listing the reasons why this variable can fall below normal values.

Four principal potential mechanisms of failure of the O_2 transport pathway can lead to a reduced arterial P_{O_2} (i.e., arterial hypoxemia):

1. Hypoventilation
2. Diffusion limitation
3. Shunt
4. Ventilation-perfusion ($\dot{V}_A/\dot{Q}$) inequality

These are the so-called "intrapulmonary" factors that directly cause hypoxemia. Modulating "extrapulmonary" factors are also important. These include changes in inspired O_2 concentration, total cardiac output, overall metabolic rate, and Hb concentration.

The four "intrapulmonary" factors are now defined and discussed.

Hypoventilation

Normal levels of ventilation produce a tightly regulated arterial P_{CO_2} at 40 ± 2 mmHg in normal subjects with several control systems in place to ensure this. However, if overall ventilation is reduced for any reason, alveolar P_{CO_2} ($P_{A_{CO_2}}$), and, therefore, arterial P_{CO_2}, must rise to maintain constant elimination of metabolically produced CO_2. Reciprocally, alveolar P_{O_2} ($P_{A_{O_2}}$), and hence, arterial P_{O_2}, will fall (and by relatively similar amounts as P_{CO_2} will rise). The alveolar gas equation quantitatively relates Pa_{O_2} and Pa_{CO_2}, and is used to calculate how much $P_{A_{O_2}}$ will change for a change in $P_{A_{CO_2}}$:

$$P_{A_{O_2}} = P_{I_{O_2}} - \frac{P_{A_{CO_2}}}{R} + P_{A_{CO_2}} \cdot F_{I_{O_2}} \cdot \frac{(1 - R)}{R} \qquad (1)$$

$P_{I_{O_2}}$ and $F_{I_{O_2}}$ are inspired O_2 partial pressure and fractional concentration, respectively, and R is the respiratory exchange ratio.

Hypoventilation represents a failure of step 1 of the gas transport pathway (see above) and can occur for several reasons: (1) The control centers in the nervous system that regulate ventilation could malfunction due to trauma, diseases, drugs, or anesthetics; (2) there could be neuronal or neuromuscular dysfunction of the nerves supplying the chest wall muscles of respiration; (3) the chest wall muscles could be fatigued, damaged, or paralyzed; or (4) the airways or chest wall could be disrupted from trauma or other mechanical derangement such as compression, or in the case of airways, obstruction.

Conceptually, this type of problem is usually thought of as a whole-lung issue, usually with obvious causes, and can be reversed by recognizing the cause and taking appropriate reparative or ventilatory supportive steps.

Diffusion Limitation

Whereas diffusive transport plays a recognizable, if small role, within the airways and alveolar gas (see above), the concept of diffusive limitation affecting arterial P_{O_2} is more usually associated with transport step 6 above—diffusion of O_2 from alveolar gas into the capillary and red cell.

This topic is specifically the focus of the following chapter and is not dealt with here. Indeed, the ensuing discussion of other factors sets aside diffusion limitation of O_2 transport for the sake of simplicity and assumes that the diffusive exchange of O_2 (and CO_2) between alveolar gas and capillary blood proceeds to completion within a single red cell's passage through the pulmonary microcirculation. This is reasonable under most conditions.

Shunt

A shunt is a blood pathway that does not allow any contact between alveolar gas and red cells, so that no gas exchange occurs in the affected region. Consequently, blood passes through a shunt maintaining a mixed venous blood composition. When this blood reaches pulmonary veins, the left atrium and eventually arterial blood, it mixes with other blood that has undergone alveolar gas exchange. The result is a fall in arterial P_{O_2} and potentially an increase in arterial P_{CO_2}. (Arterial P_{CO_2} may not increase if the patient raises his or her level of ventilation, but hypoxemia will persist.)

Classical pathophysiological scenarios giving rise to shunts are: (1) pulmonary edema, which fills alveoli with fluid, thereby abolishing their ventilation and any gas exchange; (2) alveolar filling with cellular and microorganismal debris as in pneumonia, with the same result as in edema;

(3) collapse of a region of lung due to pneumothorax, gas absorption distal to a fully obstructed airway, or to external compression; (4) rarely, the presence of abnormal arteriovenous vascular channels in the lungs, which can occur in hepatic cirrhosis, for example; and (5) direct right-to-left vascular communications at the level of the heart or great (extrapulmonary) blood vessels.

Ventilation-Perfusion ($\dot{V}_A/\dot{Q}$) Inequality

The exquisite and complex branching architecture of the airways and of the blood vessels makes the lungs very susceptible to the potential problem of nonuniform distribution of alveolar ventilation and of pulmonary blood flow. Whenever alveoli are ventilated at less than average rates; for example, if their feeding airways become partially obstructed for any reason, the ratio of ventilation to blood flow ($\dot{V}_A/\dot{Q}$ ratio) will fall. In certain other conditions, lung regions may suffer a reduction in local blood flow rather than ventilation, so that the $\dot{V}_A/\dot{Q}$ ratio rises above the average value in those areas.

Whenever there is a range of $\dot{V}_A/\dot{Q}$ ratios in a lung such that the $\dot{V}_A/\dot{Q}$ ratio is not identical everywhere, it is said that $\dot{V}_A/\dot{Q}$ inequality exists. The pathological cause of $\dot{V}_A/\dot{Q}$ inequality does not matter, nor whether the problem originates in the airways or blood vessels. The principal concept is that, compared with a lung having the same total alveolar ventilation and blood flow, a lung that has $\dot{V}_A/\dot{Q}$ inequality will exchange (all) gases in an inefficient manner. The result is hypoxemia and, potentially, hypercapnia (raised arterial P_{CO_2}). A large section of this chapter presents the physiological reasons for this effect of $\dot{V}_A/\dot{Q}$ inequality.

Understanding of $\dot{V}_A/\dot{Q}$ inequality can be demanding, but no matter what its pathological origins, the concepts are similar. $\dot{V}_A/\dot{Q}$ inequality can occur at many different scales. Not uncommonly, it can manifest on a large scale as differences between the right and left lungs. Classic examples of this include unilateral atelectasis, pneumothorax, pulmonary embolus, or pneumonia. All these are relatively common phenomena that can lead to severe gas exchange disturbances. At the other end of the scale, there can be $\dot{V}_A/\dot{Q}$ ratio differences between essentially adjacent alveoli. However, research has shown that small groups of contiguous alveoli can maintain functional homogeneity of $\dot{V}_A/\dot{Q}$ ratios via rapid gas diffusion rates, possibly augmented by collateral ventilation and blood flow. It is likely that all alveoli distal to individual respiratory (or perhaps terminal) bronchioles can retain functional homogeneity for gas exchange through these mechanisms.

In between these two extremes of scale, vascular or airway obstruction at all levels will produce $\dot{V}_A/\dot{Q}$ inequality that, depending on how widespread it is, causes hypoxemia and potentially hypercapnia.

Even the young normal lung is usually subject to $\dot{V}_A/\dot{Q}$ inequality, which explains the 5- to 10-mmHg P_{O_2} difference between alveolar gas and arterial blood generally observed in healthy young subjects. There are several mechanisms for the existence of such $\dot{V}_A/\dot{Q}$ inequality.

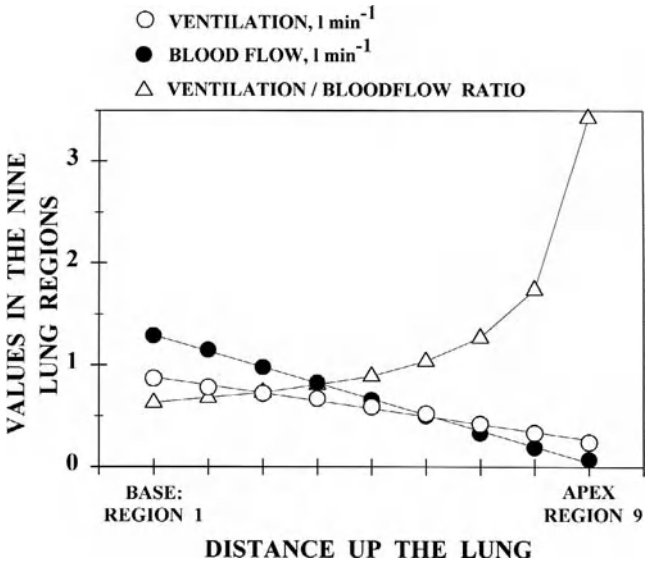

Figure 11-4 Topographical relationships between ventilation and blood flow as a function of distance up and down the upright lung (divided into nine contiguous regions). Although both ventilation and blood flow are higher at the base than at the apex, the ventilation-perfusion ratio ($\dot{V}_A/\dot{Q}$) rises exponentially from the bottom to the top of the lung. *(Adapted from West JB:* Ventilation/Blood Flow and Gas Exchange. *Oxford, Blackwell Scientific, 1990.)*

Gravity-Based Inequality

Ventilation and, even more so, blood flow, are unevenly distributed in a manner systematically influenced by gravity. This is due to the weight of the lungs and the blood in the blood vessels, respectively. Thus, dependent lung regions receive far more blood flow than nondependent regions, a finding that is independent of body position in concept. It turns out that the gravitational gradient in blood flow considerably exceeds that of ventilation. As a result, the nondependent lung regions are of *higher* than average $\dot{V}_A/\dot{Q}$ ratio, and the dependent regions are of *lower* than average $\dot{V}_A/\dot{Q}$ ratio. Average $\dot{V}_A/\dot{Q}$ ratio is about 1.0, because total alveolar ventilation and blood flow are similar. At the apex of the upright human lung, the $\dot{V}_A/\dot{Q}$ ratio is about 3; at the base it is about 0.6, fivefold lower. There is a smooth gradation between the two extremes, as depicted in Fig. 11-4. This large-scale apex-to-base gradient in $\dot{V}_A/\dot{Q}$ ratios does not produce more than about a 4-mmHg drop in arterial P_{O_2} (compared with expectations in the absence of this phenomenon); this results in a 4-mmHg alveolar-arterial P_{O_2} difference.

Fractally Based $\dot{V}_A/\dot{Q}$ Inequality

The branching airway and blood vessel structure of the lung constitutes a fractal system that is innately susceptible to $\dot{V}_A/\dot{Q}$ inequality independent of gravity. With some 23 sequential orders of branching, very small random inequalities in gas or blood flow distribution repeated at each branch point of the system can rapidly escalate into very significant degrees of nonuniform ventilation or blood flow. To illustrate, consider a branching system of just 16 dichotomous sequences—at each

of the 16 branch points, air is *not* precisely split 50/50 between each daughter pair. Rather, suppose a 49 percent/51 percent split—a nonuniform effect of trivial proportions at any one airway branch. The most poorly ventilated regions (receiving 49 percent of the split at every one of the 16 branchings) end up with only about half as much ventilation as the best ventilated regions that receive 51 percent of the split at each branch.

Unless the fractal structure somehow distributes both ventilation and blood flow in a correlated manner to preserve $\dot{V}_A/\dot{Q}$ ratios (even as $\dot{V}_A$ and $\dot{Q}$ individually vary), significant hypoxemia could result. Understanding the consequences of the fractal nature of the lung is a topic of much current interest. It appears that there must be correlation of $\dot{V}_A$ with $\dot{Q}$ since the large potential for fractally based hypoxemia is not generally realized.

Longitudinally Based Inequality

As airways and blood vessels progressively narrow with each branch point, resistance to gas and blood flow increases. Not all alveoli receive gas or blood from airways that have gone through the exact same number of branchings. Hence, some alveoli will be more and some less distant from the mouth. Such simple principles suggest the possibility of reduced $\dot{V}_A$ and/or $\dot{Q}$ of those alveoli further from the mouth compared with more proximal alveoli; therefore, the chance of a central to peripheral, or longitudinal, gradient in ventilation and blood flow. Although not universally observed, there is a fair amount of evidence that such inequality exists, but its contribution to gas exchange is hard to establish. To the extent that similar physical principles apply to both gas and blood flow in the present context, one can theorize that more distant alveoli have both less ventilation and blood flow, so again there is a natural tendency to preserve the $\dot{V}_A/\dot{Q}$ ratio between central and peripheral regions.

Anatomically Based Inequality

Another potential reason for nonuniform gas or blood flow distribution is intrinsic anatomical differences among lung regions. Perhaps the best example is in the dog and horse, in which the dorsal regions of the lower lobes often can be shown to have an unduly high share of total pulmonary perfusion independent of body position in relation to gravity. This tendency, presumably based on the overall branching architectural differences between or within lobes, becomes important in concept when patients are moved from one body position to another, to best understand consequent changes in gas exchange.

Collateral Ventilation and Blood Flow

To this point, a picture has been painted of a branching architecture that has no lateral connections between either adjacent airways or blood vessels at any level of branching. Such lateral connections can exist at several airway levels, from large airways down to alveoli. This is a species-dependent phenomenon, so that while the pig has little or no such collateral pathway structures, the dog has extensive collateral ventilatory channels. Humans are somewhere between these extremes.

Whatever the evolutionary pressure for collateral channel development, the ability to move gas around obstructions in airways by the use of collateral channels appears to be a useful property of human lungs. This is because total airway obstruction in the absence of collateral channels often leads to rapid alveolar gas absorption into the blood from the alveoli distal to the obstructed airway; this in turn leads to atelectasis and therefore vascular shunts and hypoxemia. Remarkably, chronic human lung diseases typified by airway obstruction—chronic obstructive pulmonary disease (COPD), asthma—produce $\dot{V}_A/\dot{Q}$ inequality due to presence of poorly ventilated areas, but only uncommonly lead to true shunts. The likely explanation for the paucity of shunts in COPD and asthma is the existence of collateral ventilation.

Therefore, collateral ventilation in humans appears to be a naturally occurring structural phenomenon that can counteract the gas exchange consequences of diseases to some extent.

Collateral perfusion also must occur in the alveolar capillary network. This is deduced simply from the richly interconnecting microvascular network that has the potential to allow blood to flow easily around microvascular obstructions into adjacent vessels. Just how much collateral blood flow potential exists at a larger scale is not clear, being difficult to study. However, well-documented connections occur between the bronchial and pulmonary circulations, creating a different kind of collateral circulatory network. The importance of this connection is evident when the pulmonary artery is either absent or embolized. Then, the bronchial circulation expands considerably and can support function of the affected lung regions in the long term.

Reactive Vasoconstriction and Bronchoconstriction

The distribution of ventilation or blood flow in the lung can be modified by vasoreactive or bronchoreactive functional changes that appear to be triggered by changes in alveolar gas composition. The best-documented phenomenon is that of hypoxic pulmonary vasoconstriction. Here, in response to local alveolar hypoxia produced by locally reduced ventilation, local pulmonary arterial constriction reduces blood flow in the hypoxic region. Whether this system developed to counteract disease or cope with intrauterine life and the abrupt transition to air-breathing is arguable, although most people favor the latter explanation.

Irrespective of the reason, the effect of hypoxic vasoconstriction is to help return the local ratio of ventilation to blood flow toward normal. This automatic effect (mediated by O_2-sensitive potassium channels in pulmonary arterial smooth muscle cells) is rarely able to fully restore $\dot{V}_A/\dot{Q}$ ratios to normal, but even partial improvements in $\dot{V}_A/\dot{Q}$ ratio facilitate gas exchange significantly. The negative aspect of hypoxic vasoconstriction is a rise in pulmonary vascular resistance. If this

is substantial and protracted over time, pulmonary arterial hypertension can develop, eventually leading to right heart failure. However, factors other than hypoxic vasoconstriction are generally present also, such as microvascular destruction and alveolar distortion, and these may be more important to heart failure than hypoxia per se. However, hypoxic vasoconstriction has provided a rationale for enriched O_2 therapy in patients with chronic disease to reduce the severity or delay the progression of pulmonary hypertension.

To a much less obvious extent, a counterpart to hypoxic vasoconstriction occurs in the airways known as hypocapnic bronchoconstriction. Here, especially when pulmonary embolism occurs, the $\dot{V}_A/\dot{Q}$ ratio in the embolized area rises due to loss of blood flow from vascular obstruction. This increase in $\dot{V}_A/\dot{Q}$ ratio leads to a lower local P_{CO_2} (see below), which causes bronchoconstriction in the local area. This reduces local ventilation and thus tends to normalize the local $\dot{V}_A/\dot{Q}$ ratio. Radioactive tracer ventilation scans may show evidence of this as a modest reduction in the ventilation of embolized regions.

The $\dot{V}_A/\dot{Q}$ Ratio and Gas Exchange

To this point, much space has been given to the concepts underlying the distribution of ventilation ($\dot{V}_A$), blood flow ($\dot{Q}$), and hence, their ratio, $\dot{V}_A/\dot{Q}$. The reason for this lies in the importance of $\dot{V}_A/\dot{Q}$ ratios to the basic function of the lung—to exchange O_2 and CO_2 between the blood and the air. $\dot{V}_A/\dot{Q}$ inequality, no matter what its physiological basis or pathological cause, interferes with gas exchange and causes hypoxemia and sometimes hypercapnia.

The following section explains the relationship of $\dot{V}_A/\dot{Q}$ inequality to gas exchange. The subject is complex and must be considered at several "concentric" levels. To start, consider how the $\dot{V}_A/\dot{Q}$ ratio in a small local lung region controls local P_{O_2}, P_{CO_2}, and therefore how much O_2 and CO_2 are exchanged in that region. This isolated approach requires some key assumptions at first. Removing the restrictions of these assumptions is the next "concentric" step in understanding $\dot{V}_A/\dot{Q}$ relationships. A final outer shell of modifying factors that can further affect gas exchange forms a third level of the analysis.

The $\dot{V}_A/\dot{Q}$ Ratio of a Small Homogeneous Unit of Lung and Gas Exchange

How the $\dot{V}_A/\dot{Q}$ ratio determines gas exchange is best explained by considering the flux of O_2 from the environment into and out of the alveolus with each breath as well as from the alveolar gas into the capillary blood. Equations that describe these processes and follow the fundamental principle of mass conservation must be used. Original descriptions of these appeared more than 50 years ago. Figure 11-5 provides a model of the lung and specifies the ventilation ($\dot{V}_A$) and blood flow ($\dot{Q}$) of this unit together with the key locations of the relevant O_2 levels. It can be used to consider a small homogeneous unit of lung.

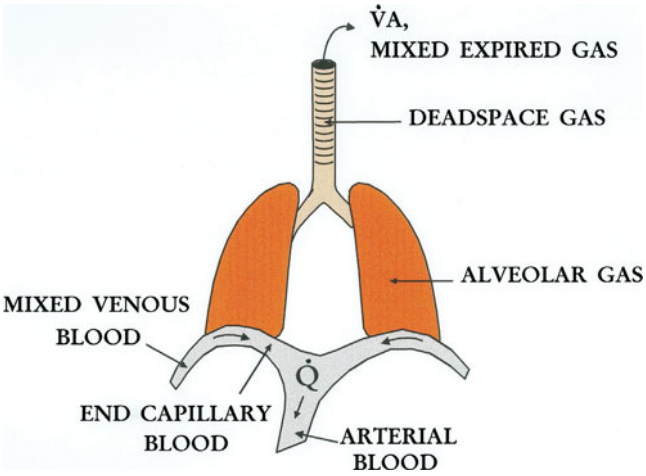

Figure 11-5 Conceptual model of the lungs indicating main sites in which oxygen and carbon dioxide partial pressures are different, together with the principal convective processes accomplishing gas exchange, ventilation ($\dot{V}_A$) and blood flow ($\dot{Q}$).

Convention has long considered ventilation over a period of time as a constant in spite of the tidal nature of breathing. In fact this is a very reasonable approximation that has stood the test of time. Similarly, blood flow is considered constant, and this too has proved reasonable. Therefore, if $\dot{V}_A$ and $\dot{Q}$ are considered as alveolar minute ventilation and blood flow of a small homogeneous unit, respectively, the following simple mass conservation equations can be written for O_2:

$$\dot{V}_{O_2} = \dot{V}_I \times F_{I_{O_2}} - \dot{V}_A \times F_{A_{O_2}} \qquad (2)$$

and

$$\dot{V}_{O_2} = \dot{Q} \times Cc'_{O_2} - \dot{Q} \times C\bar{v}_{O_2} \qquad (3)$$

In these equations, $\dot{V}_{O_2}$ is amount of O_2 transferred from the environment into the blood per unit time and, given the assumption of steady-state conditions, this equals metabolic rate when summed over all such units in the lungs. $\dot{V}_I$ and $\dot{V}_A$ are the inspired and expired volumes of gas respired per minute (less that amount remaining in the conducting airways), respectively. As anticipated, $\dot{V}_I$ and $\dot{V}_A$ are close to being identical, otherwise the lungs would blow up or collapse in a short period of time. However, $\dot{V}_I$ does not generally equal $\dot{V}_A$ because slightly more O_2 is consumed per minute than CO_2 produces (i.e., the respiratory quotient is, in general, not 1.0). Thus, $\dot{V}_A = \dot{V}_I - \dot{V}_{O_2} + \dot{V}_{CO_2}$. Mostly, the inequality of $\dot{V}_I$ and $\dot{V}_A$ can be ignored because the difference is only about 1 percent. If $\dot{V}_I$ is 6 L/min and $\dot{V}_{O_2}$ is 300 ml/min with $\dot{V}_{CO_2}$ at 240 ml/min, $\dot{V}_A = 5.94$ L/min. Although this small difference is not ignored in research applications, it can be for the present purposes, so that $\dot{V}_I$ is replaced by $\dot{V}_A$ in Eq. (1), simplifying the analysis below. In Eq. 1, $F_{I_{O_2}}$ and $F_{A_{O_2}}$ are the fractional concentrations (F) of O_2 in inspired (I) and exhaled alveolar (A) gas, respectively, from the small unit of Fig. 11-5. In Eq. (3), Cc'_{O_2} and $C\bar{v}_{O_2}$ are the O_2 concentrations (C) in the oxygenated end capillary blood leaving (c') and the deoxygenated blood entering ($\bar{v}$)

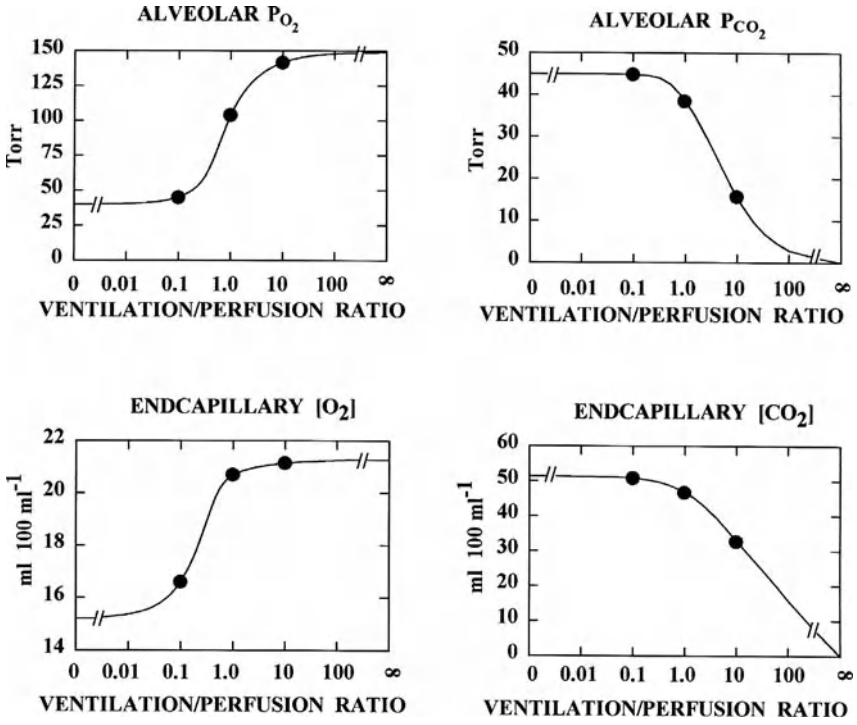

Figure 11-6 Calculated relationships between alveolar P_{O_2} and P_{CO_2} and the ventilation-perfusion ratio (top panels) and their corresponding end-capillary blood concentrations (lower panels). The three solid circles in each case represent values for ventilation-perfusion ratios of 0.1, 1.0, and 10. (See text for further details.)

the vasculature, respectively. The abbreviation c′ stands for end capillary blood; $\bar{v}$ for mixed venous (pulmonary arterial) blood.

Since Eq. (1) and (2) both describe the same O_2 flux rate ($\dot{V}_{O_2}$), they may be set equal to each other:

$$\dot{V}_A[F_{I_{O_2}} - FA_{O_2}] = \dot{Q}[Cc'_{O_2} - C\bar{v}_{O_2}] \qquad (4)$$

and rearranged so that:

$$\dot{V}_A/\dot{Q} = [Cc'_{O_2} - C\bar{v}_{O_2}]/[F_{I_{O_2}} - FA_{O_2}] \qquad (5)$$

It should further be noted that because diffusion equilibration of O_2 transfer across the alveolar-capillary membrane is assumed to be complete, alveolar P_{O_2} and end-capillary P_{O_2} are identical. Hence, the relationship between FA_{O_2} and Cc'_{O_2} is uniquely dictated by the O_2-Hb dissociation curve such that knowing FA_{O_2} allows us to determine directly Cc'_{O_2} (or vice versa).

Equation (5) is very revealing and explains directly the role of the $\dot{V}_A/\dot{Q}$ ratio in governing alveolar gas exchange. This equation states that for a *given* set of what may be called boundary conditions (i.e., composition of inspired gas and mixed venous blood, represented here by $F_{I_{O_2}}$ and $C\bar{v}_{O_2}$, respectively, and for a known O_2-Hb dissociation curve), alveolar (and, thus, end capillary) P_{O_2} is *uniquely* determined by the ratio of alveolar ventilation ($\dot{V}_A$) to blood flow ($\dot{Q}$).

Under the given assumptions, summarized as: (1) continuous and constant ventilation and blood flow; (2) steady-state conditions; (3) diffusion equilibration of alveolar-capillary exchange; and (4) equality of inspired and expired ventilation, equations identical in construct to Eq. (5) can be written for any gas being exchanged by the lung.

For CO_2, this produces Eq. (6):

$$\dot{V}_A/\dot{Q} = [C\bar{v}C_{O_2} - Cc'C_{O_2}]/[FA_{CO_2} - F_{I_{CO_2}}] \qquad (6)$$

The order of bracketed terms on the right is reversed to maintain positive numbers, since CO_2 is being eliminated from the blood. Of course, $F_{I_{CO_2}}$ is almost always zero and thus drops out of the equation.

Unfortunately, neither Eq. (5) nor (6) is amenable to simple quantitative solutions, because of the complexity of the O_2 and CO_2 dissociation curves. However, the equations are readily explored by appropriate computerized numerical analyses. Using such programs, one can explore the relationship between $\dot{V}_A/\dot{Q}$ ratio and alveolar P_{O_2} and P_{CO_2}, and this is done in Fig. 11-6. These relationships are important because they indicate what degrees of $\dot{V}_A/\dot{Q}$ abnormality are required to affect gas exchange for both O_2 and CO_2. The four panels of Fig. 11-6 show alveolar P_{O_2} and P_{CO_2} as well as end-capillary O_2 and CO_2 concentrations. The latter better reflect total gas exchange as a function of $\dot{V}_A/\dot{Q}$ ratio. Specific conditions for Fig. 11-6 are such that mixed venous blood P_{O_2} is 40 mmHg and P_{CO_2} 45 mmHg, normal resting values. Also, inspired gas is room air, and [Hb] is 15 gm dl^{-1}. In each panel, the three solid circles are positioned at the normal $\dot{V}_A/\dot{Q}$ ratio (of about 1.0) and at $\dot{V}_A/\dot{Q}$ ratios 10 times greater and less. All four relationships are highly nonlinear. Focusing on the two lower panels, it is evident for O_2 that a 10-fold reduction in $\dot{V}_A/\dot{Q}$ greatly reduces local O_2 transport, whereas a 10-fold increase barely improves it. Furthermore, as $\dot{V}_A/\dot{Q}$ falls even lower than 0.1, there is little further loss in O_2 transport. However, there is little protection against a fall in $\dot{V}_A/\dot{Q}$ below 1.0, the curve is very steep below a $\dot{V}_A/\dot{Q}$ of 1.0, as the lower left panel shows. For CO_2, the curves

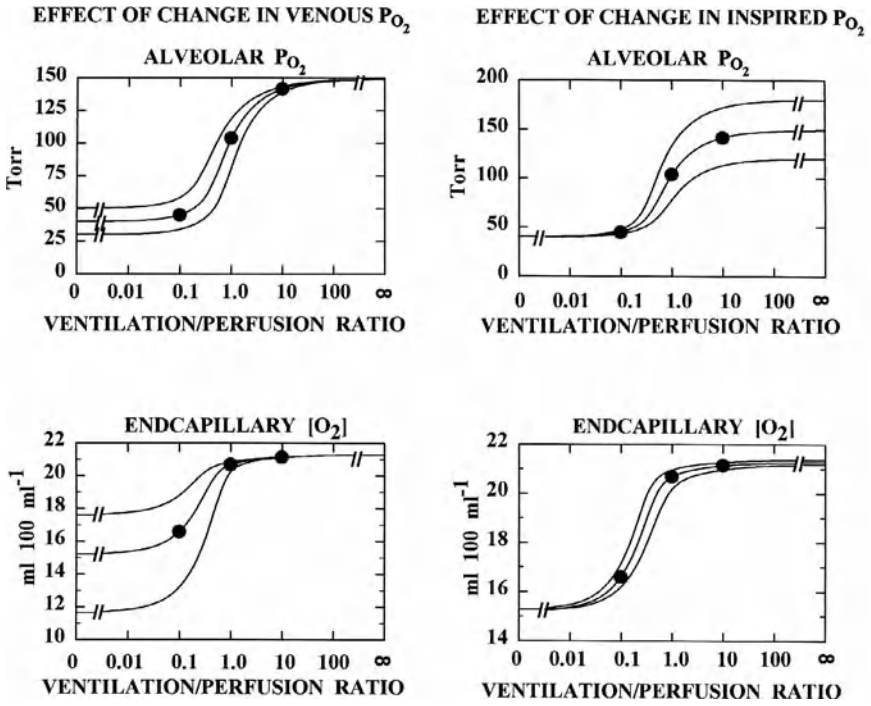

Figure 11-7 Effects of changes in mixed venous P_{O_2} (left panels) or inspired P_{O_2} (right panels) on alveolar P_{O_2} and associated end-capillary oxygen concentrations. Note that changes in venous P_{O_2} mostly affect values associated with low ventilation-perfusion ratios, whereas changes in inspired P_{O_2} affect units throughout the $\dot{V}_A/\dot{Q}$ range, especially those with medium to high $\dot{V}_A/\dot{Q}$ ratios.

are opposite in slope (P_{CO_2} falls as $\dot{V}_A/\dot{Q}$ increases). However, unlike the case for O_2, there is little difference between a $\dot{V}_A/\dot{Q}$ of 1.0 and a 10-fold reduction, whereas an increase in $\dot{V}_A/\dot{Q}$ considerably reduces alveolar P_{CO_2} and end-capillary CO_2 concentration. The reason for the differences between O_2 and CO_2 lies mainly in the slopes of their dissociation curves: That for CO_2 is about 10-fold greater than that for O_2. It has been shown that the higher the slope of the dissociation curve (or equivalently for an anesthetic gas, its solubility) the more it is sensitive to areas of high $\dot{V}_A/\dot{Q}$. The lower the slope or solubility, the more the gas is affected by areas of low $\dot{V}_A/\dot{Q}$. Consequently, areas of low $\dot{V}_A/\dot{Q}$ predictably cause more reduction in arterial P_{O_2} than increase in arterial P_{CO_2}. Although Fig. 11-6 is true strictly only for the stated "boundary" conditions (i.e., mixed venous blood and inspired gas composition), the principles hold even for different such conditions, as shown in Fig. 11-7 for O_2. The left panels illustrate how changes in mixed venous P_{O_2} alone affect alveolar P_{O_2} and end-capillary $[O_2]$ via Eq. (4). The right panels correspondingly show how change in inspired P_{O_2} affects O_2. Venous P_{O_2} is selected at 30, 40, and 50 mmHg, and inspired P_{O_2} is chosen to be 120, 150, and 180 mmHg. Changes in venous P_{O_2} dramatically affect P_{O_2} and $[O_2]$ in unventilated and poorly ventilated regions as well as regions approaching normal, but have no real effect on high $\dot{V}_A/\dot{Q}$ alveoli. Altering inspired P_{O_2} (but not venous) has the converse effect if P_{O_2} is examined (top right panel), but, because of the nonlinear shape of the O_2-Hb dissociation curve, effects on $[O_2]$ are minimal in high $\dot{V}_A/\dot{Q}$ areas, small in very low $\dot{V}_A/\dot{Q}$ areas, and more significant between $\dot{V}_A/\dot{Q}$ ratios of 0.1 and 1.0 (bottom right panel). This figure shows how the inspired and mixed venous "boundary conditions" alter the magnitude (but not basic patterns) of alveolar gas exchange.

If one returns to the normal boundary conditions ($P\bar{v}_{O_2} = 40$ mmHg, $P_{I_{O_2}} = 150$ mmHg), one can explore the consequences of $\dot{V}_A/\dot{Q}$ inequality on gas exchange. In reality, the complex structure of the lungs defies a simple analysis but conceptually even a two-compartment model is an invaluable aid to understanding this difficult area.

Figure 11-8 shows such a simple two-compartment model in three configurations: (1) each compartment equally ventilated and perfused such that there is no $\dot{V}_A/\dot{Q}$ inequality; (2) the left compartment hypoventilated due to airway obstruction, causing $\dot{V}_A/\dot{Q}$ inequality; and (3) the

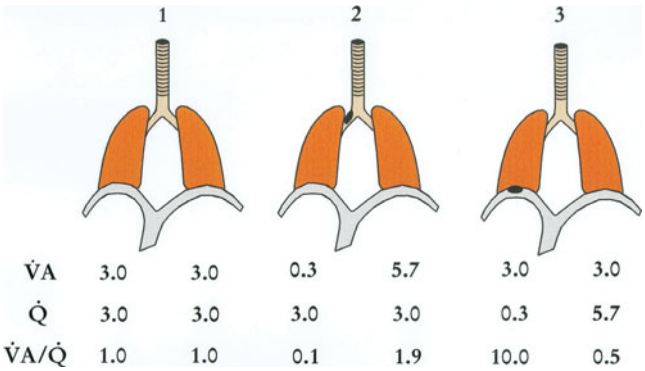

Figure 11-8 Three two-compartment models of ventilation-perfusion relationships. Model 1 represents an ideal lung without ventilation-perfusion mismatch. Model 2 represents a lung in which one compartment has a 90 percent reduction in its alveolar ventilation due to airway obstruction, and Model 3 is a lung in which one compartment has a 90 percent reduction in capillary blood flow due to vascular obstruction. Ventilation, blood flow, and ventilation-perfusion ratio of each compartment are indicated. Total ventilation and total blood flow remain the same among the three models. (See text for further details.)

left compartment hypoperfused from vascular obstruction. Table 11-1 shows the corresponding O_2 and CO_2 calculations for each compartment. Specific assumptions common to all three models are: (1) the mixed venous P_{O_2} remains at 40 mmHg; inspired P_{O_2} is constant at 150 mmHg; total alveolar ventilation summed over both compartments is constant as is total blood flow, both taken to be 6 L/min; [Hb] is constant at 15 g dl. Further, airways obstruction reduces L-hand compartmental ventilation from 3.0 to 0.3 L/min, redistributing the balance to the R-hand compartment. Vascular obstruction is of the same order as the right panel of the figure shows. Note that for *both* obstructive models, one compartment has developed a $\dot{V}_A/\dot{Q}$ ratio less than average and the other a $\dot{V}_A/\dot{Q}$ ratio greater than average, irrespective of the location of the obstruction.

Using the curves of Fig. 11-6, for $P\bar{v}_{O_2} = 40$ mmHg and $P_{I_{O_2}} = 150$ mmHg, $P\bar{v}_{CO_2} = 45$ mmHg and $P_{I_{CO_2}} = 0$ mmHg, alveolar P_{O_2} and P_{CO_2} are listed for each compartment of Fig. 11-8 in Table 11-1.

In Table 11-1, alveolar diffusion equilibration is assumed to be complete such that alveolar P_{O_2} ($P_{A_{O_2}}$) equals end capillary P_{O_2} (Pc'_{O_2}); the same holds for P_{CO_2}. In each obstructive model, the low $\dot{V}_A/\dot{Q}$ compartment has a lower-than-average P_{O_2} and higher-than-average P_{CO_2}, as Fig. 11-6 dictates. The converse is seen for the compartment of high $\dot{V}_A/\dot{Q}$ ratio. Corresponding end capillary O_2 and CO_2 concentrations are also listed in Table 11-1.

The question is what will the mixed arterial blood and mixed expired gas O_2 and CO_2 levels change to as a result of obstruction of one compartment, and how will this affect the ability of the total system to exchange O_2 and CO_2? To answer these questions one applies simple mixing equations to the two individual compartments (left [L] and right [R]):

For O_2:

$$P\bar{A}_{O_2} = (P_{A_{O_{2L}}} \times \dot{V}_{A_L} + P_{A_{O_{2R}}} \times \dot{V}_{A_R})/(\dot{V}_{A_L} + \dot{V}_{A_R})$$
$$Ca_{O_2} = (Cc'_{O_{2L}} \times \dot{Q}_L + Cc'_{O_{2R}} \times \dot{Q}_R)/(\dot{Q}_L + \dot{Q}_R) \quad (7)$$

For CO_2, identical equations apply. These mixing equations conserve mass and use the principle that the two gas or blood streams combine in a manner proportional to their relative ventilation and blood flow, respectively. Table 11-1 lists the results of these calculations, giving mixed alveolar partial pressure ($P\bar{A}_{O_2}$, $P\bar{A}_{CO_2}$) and mixed arterial concentrations (Ca_{O_2}, Ca_{CO_2}). From the blood gas concentration, corresponding arterial partial pressures (Pa_{O_2}, Pa_{CO_2}) are read directly off the O_2 and CO_2 dissociation curves. Finally, whole-lung computations of O_2 and CO_2 exchange rates (ml/min^{-1}) are determined using relevant equations and the mixed alveolar or arterial data, respectively, and the mixed alveolar to arterial partial pressure differences expressed for each gas.

The results are very instructive. Both obstructive models result in hypoxemia and slight hypercapnia, but the effects on arterial P_{O_2} and on the alveolar-arterial P_{O_2} difference greatly exceed those for CO_2 due to both shape and slope differences between the dissociation curves of the two gases. Airways obstruction produces *more* hypoxemia but *less* hypercapnia than the identical degree of vascular obstruction. This reflects the 10-fold greater dissociation curve slope of CO_2 compared to O_2, rendering O_2 relatively more susceptible to the lower $\dot{V}A/\dot{Q}$ areas seen in the airway obstruction model (0.1 vs. 0.5) (Fig. 11-8) and CO_2 relatively more susceptible to the higher $\dot{V}A/\dot{Q}$ areas of vascular obstruction (10.0 vs. 1.9) (see Fig. 11-8) as Fig. 11-6 would predict.

Both models have impaired overall O_2 and CO_2 exchange (recall that venous blood, inspired gas, total ventilation, and blood flow were all considered fixed and identical for all three models) as a result of the development of $\dot{V}A/\dot{Q}$ mismatch. In keeping with the differential sensitivity of O_2 and CO_2 to regions of low and high $\dot{V}A/\dot{Q}$, as discussed above, total O_2 transport is diminished to a greater extent in the airway obstruction model than in the vascular obstruction model (see Table 11-1). The converse is true for CO_2, also shown in Table 11-1.

The principal effects of $\dot{V}A/\dot{Q}$ inequality as they apply to O_2 and CO_2 exchange may thus be listed: $\dot{V}A/\dot{Q}$ inequality:

1. Affects both gases, no matter what the pathological basis of the inequality
2. Causes arterial hypoxemia and hypercapnia
3. Causes usually more severe hypoxemia than hypercapnia
4. Affects O_2 more than CO_2 when very low $\dot{V}A/\dot{Q}$ regions develop
5. Affects CO_2 more than O_2 when very high $\dot{V}A/\dot{Q}$ regions develop
6. Impairs total O_2 and CO_2 exchange by the lung
7. Creates alveolar-arterial differences for both gases

Compensation for Effects of $\dot{V}_A/\dot{Q}$ Mismatch

The preceding analysis shows that if no changes in total ventilation, blood flow, mixed venous blood, or inspired gas composition occur, O_2 and CO_2 transfer across the lung is compromised. This is not viable in the steady state: The lungs must find a way to restore total O_2 and CO_2 transfer to levels equal to metabolic use of O_2 and production of CO_2. This leads to the next concentric level of consideration of $\dot{V}A/\dot{Q}$ inequality referred to at the start of this section.

What compensatory mechanisms exist to achieve restoration of O_2 and CO_2 transfer, assuming that the initial pathophysiological insults have persisted unchanged? The same models as in Fig. 11-8 and Table 11-1 are used.

CHANGES IN MIXED VENOUS BLOOD The only possible short-term compensatory changes are in mixed venous blood, total ventilation, and cardiac output. (Hb change in response to tissue hypoxia requires days to weeks to develop and then is by no means always observed; changing inspired P_{O_2} is not usually an option until the patient seeks medical attention.) To reduce complexity, changes in venous blood alone are addressed first.

If it is assumed that there is no limit to how much O_2 can be extracted from the arterial blood by the peripheral tissues, it is evident that $\dot{V}A/\dot{Q}$ inequality will passively lead to a reduced venous P_{O_2} and increased venous P_{CO_2}. This is deduced simply from the hypoxemia and hypercapnia initially produced by the $\dot{V}A/\dot{Q}$ insult, together with the need to extract the same amount of O_2 from (and add CO_2 to) each ml of blood perfusing the tissues as before the $\dot{V}A/\dot{Q}$ insult developed.

If venous P_{O_2} falls (and P_{CO_2} rises), Fig. 11-7 indicates that alveolar P_{O_2} will fall in each $\dot{V}A/\dot{Q}$ compartment (as will P_{CO_2} rise). Thus, a circle of events is set so that if a single red cell were followed around the circulation, at each passage through the lungs and then tissues, P_{O_2} would fall progressively with each circuit of the body.

Although not intuitively obvious, this reduction in both arterial and venous P_{O_2} will not "bottom out" at zero (or in the case of CO_2 rise toward infinity) unless the $\dot{V}A/\dot{Q}$ insult was fatally overwhelming in the first place. Both arterial and venous P_{O_2} restabilize at new lower values (P_{CO_2} values will be higher) than were present immediately after the $\dot{V}A/\dot{Q}$ insult developed. In so doing, $\dot{V}_{O_2}$ and $\dot{V}_{CO_2}$ are restored to normal values.

To explore this quantitatively, we continue on with the models of Fig. 11-8 and Table 11-1 to show just what changes in venous and arterial P_{O_2} and P_{CO_2} must occur as a result of this process in order to restore pulmonary O_2 and CO_2 exchange to normal. The values are shown in Table 11-2. For the airways obstruction model, the passive blood gas changes are greater for O_2 than CO_2, consonant with the greater initial decrement in O_2 exchange caused by airways obstruction in the first place. For the vascular obstruction model, the effects are more marked for CO_2, for corresponding reasons. To restore $\dot{V}_{O_2}$ and $\dot{V}_{CO_2}$ in the airways obstruction model, hypoxemia is now more severe, but hypercapnia is mild. However, with vascular obstruction, hypoxemia remains mild, while hypercapnia is severe. In both cases, the lung is meeting the original healthy requirement of transferring 328 and 270 ml/min of O_2 and CO_2, respectively.

The speed of passive venous blood composition changes is very rapid, taking place in seconds to minutes as the blood moves continuously around the vascular system

Table 11-2

Gas Exchange Effects of Passive Changes in Mixed Venous Blood-Gas Values Required to Restore $\dot{V}_{O_2}$ and $\dot{V}_{CO_2}$ to Normal in the Models of Figure 11-8

	Airways Obstruction Model		Vascular Obstruction Model	
	Before Change	After Change	Before Change	After Change
$P\bar{v}_{O_2}$, mmHg	40.0	30.4	40.0	39.5
$P\bar{v}_{CO_2}$, mmHg	45.0	50.7	45.0	62.4
Pa_{O_2}, mmHg	55	46	77	67
Pa_{CO_2}, mmHg	39.0	44.5	40.9	55.6
$\dot{V}_{O_2}$, ml/min	212.0	328 (normal)	294.0	328.0
$\dot{V}_{CO_2}$, ml/min	234.0	270 (normal)	203.0	270.0

between lungs and tissues. The principal effects of the changes can be summarized as follows:

1. Following development of $\dot{V}A/\dot{Q}$ mismatch, and a fall in $\dot{V}_{O_2}$ and $\dot{V}_{CO_2}$ at the lungs, mixed venous P_{O_2} will fall and mixed venous P_{CO_2} will rise to restore pulmonary $\dot{V}_{O_2}$ and $\dot{V}_{CO_2}$ to equal the original metabolic requirements for O_2 and CO_2 transport.
2. As a result, there will always be a further fall in arterial P_{O_2} and rise in arterial P_{CO_2}, compared with conditions prior to mixed venous blood changes.
3. When the $\dot{V}A/\dot{Q}$ insult primarily involves development of extremely low $\dot{V}A/\dot{Q}$ areas, those effects are more marked for O_2 than for CO_2.
4. When the $\dot{V}A/\dot{Q}$ insult primarily consists of high $\dot{V}A/\dot{Q}$ areas, CO_2 is affected more than O_2.

CHANGES IN TOTAL VENTILATION When either low or high $\dot{V}A/\dot{Q}$ areas develop and the mixed venous and arterial adjustments occur as described, there is hypoxemia and hypercapnia. Either or both may well stimulate an immediate increase in total ventilation, which will alleviate to some extent both the hypoxemia and hypercapnia. Fig. 11-9 shows for the same two examples used above how increases in alveolar ventilation (distributed in the same proportions as in each of the two $\dot{V}A/\dot{Q}$ models of Fig. 11-8) variably improve arterial P_{O_2} and P_{CO_2}. In the low $\dot{V}A/\dot{Q}$ (airways obstruction) model, a 50 percent increase in total alveolar ventilation from the normal value of 6 L/min^{-1} to 9 L/min^{-1} drops arterial P_{CO_2} to almost 30 mmHg, well below the normal standard value of 40 mmHg. Arterial P_{O_2}, however, is not affected at all. This is because even a 50 percent increase in ventilation of the very poorly ventilated unit fails to significantly increase

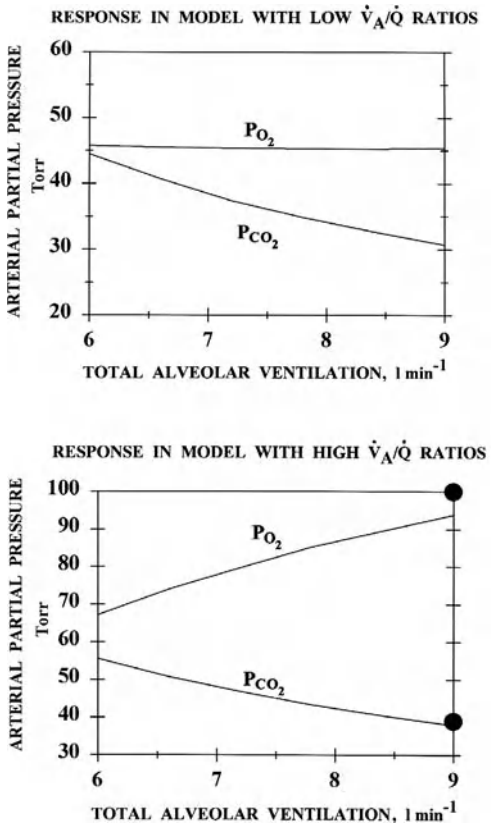

Figure 11-9 Effect of increasing alveolar ventilation on arterial P_{O_2} and P_{CO_2} in the two models with ventilation-perfusion inequalities in Fig. 11-8. The top panel is that for Model 2, and the bottom panel is that for Model 3. Increasing ventilation is ineffective in restoring arterial P_{O_2} in the low $\dot{V}A/\dot{Q}$ model 2, but much more effective in the high $\dot{V}A/\dot{Q}$ model 3. Both models respond in terms of P_{CO_2}. The filled circles in the lower panel indicate arterial P_{O_2} and P_{CO_2} for a lung with normal alveolar ventilation and no $\dot{V}A/\dot{Q}$ inhomogeneity.

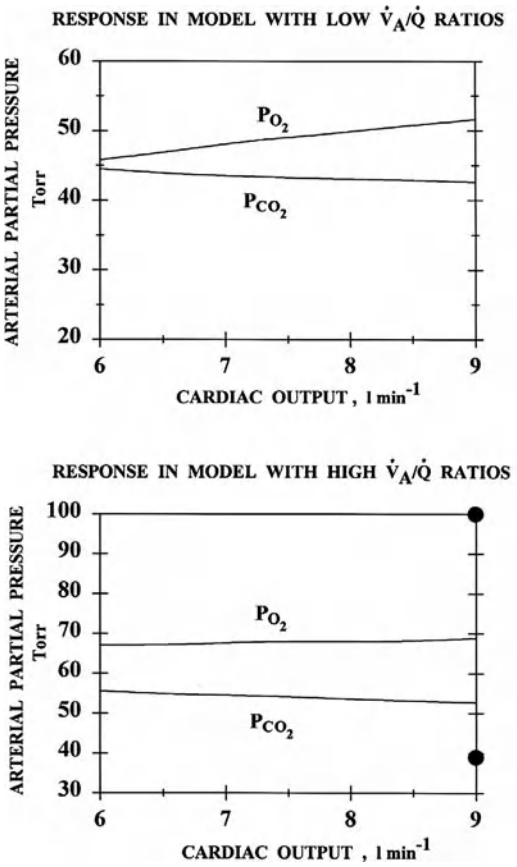

Figure 11-10 Effects of increases in cardiac output on arterial P_{O_2} and P_{CO_2} in Models 2 and 3 of Fig. 11-8. Cardiac output produces a significant rise in P_{O_2} in the presence of regions of very low ventilation-perfusion ratio (top panel) but has little influence in the presence of higher ventilation-perfusion ratios (bottom panel). P_{CO_2} is affected only minimally in either case. The filled circles in the lower panel indicate arterial P_{O_2} and P_{CO_2} for a lung with normal alveolar ventilation and no $\dot{V}_A/\dot{Q}$ inhomogeneity.

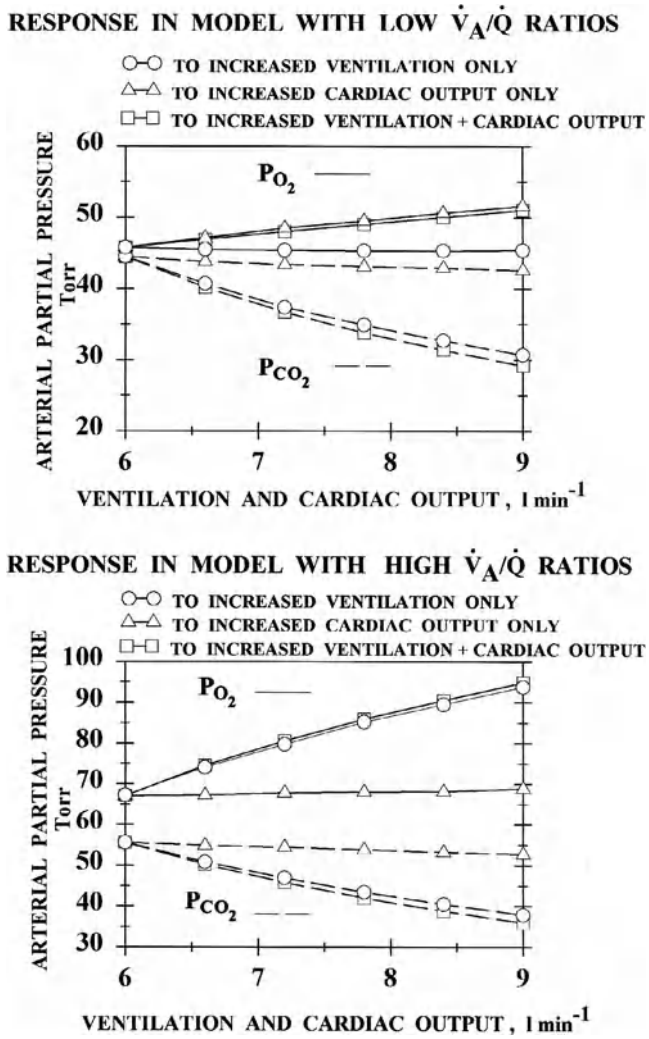

Figure 11-11 Responses to simultaneous increases in ventilation and cardiac output (compared to responses to individual increases as shown in Figs. 11-9 and 11-10). Simultaneous increases do not provide for significantly more improvement than with either alone. o-o = response to increased ventilation only; Δ-Δ = response to increased cardiac output only; □-□ = response to simultaneously increased ventilation and cardiac output.

end-capillary P_{O_2} of that unit (see Fig. 11-6), whereas in the better ventilated unit of that model, Hb in the end-capillary blood was already virtually fully saturated before the increase in ventilation.

For the model with vascular obstruction, a 50 percent increase in alveolar ventilation returns both P_{O_2} and P_{CO_2} to near-normal values (see Fig. 11-9, lower panel). The difference in the two model responses to ventilation reflects the original $\dot{V}_A/\dot{Q}$ ratios of the two compartments; that is, where they lie on the curves of Fig. 11-6.

CHANGES IN CARDIAC OUTPUT One final compensatory adjustment is possible—an increase in cardiac output. Adrenergic stimulation by arterial hypoxemia can raise cardiac output by 50 percent or more, and this also tends to improve arterial blood gases by raising mixed venous P_{O_2} (and lowering mixed venous P_{CO_2}). Fig. 11-10 shows the effects on arterial P_{O_2} and P_{CO_2} of such increases, as done for ventilation in Fig. 11-9, again assuming that the relative distribution of blood flow remains unaltered between the two compartments as total blood flow is increased. For a lung with airways obstruction causing very low $\dot{V}_A/\dot{Q}$ regions (upper panel), an increase in cardiac output significantly improves arterial oxygenation—more so than does the same relative increase in ventilation. However, arterial P_{CO_2} is only slightly improved. In stark contrast, increases in cardiac output barely alter arterial P_{O_2} and P_{CO_2} in the high $\dot{V}_A/\dot{Q}$ ratio model (see Fig. 11-9), especially when it is recalled how effective an increase in ventilation is in restoring arterial P_{O_2} and P_{CO_2}.

When both ventilation and cardiac output are simultaneously increased, there is no real synergistic effect (Fig. 11-11): P_{O_2} and P_{CO_2} are improved as predicted from the individual changes (i.e., as shown above in Figs. 11-9 and 11-10).

In all the calculations depicted in Figs. 11-9 to 11-11, the two-compartment models are exchanging the necessary

amounts of O_2 and CO_2 to sustain normal metabolism. Depending on the ventilatory and cardiovascular responses to the original insult causing $\dot{V}_A/\dot{Q}$ mismatch and the fundamental pattern of $\dot{V}_A/\dot{Q}$ mismatch (i.e., the preponderance of low and/or high $\dot{V}_A/\dot{Q}$ areas), it is possible to observe hypercapnia, normocapnia, or hypocapnia. However, it is very uncommon for arterial P_{O_2} to be fully normalized by the compensatory mechanisms, and the observed degree of hypoxemia can be extremely variable. As an important clinical corollary, it becomes difficult to establish the severity of the $\dot{V}_A/\dot{Q}$ insult per se when the extent of compensating mechanisms cannot be easily established, since these two aspects are so intertwined in their resulting effect on gas exchange.

ASSESSMENT OF VENTILATION-PERFUSION INEQUALITY

Whereas the preceding discussion highlights the complexity of how $\dot{V}_A/\dot{Q}$ inequality impairs gas exchange, there is a need for methods to assess the extent of such mismatch in the clinical setting. The *multiple inert gas elimination technique* was developed expressly for this purpose. Although the technique provides the necessary descriptions of the extent and pattern of inequality, it remains a complex technique that is not well-suited to routine clinical use. Several traditional quantifying indices of $\dot{V}_A/\dot{Q}$ mismatch remain useful on a daily basis. They all make use of O_2 and CO_2 as indicator gases:

The first is the alveolar-arterial P_{O_2} difference, $P_{AO_2} - Pa_{O_2}$. This is the difference between alveolar P_{O_2} (P_{AO_2}, calculated from the alveolar gas equation presented below) and the measured arterial P_{O_2} (Pa_{O_2}). The $P_{AO_2} - Pa_{O_2}$ is therefore given by:

$$P_{I_{O_2}} - P_{CO_2}/R + P_{CO_2} \times F_{I_{O_2}} \times (1 - R)/R - Pa_{O_2} \quad (8)$$

Use of this equation requires knowledge of inspired P_{O_2} and $[O_2]$, the respiratory exchange ratio R, and the ideal alveolar P_{CO_2}, which is that P_{CO_2} would be observed in alveolar gas of a homogeneous lung having the R value of the patient's actual lung at the time. Three problems arise with the application of this equation. First, the result is very dependent on $P_{I_{O_2}}$ even when the amount of $\dot{V}_A/\dot{Q}$ inequality does not change as $P_{I_{O_2}}$ is varied. Second, the value of R is generally not known and must be assumed. Third, in some cases, the usual substitution for the ideal alveolar P_{CO_2}, the measured arterial P_{CO_2}, leads to a systematic error because arterial P_{CO_2} can be significantly higher than the ideal alveolar value. However, $P_{AO_2} - Pa_{O_2}$ remains a useful index of $\dot{V}_A/\dot{Q}$ inequality providing these limitations are kept in mind.

The second index is simply the ratio of arterial P_{O_2} to $F_{I_{O_2}}$, which in a perfectly normal lung is virtually insensitive to $P_{I_{O_2}}$, a major advantage. However, even that is an oversimplification, because this ratio may not be as constant as hoped for depending on the pattern of $\dot{V}_A/\dot{Q}$ inequality present.

A third index is venous admixture ($\dot{Q}_S/\dot{Q}_T$) or, equivalently, physiological shunt. This is a parameter that expresses what magnitude shunt would have to be present in a particular case to explain a patient's arterial P_{O_2} if that shunt were the sole cause of hypoxemia. The formula is:

$$\text{percent } \dot{Q}_S/\dot{Q}_T = 100 \times [Cc'_{O_2} - Ca_{O_2}]/[Cc'_{O_2} - C\bar{v}_{O_2}] \quad (9)$$

where

Cc'_{O_2} = the calculated end capillary $[O_2]$ of blood perfusing a hypothetical alveolus exchanging gas at the overall respiratory exchange ratio of the patient's actual lungs

Ca_{O_2} is arterial and $C\bar{v}_{O_2}$ mixed venous $[O_2]$, respectively. This parameter, working in the O_2 concentration domain (rather than the partial pressure domain of the $P_{AO_2} - Pa_{O_2}$), better reflects the degree of gas exchange defect but requires knowledge of the ideal alveolar conditions to calculate Cc'_{O_2}, as well as [Hb]. It also is sensitive to $P_{I_{O_2}}$ in that when $\dot{V}_A/\dot{Q}$ inequality is present, its contribution to $\dot{Q}_S/\dot{Q}_T$ diminishes progressively as $P_{I_{O_2}}$ is raised. However, the most limiting aspect of this parameter is the need to know the value of $C\bar{v}_{O_2}$, reflecting mixed venous blood. If this must be assumed rather than measured, the value of $\dot{Q}_S/\dot{Q}_T$ will be only as good as the assumption, which may be extremely misleading if changes in $C\bar{v}_{O_2}$ in fact occur but are not accounted for in the $\dot{Q}_S/\dot{Q}_T$ calculation.

Finally, using the arterial and mixed expired partial pressures of CO_2 (Pa_{CO_2}, $P\bar{E}_{CO_2}$, respectively), a very similar calculation to $\dot{Q}_S/\dot{Q}_T$ can be performed to compute the percentage of total ventilation that is wasted on nongas exchanging (dead space) areas of the lungs. As for $\dot{Q}_S/\dot{Q}_T$, the calculation determines the magnitude of the dead space that would have to be present to dilute the arterial P_{CO_2} down to the mixed expired level if that dead space were the only abnormality in ventilation. Expressed as dead space (V_D)/tidal volume (V_T) percentage:

$$\text{percent } V_D/V_T = 100 \times [Pa_{CO_2} - P\bar{E}_{CO_2}/[Pa_{CO_2}] \quad (10)$$

This parameter is independent of $P_{I_{O_2}}$, but is weakened by the fact that the normal airway conducting volume is included in the computed result. Thus, it may be difficult to separate how much the V_D/V_T value represents this normal anatomic dead space as opposed to reflecting $\dot{V}_A/\dot{Q}$ inequality among the alveoli. This problem is amplified because normally V_D/V_T is very dependent on the size of the tidal volume even if the dead space volume itself is essentially constant. Thus, for a dead space volume of 150 ml and a tidal volume of 500 ml, V_D/V_T is 30 percent, but if tidal volume were to drop to 400 ml, V_D/V_T would become 38 percent, not because $\dot{V}_A/\dot{Q}$ inequality has developed, but simply because smaller breaths are being taken.

In summary, no index of $\dot{V}_A/\dot{Q}$ inequality is without potentially significant limitations, both quantitative and qualitative. However, if these limitations are recognized and the

data interpreted accordingly, they still remain very useful indices of clinical gas exchange function.

Diffusion, Chemical Reactions, and Diffusing Capacity

Robert A. Klocke

Uptake of oxygen and excretion of carbon dioxide require rapid, efficient exchange in the lung. The quantities of exchanged gases are staggering. For example, an 1800-calorie diet requires absorption of 375 L of oxygen per day, as well as excretion of a slightly smaller volume of carbon dioxide. Because blood remains in the pulmonary capillary bed for a limited time, the process of exchange must be accomplished in less than 1 s at rest and one-half that time during exercise. This rapid, high-volume exchange occurs efficiently despite numerous interacting processes of diffusion and chemical reaction that occur in the lung. The rates of these processes not only are affected by intrinsic characteristics of blood, but also are determined by a host of other factors, including inspired oxygen fraction, alveolar gas tensions, cardiac output, and metabolic activity. The ease of exchange of respiratory gases belies the complexity of the overall process.

DIFFUSION

Gases diffuse from a higher to a lower partial pressure, not necessarily from a higher to a lower concentration. This fact is especially pertinent when a gas diffuses between two phases, as occurs when O_2 and CO_2 are exchanged between alveolar gas and blood. For example, dissolved CO_2 diffuses down a partial pressure gradient from blood (46 mmHg) into the alveolus (40 mmHg), even though its actual concentration (millimoles of molecular CO_2 per liter of gas or blood) is greater in alveolar gas (2.5) than it is in venous blood (1.4).

Influence of Physical Properties

The concentration (C) of a gas (x) dissolved in fluid depends upon its partial pressure (P) and solubility (α)

$$C_x = \alpha_x P_x \qquad (1)$$

Gas diffusion occurs down a partial pressure gradient, but the quantity of gas transported is critically dependent on its solubility in the medium in which diffusion occurs. Hence, the rate ($\dot{V}_x$) of a gas (x) crossing the alveolar-capillary membrane at any instant in time (t) is

$$\dot{V}_x(t) = \frac{Ak_x\alpha_x[P_{A_x}(t) - P_{cap_x}(t)]}{h} \qquad (2)$$

where

A and h = the surface area and thickness of the membrane

k_x and α_x = the diffusion and solubility coefficients of the gas in the membrane

$[P_{A_x}(t) - P_{cap_x}(t)]$ = the partial-pressure gradient between alveolar and capillary blood at time (t)

The diffusion coefficient (k_x) of a gas in the alveolar-capillary membrane is largely a function of the size of the gas molecule, which is inversely proportional to the square root of its molecular weight (MW). Oxygen (MW 32) has a slightly greater diffusion coefficient than carbon dioxide (MW 44) in the alveolar membrane. However, the solubility of CO_2 in water, the major component of tissue composing the membrane, is 20-fold greater than the solubility of O_2. This difference far outweighs the effect of the slightly smaller size of the oxygen molecule. Thus, CO_2 transfer across the alveolar membrane is approximately 20 times greater than O_2 transfer when both gases diffuse under the same partial-pressure gradient. As a result, a much greater P_{O_2} gradient across the membrane is required to maintain O_2 transfer equal to that of CO_2.

The rate of diffusion is affected by the viscosity of the medium through which the diffusion occurs. Diffusion of a gas in air occurs at a rate that is four orders of magnitude greater than diffusion in water. Diffusion coefficients in tissues are only moderately less than those in water, since most tissues are composed primarily of water. The interior of the erythrocyte is an exception to this general rule. As a consequence of the high concentration of hemoglobin inside the red cell, the viscosity of the cell contents is substantially greater than that of water. This greater viscosity reduces the diffusion coefficient for oxygen to one-third of its aqueous coefficient. The combination of increased viscosity and the large size of the hemoglobin molecules decreases the diffusion coefficient of hemoglobin within the red cell to less than 10 percent of its diffusion coefficient in a dilute aqueous solution. As a result, significant diffusion gradients are thought to exist within the red cell even though the distance between the cell membrane and the innermost portion of the cell is only a few microns.

Effect of Different Capacitances

The alveolar-capillary membrane is the only barrier to diffusion of gases between the alveoli and the capillaries. The rate of approach to diffusion equilibrium of a gas in the lung is dependent on the capacitances of the gas in the alveoli and blood relative to its solubility in the alveolar-capillary membrane. Normal ventilation of alveoli results in a large reservoir of oxygen with a pressure of ~100 mmHg to promote diffusive transfer across the alveolar-capillary membrane. The ability of hemoglobin to bind O_2 increases the oxygen capacity of blood by two orders of magnitude compared with that of the alveolar-capillary membrane. This large capacitance for oxygen in blood requires substantial oxygen transfer across the membrane to reach diffusion equilibrium. Because the solubility of oxygen in the membrane is small relative to the large capacitances in alveolar gas and blood, oxygen exchange across the membrane requires 0.3 to 0.4 s to reach equilibrium. Fortunately, this delay in reaching equilibrium is less than the average of 0.5 to 1.0 s that blood remains in the pulmonary capillary bed.

In contrast to oxygen, the solubility of carbon dioxide in the membrane is sufficiently great compared to the capacitances of CO_2 in blood and alveoli to permit rapid equilibration of CO_2 across the alveolar-capillary membrane. As discussed below, CO_2 exchange requires a finite time for completion, but this delay is the result of the time needed to complete chemical and transport processes in blood, and is not the result of impairment of diffusion across the alveolar-capillary membrane.

Gases transported in blood only in dissolved form are exchanged almost instantaneously across the alveolar-capillary membrane. As long as gas solubilities in the membrane and blood are similar, diffusion equilibrium between alveolar contents and blood is reached within 0.01 s because the normal alveolar-capillary membrane is extremely thin (median thickness of 0.3 μm). Only gases such as oxygen or carbon monoxide that have large alveolar and blood capacitances and reduced solubility in the alveolar-capillary membrane will require a finite time to reach diffusive equilibrium.

CHEMICAL REACTIONS OF GASES

Transport of respiratory gases entails numerous chemical reactions with components of the blood. Like diffusive transport of oxygen, these chemical reactions are not instantaneous and require finite periods of time to reach completion. It is commonly thought that diffusion provides the greatest time-dependent impediment to gas exchange, but in actuality, chemical processes, especially those occurring in combination with diffusion or other chemical reactions, are more likely to slow rates of exchange.

Oxygen and Carbon Monoxide

From a stoichiometric viewpoint, the binding of O_2 to each of the four heme moieties of the hemoglobin tetrameter is described by four successive steps, each with a separate association and dissociation rate constant. If the four heme rings acted independently, these constants would be the same for each heme ring and the resulting dissociation curve would have a hyperbolic shape. However, binding of oxygen to one of the heme rings affects the affinity for O_2 of the remaining heme moieties of the tetrameric molecule, leading to the familiar sigmoid shape of the oxygen dissociation curve (see Chapter 13).

Reactions of oxygen and hemoglobin during capillary transit are further complicated by the rate of oxygen diffusion through the viscous interior of the red cell. The chemical reactions of oxygen and hemoglobin occur quite rapidly in dilute hemoglobin solutions but proceed more

slowly in red cell suspensions. Because of the large size of the hemoglobin molecule and increased viscosity of the red cell contents, hemoglobin remains relatively immobile. As the red cell enters the pulmonary capillary, oxygen molecules bind to reduced hemoglobin molecules just inside the erythrocyte membrane. As these hemoglobin molecules become saturated, subsequent oxygen molecules entering the red cell must diffuse more deeply into the interior of the cell to reach reduced hemoglobin molecules. This combination of diffusion and chemical reaction causes oxygen uptake to occur as an "advancing front" that proceeds at a rate that is an order of magnitude slower than O_2 uptake in well-mixed, dilute hemoglobin solution. This combined process is complex and not easily described from a theoretical standpoint. As a result, the rate of oxygen uptake by hemoglobin contained in red cells is described by a single overall descriptive rate constant, θ_{O_2}, which incorporates all the processes into a single phenomenological value. θ_{O_2} varies with oxygen saturation, pH, and hemoglobin type. The same approach is used to describe carbon monoxide uptake in blood. The rate at which CO replaces bound O_2 in blood with a normal hemoglobin concentration is described by the constant θ_{CO}.

The rates of O_2 and CO uptake by erythrocyte suspensions are determined in vitro and assumed to be representative of the rates of gas exchange in vivo. However, measurements of these rate constants in red cell suspensions in vitro may be affected adversely by methodologic artifacts. The actual rates of combination of O_2 and CO with red cells in vivo have not been measured and this lack of data leads to uncertainties in our understanding of exchange of the two gases in the lung.

Carbon Dioxide

CO_2 is transported in blood as dissolved molecular CO_2, bicarbonate ion, and carbamate ion. The latter is a salt of a carbamic acid formed by reaction of CO_2 with certain amino groups on the hemoglobin molecule. The relation between the partial pressure of CO_2 and the total content of CO_2 in all forms is described by the CO_2 dissociation curve of blood (see Chapter 13). Because CO_2 is more soluble than O_2 in the alveolar-capillary membrane, it has been assumed that CO_2 exchange occurs much more rapidly than O_2 exchange. However, only dissolved CO_2 can cross the alveolar capillary membrane, and conversion of bicarbonate and carbamate to dissolved CO_2 limits the rate of CO_2 exchange. As indicated in Fig. 12-1*A*, when a bolus of dissolved CO_2 is injected into an isolated lung perfused with saline buffer, CO_2 is instantaneously exchanged similar to the inert gas acetylene. In contrast, when a bicarbonate bolus is injected into the same preparation (Fig. 12-1*B*), CO_2 exchange lags behind acetylene excretion because a finite period of time is required to convert bicarbonate into dissolved CO_2 that can cross the alveolar-capillary membrane.

Dissolved CO_2 is excreted immediately as blood enters the pulmonary capillary bed, but constitutes only 8 percent of the total quantity of CO_2 exchanged during capillary transit. The majority (79 percent) of excreted CO_2 enters the capillary bed as bicarbonate ion. As dissolved CO_2 leaves capillary blood, the equilibrium between bicarbonate ion and CO_2 is disturbed, leading to further production of CO_2.

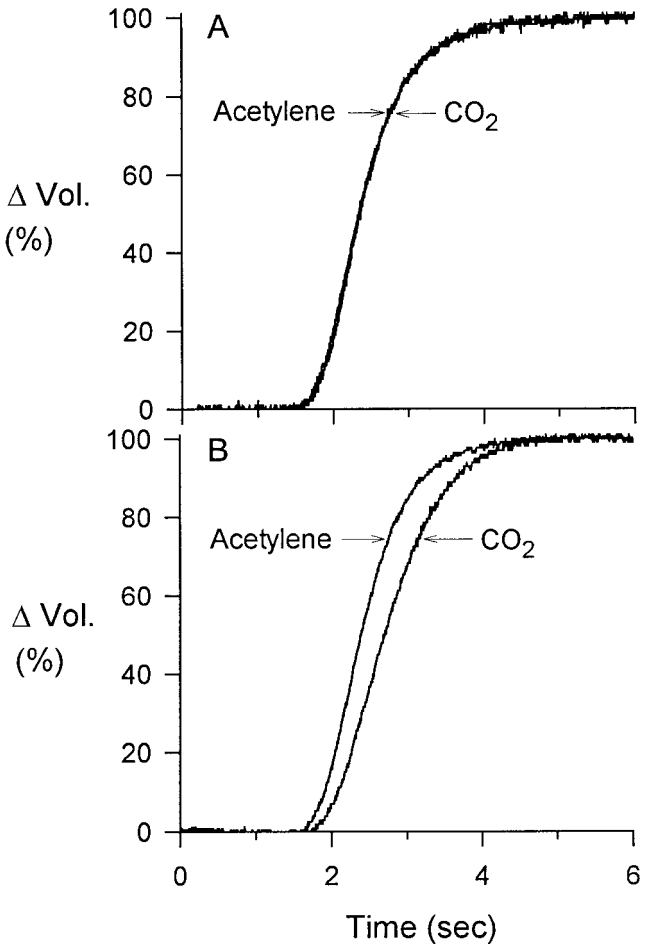

Figure 12-1 Rate of acetylene and CO_2 excretion after bolus injections into the pulmonary artery of isolated lungs perfused with buffer. Volume changes are normalized to facilitate comparison. *A.* The excretion of both acetylene and CO_2 proceed at the same rate after injections of buffer containing either dissolved CO_2 or acetylene. *B.* The excretion of CO_2 lags behind that of acetylene after injection of buffer containing bicarbonate ion. In this example, the mean time of CO_2 excretion lags 0.312 s behind that of acetylene. This slower excretion of CO_2 is caused by the time required to convert bicarbonate to CO_2 with catalysis in this experiment provided by carbonic anhydrase localized to the capillary endothelium. *(Based on data of Schunemann HJ, Klocke RA: Influence of CO_2kinetics on pulmonary carbon dioxide exchange. J Appl Physiol 74:715, 1993. Reproduced with permission from Klocke RA. Carbon dioxide transport, in, Crystal RG, West JB, Weibel ER, et al (eds), The Lung: Scientific Foundation, 2nd ed. New York, Lippincott, Williams & Wilkins; 1997, p 1633.)*

$$HCO_3^- + H^+ \rightarrow H_2CO_3 \xrightarrow{CA} CO_2 + H_2O \qquad (3)$$

Bicarbonate ion combines with hydrogen ion extremely rapidly to form carbonic acid (H_2CO_3). The natural rate of dehydration of carbonic acid to CO_2 and water is a slow process, but is catalyzed by a factor of 10,000 to 16,000 by the large concentration of carbonic anhydrase (CA) inside the

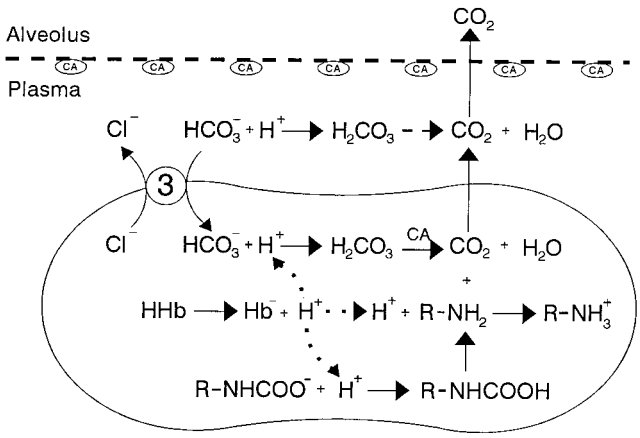

Figure 12-2 Pathways of CO_2 transport and exchange in the lung. CA = carbonic anhydrase within the erythrocyte or localized to the capillary endothelium; dashed arrow indicates that the production of CO_2 from plasma bicarbonate proceeds more slowly than the same reaction inside the erythrocyte; dotted arrows indicate that hemoglobin provides protons that partake in these reactions; R-NH_2 = amino groups of hemoglobin molecule that bind CO_2 to form carbamate compounds, R-NHCOOH; 3 = band 3 anion exchange protein in the cell membrane, which facilitates exchange of bicarbonate and chloride ions across the membrane. *(Reproduced with permission from Klocke RA. Carbon dioxide transport. In: Crystal RG, West JB, Weibel ER, et al (eds), The Lung: Scientific Foundation, 2nd ed. New York, Lippincott, Williams & Wilkins, 1997, p 1633.)*

erythrocyte (Fig. 12-2). The substantial buffering capacity of hemoglobin provides the hydrogen ions required for this reaction and intracellular pH changes minimally. This rapid conversion of bicarbonate to CO_2 depletes the concentration of intracellular bicarbonate after a short time (0.1 s), slowing the production of CO_2.

As intracellular concentration of bicarbonate decreases, plasma bicarbonate enters the cell in exchange for intracellular chloride (Fig. 12-2). Bicarbonate-chloride movement across the erythrocyte membrane occurs in an electrically neutral, one-for-one exchange that is facilitated by a carrier, termed band 3 protein, present in the erythrocyte membrane. Despite the presence of approximately 1 million carrier sites with an extremely rapid turnover number (50,000 ions per second) in the cell membrane of each erythrocyte, bicarbonate-chloride exchange has a half-time of 0.1 s and requires 0.4 to 0.5 s to reach completion. Computational models suggest that in some circumstances the time required for the combined processes of dehydration of carbonic acid and transmembrane ionic exchange is sufficiently long that CO_2 exchange is not quite completed prior to blood leaving the pulmonary capillary. Even in the worst case, the degree of disequilibrium is small and a minimal increase in ventilation can easily compensate for a slight impairment of CO_2 exchange.

Approximately one-half of the total quantity of CO_2 excreted in the lung entered the pulmonary capillaries as plasma bicarbonate, but before being excreted first had to enter the erythrocyte to be converted into dissolved CO_2 under the influence of intracellular carbonic anhydrase. A small amount of plasma bicarbonate is converted into CO_2 without entering the erythrocyte. Carbonic anhydrase is localized on the interior surface of the pulmonary capillary in sufficient concentration to catalyze the dehydration reaction by a factor of 100 to 150. Mathematical models of CO_2 exchange indicate that this relatively small catalytic activity, together with plasma buffering power that is substantially less than that of hemoglobin, result in relatively little production of CO_2 from bicarbonate within the plasma.

Besides exchange of dissolved CO_2 and bicarbonate, a modest amount of CO_2 excretion (13 percent) results from release of CO_2 bound to hemoglobin as carbamate (Fig. 12-2). This exchange is facilitated by the alteration of the molecular conformation of hemoglobin that accompanies oxygenation. This pathway accounts for a portion of the Haldane effect, the change in the CO_2 dissociation curve that results from oxygenation of blood (see Chapter 13).

Carbon dioxide transport processes may not quite reach equilibrium in the pulmonary capillary bed because of the time required to complete chemical reactions and ionic exchanges. However, CO_2 itself crosses the alveolar-capillary membrane as rapidly as an inert gas, and the diffusing capacity for CO_2 is so great that to date it has not been possible to measure it accurately.

DIFFUSING CAPACITY

The pulmonary diffusing capacity (D_L) of a gas provides an estimate of its rate of transfer from the alveoli into capillary blood. Initially it was thought that only diffusion of gas across the membrane limited exchange, as described by Eq. (2). This is the case for inert gases and, as noted above, equilibrium of these gases is achieved rapidly even in disease. However, transfer of gases that combine with hemoglobin may be limited both by diffusion across the alveolar membrane and by the rate of reactions in blood. The only gases that have measurable diffusing capacities are those with low solubility in the pulmonary membrane and high capacitance in blood. These gases include oxygen (O_2), carbon monoxide (CO), and nitric oxide (NO).

Diffusing Capacity for Oxygen ($D_{L_{O_2}}$)

The diffusing capacity is calculated as the volume of gas absorbed by pulmonary blood per unit time ($\dot{V}$) divided by the pressure gradient between alveolar gas (P_A) and capillary blood (P_{cap}).

For oxygen,

$$D_{L_{O_2}} = \frac{\dot{V}_{O_2}}{P_{A_{O_2}} - P_{cap_{O_2}}} \qquad (4)$$

Measurement of $D_{L_{O_2}}$ is difficult because, in addition to diffusion, O_2 transfer may be limited by other mechanisms, such as ventilation-perfusion mismatching and shunting

(see Chapter 13). The measurement is further complicated by a changing capillary P_{O_2} during capillary transit that cannot be accurately determined. These difficulties have led clinicians and investigators to abandon attempts to measure.

Diffusing Capacity for Carbon Monoxide ($D_{L_{CO}}$)

Carbon monoxide provides an excellent alternative to measuring diffusing capacity because CO normally is present in minimal amounts in blood and binds to hemoglobin in the same manner as O_2. Because capillary P_{CO} is so low in usual circumstances, it can be assumed to be negligible and $D_{L_{CO}}$ is calculated by dividing CO uptake ($\dot{V}_{CO}$) by alveolar P_{CO}. However, CO uptake is limited both by diffusion across the alveolar-capillary membrane and by chemical reaction of CO with intracellular hemoglobin. As described by Roughton and Forster, $D_{L_{CO}}$ is comprised of two elements

$$\frac{1}{D_{L_{CO}}} = \frac{1}{Dm_{CO}} + \frac{1}{\theta_{CO} V_c} \qquad (5)$$

where

Dm_{CO} = the diffusing capacity of the alveolar-capillary membrane for CO
θ_{CO} = the rate of displacement of O_2 from intracellular hemoglobin by CO
V_c = the volume of blood in the pulmonary capillary bed

Because O_2 and CO compete for binding sites on hemoglobin, CO binding is inhibited by increases in P_{O_2}. Thus, $D_{L_{CO}}$ and θ_{CO} vary inversely with P_{O_2}. Using known in vitro values of θ_{CO} and two measurements of $D_{L_{CO}}$ at normal and elevated inspired O_2 concentrations, Eq. (5) can be solved to provide values of both Dm_{CO} and V_c. Calculation of the diffusing capacity is based on the assumption that the lung is homogeneous, i.e., all portions of the lung have the same relative ventilation, perfusion, alveolar volume, and diffusing capacity.

Diffusing Capacity for Nitric Oxide ($D_{L_{NO}}$)

Nitric oxide binds to hemoglobin at the same site as O_2 and CO, but the rate of NO binding is much more rapid. It is estimated that NO binding in red cells occurs more than two orders of magnitude faster than CO binding ($\theta_{NO} \gg \theta_{CO}$). Thus, the time required for binding of NO to intracellular hemoglobin, analogous to the $1/\theta_{CO}V_c$ term in Eq. (5), should approach zero and contribute little to the measured value of $D_{L_{NO}}$. As a result, $D_{L_{NO}}$ is assumed to be equal to Dm_{NO}. This conclusion is supported by the lack of effect of changes in inspired O_2 concentration on $D_{L_{NO}}$. In contrast, $D_{L_{CO}}$ is markedly sensitive to such changes because the θ_{CO} is diminished by competition with O_2. Measurements of D_L with CO and NO in the same subjects demonstrate that $D_{L_{NO}}$ is 4.1 to 5.2 times greater than $D_{L_{CO}}$ (Fig. 12-3*A*).

Key assumptions in the measurement of $D_{L_{NO}}$ are that NO binds negligibly to receptors in lung parenchyma other than hemoglobin and that NO has no major physiological effects during the measurements. Measurements with different breath-hold times and inspired NO concentrations yield constant values of $D_{L_{NO}}$, supporting the validity of these assumptions. Recent work indicates that NO is produced in the lung and nasal sinuses, but these concentrations of NO are well below the NO concentrations used in the measurement of $D_{L_{NO}}$ and it is unlikely that this NO production causes errors in measurement. Since NO is highly reactive with oxygen, requires special equipment for analysis, and has potential cardiovascular effects, measurements of $D_{L_{NO}}$ are confined to research settings.

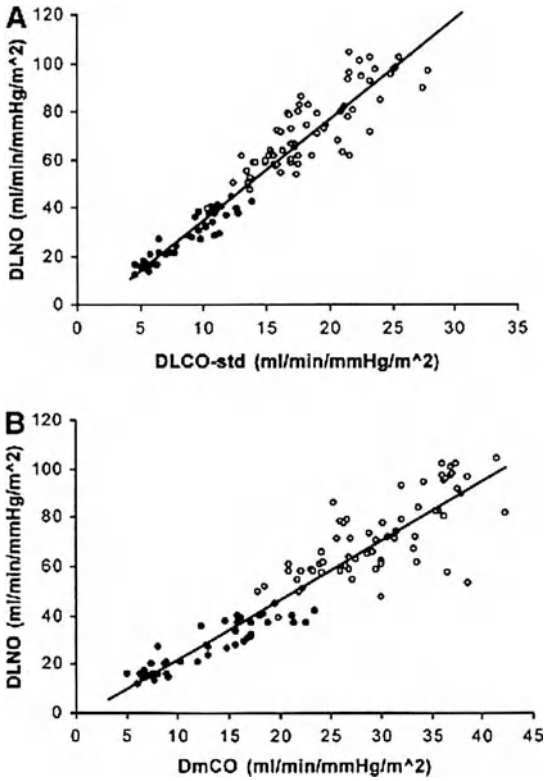

Figure 12-3 The relationships between (A) $D_{L_{NO}}$ and $D_{L_{CO}}$ and (B) between $D_{L_{NO}}$ and Dm_{CO} are similar for patients (closed circles) and normal subjects (open symbols) normalized by body surface area (m^2). $D_{L_{CO}}$ was standardized to hemoglobin concentration of 14.6 g/dl and alveolar O_2 tension of 120 mmHg. Regression lines through the pooled data are (A) $D_{L_{NO}} = 4.16\ D_{L_{CO}} - 6.82$, $r^2 = 0.918$ and (B) $D_{L_{NO}} = 2.42\ Dm_{CO} - 1.87$, $r^2 = 0.865$. *(Reproduced with permission from Phansalkar AR, Hanson CM, Shakir AR, et al: Nitric oxide diffusing capacity and alveolar microvascular recruitment in sarcoidosis. Am J Respir Crit Care Med 169:1034, 2004.)*

Methods for Measuring the Diffusing Capacity

Several different techniques are used to measure the carbon monoxide diffusing capacity. In clinical settings the single breath method is utilized almost exclusively. The steady-state and rebreathing methods of determining $D_{L_{CO}}$ are employed primarily in research. The steady-state method usually is performed in subjects who are exercising, thereby limiting its clinical application in patients with restricted ability

to exercise. The rebreathing methodology requires rapid-responding gas analyzers and has technical requirements beyond those available in most clinical laboratories.

Single-Breath Method

With the single-breath technique the subject exhales to residual volume, inhales a maximal breath of 0.3 percent CO and a tracer gas (usually 10 percent helium) in air, holds the breath for approximately 10 s, and then exhales maximally. After sufficient expiration to clear the dead space, a gas sample is collected to estimate final alveolar CO and helium fractions. After inspiration, the alveolar partial pressure of CO falls exponentially as CO enters the capillary blood. The volume of CO absorbed in the lungs can be calculated from the volume of inspired gas and the initial and final concentrations of CO in alveolar gas. The rate of CO uptake during the breath-hold varies as a function of the alveolar $P_{A_{CO}}$, which falls throughout the breath-hold. Capillary CO pressure is assumed to be equal to zero. The single-breath diffusing capacity is calculated by

$$D_{L_{CO}} = \frac{60\ V_A}{t_{bh}(P_B - 47)} \cdot \ln \frac{F_{A_{CO\ initial}}}{F_{A_{CO\ final}}} \qquad (6)$$

where

60 = the number of seconds per minute
V_A = the alveolar volume of gas (ml_{STPD}) present in the lung at the start of the breath-hold
t_{bh} = the duration of the breath-hold (seconds)
P_B = the barometric pressure (mmHg)
$F_{A_{CO}}$ = the alveolar fraction of carbon monoxide at the initial and final times of the breath-holding period

The insoluble inert gas, usually helium, included in the inspired volume is diluted in the alveolar volume but is not absorbed in capillary blood. V_A is calculated from the dilution of the inert gas and the inspired volume (V_I)

$$V_A = V_I \frac{F_{I_{He}}}{F_{A_{He}}} \qquad (7)$$

where

$F_{I_{He}}$ and $F_{A_{He}}$ = the inspired and alveolar helium concentrations

The alveolar fraction of He and the final alveolar CO fraction are obtained by measuring CO and He concentrations in the expired alveolar gas sample. The initial alveolar CO fraction is calculated from the dilution of the inspired CO in the volume of gas present in the lung during the breath-hold,

$$F_{A_{CO\ initial}} = F_{I_{CO}} \frac{V_I}{V_A} \qquad (8)$$

where

$F_{I_{CO}}$ = the inspired CO fraction

The single-breath method requires some degree of patient cooperation to perform the necessary respiratory maneuvers. A patient with reduced lung volume may not have a vital capacity large enough to clear the dead space and provide a sufficient sample for analysis of alveolar gas concentrations. The ability to hold the breath for 10 s also limits applicability to some patients. Finally, this method can be employed only in the resting state since few patients can breath-hold during exercise. Despite these limitations, the single-breath $D_{L_{CO}}$ is the most practical and widely used method for measuring $D_{L_{CO}}$.

Measurement of Dm and V_c

Using values of θ_{CO} measured in vitro and values of $D_{L_{CO}}$ determined with different inspired O_2 concentrations, Eq. (5) can be solved for the membrane diffusing capacity (Dm_{CO}) and capillary blood volume (V_c). However, there is considerable uncertainty regarding values of θ, the rate of red cell uptake of gases that bind to hemoglobin. Most in vitro measurements of θ have utilized rapid reaction techniques that are flawed due to unstirred layers of fluid surrounding the red cells. This artifact is greater the more rapidly that the gas reacts with hemoglobin ($NO > O_2 > CO$). Furthermore, the rate of gas uptake by erythrocytes is influenced by the ability of the red cells to be deformed during passage through the pulmonary capillaries, a factor not present during in vitro measurements of θ. Mathematical models suggest that the rate of uptake of gases also depends on erythrocyte orientation and spacing within capillaries. Since the characteristics of erythrocyte transit in the capillary bed have not been defined, extrapolation of in vitro measurements to the in vivo situation introduces an element of uncertainty. Despite these reservations, solution of Eq. (5) using values of θ_{CO} determined in vitro yields values of Dm_{CO} and V_c that agree with independent estimates of these variables.

Several research groups have investigated the use of NO to determine the role of diffusion across the alveolar-capillary membrane in gas exchange. As noted previously, it is likely that the reaction of NO with hemoglobin contained in erythrocytes is so rapid that the only resistance to NO uptake is diffusion across the alveolar-capillary membrane. Thus, since $D_{L_{NO}}$ is equal to Dm_{NO}, the value of Dm_{CO} can be calculated from the relative solubilities and diffusion coefficients of NO and CO. The diffusion coefficients of the both gases are similar, but the aqueous solubility of NO is approximately twice that of CO. Therefore, Dm_{CO} is approximately one half of the value of $D_{L_{NO}}$ (Fig. 12-3*B*). This approach to estimation of Dm_{CO} has yielded results similar to determinations of Dm_{CO} using two levels of inspired oxygen and in vitro values of θ_{CO} as originally described by Roughton and Forester. These similar values of Dm_{CO} were obtained during simultaneous measurements of both CO and NO uptake, thereby insuring that experimental conditions were identical for both gases. Most recent measurements indicate that Dm_{CO} under resting conditions is 75 to 100 ml/min/mmHg in men. Values in women are slightly lower due to smaller lung volumes, but data in women are sparse.

Calculation of pulmonary capillary blood volume (V_c) from measurements of $D_{L_{CO}}$ is dependent upon the value of

θ_{CO} chosen for the computation. Using in vitro data for θ_{CO} yields values at rest of 75 to 100 ml for men and slightly less for women. V_c measured by the CO method is dependent upon the quantity of hemoglobin present in the capillary bed in addition to the actual capillary volume. Calculation of V_c assumes a normal hemoglobin concentration in capillary blood and variation in this parameter affects the $\theta_{CO}V_c$ component of D_{LCO}.

Dm and V_c have been estimated from morphometric data obtained from excised, fixed canine lungs. Calculations of D_{LCO} using these post-mortem morphometric values and in vitro values of θ_{CO} have yielded estimates of D_{LCO} that are much greater than measurements of D_{LCO} under resting conditions in the same intact animal. This discrepancy arises because morphometric measurements are obtained in maximally inflated lungs. The morphometric estimates reflect a fully recruited alveolar surface area and capillary blood volume, a circumstance seen during maximal oxygen uptake during exercise. When D_{LCO} calculated from morphometric data is compared to D_{LCO} measured in intact animals under conditions of maximum exercise, there is good agreement between the two estimates.

Factors Influencing Diffusing Capacity

The CO diffusing capacity originally was thought to reflect the resistance of the alveolar-capillary membrane to transfer of CO from the alveoli to capillary blood. The classic work of Roughton and Forster elucidated the influence of chemical reactions on transfer of CO. D_{LCO} may be a measure of decreased gas transfer caused by abnormal diffusion, but also can reflect reduction in hemoglobin concentration, nonuniform distribution of physiological properties throughout the lung, loss of lung tissue, or artifacts in measurement. Since multiple factors in addition to diffusion can affect D_{LCO}, in Europe this test is termed the CO transfer factor, rather than the CO diffusing capacity.

Hemoglobin Concentration

Capillary blood volume (V_c) is a prime variable in the diffusing capacity; its importance is due to the quantity of hemoglobin available to combine with CO within the capillary bed. The calculated value of V_c can be reduced directly by diseases that decrease capillary volume, but also can vary with the concentration of hemoglobin in blood. For this reason, the predicted D_{LCO} is corrected for alterations in hemoglobin concentration. For adult males and adolescents

$$\text{Predicted } D_{LCO} \text{ (Corrected)} = \text{Predicted } D_{LCO}(1.7\,\text{Hb}/(10.22 + \text{Hb})) \quad (9)$$

where

$$\text{Hb} = \text{hemoglobin concentration expressed in g/dL}$$

For adult women and children less than age 15, the factor of 10.22 in Eq. (9) is replaced by a factor of 9.38.

Alveolar Partial Pressure of Oxygen

As indicated previously, θ_{CO} depends on P_{O_2}, and increased alveolar P_{O_2} will reduce measured D_{LCO}. Therefore, D_{LCO} will be lowered if patients receive supplemental oxygen during the measurement. Conversely, reduced alveolar P_{O_2} will lead to an increment in measured D_{LCO}. This has led to the suggestion to apply a correction to D_{LCO} if the measurement was made with an altered inspired oxygen fraction or at altitude. Even when alveolar P_{O_2} is kept at a sea level value during the measurement, lifelong residents of a community located 10,000 feet above sea level have slightly greater diffusing capacities than sea-level residents. Short-term residence (6 weeks) at altitude does not cause an increase in D_{LCO}. Even after reacclimation to sea level, beagles raised at altitude still have slightly greater diffusing capacities than beagles raised at sea level. However, adult dogs taken to altitude for 3 years do not exhibit an increased D_{LCO}, suggesting that residence at altitude during growth is the basis for the increased D_{LCO}.

Body Position

D_{LCO} is 5 to 15 percent greater in the supine position than in the erect position. Blood volume shifts from the lower trunk and legs to the lungs in the supine position. Most of the increase in D_{LCO} appears to be due to a 13 to 27 percent increase in V_c accompanying the fluid shift. However, there is also a minimal increase in Dm_{CO} in the supine position. The effect of posture on D_{LCO} decreases with age, but the reasons underlying this observation remain unknown.

Exercise

D_{LCO} can increase as much as twofold during exercise. This increase is attributed to proportionally equal increases in both D_M and V_c. Both alveolar-capillary surface area and capillary volume are recruited by the increase in cardiac output that accompanies exercise. The transit time through the capillary bed decreases, but not to the same degree as would be predicted in a vascular bed with fixed resistance. The potential reduction in transit time is partially offset by recruitment and distention of the pulmonary capillary bed. Values of Dm_{CO} during exercise are essentially the same when calculated by either the Roughton-Forster method or from simultaneous measurements of D_{LCO} and D_{LNO}. Similar agreement is observed with values of V_c measured using both methods.

Theoretically, D_{LCO} must have a maximum that cannot be exceeded when the entire pulmonary capillary bed and alveolar surface have been recruited. This should lead to a plateau in measured D_{LCO} even though the level of exercise continues to increase. This has never been observed in humans. Using a unique animal preparation of conscious greyhounds exercising on a treadmill, Carlin and coworkers could not demonstrate a plateau in D_{LCO} with increasing exercise even though oxygen uptake reached a level of approximately 120 ml/kg/min. This level of O_2 uptake is almost twice that seen in highly trained humans. Thus, it seems unlikely that the diffusing capacity in humans reaches a plateau during maximal exercise, but this does not rule out the possibility

that gas exchange is limited by diffusion in this circumstance. Disequilibrium may occur before maximum recruitment of the diffusing capacity because capillary transit time may be less than the time required for O_2 exchange to be completed. Indirect evidence in humans suggests that blood may leave the capillary bed without attaining complete equilibrium between alveolar P_{O_2} and capillary P_{O_2} during maximal exercise at sea level.

Measurements of D_{LCO} after exercise have led to the interesting observation that D_{LCO} decreases by approximately 10 to 15 percent after strenuous exercise of any type. This decrement persists for at least 6 h but returns by 24 h to the level present before the exercise. The mechanism underlying this phenomenon has not been elucidated. Interestingly, despite the reduction in D_{LCO}, a second bout of exercise is not associated with decrements in blood oxygenation or maximal oxygen uptake compared to values obtained in the first period of exercise. Thus, it is uncertain if the reduction in D_{LCO} following exercise has physiological importance.

Alveolar Volume

D_{LCO} decreases with reduction in alveolar volume due to accompanying decreases in Dm_{CO} and V_c. This occurs with an inadequate inspiration to total lung capacity in persons with normal lungs, or with maximal inspiration in patients whose total lung capacities have been reduced by disease. In an effort to correct for alterations in alveolar volume rather than a true loss of diffusing capacity, some clinicians and investigators normalize D_{LCO} by dividing the observed D_{LCO} by the alveolar volume present during the measurement. This ratio of D_{LCO}/V_A will be a useful index only if two assumptions are valid. First, there must be an approximately linear relation between D_{LCO} and V_A. This assumption appears to be reasonable at lung volumes greater than 50 percent of total lung capacity, but not at lower lung volumes. Second, the relation between D_{LCO} and V_A must be directly proportional (i.e., a graph of D_{LCO} versus V_A must pass through the origin of the graph). This clearly is not the case. Multiple investigators have demonstrated that D_{LCO}/V_A is not constant in normal persons and varies as alveolar volume changes. Although frequently used, the D_{LCO}/V_A ratio alone does not provide a valid index of the effect of changes in alveolar volume.

Non-uniform Distribution of Physiological Properties

Calculations of D_{LCO}, regardless of the method used to make the measurement, implicitly assume that the lung is completely uniform with regard to ventilation, volume, perfusion, and diffusive properties. This requires that each alveolus possesses the same relationship between all these physiological properties—an assumption that is not completely valid even in normal, healthy persons. The most important factor determining CO uptake is the relationship of local diffusing capacity to local blood flow, the ratio of D_{LCO}/Q. In addition, computational models indicate that factors such as the alteration of shape or uneven distribution of erythrocytes during capillary transit will diminish gas exchange. Non-uniform distribution of these important physiological variables throughout the lung produces a decrease in diffusing capacity and, by analogy, a reduced ability to transfer oxygen from the inspired air to capillary blood. Transfer is further complicated by the nonlinear nature of the processes involved. For example, the oxygen dissociation curve of hemoglobin has a sigmoid shape and a change in alveolar P_{O_2} may have a large or a minimal effect on the quantity of O_2 exchanged depending on the absolute value of the P_{O_2}. Disruptions of these complex relationships among physiological parameters have variable effects on O_2 transfer. The contributions of individual pathophysiological deviations cannot be assessed by a global measurement such as the diffusing capacity. Thus, D_{LCO} provides a means of assessing overall oxygen transport but does not indicate specific defects in gas exchange.

Technical Considerations

Measurements of D_{LCO} have greater variation than spirometric observations such as the forced vital capacity (FVC) or forced expiratory volume in one second ($FEV_{1.0}$). Criteria for acceptable measurements of D_{LCO} have been based upon relative or absolute differences between repeated measurements. The American Thoracic Society/European Respiratory Society (ATS/ERS) consensus statement recommends reporting the average of two measurements, both of which agree within 3.0 ml/min/mmHg or within 10 percent of the higher measured value. Punjabi et al. reported that an absolute difference of 2.5 ml/min/mmHg between duplicate measurements could be achieved in 96 percent of patients. This criterion was deemed more reasonable than a percentage variation because it remained constant over a wide range of measured values in contrast to a changing percentage criterion. The strength of this study is in its size (over 6000 patients) and its performance during routine pulmonary testing in a clinical setting. A drawback to its universal application is that more than two determinations of D_{LCO} were required in one-half of patients to meet this criterion of acceptability.

The time of the breath-holding maneuver in the single-breath method requires patient cooperation. Because of non-uniform distribution of physiological variables, CO uptake does not occur in a strictly exponential fashion even in healthy persons. As a result, measured D_{LCO} decreases slightly with prolonged breath-hold in normal subjects. This decrement can be substantially greater in patients. The empirical breath-holding time of 10 s was chosen as a practical compromise to permit measurable CO uptake but still be feasible for patients to perform. Many laboratories set a breath-hold range of 9 to 11 s as acceptable, although the ATS/ERS consensus report accepts a range of 8 to 12 s.

Patients with lung disease often cannot perform rapid respiratory maneuvers mandated by the single-breath D_{LCO} measurement. Slower flow rates prolong the time required for inspiration and expiration. As a result, instantaneous, uniform mixing of alveolar contents assumed in the calculation

of D_{LCO} is not achieved. A series of three equations, rather than a single equation, more accurately describes conditions during CO uptake in this circumstance and minimizes errors. However, the calculations are more complex and may not be available in some automated, commercial equipment.

Most laboratories request that patients refrain from smoking for variable periods of time prior to measurement of D_{LCO} to avoid accumulation of CO in blood. Significant elevation of carboxyhemoglobin reduces measured D_{LCO} in two ways. First, the presence of carboxyhemoglobin produces a functional anemia, lessening the capacity of hemoglobin to bind O_2 or CO. This reduces the $\theta_{CO}V_c$ component of D_{LCO}. Second, calculation of D_{LCO} assumes that the back pressure of CO in the capillary is zero, and the gradient for CO transfer is equal to P_{ACO}. The presence of carboxyhemoglobin in blood produces an actual alveolar-capillary P_{CO} gradient less than that assumed in the calculation, thereby leading to a lower calculated value of D_{LCO}. Graham and colleagues measured the effect of experimental elevation of carboxyhemoglobin in normal individuals. Values of D_{LCO} obtained with the usual single breath calculation decreased approximately 1.5 percent from the true value for each 1.0 percent elevation of carboxyhemoglobin. Although algorithms are available to correct observed D_{LCO} for carboxyhemoglobin effects, it is preferable to make the measurement without a significant elevation of carboxyhemoglobin. Twelve hours of abstinence from smoking is advisable in patients who smoke extensively because carboxyhemoglobin levels as great as 6 to 12 percent are observed immediately following tobacco usage.

Controversies in Interpretation of D_{LCO}

As noted previously, D_{LCO} is affected by a number of circumstances. Alveolar P_{O_2} and body position do not present significant problems since a standard inspired P_{O_2} and the sitting position are utilized during measurements in most clinical laboratories. Equations to correct for alterations of alveolar P_{O_2} are available if needed. Empirical equations also can adjust the predicted value of D_{LCO} to compensate for anemia or polycythemia.

Variability in cardiac output and the alveolar volume present during the measurement provide more significant problems. The increases in D_{LCO} observed during exercise are the result of large increases in cardiac output. Clinical measurements of D_{LCO} are accomplished under resting conditions, minimizing but not obviating, variability in cardiac output. In addition, disease can alter the distribution of blood flow in the lung in patterns that do not match the distribution of diffusive properties. Unfortunately, measurements of pulmonary blood flow and its distribution are not measured conveniently in clinical laboratories. As a result, the effect of cardiac output on D_{LCO} may not be appreciated in routine determinations. The only practical alternative is to minimize conditions that might alter pulmonary blood flow.

Reduction in alveolar volume by disease processes is the largest potential source of error in interpreting D_{LCO}. Correction for the effect of altered alveolar volume has been attempted by reporting the ratio of D_{LCO}/V_A. However, this attempt to normalize measurements by alveolar volume leads to errors because D_{LCO}/V_A does not remain constant as alveolar volume changes. Stam and colleagues reported values of D_{LCO} and D_{LCO}/V_A obtained at different alveolar volumes in normal subjects. They recommend setting predicted values of D_{LCO} or D_{LCO}/V_A for patients with reduced alveolar volumes equal to values in normal subjects measured at the same reduced alveolar volume. This assumes that disease processes that reduce alveolar volume in patients produce the same changes in D_{LCO} as voluntary reduction in alveolar volume in normal subjects. In a subsequent report, they demonstrated this to be the case in patients with normal lung function tested prior to, during, and after undergoing treatment with bleomycin for malignancies. In these patients, the linear relationship of D_{LCO}/V_A measured at different alveolar volumes shifted downward in parallel fashion as bleomycin produced lung injury. This finding supports the adjustment of predicted values on the basis of reduced alveolar volumes in normal subjects since the slope of the D_{LCO}/V_A ratio in relation to V_A was the same before and after lung injury. These data were obtained by measuring D_{LCO} at a variety of alveolar volumes prior to and after the pulmonary insult, a situation that is rarely possible. Recent data obtained in patients with sarcoidosis also support the concept of using predicted values obtained at lower lung volumes in normal subjects. However, other reports in different clinical conditions suggest that some diseases may not affect D_{LCO} in the same manner as voluntary changes in normal subjects. These uncertainties have led to substantial controversy regarding the value of the ratio D_{LCO}/V_A. Final judgment will require collection of extensive data in a variety of disease states. Regardless of the outcome of this controversy, it is apparent that if D_{LCO}/V_A is to be used in the interpretation of measurements of D_{LCO}, there must be some adjustment of predicted values of D_{LCO}/V_A to reflect reductions in alveolar volume. Use of D_{LCO}/V_A alone as a correction for changes in alveolar volume will lead to errors in interpretation of the diffusing capacity.

Blood-Gas Transport

Michael P. Hlastala • Erik R. Swenson • Robert A. Klocke

OXYGEN TRANSPORT

The circulatory system provides special mechanisms in order to deliver the large quantities of oxygen required by the peripheral tissues. The major factor is the presence of hemoglobin in blood. Reversible binding of O_2 greatly enhances the effective solubility of O_2 in blood compared with that in other body fluids. In addition to quantitative transport requirements, O_2 must be delivered at a pressure sufficient to allow for its diffusion to the intracellular mitochondria where it is utilized.

Oxygen Equilibrium Curve

The relationship between content and pressure for gases dissolved in blood is linear (Henry's law). Inert gases (e.g., nitrogen and argon) are carried only in the dissolved form in blood. Oxygen differs from inert gases because of its binding with hemoglobin. Four O_2 molecules can bind with each hemoglobin molecule but produce complex interactions that occur among the four heme moieties. Binding of an O_2 molecule to one heme site affects the affinity for ligands at other heme sites on the molecule. This results in an S-shaped content-pressure relationship, the *O_2 equilibrium curve* (also called the *O_2 dissociation curve*) of blood. This relationship also can be normalized to account for varying blood hemoglobin concentration by expressing O_2 content as a fraction of the maximum quantity of O_2 that can be bound to hemoglobin (percent saturation) as shown in Fig. 13-1. The physiological portion of the curve includes the partial pressures and contents normally seen in arterial blood and in the venous effluent of various organs under resting (Fig. 13-2) and exercising conditions. The flatness of the curve in the arterial range is an advantage because decrements in arterial P_{O_2} (as might be caused by lung disease or excursions to altitude) will still allow for a relatively normal arterial O_2 content as long as arterial P_{O_2} remains greater to or equal to 60 mmHg. Because of the steep nature of the equilibrium curve below 50 mmHg, increased O_2 extraction can be achieved with only a relatively modest decrease in partial pressure of oxygen. Thus, large quantities of O_2 can be released and blood P_{O_2} remains sufficiently high to support diffusion of O_2 into metabolizing tissues. The normal mixed venous O_2 content at rest is 4 to 5 ml/100 ml less than arterial content, providing substantial reserve for oxygen consumption during increased metabolic activity or decreased blood flow (Fig 13-2). However, the O_2 contents of venous blood leaving some organs, such as the heart, are substantially less than the mixed venous value and increased oxygen requirements are largely met through increasing blood flow to the organ. During exercise or in pathological circumstances, the arterial-mixed venous O_2 content difference may increase substantially to meet tissue oxygen requirements.

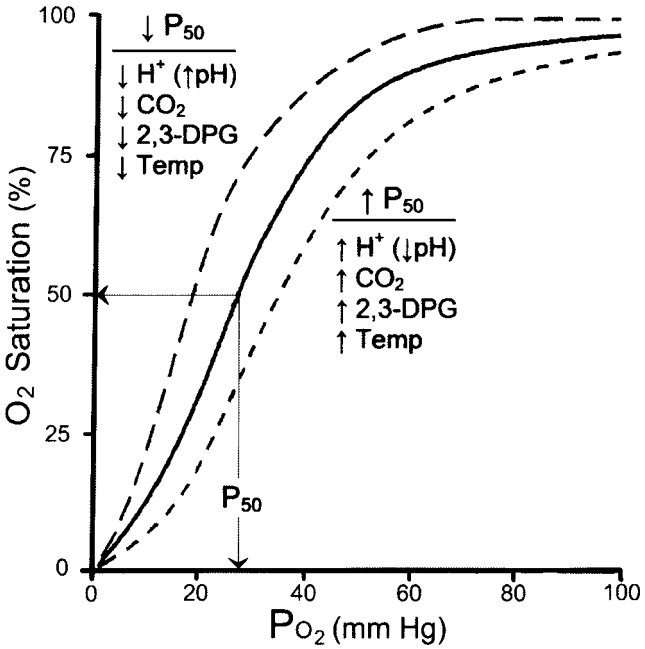

Figure 13-1 The oxygen equilibrium curve of human blood. The normal curve (solid line) has a P_{50} (P_{O_2} at 50 percent saturation) of 27 mmHg. The curve of fetal blood with increased oxygen affinity (decreased P_{50} of 19 mmHg) is indicated by the line with the long dashes. A curve with decreased oxygen affinity (increased P_{50} of 34 mmHg) as seen in severe anemia is indicated by the line with short dashes. The factors that decrease or increase P_{50} are shown to the left and right, respectively, of the equilibrium curves.

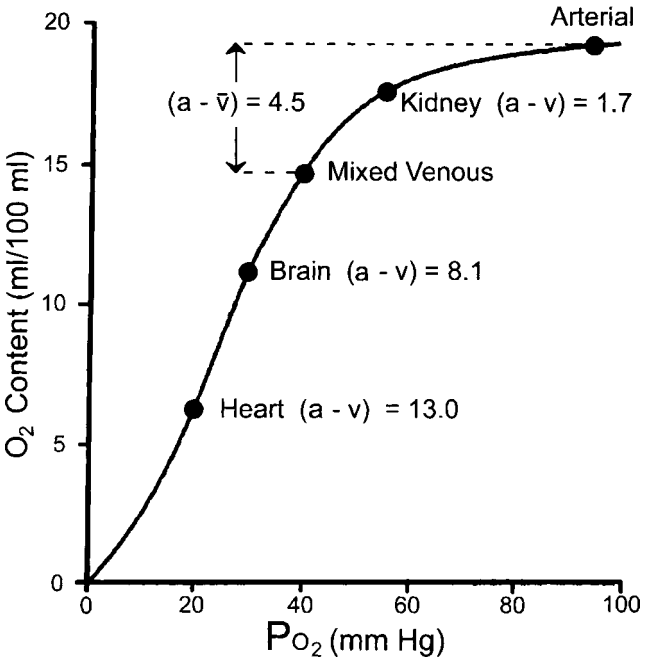

Figure 13-2 The normal oxygen equilibrium curve expressed in terms of O_2 content (ml/100 ml). The arterial-mixed venous ($a-\bar{v}$) content difference under resting conditions is indicated for the body as a whole. Differing (a-v) content differences for several organs are shown to emphasize the differing quantities of oxygen extracted by organs. In contrast to the kidney, the heart normally extracts large quantities of oxygen and little oxygen reserve in blood is available for changing conditions of metabolism or perfusion.

Oxygen Affinity

The relative affinity of hemoglobin for oxygen, and the position of the O_2 equilibrium curve can change under a variety of different physiological conditions. However, the sigmoid shape of the curve remains unchanged and the curve is either compressed or stretched along the P_{O_2} axis. The magnitude of change in O_2 affinity is indicated by the change in P_{50}, i.e., the oxygen partial pressure needed to achieve 50 percent saturation of hemoglobin. The curve to the left of the normal curve in Fig. 13-1 has a P_{50} of 19 mmHg, indicating that the O_2 affinity is high since the P_{O_2} required to half-saturate blood is less than normal (27 mmHg). Shifts of the equilibrium curve can be physiologically important—a left shift permits greater O_2 binding, an important factor in O_2 uptake in the fetus in utero or in normal lungs at altitude. However, an increased affinity (lower P_{50}) may impair tissue O_2 delivery since greater binding can limit O_2 release in the periphery. A shift of the curve to the right may enhance O_2 delivery to tissues because oxygen can be delivered while maintaining a higher-than-normal P_{O_2}, thereby promoting diffusion from the capillaries to the cells. Shifts in the curve in either direction are mediated by substances (carbon dioxide, hydrogen ions, and 2,3-diphosphoglycerate) that bind to hemoglobin and affect the affinity of hemoglobin for oxygen, even though they bind at different sites than O_2 molecules. Changes in temperature also can affect oxygen affinity, but the narrow temperature range seen in most clinical circumstances does not have much effect on the P_{50}. All these factors are additive in their effects on the position of the O_2 equilibrium curve (Fig. 13-1).

Bohr Effect

An increase in plasma (and therefore intracellular) hydrogen ion concentration [H^+] displaces the equilibrium curve to the right. Originally, the shift in the curve was attributed entirely to a change in pH, whether mediated by the addition of fixed acid or a change in P_{CO_2}. However, CO_2 does have a direct effect on O_2 affinity in addition to that associated with a change in pH. This direct effect results from binding of CO_2 to the hemoglobin molecule, but is small compared with the H^+ effect. A shift of the curve produced by a fixed acid, such as lactic acid, is less than the shift caused by CO_2 with the same change in pH.

The Bohr effect assists O_2 exchange to a small extent. In the tissues, addition of CO_2 to blood shifts the O_2 equilibrium curve to the right, releasing O_2 bound to hemoglobin. In the lungs, as the equilibrium curve returns to its normal position with excretion of CO_2, O_2 binding is enhanced. However, it has been calculated that the Bohr effect accounts for only 2 percent of total O_2 uptake at rest, less than assumed previously, because of the small pH changes that occur between arterial and venous blood.

2,3-Diphosphoglycerate

The human erythrocyte contains large quantities of 2,3-diphosphoglycerate (DPG), an organic phosphate that binds

to hemoglobin and affects O_2 affinity. Two mechanisms are involved: (1) DPG binds more readily to reduced hemoglobin than to oxyhemoglobin, tending to "hold" the molecule in the reduced configuration; and (2) at body pH DPG has four negative charges and reduces intraerythrocytic pH by the Donnan effect since this large, negatively charged molecule does not cross the cell membrane. This reduction in intracellular pH causes a decrease in affinity through the Bohr mechanism.

An increased concentration of DPG is a compensatory mechanism in some pathological states characterized by reduced O_2 transport. The shift of the O_2 dissociation curve to the right facilitates O_2 delivery, maintaining tissue oxygenation despite a reduction in the absolute quantity of O_2 delivered to peripheral tissues.

Blood stored in acid solution is deficient in DPG, leading to questions concerning its efficacy after transfusion in O_2 delivery. Fortunately, normal levels of DPG are regenerated in transfused cells within a day after transfusion. In the intervening period, O_2 exchange continues to take place even though efficiency may be somewhat reduced.

Abnormal Hemoglobins

Most abnormal hemoglobins per se have normal equilibrium curves despite differences in amino acid sequences. Although shifts of the equilibrium curve to the right are common in hemoglobinopathies, this alteration is usually due to other factors, such as increased DPG concentration or mean corpuscular hemoglobin concentration. However, a few mutant hemoglobins are exceptions to this rule and exhibit altered O_2 affinity.

Carbon Monoxide

Carbon monoxide (CO) poisoning is the most serious toxicological problem in the United States. Annually, it accounts for 40,000 hospital visits or admissions and 5000 deaths. One-half of the former and 90 percent of the latter events are intentional in origin. CO has an affinity for hemoglobin 200 to 250 times that of oxygen. Both CO and O_2 compete for the same ferrous binding sites on the heme components of hemoglobin. Although small quantities of CO are produced in the body by the breakdown of heme proteins, CO is important clinically only when it contaminates inspired air (as caused by cigarette smoke or automobile exhaust). The adverse effects of CO poisoning are twofold: (1) binding of CO to hemoglobin interferes with oxygen binding and produces a functional anemia; and (2) binding of CO to hemoglobin also increases the affinity of hemoglobin for oxygen, thereby shifting the oxygen equilibrium curve to the left. This increased affinity hinders the release of oxygen in the tissues. The combined effect of these two mechanisms produces a greater deficit in the ability to exchange O_2 than the loss of comparable O_2 carrying capacity in anemia.

Severe CO poisoning can be treated by increasing inspired oxygen concentration and, to a lesser extent, by increasing ventilation. The half-time of CO clearance from the body is 4 to 5 h, but inspiration of 100 percent O_2 reduces the half-time to less than 1 h by increasing the O_2 competition with CO for binding sites on hemoglobin. Inhalation of 5 percent CO_2 in O_2 has been used to treat CO poisoning. Although it was once postulated that CO_2 has a specific effect on CO release from hemoglobin, it has now been demonstrated that the faster elimination of CO while breathing a CO_2-O_2 mixture is the result of the hyperventilation produced by CO_2 inhalation. If patients treated with CO_2-O_2 mixtures cannot increase ventilation sufficiently to avoid respiratory acidosis during CO_2 inhalation, this treatment can be dangerous. For this reason, the treatment of choice for CO poisoning is inhalation of 100 percent O_2.

Studies of the benefit of hyperbaric oxygenation in treatment of CO poisoning have produced equivocal results because of problems with methodology and small sample size. A recent study by Weaver and colleagues has produced encouraging results supporting treatment with 100 percent oxygen at 2 to 3 atmospheres pressure for three 2 to $2^1/_2$ hour periods delivered over the first 24 hours after reaching a hyperbaric facility. In this study, cognitive impairment was significantly lower (25 percent vs. 46 percent) at 6 weeks and one year (18 percent vs. 33 percent) after CO exposure in those patients treated with hyperbaric oxygenation as compared with control subjects. Delayed neurological sequelae, especially cognitive dysfunction, are the most serious complications of CO toxicity in survivors. Although further study is required to confirm the value of hyperbaric oxygen therapy, many experts currently recommend its use, if available, for pregnant individuals who have had 20 percent of hemoglobin sites bound by CO (COHb) or non-pregnant patients who have experienced 40 percent COHb levels or have lost consciousness.

In the past there has been considerable controversy regarding the impact of low-level CO exposure, but recent studies have suggested that 5 percent COHb can impair exercise performance in healthy individuals. Patients with cardiac disease may have adverse effects associated with COHb levels as low as 6 percent. Further investigation is required to better define the effects of low concentrations of CO in the atmosphere.

CARBON DIOXIDE TRANSPORT

Carbon dioxide (CO_2) is produced principally by aerobic metabolism, but also is generated in the buffering of hydrogen ions by intracellular and extracellular bicarbonate ions (HCO_3^-). Bicarbonate stores are utilized to buffer organic acids, such as lactic acid and ketoacids, generated by anaerobic metabolism, starvation, and uncontrolled diabetes. CO_2 produced by these mechanisms in tissues diffuses into capillary blood and is carried in chemical combination and physical solution to the lungs where it is eliminated in the expired ventilation (see Chapter 12). As is the case with the transport of O_2 by blood, most CO_2 is not carried as the gas itself, but rather in several chemical forms directly or indirectly dependent

on hemoglobin. CO_2 is not an acid but forms carbonic acid in combination with water and needs to be eliminated continuously by the lungs to avoid acidosis. Body acid-base status is maintained by a balance between excretion of CO_2 in the lungs and renal regulation of body HCO_3^- stores.

Carbon Dioxide Equilibrium Curve

The relationship between blood content and partial pressure is considerably different for CO_2 compared with O_2. The total quantity of CO_2 contained in arterial blood is more than twice that of O_2 despite the generally lower CO_2 partial pressures that are involved. Because the slope of the CO_2 equilibrium curve is quite steep, CO_2 partial pressures in arterial and venous blood normally range between 40 and 50 mmHg in contrast to large arterial-venous differences in blood P_{O_2}. The entire CO_2 curve is curvilinear, but over the range encountered under normal conditions the content-pressure relationship is nearly linear (Fig. 13-3). This characteristic helps maintain efficiency of CO_2 exchange when mismatching of ventilation to blood flow occurs in the lungs. Despite the 20-fold greater solubility of CO_2 compared with oxygen, there still must be transport of CO_2 in blood in other than simple physical solution if CO_2 transport is to be maintained without large increases in cardiac output and/or venous P_{CO_2}. The total content of CO_2, i.e., the vertical axis of the CO_2 equilibrium curve, is the sum of three forms: dissolved CO_2, bicarbonate ion and carbamate compounds (see Chapter 12).

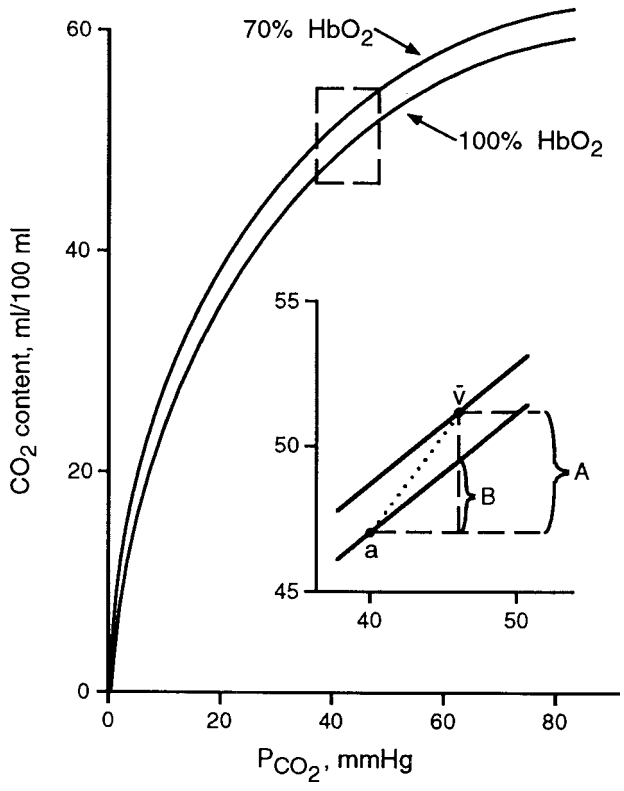

Figure 13-3 The carbon dioxide equilibrium curves of completely oxygenated (100 percent HbO_2) and partially oxygenated (70 percent HbO_2) human blood. The inset shows the enhancement of pulmonary CO_2 exchange by the Haldane effect. Mixed venous ($\bar{v}$) and arterial (a) points are shown. The CO_2 exchange resulting from the Haldane effect is the difference between the total ($\bar{v}$-a) difference *(A)* and the exchange that would occur without the Haldane effect *(B)*.

Dissolved Carbon Dioxide

Approximately 5 percent of total CO_2 content is transported in physical solution in plasma and red cell water. This dissolved form is critical for CO_2 transport because only molecular CO_2 can rapidly cross cell membranes to be excreted in the lungs. The partial pressure of carbon dioxide, P_{CO_2}, is directly proportional to the quantity of dissolved CO_2. It is indirectly related to CO_2 content through the equilibrium curve.

Bicarbonate

Under the influence of the enzyme carbonic anhydrase (CA) contained within the cytosol of the erythrocyte, approximately 80 to 90 percent of CO_2 entering blood from the tissues is rapidly converted into bicarbonate ion (HCO_3^-) inside the red cell

$$CO_2 + H_2O \overset{CA}{\leftrightarrow} H_2CO_3 \leftrightarrow H^+ + HCO_3^- \qquad (1)$$

Catalysis of this otherwise very slow reaction permits rapid interconversion between CO_2 and HCO_3 so that large quantities of CO_2 can be absorbed by blood in tissues and transported to the lungs. Although the isoenzyme CA I is present in high concentration in erythrocytes, its activity in limited by intracellular chloride ion. Another isoenzyme, CA II, is present in only one-sixth the concentration of CA I within red cells, but CA II is not inhibited by chloride ion and has intrinsic activity sevenfold greater than CA I. CA II is responsible for almost all the catalysis of the CO_2-bicarbonate reaction in vivo. Hydrogen ions generated by the conversion of CO_2 to HCO_3^- must be buffered to prevent large changes in pH and limitation of CO_2 uptake. In blood, this is accomplished by proton binding to hemoglobin, enhanced to a significant degree by the simultaneous off-loading of oxygen (the Haldane effect; see below).

A rate-limiting build-up of bicarbonate in the red cell as CO_2 enters blood is avoided by one-for-one electrically neutral exchange across the red cell membrane of intracellular bicarbonate for plasma chloride. The latter exchange is mediated by an integral membrane glycoprotein, band 3 protein (also known as AE1, i.e., anion exchanger 1). It has been postulated that exchange is facilitated by binding of CA II, but not CA I, to a specific carboxyl-terminal site on the anion exchanger. The efficacy of CO_2 exchange would be enhanced since bound CA II provides local substrate for transport of HCO_3^- out of the red cell in peripheral tissues and conversion of HCO_3^- entering the cell to CO_2 in the lung. The close association of these two proteins would avoid limitation of HCO_3^- exchange as a result of impaired diffusion of bicarbonate ions through the viscous interior of the erythrocyte.

Further evidence is needed to support possible binding of CA II to the exchanger.

Carbamates

Less than 10 percent of CO_2 binds directly to terminal α-amino groups of hemoglobin as carbamate compounds. Because reduced hemoglobin binds more CO_2 than the oxygenated protein, more CO_2 can be carried in venous blood at any given P_{CO_2} than in oxygenated arterial blood. The physiological importance of this process would be twice as great except that binding of DPG to hemoglobin limits carbamate formation. However, changes in carbamate concentration still account for 10 to 15 percent of the difference between arterial and venous CO_2 contents during normal gas exchange.

Haldane Effect

Oxygenated blood at any P_{CO_2} has a lower CO_2 content than reduced blood at the same partial pressure. This difference, illustrated in Fig. 13-3, is known as the *Haldane effect*. The effect of oxygenation on CO_2 transport is analogous to the Bohr effect, but has far greater physiological importance. Deoxygenation of hemoglobin permits greater binding of H^+ since reduced hemoglobin is a weaker acid (stronger base) than oxyhemoglobin. In peripheral blood, hydrogen ions formed by the conversion of CO_2 to HCO_3^- are buffered by binding to hemoglobin. As a result of this proton binding, at any P_{CO_2} more HCO_3^- is present in blood and total CO_2 content is greater when hemoglobin is reduced. As mentioned previously, direct CO_2 binding to hemoglobin as carbamate compounds is also facilitated in deoxygenated blood, increasing the total CO_2 content in deoxygenated as compared with oxygenated blood. At normal H^+ and DPG concentrations, approximately 40 percent of the Haldane effect is the result of direct binding of CO_2; the remainder is the result of H^+ binding to hemoglobin. The relative contribution of carbamate compounds to the Haldane effect is inversely proportional to the combined effect of H^+ and DPG, increasing as their concentrations decrease, and conversely decreasing as $[H^+]$ and [DPG] become greater.

The physiological importance of the Haldane effect is illustrated in the inset in Fig. 13-3. The change in CO_2 content between normal arterial and mixed venous CO_2 partial pressures in oxygenated blood is indicated by bracket B on the right side of the inset. However, under physiological circumstances, the CO_2 equilibrium curve shifts from the position of the partially oxygenated curve to that of fully oxygenated blood. Thus, as is shown by bracket A on the right side of the inset, the shift from one curve to the other produces a greater change in blood CO_2 content between arterial and mixed venous partial pressures. As a result, changes in venous pH and P_{CO_2} are minimized despite transport of large amounts of CO_2.

Quantitatively, the Haldane effect has a much larger effect on gas transport under physiological circumstances than does the Bohr effect. Under resting normoxic conditions, the Bohr effect is responsible for only a few percent of O_2 uptake in the lung and 10 to 15 percent in the systemic capillaries. Binding of oxygen to hemoglobin alters both binding of CO_2 directly as carbamate compounds and the overall pK (buffering capacity) of hemoglobin. The first effect accounts for virtually all the contribution of carbamate compounds to CO_2 transfer between tissues and the lungs. The remainder derives from the reduced buffering capacity of hemoglobin as it is fully oxygenated. Model calculations and in vitro data suggest that the Haldane effect accounts for 40 to 50 percent of total CO_2 exchange under normal conditions. Either cardiac output or the difference between arterial and venous (and therefore tissue) P_{CO_2} would have to increase by a similar percentage if the Haldane effect were not operative to aid in transport of CO_2.

Kinetic Aspects of CO_2 Exchange

It is conventionally taught that CO_2 equilibration reaches completion very quickly during capillary gas exchange because diffusion exchange of CO_2 occurs 20 times more rapidly than O_2. If CO_2 transport by blood were accomplished solely as dissolved CO_2, this would be correct. However, chemical reactions and exchange rates involved in CO_2 transport occur far more slowly than diffusion of CO_2 across membranes (Table 13-1). These individual rates provided in the table are less than the usual transit times of blood through the pulmonary capillaries. However, when more than one reaction occurs in series, the approach to equilibrium is substantially slower than the individual rates of single processes. Although controversy persists regarding the true magnitude and

Table 13-1

Rates of CO_2 and O_2 Exchange Processes

Process	Time to 90% Completion (S)
Diffusion of CO_2	0.001–0.003
Carbamate-CO_2 binding/release*	0.250–0.300
Chloride-bicarbonate exchange	0.400–0.500
Bohr/Haldane effects	0.250
CO_2 hydration/HCO_3^- dehydration	
Uncatalyzed	40.0
Catalyzed by carbonic anhydrase	0.005
Uptake of O_2 by red cells	0.050–0.100

** This value reflects the predominant rate-limiting effect of O_2 uptake by red cells, because all the carbamate-CO_2 contribution is O_2 exchange-dependent.*

physiological significance of failure to reach end-capillary CO_2 equilibrium, it is becoming increasingly clear that CO_2 exchange cannot be considered fully complete in the duration of normal capillary transit times.

The uncatalyzed rates of CO_2 hydration and HCO_3^- dehydration are exceedingly slow but are accelerated sufficiently by carbonic anhydrase. The degree of catalysis by carbonic anhydrase is so great that more than 99 percent inhibition is necessary before CO_2 hydration becomes a limiting factor in CO_2 exchange. The rate of red cell anion exchange, on which significant CO_2 exchange depends, may be rate-limiting even at rest in normal individuals. As capillary transit times decrease, the potential exists for significant CO_2 disequilibrium between arterial blood and alveolar gas and between peripheral tissues and venous blood. Drugs interfering with either carbonic anhydrase (acetazolamide, methazolamide) or red cell anion exchange (high-dose salicylate or loop diuretic therapy) may cause end-capillary CO_2 disequilibrium. Since the Haldane effect plays a large role in CO_2 exchange and is dependent upon prior completion of O_2 exchange, delay in O_2 exchange magnifies any delay in reaching CO_2 equilibrium.

The physiological consequences of any in vivo CO_2 end-capillary disequilibrium at rest in a healthy person are minimal. P_{CO_2} gradients between blood and tissues or between blood and the alveoli are fairly small (4 to 8 mmHg), and a lack of equilibration that would raise P_{CO_2} can be countered easily by slight increases in ventilation and/or cardiac output. At rest lung CO_2 equilibration is about 97 percent complete, which would lead to less than a 1 mmHg difference between arterial and alveolar P_{CO_2}. With maximal exercise, equilibration likely is more impaired and the arterial-alveolar P_{CO_2} difference is larger. However, if normal ventilatory and cardiac responses are limited, and/or parenchymal lung disease exists, then significant CO_2 retention possibly could develop. It should also be noted that with severe $\dot{V}_A/\dot{Q}$ mismatching or shunting, significant arterial-alveolar P_{CO_2} differences can occur which have been ascribed to these factors alone and not to end-capillary CO_2 disequilibrium.

Acid-Base Balance

Stanley Goldfarb • Kumar Sharma

Regulation of $[H^+]$ is of crucial importance for maintenance of normal cellular functions. The normal $[H^+]$ is maintained at about 40 neq/L. When there is even a small change in the $[H^+]$, intracellular proteins gain or lose H^+ ions resulting in alterations in charge distribution, which may affect molecular structure and protein function. The hydrogen ion concentration in bodily fluids is largely regulated by the ratio of the concentrations of carbon dioxide and bicarbonate. This is predicated upon the relationship demonstrated in the Henderson-Hasselbalch equation:

$$pH = pKa + \frac{[HCO_3^-]}{0.03\,P_{CO_2}} \qquad (1)$$

where

$pH = -\log[H^+]$ (the H^+ concentration measured in moles per liter)

$pKa = 6.10$

Whereas the lungs are responsible for modulating arterial P_{CO_2}, the kidneys are primarily responsible for modulating the concentration of bicarbonate in plasma. In concert these organs maintain a stable extracellular acid-base milieu that is readily assessed by measuring arterial pH.

The normal internal environment is maintained within narrow limits: The arterial blood pH is kept remarkably close to 7.40, the bicarbonate concentration is maintained around 24.5 mEq/L, and the P_{CO_2} is maintained at about 40 mmHg. Deviations of the pH with accompanying changes in the P_{CO_2} and $[HCO_3^-]$ result in the four major categories, as denoted in Table 14-1. Metabolic acidosis is characterized by acidemia (pH less than 7.35) that is due to a reduced plasma $[HCO_3^-]$. Metabolic alkalosis is characterized by an alkalemia (pH greater than 7.45) that results from an elevation in the plasma $[HCO_3^-]$. Respiratory acidosis is due to hypoventilation, resulting in a net increase in P_{CO_2} (hypercapnia) and a concomitant fall in pH. Respiratory alkalosis is due to primary hyperventilation leading to a fall in P_{CO_2} (hypocapnia) and a rise in pH.

In this chapter, we first review the basic physiological roles that the kidneys and lungs play in maintaining acid-base

Table 14-1

Patterns of P_{CO_2} and HCO_3 Changes in Acid-Base Disorders

Primary Disturbance	Initial Abnormality	Compensatory Response	Expected Compensation
Metabolic acidosis	Decreased pH, decreased $[HCO_3^-]$	Decreased P_{CO_2}	$P_{CO_2} = 1.5 \times [HCO_3^-] + 8 \pm 2$ (Winter's formula)
Metabolic alkalosis	Increased pH, increased $[HCO_3^-]$	Increased P_{CO_2}	P_{CO_2} increases 0.6 mmHg per mEq/L rise in $[HCO_3^-]$
Respiratory acidosis	Decreased pH, increased P_{CO_2}	Increased $[HCO_3^-]$	Acute: $[HCO_3^-]$ increases 1 mEq/L per 10 mmHg rise in P_{CO_2} Chronic: $[HCO_3^-]$ increases 3.5 mEq/L per 10 mmHg rise in P_{CO_2}
Respiratory alkalosis	Increased pH, increased P_{CO_2}	Decreased $[HCO_3^-]$	Acute: $[HCO_3^-]$ falls 2 mEq/L per 10 mmHg fall in P_{CO_2} Chronic: $[HCO_3^-]$ falls 5 mEq/L per 10 mmHg fall in P_{CO_2}

balance and then discuss their adaptation in primary acid-base disorders. The following section then focuses on clinical application of physiological concepts in analyzing acid-base problems as encountered by the clinician.

BASIC PHYSIOLOGY OF THE ROLE OF THE KIDNEY IN ACID-BASE BALANCE

Normal metabolism generates large quantities of volatile acid (CO_2) and nonvolatile acid daily. The complete metabolism of carbohydrates and fats generates 15,000 mmol of CO_2 daily. This leads to acid generation as the CO_2 combines with H_2O to form carbonic acid (H_2CO_3). As the volatile fraction is excreted by the lungs during respiration, acid accumulation does not occur. The nonvolatile or "fixed" fraction is produced at a rate of 1 mEq/kg per day. The major source of the nonvolatile acid fraction is the oxidation of sulfur-containing proteins from the diet to sulfuric acid. If this amount of nonvolatile acid is not excreted, life-threatening metabolic acidosis ensues. Therefore, for a normal individual to maintain acid-base balance, 50 to 100 mEq of nonvolatile acid must be excreted daily by the kidneys.

The addition of 50 to 100 mEq of acid requires initial buffering before it can be excreted. Whole-body buffering capacity is composed of interacting buffer systems: the bicarbonate and nonbicarbonate buffers (Buf^-), consisting primarily of hemoglobin, proteins, and phosphates. The sum of the buffer anions $[HCO_3^-]$ and $[Buf^-]$ is the total buffer base and defines total-body buffering capacity. Since all body buffer systems are in equilibrium, a change in the serum $[HCO_3^-]$ reflects concurrent changes in the other body buffer systems. The importance of bicarbonate in buffering is due to its relationship with CO_2. As H^+ are buffered by HCO_3^-, there is a decrease in the $[HCO_3^-]$ and a concurrent increase in the dissolved $[CO_2]$. As the $[CO_2]$ can be excreted by the lungs to maintain a constant $[CO_2]$, this substantially increases the buffering capacity of bicarbonate. Since the kidney plays a major role in controlling the $[HCO_3^-]$ and $[HCO_3^-]$ is easily measured in serum, the HCO_3^- anion is a useful parameter to evaluate the renal response to an acid load.

The H^+ ions released from the dissociation of sulfuric acid are titrated by blood bicarbonate and nonbicarbonate buffers.

$$\begin{aligned} H_2SO_4 + 2NaHCO_3 &\rightarrow Na_2SO_4 + 2H_2CO_3 \\ &\rightarrow 2H_2O + CO_2 \end{aligned} \qquad (2)$$

Although the added H^+ is excreted via CO_2 elimination by the lungs, this occurs at the cost of depletion of $[HCO_3^-]$. In order to *replenish* the consumed base, bicarbonate is reabsorbed by the kidneys and returned to the blood. This process does not accomplish the replacement of consumed base, since continuous metabolic production of acid will ultimately decrease the available base present. The process of renal *regeneration* of base requires the urinary excretion of acid or H^+ ions in the absence of any urinary bicarbonate. For every H^+ ion excreted, bicarbonate is returned to the body. If there is any bicarbonate in the urine, there will be a net gain of H^+. Therefore, the kidney has two major functions in this context: (a) reabsorption of all the filtered bicarbonate—this takes place primarily in the proximal tubule; and (b) the base consumed by metabolism must be generated in the process of urinary acid excretion. This takes place in the distal

portions of the nephron, distal collecting tubule, and collecting ducts.

BICARBONATE RECLAMATION

The proximal tubule is responsible for reclaiming 70 to 90 percent of the filtered bicarbonate. This may occur either by direct bicarbonate absorption at the proximal tubule or via proton secretion into the lumen of the tubule. The latter mechanism appears to be the predominant pathway. Protons generated from intracellular water are secreted into the tubular lumen via a Na^+/H^+ antiporter, where they can then combine with filtered bicarbonate to form carbonic acid. The carbonic acid is dehydrated by carbonic anhydrase in the brush border of the proximal tubular epithelium to form CO_2 and H_2O. The CO_2 diffuses into the cell and combines with hydronium ion (OH^-) to form bicarbonate (via intracellular carbonic anhydrase). The bicarbonate is transported in the basolateral direction back into the blood via a Na^+/HCO_3^- cotransporter (Fig. 14-1). It is important to understand that this process reclaims filtered bicarbonate but does not result in a net gain of bicarbonate. At the end of the proximal tubule there is a lowering of the luminal pH from 7.26 to 6.70, and the bicarbonate concentration is lowered from 24 to 8 mEq/L. The fluid delivered to the distal tubule is essentially the same with respect to pH and bicarbonate concentration as that which leaves the proximal tubule. The reclamation of the remaining bicarbonate occurs in the thick ascending limb and the outer medullary collecting tubule. At the collecting tubule, H^+ secretion occurs primarily by an H^+-ATPase pump at the luminal membrane and bicarbonate entry to the blood is via a Cl^-/HCO_3^- exchanger at the basolateral membrane.

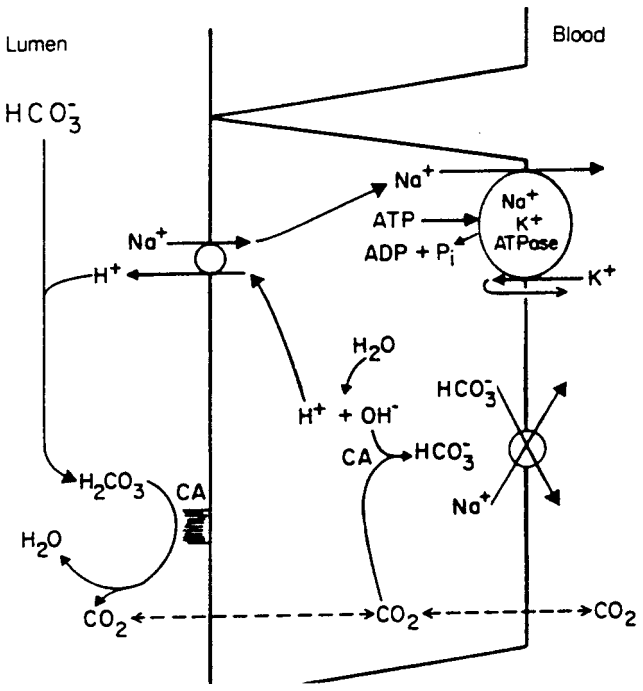

Figure 14-1 Schematic representation of proximal tubular reclamation of filtered bicarbonate. In the lumen, filtered bicarbonate reacts with secreted H^+, generating carbonic acid, which is dehydrated by carbonic anhydrase (CA), located on the brush border. The cell secretes H^+ by a process that exchanges H^+ for filtered Na^+. The source of secreted H^+ is water, which in turn generates OH^- and subsequently bicarbonate because of the presence of intracellular CA. Bicarbonate exits the basolateral side of the cell linked in some fashion with Na^+; sodium is also actively pumped out of the cell.

The crucial role of carbonic anhydrase is demonstrated by the fact that carbonic anhydrase inhibitors (i.e. acetazolamide) result in bicarbonate wasting and the generation and maintenance of metabolic acidosis. The most physiologically important regulators of reclamation of bicarbonate are the pH, the P_{CO_2} and the extracellular volume status of the patient. In states of acidosis, there is enhanced luminal Na^+/H^+ exchange that may be mediated by an increase in intracellular H^+ ions and the number of new exchangers as well as increased activity of the Na^+/HCO_3^- cotransporter at the basolateral membrane. Elevation of the P_{CO_2} will promote higher proximal tubular concentration of CO_2 and lead to intracellular acidosis, giving rise to further secretion of H^+ ions and reclamation of bicarbonate. If there is volume depletion, there will be avid Na^+ reabsorption at the proximal tubule in exchange for H^+ and thus greater reabsorption of bicarbonate. Other factors that are important include the luminal bicarbonate concentration, tubular flow rate, and serum potassium.

NET RENAL ACID EXCRETION

Net excretion of acid occurs primarily in the distal nephron and is largely mediated by the active secretory pumps, H^+-K^+ ATPase and H^+-ATPase. The latter appears to be linked in some way to Cl^- reabsorption to preserve electroneutrality. By definition, to produce net H^+ excretion the secreted H^+ will have to be excreted in processes that do not consume bicarbonate.

To achieve net secretion of protons in the luminal fluid of the distal nephron requires association of the protons with urinary buffers other than bicarbonate. Although secreted protons lower the urinary pH to 4.5 resulting in a 3-pH unit differential from arterial pH (a thousandfold increase in H^+ concentration), the quantity of acid excreted as free H^+ is trivial. For example, daily excretion of 2 L of urine with a pH of 5 would result in excretion of only 0.02 mEq of dissociated H^+ ions in contrast to the 50 to 100 mEq of H^+ generated each day from dietary sources. The nonbicarbonate buffers present in the urine that carry out the role of net acid excretion are the titratable buffers, primarily phosphate, which accounts for 40 percent of net acid excretion, and ammonia, which accounts for the remainder.

The ability of phosphate to act as proton acceptor in the urine is based on its pKa of 6.8. As the urine pH is lowered below the pKa of 6.8, there is conversion of HPO_4^- to

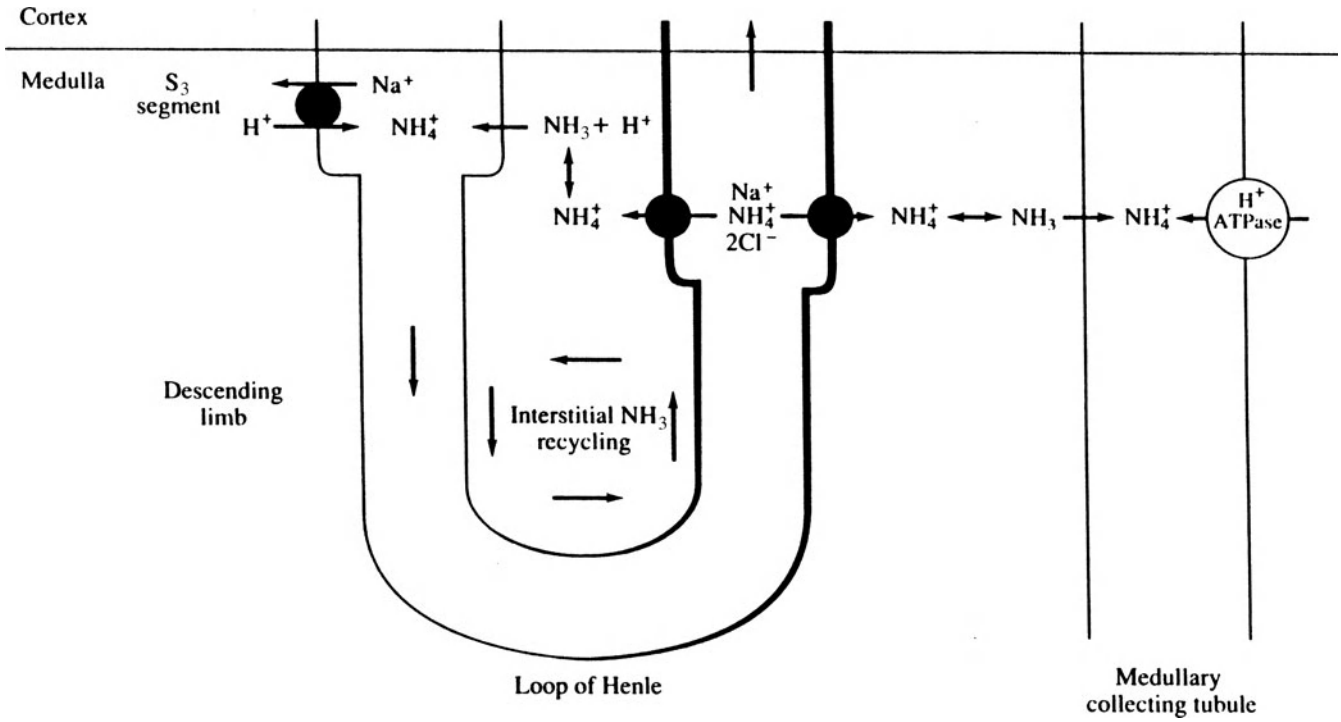

Figure 14-2 Schematic representation of ammonia recycling within the renal medulla. Although NH_4^+ production occurs predominantly in the proximal tubule, most of the NH_4^+ is then reabsorbed in the thick ascending limb, apparently by substitution for K^+ on the Na^+-K^+-$2Cl^-$ carrier in the luminal membrane. Partial dissociation into NH_3 and H^+ then occurs in the less acid tubular cell. The NH_3 diffuses into the medullary interstitium, where it reaches relatively high concentrations; it then diffuses back into those segments that have the lowest pH and therefore have the most favorable gradient: The S_3 segment of the late proximal tubule and, more important, the medullary collecting tubule, where the secreted NH_3 is trapped as NH_4^+ and then excreted. *(From Rose B: Clinical Physiology of Acid-Base and Electrolyte Disorders, 4th ed. New York, McGraw-Hill, 1994, with permission.)*

H_2PO_4. This transfer continues until the urine pH reaches 5.5, at which point almost all the phosphate present is in the associated form, H_2PO_4. Other components of this system are uric acid (pKa = 5.75) and creatinine (pKa = 4.97). Although the titratable buffers account for a sizable fraction of net basal acid excretion, they cannot increase in amount to enhance acid excretion in settings of acid loading.

However, the rate of ammonium ($NH4^+$) production and excretion can be varied according to physiological needs. Ammonia (NH_3) combines with H^+ to form ammonium, which is trapped in the collecting tubule lumen and excreted in the urine. The pKa for this reaction is 9.0. The majority of ammonia is synthesized in the proximal tubular cell by the enzymatic breakdown of glutamine. Glutamine is actively taken up by the proximal tubule at the apical and basolateral membranes and transported to mitochondria. Deamidation by glutaminase forms ammonium and glutamate. The latter is further metabolized by glutamate dehydrogenase to form ammonium and α-ketoglutarate. Metabolism of α-ketoglutarate to bicarbonate in the liver leads to return of bicarbonate to the systemic circulation (Fig. 14-2).

The ammonium that is formed is transported into the proximal tubular lumen via the Na^+-H^+ antiporter, working in this case as a Na^+-NH_4^+ antiporter. The ammonium is then reabsorbed in the thick ascending limb by substitution of NH_4^+ for K^+ on the Na^+-K^+-$2Cl^-$ carrier. The intracellular ammonium in the thick ascending limb cell is then dissociated into ammonia and H^+. The ammonia accumulates in the medullary interstitium and is finally secreted into the lumen of the medullary collecting tubule. At this site, due to the low lumen pH (4.5 to 5), the ammonia accepts a H^+ and is trapped in the lumen and excreted in the urine as NH_4Cl.

The importance of the ammonia system is that it can be regulated by the systemic acid-base state. An acid load initially leads to an increase in ammonium excretion within 2 h due to formation of more acid urine, which enhances ammonia diffusion into the lumen at the collecting duct. After 5 to 6 days there is maximal NH_4^+ excretion due to increased glutamine uptake and enhanced activity of phosphate-dependent glutaminase and glutamate dehydrogenase to produce more ammonium in the proximal tubule. This is presumably mediated by intracellular acidosis of the proximal tubular cell. The net effect is that NH_4^+ excretion can increase from about 30 mEq per day to as much as 300 mEq per day in severe metabolic acidosis. The plasma potassium is an important regulator of ammonia synthesis as hyperkalemia results in a transcellular influx of K^+ in exchange for H^+, resulting in lowering of the intracellular H^+ concentration, thus causing intracellular alkalosis with consequent inhibition of ammonia synthesis. Hypokalemia would have the opposite effect. Urinary acidification is also very important, since an inability to lower urinary pH results in a reduction in NH_3 trapping in

the collecting duct lumen and a subsequent inhibition of the degree of ammonium formation. Inadequate acidification of the urine also inhibits H_2PO_4 formation.

RESPIRATORY CONTRIBUTION TO ACID-BASE BALANCE

The major roles of the lungs in acid-base balance are to excrete the CO_2 produced daily by aerobic metabolism and compensate for primary metabolic acid-base disturbances by altering the rate and depth of ventilation. The CO_2 generated by the tissues diffuses into the plasma, at the peripheral capillaries, and is present in the blood in three compartments. Part of the CO_2 remains in the gas phase, but the amount is limited by the solubility coefficient of CO_2 (0.03 mM/mmHg). CO_2 may also react with amino groups of proteins and form carbamino compounds. The majority of the CO_2 is carried within red blood cells. The red cells contain carbonic anhydrase, which hydrates the CO_2 and thus forms carbonic acid which dissociates to H^+ and HCO_3^-. The protons are buffered by hemoglobin, which has an increased affinity for H^+ at the low oxygen tension present in the peripheral capillaries and venous blood. The bicarbonate produced in the red cell leaves the cell in exchange for chloride. This chloride shift is a characteristic response to elevation of CO_2 in the blood, resulting in an acute elevation of bicarbonate in exchange for a drop in serum chloride. When the blood enters the pulmonary circulation, the enhanced oxygenation of hemoglobin promotes release of bound H^+. The H^+ and HCO_3^-, via carbonic anhydrase, combine to reform CO_2, which passively diffuses from the blood into the pulmonary interstitium where the CO_2 tension is very low. Subsequently CO_2 is lost into the alveolar space.

The rate of minute ventilation is controlled by two sets of chemoreceptors: those in the respiratory center in the brain stem and those in the carotid and aortic bodies located at the bifurcation of the carotid arteries and in the aortic arch, respectively. The central chemoreceptors are stimulated by an increase in the P_{CO_2} or by metabolic acidosis, both of which appear to be sensed by a fall in the pH of the surrounding cerebral interstitial fluid. The peripheral chemoreceptors are primarily stimulated by hypoxemia, although they may also respond to acidemia. The level of alveolar or effective ventilation varies in accord with the total minute ventilation. The level of total ventilation changes as a function of metabolic demand. Under normal circumstances, P_{CO_2} is well controlled between 38 and 42 mmHg according to the relationship:

$$P_{CO_2} = \frac{\dot{V}_{CO_2}}{\dot{V}_A} \qquad (3)$$

where

$\dot{V}_{CO_2}$ = CO_2 production (reflecting metabolic rate)
$\dot{V}_A$ = alveolar ventilation (reflecting CO_2 clearance)

Under basal conditions the volatile acid production or CO_2 that is metabolically generated is completely eliminated by the lungs. The mechanism of the central stimulation of respiration in response to an elevated CO_2 is a topic of intense debate and will not be focused upon in this section. However, intracranial adjustments to pH have been consistently observed and have interesting parallels to the effects of acidosis on the proximal tubular cell in the kidney. Increased concentrations of CO_2 in the cerebrospinal fluid (CSF) result in intracellular acidosis, an increase in CSF bicarbonate concentration, and an equimolar reduction in CSF chloride concentration. As brain cells increase their bicarbonate concentration, there is increased buffering, and intracellular brain pH is returned toward normal. The major group of cells within the central nervous system (CNS) responsible for acid-base regulation are the glial cells and the cells of the choroid plexus. These cells contain carbonic anhydrase which converts intracellular CO_2 H_2O to H^+ and HCO_3^-. The H^+ is exchanged for Na^+ on the blood side, allowing the intracellular pH to increase. The administration of acetazolamide into the cerebral ventricles blocks the expected increase in CSF bicarbonate in response to hypercapnia. In addition to changes in bicarbonate concentration in the CSF in response to hypercapnia, there are also changes in the levels of ammonia. Brain and CSF ammonia increase in hypercapnia; ammonia acts to enhance H^+ buffering, thereby preventing a fall in the bicarbonate concentration.

ACUTE AND CHRONIC ADAPTATION TO RESPIRATORY ACIDOSIS

Figure 14-3 depicts the acute steady-state relationships among P_{CO_2} plasma bicarbonate concentration, and plasma hydrogen concentration during graded degrees of acute hypercapnia. These observations were obtained by sequentially exposing unanesthetized normal human volunteers to increasing concentrations of inspired carbon dioxide in a large environmental chamber. Increasing degrees of hypercapnia are associated with a curvilinear rise in plasma bicarbonate concentration, with higher levels of P_{CO_2}, resulting in lesser incremental changes in bicarbonate concentration. This acute rise in bicarbonate is largely due to the chloride shift as described above. As a result of the modest increment in bicarbonate, the average rise in plasma $[H^+]$ is limited to 0.75 neq/L per mmHg rise in P_{CO_2} rather than the 1 neq/mmHg rise that would have occurred if the plasma bicarbonate concentration did not change.

The quantitative aspects of the adaptive response to acute hypercapnia are influenced markedly by the baseline acid-base status. Acute hypercapnia induces a larger increment in both plasma bicarbonate and H^+ ion concentrations in animals with preexisting hypobicarbonatemia (whether from metabolic acidosis or from chronic respiratory alkalosis) than in animals with preexisting hyperbicarbonatemia (whether from metabolic alkalosis or from chronic respiratory acidosis). This points out that the factor controlling the amount of bicarbonate generated from an acute rise in P_{CO_2} is not only the initial pH but also the initial bicarbonate

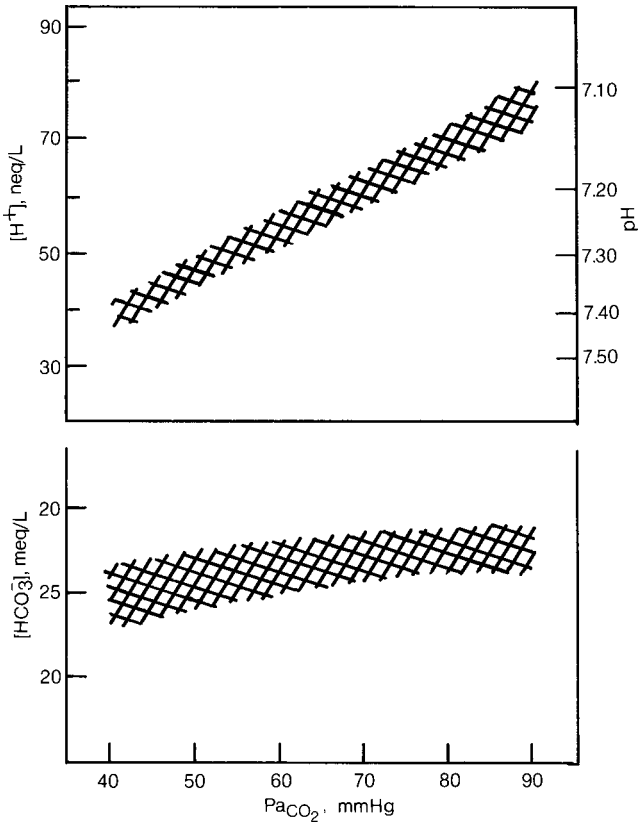

Figure 14-3 Ninety-five percent confidence bands for plasma hydrogen ion and bicarbonate concentrations during acute hypercapnia in normal humans. *(From Brackett NC Jr, Cohen JJ, Schwartz WB: Carbon dioxide titration curve of normal man: Effect of increasing degrees of acute hypercapnia on acid-base equfl ibrium. N Engl J Med 272:6, 1965, with permission.)*

concentration. Although the rise in bicarbonate in response to hypercapnia limits the fall in pH acutely, to excrete the gain of H^+ produced from the rise in P_{CO_2} requires renal compensatory mechanisms.

During the initial period of respiratory acidosis, renal compensation takes about 3 to 5 days, during which time there is enhanced reabsorption of proximal tubular bicarbonate, enhanced secretion of H^+, and increased ammonia production. These processes will lead to an increase of the serum bicarbonate concentration and a rise in the systemic pH toward normal. However, when steady state is achieved and a stable P_{CO_2} is present, there is no longer an increase in ammonia production: As filtered bicarbonate is increased, there is enhanced proximal secretion of H^+ and a normalization of intracellular pH, removing the stimulus for ammonia synthesis.

RENAL ADAPTATION TO RESPIRATORY ALKALOSIS

The adaptive responses to respiratory alkalosis occur in two distinct steps, in close analogy with respiratory acidosis. Hypocapnia reduces the carbonic acid concentration and causes a prompt fall in H^+. Acutely this alkalemia is ameliorated by a secondary, adaptive reduction in plasma bicarbonate concentration that stems principally from titration of nonbicarbonate body buffers. During protracted hypocapnia, renal adaptive mechanisms yield a further and larger secondary reduction in plasma bicarbonate that results in still greater amelioration of the alkalemia.

In acute uncomplicated respiratory alkalosis the plasma bicarbonate concentration falls by approximately 0.2 mEq/L for each mmHg reduction in P_{CO_2}; thus a reduction in plasma bicarbonate of 3 to 4 mEq/L occurs within minutes after P_{CO_2} is lowered to 20 to 25 mmHg. The resulting change in plasma H^+ concentration is approximately 0.75 mEq/L for each mmHg fall in P_{CO_2}, similar to the relationship between P_{CO_2} and H^+ in acute hypercapnia.

When hypocapnia persists beyond the acute phase, the additional decrement in plasma bicarbonate concentration is a consequence of renal adaptive responses and reflects a dampening of hydrogen ion secretion by the renal tubule. As a result, a transient suppression of net acid excretion occurs, largely manifested by a fall in ammonium excretion and an increase in net bicarbonate excretion. These changes lead, in turn, to a positive hydrogen ion balance and a reduction in the body's bicarbonate stores. Persistence of the resulting hypobicarbonatemia is explained by the continued inhibition of tubular hydrogen ion secretion and suppression of bicarbonate reabsorption.

The adaptive retention of acid during chronic hypocapnia is normally accompanied by a loss of sodium into the urine; the resultant decrease in the extracellular volume promotes chloride retention and the typical hyperchloremia of chronic respiratory alkalosis. Upon reaching a new steady state, the net excretion of acid returns to control levels, and the altered anionic concentration of the extracellular fluid (ECF), namely hypobicarbonatemia and hyperchloremia, is maintained by a reduced bicarbonate reabsorption and enhanced chloride reabsorption. On average, the combined effect of cell buffers and renal compensation results in a new steady state in which the plasma HCO_3^- concentration falls approximately 4 mEq/L for each 10 mmHg reduction in the P_{CO_2}. The renal adaptation to persistent hypocapnia appears to be mediated by some direct effect of P_{CO_2} itself, not the systemic pH. In animals in which plasma bicarbonate was reduced by HCl loading prior to adaptation to sustained hypocapnia, the renal response to a primary reduction in P_{CO_2} was the same as in normal individuals, even though the net effect of this adaptation was an overt fall in pH.

RESPIRATORY ADJUSTMENT TO METABOLIC ACIDOSIS

Metabolic acidosis stimulates both central and peripheral chemoreceptors to increase alveolar ventilation and decrease P_{CO_2} to limit the fall in pH. Although peripheral chemoreceptors appear to play a role, in animal experiments the same

degree of respiratory compensation occurs with intact and with ablated peripheral chemoreceptors. The increase in ventilation begins within 1 to 2 h and reaches its maximal level at 12 to 24 h. The stereotype is Kussmaul's breathing in acute diabetic ketoacidosis, in which tidal volume is characteristically large with minute ventilation increasing by as much as 35 L. On average, studies in otherwise normal patients with metabolic acidosis reveal that the P_{CO_2} will fall 1.2 mmHg for every 1.0 mEq/L reduction in plasma HCO_3^- down to a minimum P_{CO_2} of 10 to 15 mmHg.

On the other hand, failure to mount the expected ventilatory response to metabolic acidosis is an important indicator of respiratory decompensation. Subashini and coworkers in a study of 140 critically ill trauma patients with metabolic acidosis applied the traditional formula derived from patients with chronic metabolic acidosis. Those whose Pa_{CO_2} exceeded the predicted Pa_{CO_2} by 2 mmHg or more were 4.2 times more likely to be intubated and compensation status was an independent predictor of intubation as early as 60 minutes after episodes of significant hypotension.

RESPIRATORY ADJUSTMENT TO METABOLIC ALKALOSIS

The development of metabolic alkalosis is sensed by the respiratory chemoreceptors resulting in a decline in alveolar ventilation and an elevation of the P_{CO_2}. On average, the P_{CO_2} rises 0.7 mmHg for every 1.0 mEq/L increment in the plasma HCO_3^- concentration. Values significantly different from the predicted value represent superimposed respiratory acidosis or alkalosis. However, it is unclear whether this response significantly protects the pH from rising. In experimental animals, the rise in P_{CO_2} in metabolic alkalosis increases net H^+ excretion leading to an increase in the HCO_3^- concentration. The effect after several days is that the arterial pH is the same as it would have been if there had been no respiratory compensation.

Ventilation may be strongly affected by influences other than acid-base balance. Among these influences are body temperature, increases in circulating catecholamines, changes in cerebral blood flow, changes in systemic blood pressure, and changes in metabolic activities of different organs (e.g., liver), as well as the physiological state of the lung itself. Perhaps for teleological reasons, the defense of chronic metabolic acid-base imbalances by ventilatory compensation is not of major importance.

ALTERNATIVE CONCEPTS OF ACID-BASE BALANCE

The preceding discussion has tacitly assumed that the systemic pH is the final control that affects the renal and respiratory response to an acid-base disorder; however, this issue is certainly not settled. The proximal tubular cell of the kidney can often have effects that are more predictably based on the P_{CO_2} rather than the arterial pH. If P_{CO_2} is elevated, the proximal tubular cells acts to secrete protons and reabsorb bicarbonate whether or not there is systemic alkalosis or acidosis. This may be explained if an elevation in P_{CO_2} results in intracellular acidosis and the cell is responding appropriately to its internal milieu. Similarly, in the central control of respiration, it is controversial as to whether it is CSF pH, interstitial pH, P_{CO_2}, or the bicarbonate concentration that stimulates compensatory changes in ventilation.

In addition to the preceding observations, it is also known that changes in salt and water balance may affect acid-base status. For example, Schwartz's group found that a low dietary sodium chloride intake in dogs with a stable amount of water intake results in hypoventilation, increased P_{CO_2}, and increased HCO_3^- concentration. Studies in dogs have demonstrated that increasing dietary NaCl with a fixed water intake increases the acidity of body fluids, whereas decreasing the NaCl in diet with a fixed water intake decreases the acidity of body fluids.

An alternative view to understanding acid-base disorders and the regulatory response of the lungs and kidneys is offered by the theories initially proposed by Stewart. Based on physicochemistry, Stewart emphasized the important principle that H^+ and HCO_3^- as well as the acidic and anionic forms of weak acids are actually dependent variables in a solution. The three independent variables, P_{CO_2}, the strong ion difference, and the total weak anion concentration, can be manipulated externally and serve to determine the concentration of the dependent variables, H^+ and HCO_3^-. The major components of the weak anions in plasma are the albumin and inorganic phosphate concentrations. The strong ion difference (SID) is the difference between the sums of all strong cations and all strong anions:

$$\begin{aligned} SID = ([Na^+] + [K^+][Ca^{2+}][Mg^{2+}])([Cl^-] \\ + [\text{other strong anions (lactate}^-)]) \end{aligned} \quad (4)$$

This equation is based on the principles of: (a) electroneutrality; (b) dissociation equilibria of all incompletely dissociated substances; and (c) conservation of mass. This concept appears to better explain the basis for renal and ventilatory response in a variety of states that also affect acid-base balance. Practically, it is observed that the plasma SID is primarily regulated by the kidneys, whereas the P_{CO_2} is regulated by alveolar ventilation. The weak anion concentration is generally not regulated and often may be assumed to be stable.

This concept has primarily been used by investigators in relation to the study of central regulation of ventilation. As albumin and other proteins are not present in the CSF, it is the SID and P_{CO_2} that determine the concentration of weakly dissociating electrolytes, H^+, OH^-, and HCO_3^-. In analyzing various acid-base disturbances, it appears that the change in CSF SID can predict the concentration of CSF bicarbonate.

In evaluating acid-base balance in many species, note that there is a consistent inverse relationship between the pH and body temperature, whereas the CO_2 content remains stable. To explain this relationship, Reeves and his coworkers provided evidence that the imidazole ring structure of histidine is responsible for the pH-temperature relationship. This is because imidazole has a pKa in the physiological range (7), is relatively ubiquitous, and has enthalpy of ionization (7 kcal/mol). To integrate acid-base regulation with receptor function and control of respiration, Reeves and Rahn have proposed the hypothesis that it is not the arterial or intracellular pH that is being regulated per se but rather the constancy of the fractional dissociation of the imidazole moiety of histidine contained in proteins throughout the body. α-imidazole is defined as the ratio of the absolute amount of unprotonated imidazole (Im) to total imidazole (HIm + Im):

$$\alpha \text{ imidazole} = \frac{\text{Im}}{\text{HIm} + \text{Im}} \qquad (5)$$

α-Imidazole regulation (alphastat regulation) would have the effect of maintaining cellular protein charge states and enzymatic functions constant. It would also maintain the OH^-/H^+ ratio constant in all compartments. There is also evidence that alphastat regulation directly influences ventilatory status. For example, application of an imidazole blocker to the chemosensitive area of the medulla in cats blocked increases in ventilation caused by local application of acid. Thus, changes in P_{CO_2}, reflecting alveolar ventilation, may be determined by alphastat regulation, which maintains the OH^-/H^+ ratio constant in membranes of the cells in the chemosensitive areas of the medulla.

The difficulty with using these concepts lies in the practical measurement of the relevant molecules. For example, although the imidazole moiety of histidine is considered the most important of the intracellular buffers, its pKa and enthalpy of ionization may vary widely due to the influence of the local configuration of molecules into which they are incorporated. Thus, even in lower animals such as fish under different temperatures, calculations based on the alphastat model do not accurately predict the acid-base disturbance, since the pKa and enthalpy of ionization vary with temperature and are difficult to measure.

Similarly, measurement of the plasma SID is problematic and is often replaced by the "SID effective," which is roughly equal to the bicarbonate concentration plus albumin and inorganic phosphate. Calculation of the anion gap—$[Na^+] - [Cl^-] - [HCO_3^-]$—accounts for the roles of the strong ions Na^+ and Cl^- as well as bicarbonate but does not account for the role of inorganic phosphate or plasma proteins. Although the bicarbonate concentration may not be strictly speaking an independent variable, the anion gap calculation does indicate the quantity of unmeasured anions and hence is an indirect measure of the strong ion difference. If one considers the impact of serum proteins and inorganic phosphate in the unmeasured anion pool, the anion gap gives a very useful parameter in evaluating acid-base disturbances. As will be described in more detail in the following section, the use of the anion gap is still the most clinically useful tool to determine the contribution of different metabolic etiologies of metabolic acidosis.

APPROACH TO THE PATIENT WITH AN ACID-BASE DISTURBANCE

In this section, we examine the diagnostic approach to disorders of acid-base balance with a particular emphasis on the ventilatory response and its role in mitigating or exacerbating acid-base disorders. We will also review the approach to the patient with complex acid base disorders.

Analysis of Clinical Information

Table 14-1 summarizes the pattern of abnormality of arterial blood acid-base parameters in the four classic acid-base disorders. It also indicates the physiological or compensatory response induced in pulmonary or renal function in response to the initial disturbance.

Base Excess and Base Deficit Notations

Base excess and *base deficit* are terms applied to an analytical method for determination of the appropriateness of responses to disorders of acid-base metabolism. The base excess or deficit is determined by measuring blood pH against ambient P_{CO_2} and against a P_{CO_2} of 40 mmHg. If the calculated HCO_3^- is below 25 when the P_{CO_2} is 40 mmHg and the original pH is low, a base deficit is indicated. The magnitude of the deficit is expressed as the number of mEq of bicarbonate needed to restore the serum bicarbonate to 25 mEq/L at a P_{CO_2} of 40 mmHg compared with that at the ambient P_{CO_2}. The use of notations for base excess and deficit has been debated in the medical literature. This notation is favored in the evaluation of acid-base status in the operating room because acute changes in P_{CO_2} and in HCO_3^- can be simply evaluated by this approach. However, this notation can be misleading in chronic respiratory alkalosis or acidosis, since the patient with chronic respiratory alkalosis will be categorized as suffering from a base deficit because of the low serum bicarbonate induced as compensation for the reduced P_{CO_2}. In fact, a "base deficit" is a normal physiological response to the chronic reduction in P_{CO_2}. Unfortunately, lack of familiarity with the complete analytical paradigm used for this analysis of acid-base disorders has led some to focus on the designations "base deficit" and "base excess" as guides to bicarbonate or acid therapy in chronic respiratory disorders. In addition, discrepancies among the buffering characteristics of plasma, blood, and whole body have also been cited as potential weaknesses in a system for assessing acid-base disorders, which relies on in vitro CO_2 titration methods. Therefore, we recommend that the physiological evaluation of the patient be the mode of analysis of acid-base disorders rather than an emphasis on derived formulae.

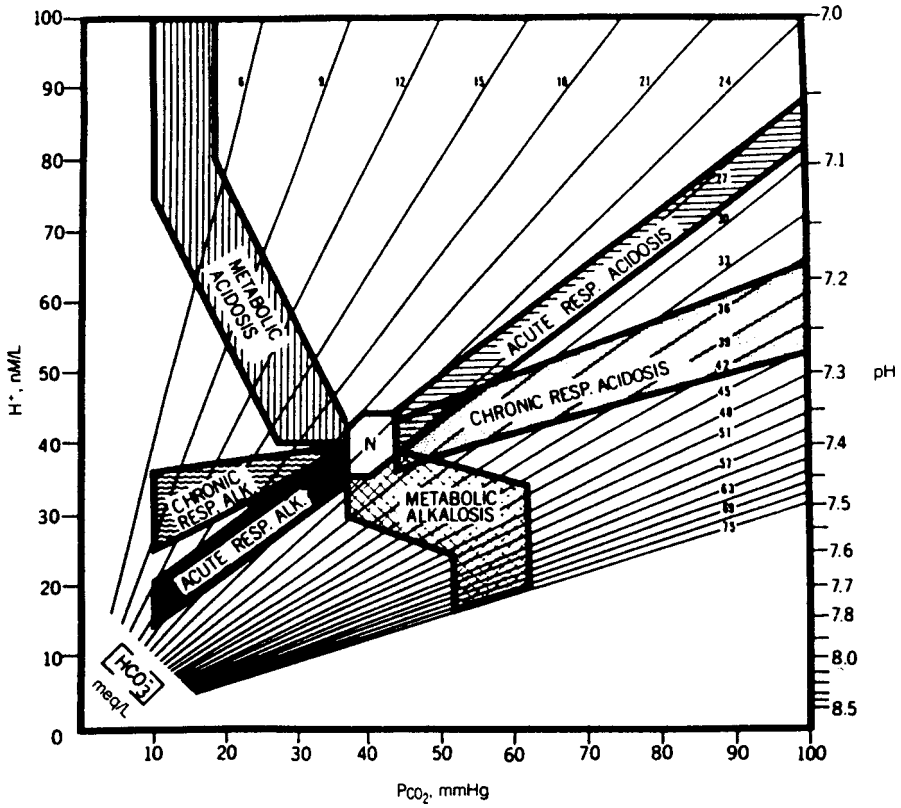

Figure 14-4 Acid-base map showing the normal range (N) and the confidence bands for acute or chronic respiratory and metabolic acid-base disturbances. The ordinates are the partial pressure of CO_2 and the hydrogen-ion activity given in nmol/L and pH units. Isopleths for bicarbonate concentration, in milliequivalents per liter, are also shown. *(From Goldberg M, Green SB, Moss ML, et al: Computer-based instruction and diagnosis of acid-base disorders. A systematic approach. JAMA 223:269, 1973, with permission.)*

Use of Nomograms

As indicated, the body buffers and the kidneys respond in a predictable fashion to a change in P_{CO_2}, whereas ventilatory response to changes in $[HCO_3^-]$ is also predictable. Also, the resulting changes in bicarbonate and pH are time dependent so that a larger change occurs in several days than in the first hours. The confidence bands for changes in P_{CO_2} or HCO_3^- in response to primary disturbances are shown in Fig. 14-4. Any deviation can be interpreted as a reflection of processes other than a compensatory response. For example, in a patient with chronic obstructive airways disease, other factors affecting the acid-base status are the concentration of potassium in the plasma, the size of extracellular fluid volume, chloride depletion, diuretics, renal hypoperfusion, and coexisting renal disease. The special case of posthypercapneic alkalosis is discussed in the next section.

In evaluating an acid-base disorder, the history and physical examination are invaluable in focusing attention on potential pathological processes. The composition of blood, with respect to serum electrolytes and blood gases, is then examined for consistency with the clinical impressions. However, in using the acid-base map (Fig. 14-4), remember that the map is based on data from individuals who had a single disorder. Therefore, the map does not take into account the possibility of multiple disorders. For example, in a patient with chronic obstructive airways disease whose sputum has turned purulent and who develops nausea and vomiting, the possibility arises of coexistent metabolic alkalosis and acute respiratory acidosis. However, ill-advised application of the arterial blood-gas values from this patient (e.g., pH = 7.25 and P_{CO_2} = 75 mmHg) to the acid-base map would lead to the erroneous conclusion that a chronic respiratory acidosis is present. Thus, the clinician needs to integrate laboratory data with clinical assessments to properly analyze clinical disorders of acid-base balance.

Approach to the Patient with Metabolic Acidosis

An increase in the H+ concentration of the extracellular fluid will result in a series of predictable responses that allow the clinician to ascertain the appropriateness of organized homeostatic responses to the perturbation. The pathophysiological basis for the initiation of metabolic acidosis and homeostatic responses in the defense of systemic pH have been defined above in descriptions of the buffering of newly introduced acid [see Eq. (1)] and in the demonstration of the normal confidence band for the ventilatory response to metabolic acidosis as detailed in the acid-base nomogram (Fig. 14-4).

An essential clinical distinction in the pathogenesis of metabolic acidosis is whether the production of the acidosis is rapid or slow. If the etiology of the metabolic acidosis is merely the continued ingestion of a diet that generates a variety of fixed acids such as H_2SO_4 [see Eq. (2)] from the metabolism of methionine residues, then the serum HCO_3^- will fall slowly, as only that fraction of the 50 to 100 mEq of H^+ generated from diet that is not excreted would be added to the body fluids each day. However, if the addition occurs because of an acute increase in the acid load such as may occur with lactic acidosis, the kidney capacity can be rapidly overwhelmed,

Table 14-2

Causes of Metabolic Acidosis (Common)

Failure to generate new bicarbonate to replace that consumed in buffering dietary acid load
- Diminished NH_4^+ production and excretion
  - Reduced renal mass
  - Chronic hyperkalemia
  - Chronic aldosterone deficiency
- Decreased H^+ ion secretion (primary)
  - Distal renal tubular acidosis
- Increased H^+ ion production
  - Lactic acidosis
  - Ketoacidosis
  - Toxic ingestion
- Bicarbonate or equivalent losses from body fluids
  - Renal-proximal RTA, carbonic anhydrase inhibitors
  - GI-diarrhea, villous adenoma, fistula

and serum bicarbonate may fall precipitously. See Table 14-2 for the common causes of metabolic acidosis.

Utility of the Anion Gap

As seen in Eq. (6), the buffering of mineral acids will result in the production of the salt of the acid, NaA.

$$NaHCO_3 + HA \; NaA + H_2CO_3^- + H^+ \; CO_2 + H_2O + NaA \tag{6}$$

If the kidney is able to excrete this salt or, in the case of the production of the salts of organic acids such as lactic acid, if the liver can metabolize the anion to HCO_3^-, then there will be no accumulation of the anion in the extracellular fluid. Typically, anions associated with strong organic acids are not measured with routine electrolyte determinations and contribute to the so-called anion gap. Determination of the plasma anion gap is primarily used in the differential diagnosis of metabolic acidosis. However, the anion gap also changes in other conditions, a finding that may be of diagnostic importance.

The plasma anion gap (AG) is calculated from the following formula based on routine laboratory determination:

$$AG = (\text{cations}) - (\text{anions})$$

Since Na^+ is the primary measured cation and Cl^- and HCO_3^- are the primary measured anions,

$$AG = [Na^+] - ([Cl^-] + [HCO_3^-]) \tag{7}$$

and normal $= 12 \pm 2$ mEq/L.

An increase in the anion gap can be produced by an increase in unmeasured anions or by a reduction in unmeasured cations. Hypokalemia, hypocalcemia, or hypomagnesemia can only raise the anion gap by a few mEq/L, since these ions can only deviate from normal by an mEq/L or less and maintain a physiological condition. The predominant extracellular unmeasured anion is actually albumin with many negative charge sites per molecule. Hence, a mild elevation in the anion gap can occur in conditions in which the albumin concentration or the charge characteristics of albumin are altered, for example, in metabolic alkalosis. In that instance, a number of factors may contribute to the increment, including a rise in the plasma albumin concentration due to extracellular volume depletion and contraction of plasma constituents, an increase in the number of negative charges per albumin molecule induced by the rise in extracellular pH titrating protons off the albumin molecule, and a tendency for systemic alkalemia to induce an increase in lactate production. This latter response serves a homeostatically beneficial function.

In forms of metabolic acidosis in which there is buffering of excess hydrochloric acid by extracellular bicarbonate, then,

$$HCl + NaHCO_3 \; NaCl + H_2CO_3CO_2 + H_2O \tag{8}$$

Bicarbonate is replaced on an equimolar basis by chloride, and there is no change in the anion gap; this disorder is also called a *hyperchloremic acidosis* because of the rise in the plasma chloride concentration. Both diarrhea and type 2 (proximal) renal tubular acidosis can lead to the loss of $NaHCO_3$. The kidneys compensate by retaining NaCl in an attempt to preserve volume, with the net effect being an mEq-for-mEq exchange of chloride for bicarbonate.

If the retained acid is not HCl but an organic acid whose anion is not routinely measured such as lactic acid, then the increase in the unmeasured lactate anion will raise the anion gap. It is important to emphasize that the acidosis is due to the retained proton; the anion is irrelevant to the change in acid-base status or systemic pH but is important as a diagnostic tool. The major causes of a high anion gap metabolic acidosis include those listed in Table 14-2 under disorders of increased H^+ production. Although renal failure produces an acidosis because of failure of H^+ excretion and bicarbonate production, most patients with severe renal failure retain both hydrogen and anions, such as sulfate, phosphate, and urate, and hence demonstrate a high anion gap.

The diagnostic utility of a high anion gap is greatest when the anion gap is above 20 mEq/L; in this setting, renal failure, lactic acidosis, or evidence of a toxic ingestion will almost always be present. When the anion gap is less than 20 mEq/L, identifying the anions which contribute to the mild elevation10 often is impossible.

Urine Anion Gap

Estimation of the urinary ammonia content may be a useful clue to the etiology of metabolic acidosis, as the value will increase in diseases in which kidney function affecting acid-base balance is completely intact but in which bicarbonate is lost from the body fluids. The calculation of the urinary anion gap is shown in Eq. (9):

$$\text{Urine anion gap} = (\text{Urine}[Na^+] + \text{Urine}[K^+]) - \text{Urine}[Cl^-] \tag{9}$$

The usual value will be negative, between –25 and –50 mEq/L, as the ammonium content of the urine is typically in this range, and ammonium accounts for the apparent discrepancy between the level of cations and anions in the urine. In states of metabolic acidosis due to diarrhea or to chronic acid ingestion, the value will be greater than 50 mEq/L as ammonium production is stimulated.

In three conditions, the urine anion gap will be very low or even positive in the face of metabolic acidosis. In all forms of renal insufficiency, ammonia production by the kidney will be deficient and significantly contribute to a reduced urinary anion gap and metabolic acidosis. In type I distal RTA, inability to maintain a steep gradient for protons in the distal tubular lumen and in the collecting duct results in a deficiency in ammonia trapping in the luminal fluid and therefore a decreased excretory rate for ammonia. This in turn leads to metabolic acidosis, a low ammonia excretion, and an abnormally low urinary anion gap. Type IV RTA, a condition in which hyperkalemia and mild renal insufficiency are found, hyperkalemia suppresses renal ammonia production, and a low urinary anion gap is found.

In any condition associated with hypokalemia, increased intracellular proton accumulation (which results from the exchange of cellular potassium for extracellular protons) will lead to an exaggerated ammonia production in the kidney. Hence, the use of the anion gap in the urine will be particularly useful to differentiate classic type I RTA from hypokalemia and acidosis due to diarrhea. The former will show a very low urine anion gap. Typically, a careful history will elicit the crucial information, and measurement of the urine anion gap will be confirmatory.

Clinical Assessment of Metabolic Acidosis

In approaching a patient with metabolic acidosis, the clinician should first assess the history and clinical circumstances. For example, patients with renal failure or uncontrolled diabetes may be presumed to have a metabolic acidosis until disproved by laboratory analysis. The next step is to evaluate the serum electrolytes to determine the level of the serum HCO_3^- and the presence of a anion gap of greater than 12 ± 2 mEq/L. If both are present, then one must consider the possibility of a metabolic acidosis secondary to increased acid production as listed in Table 14-2. If the HCO_3^- is reduced but the serum anion gap is normal, then one is dealing with either a respiratory alkalosis or a metabolic acidosis due to reduced renal capacity to generate replacement HCO_3^- to compensate for that lost as a result of decreased acid excretion or increased HCO_3^- loss.

At this point arterial blood gases should be assessed to determine the pH and ventilatory response. Finding a low pH establishes the diagnosis of metabolic acidosis. Reference to the acid-base nomogram (Fig. 14-4) will verify whether the clinical response is consistent with a simple metabolic acidosis with a normal ventilatory response or whether some other disturbance in ventilation is present.

Table 14-3

Causes of Metabolic Alkalosis

Gastrointestinal hydrogen loss
Removal of gastric secretions
Renal hydrogen loss
Primary mineralocorticoid excess
Loop or thiazide diuretics
Posthypercapneic alkalosis
Intracellular shift of hydrogen
Hypokalemia
Alkali administration
Contraction alkalosis

Metabolic Alkalosis

Two separate processes are involved in metabolic alkalosis: an excess load of base that is generated either endogenously or exogenously (Table 14-3) and maintenance of an abnormally high concentration of bicarbonate in the plasma. During hypercapnia, the load of base is the result of renal compensation and de novo bicarbonate generation; in posthypercapneic alkalosis, the key abnormality is maintaining the bicarbonate level in plasma at inordinately high levels, as discussed below.

Generation of Metabolic Alkalosis

Causes of metabolic alkalosis are predominantly events that remove H^+ ions from the body but also include circumstances in which excess base is added to the body fluids. Hydrogen loss can occur from the gastrointestinal tract or in the urine. Each mEq of hydrogen lost generates 1 mEq of bicarbonate, as the source of hydrogen ions in cells that produce and secrete protons is:

$$H_2O \; H^+ + OH^- + OH^- + CO_2 \; HCO_3^- \qquad (10)$$

When vomiting or tube drainage prevents stomach acid from reaching the duodenum and combining with HCO_3^- released from pancreatic secretions, the net balance of bicarbonate in body fluids becomes positive, and serum HCO_3^- begins to rise.

Increased renal acid losses may result from enhanced distal hydrogen secretion. Aldosterone acts both by directly stimulating the secretory H^+-ATPase pump and, via the stimulation of sodium reabsorption, by making the lumen more electronegative, thereby favoring hydrogen ion secretion. Increased distal nephron delivery and reabsorption of sodium further stimulates hydrogen ion secretion as the accompanying anion is less avidly reabsorbed than is sodium, and the lumen of the distal nephron becomes more negatively charged. Excess secretion of mineralocorticoids can lead to metabolic alkalosis by this pathway. In patients treated with loop-active or thiazide diuretics, enhanced distal delivery of sodium and increased secretion of aldosterone are usually present, thereby enhancing renal bicarbonate production as

a result of enhanced hydrogen ion secretion. This pattern commonly leads to the development of metabolic alkalosis.

Chronic respiratory acidosis leads to a secondary increase in renal hydrogen secretion, as the subsequent rise in the plasma bicarbonate concentration will restore the pH toward normal as a compensatory response. If the patient undergoes a therapeutic maneuver such as rapid lowering of the P_{CO_2} by mechanical ventilation, a posthypercapneic form of metabolic alkalosis will ensue as the patient is left with an elevated plasma bicarbonate concentration.

Hypokalemia is a frequent finding in patients with metabolic alkalosis and may not only be the consequence of some of the disorders that lead to the initiation of metabolic alkalosis but may also actually induce an alkalotic tendency. Gastric drainage, diuretics, and mineralocorticoid excess all induce potassium as well as hydrogen losses through the gastrointestinal tract and kidney, respectively. Hypokalemia also induces a transcellular shift in which potassium is exchanged in an electroneutral fashion for hydrogen ions in the extracellular fluid. This exchange directly raises the extracellular pH, lowers the intracellular pH, and mitigates the hypokalemia. Intracellular acidosis in renal tubular cells promotes hydrogen secretion and therefore bicarbonate reabsorption (see above).

Administering large amounts of alkali does not maintain metabolic alkalosis in normal individuals because of rapid urinary excretion, but it may induce the initiation stage of metabolic alkalosis if factors are active to sustain a high rate of renal HCO_3^- reabsorption. A form of metabolic alkalosis termed *contraction alkalosis* occurs when there is loss of relatively large volumes of bicarbonate-free fluid. Administration of a loop diuretic to induce rapid fluid removal in a markedly edematous patient is the most common cause of a contraction alkalosis. The plasma bicarbonate concentration rises in this setting because there is contraction of the extracellular volume around a relatively constant quantity of extracellular bicarbonate. The degree to which this occurs is in part minimized by intracellular buffering, as the release of hydrogen ions from cells buffers lowers the plasma bicarbonate concentration toward the baseline value. Even this form of alkalosis is probably critically dependent on increases in renal bicarbonate production for its manifestation, since the diuretics promote excess renal hydrogen ion secretion as noted above.

Maintenance Phase of Metabolic Alkalosis

Maintenance of metabolic alkalosis requires an increase in the reabsorption of bicarbonate by the renal tubule. Four factors are known to be important in the maintenance phase of metabolic alkalosis: extracellular volume depletion, chloride depletion, hypokalemia, and mineralocorticoid excess.

A reduction in extracellular fluid volume and possibly a fall in the glomerular filtration rate secondary to extracellular volume depletion are major stimuli for increasing the proximal reabsorption of bicarbonate. The enhanced proximal tubular bicarbonate reabsorption is likely the most important factor. This reabsorption is stimulated by the extracellular volume depletion that is a frequent accompaniment of metabolic alkalosis. Enhanced proximal tubular reabsorption of sodium ions is a major factor in the enhanced rate of proton secretion, a key factor in the proximal tubular reabsorptive pathway for bicarbonate. Enhanced activity of the sodium-proton exchanger in the luminal membrane of the proximal tubule is an important component of the transport system.

In addition, an important role is played by the distal nephron in maintaining metabolic alkalosis by way of the secondary phenomena of chloride depletion, extracellular volume depletion, and hypokalemia. Cells of the cortical collecting tubule can either reabsorb or secrete bicarbonate depending on homeostatic requirements. For example, during excess bicarbonate ingestion, the secretory process predominates, and excess bicarbonate is lost into the urine. Chloride depletion enhances the bicarbonate reabsorptive pathway by reducing chloride availability at an anion exchange site on the luminal membrane of the type A intercalated cell. This exchange process normally allows bicarbonate entry into the urine in exchange for chloride absorption. Chloride depletion thus blocks bicarbonate loss.

Hypokalemia acts to stimulate bicarbonate reabsorption through several mechanisms. First, loss of potassium from the extracellular fluid leads to a shift of protons into the cell as potassium leaves the cell. Hence, intracellular pH falls, driving enhanced tubular bicarbonate reabsorption. Also, severe potassium depletion produces a defect in tubular fluid chloride reabsorption, thus mimicking a chloride depletion state. Finally, excess mineralocorticoid hormone, either as a result of primary overproduction or due to a variety of secondary hyperreninemic states, stimulates H^+ secretion in the cortical collecting tubule and thereby stimulates increased renal tubular bicarbonate production and helps maintain metabolic alkalosis.

Typically, all four components coexist in patients with metabolic alkalosis secondary to vomiting or gastric drainage following gastric intubation. If any of the factors is present in a patient with metabolic alkalosis, therapy will be only partially successful until all the factors have been eliminated.

Depression of ventilation in metabolic alkalosis is a normal physiological response to the elevation in serum bicarbonate but is difficult to assess clinically and may not be found in many patients, as detailed above.

Posthypercapneic Metabolic Alkalosis

In response to sustained hypercapnia, the increased excretion of hydrogen ion in the urine and the increased bicarbonate generated by the acid secretory process increase the concentration of bicarbonate in the plasma as described above. During this process, the total sodium content of the body remains stable as does the extracellular fluid volume (unless there is a separate reason for a volume abnormality, such as right ventricular failure and the use of diuretics). If correction of hypercapnia occurs (e.g., through the use of mechanical ventilation without simultaneous replacement of sodium chloride), the urinary loss of sodium bicarbonate may lag for several hours

or days. This is particularly true if there is concomitant depletion of the extracellular fluid volume. This leads to an increase in the reabsorption of solute, including sodium bicarbonate, by the proximal tubule, sustaining the high bicarbonate concentration in blood. This process is similar to the maintenance phase of metabolic alkalosis described above; the other processes outlined also could pertain to this posthypercapneic state and produce a persistent metabolic alkalosis following correction of hypercapnia.

Approach to the Patient with a Mixed Acid-Base Disorder

The approach to patients with mixed acid-base disorders, that is, more than one disturbance in acid-base metabolism, is particularly challenging because no nomogram, calculation of base excess or deficit, or other formula can allow the clinician to parse the pathophysiological disorders and allow a rational therapeutic plan. Rather, it is the combination of clinical assessment, application of expected compensatory responses, assessment of the anion gap, and application of principles of physiology that together allow a successful analysis.

In order to determine the presence of a mixed or complex acid-base disorder, the clinician must follow a rigorous approach that integrates clinical observation with assessment of a variety of laboratory parameters. No single nomogram or other shortcut device will suffice. The initial step is to perform a history and physical examination to seek processes which could contribute to acid-base disorders. For example, any patient who has vomited has the potential for developing a metabolic alkalosis, and any patient with chronic renal failure surely has metabolic acidosis as an ongoing process for which compensation will be necessary. Moreover, many clinical conditions are typically characterized by the presence of more than one concurrent disorder. Patients with severe liver failure usually experience respiratory alkalosis as a consequence of hepatic encephalopathy so that any other conditions associated with abnormalities of acid-base balance that may develop in these patients will result in mixed acid-base disorders. Septic shock is associated with the mixed disorders of respiratory alkalosis and metabolic acidosis due to lactic acid production. Immediately following cardiac arrest, patients will have both a respiratory and a metabolic acidosis. Patients with renal failure who undergo gastric drainage will manifest both metabolic alkalosis and metabolic acidosis as a result of the underlying conditions. The clinician must consider these expected abnormalities in acid-base balance when addressing laboratory results.

The second step in the process is to evaluate a venous blood sample for determination of the electrolytes, blood urea nitrogen (BUN), creatinine, and other parameters indicative of liver function. Here, the evaluation of the $[HCO_3^-]$ and analysis of the anion gap is invaluable. Decrements or elevations of $[HCO_3^-]$ will point toward a disturbance in the body's buffering system. The anion gap measurement, if elevated, will clarify whether a metabolic acidosis is present, as described above. Also, analyzing the anion gap together with the venous $[HCO_3^-]$ can provide important information. Because the anions that accumulate in most forms of organic acidosis (lactic acidosis, ketoacidosis, many toxic ingestions) can be metabolized in the liver to bicarbonate through the Kreb's cycle, adding the unmeasured anion concentration to the current plasma HCO_3^- concentration indicates the level of $[HCO_3^-]$ prior to the onset of the metabolic acidosis.

APPENDIX

The following cases illustrate the clinical approach to the patient with acid-base disturbances.

Metabolic Acidosis

A 75-year-old patient presented with a 7-day history of intermittent diarrhea and a 5-lb weight loss. The rest of the history was unrevealing. Physical examination only revealed signs of volume depletion. Laboratory values were as follows:

$[BUN] = 18$ mg/dl
$[Na^+] = 138$ mEq/L
$[K^+] = 3.0$ mEq/L
$[Cl^-] = 110$ mEq/L
$[HCO_3^-] = 13$ mEq/L

At this point, the lack of an elevated anion gap (12 mEq/L) and the reduced bicarbonate concentration together suggest the possibility of either respiratory alkalosis or metabolic acidosis of the non–anion-gap variety, i.e., in which the chloride concentration has risen as bicarbonate has been utilized in buffering reactions or has been lost from body fluids. The history of diarrhea strongly suggests that a metabolic acidosis is the culprit in the disorder. The relatively low BUN supports the theory that diarrhea and not renal insufficiency is the main etiologic factor.

Arterial blood gases are then obtained:

pH = 7.24
$P_{CO_2} = 27$ mmHg
$P_{CO_2} = 100$ mmHg
$[HCO_3^-] = 13$ mEq/L

The low serum bicarbonate in association with a low arterial blood pH indicates that the patient has a metabolic acidosis. Finding that the rate of ventilation produces a P_{CO_2} of 27 is consistent with the expected P_{CO_2} of 27.5 ± 2 mmHg calculated from Winters' formula (Table 14-1). Reference to the acid-base nomogram (Fig. 14-4) reveals the graphical equivalent of this calculation as the values for pH, P_{CO_2}, and $[HCO_3^-]$ fall in the confidence band for metabolic acidosis. Other possible etiologies for this form of non–anion-gap metabolic acidosis include mild renal insufficiency, wherein the decline of GFR has not reached a level in which the unmeasured anions such as SO_4^{2-} would begin to accumulate in plasma, and the ingestion of salts such as ammonium chloride, which are

metabolized in the liver to urea and hydrochloric acid. Urinary electrolyte analysis confirms the diagnosis:

$[Na^+] = 50$ mEq/L
$[K^+] = 20$ mEq/L
$[Cl^-] = 140$ mEq/L
Urine volume = 2 L
Urinary anion gap = −70 mEq/L

The discrepancy between the sum of urine cations and anions in the negative range indicates that an unmeasured cation, in this case ammonium, is being excreted into the urine. It is the excretion of protons in association with ammonia that allows the renal excretion of the accumulated acid load and the attempted regeneration of body HCO_3^- stores. If this value were not greater than –20 to –50 mEq/L, a defect in ammonia production or excretion such as could be found in renal insufficiency or in renal tubular acidosis could be present. In this case, diarrhea is the culprit.

Metabolic Alkalosis

A 65-year-old patient experienced severe and unremitting vomiting for 4 days. He has had a history of peptic ulcer disease, but he decided to medicate himself with an antacid, which he could not keep from vomiting. There was no other significant past medical history. Physical examination showed a moderate degree of orthostatic hypotension as blood pressure fell from 100/70 mmHg supine to 90/60 mmHg when seated. The rest of the examination was not remarkable except for some abdominal tenderness.

Laboratory results revealed the following:

[BUN] = 28 mg/dl
$[Na^+] = 43$ mEq/L
$[K^+] = 3.0$ mEq/L
$[Cl^-] = 85$ mEq/L
$[HCO_3^-] = 39$ mEq/L

The elevation in HCO_3^- content is consistent with either metabolic alkalosis or chronic respiratory acidosis with renal compensation. The clinical circumstances strongly imply that metabolic alkalosis will be found, since the patient has been vomiting and therefore has been generating new alkali in the body fluids as gastric hydrochloric acid is lost. Also, the vomiting-induced deficit in extracellular fluid volume and body fluid chloride content will likely act to help sustain the metabolic alkalosis by stimulating a high rate of renal bicarbonate transport by the proximal tubule and inhibiting distal nephron bicarbonate secretion.

Arterial blood gases are then obtained:

H = 7.52
$P_{CO_2} = 46$ mmHg
$[HCO_3^-] = 36$ mEq/L

These confirm the diagnosis. Note that the hypoventilatory response is modest, probably because of the degree of hypokalemia, which tends to acidify the intracellular fluid and stimulate ventilation. Correction of this abnormality requires both replacement of fluid with sodium and chloride and adequate intake of potassium to fully restore acid-base balance to normal.

Mixed Acid-Base Disturbance

An insulin-dependent diabetic patient with several days of vomiting developed diabetic ketoacidosis. The following set of electrolytes is obtained:

$[Na^+] = 140$ mEq/L
$[K^+] = 5$ mEq/L
$[Cl^-] = 90$ mEq/L
$[HCO_3^-] = 15$ mEq/L
Anion gap = 35 mEq/L

Since the normal anion gap is 12 ± 2 mEq/L, this individual has utilized 23 mEq/L of HCO_3^- to buffer the ketoacids. If the production of ketoacids ceases and hepatic metabolism is restored through insulin administration, then 23 mEq/L of HCO_3^- could be added to body fluids. The new set of electrolytes would be:

$[Na^+] = 140$ mEq/L
$[K^+] = 5$ mEq/L
$[Cl^-] = 90$ mEq/L
$[HCO_3^-] = 38$ mEq/L
Anion gap = 12 mEq/L

By assessing the value—(anion gap increment above 12 mEq/L) + (serum $[HCO_3^-]$)—and finding a value greater than 30, one can infer that some process has previously raised the bicarbonate content above normal even if the ambient total CO_2 level is subnormal at the current moment. Hence either metabolic alkalosis or respiratory acidosis is a component process of the acid-base disorder. Conversely, finding a value less than 20 suggests that the patient had a preexistent metabolic acidosis or a respiratory alkalosis prior to the onset of the organic acidosis. Finally, the clinician may assess the alveolar-arteriolar O_2 gradient to determine the effectiveness of oxygenation as an initial assessment of respiratory intactness.

At this point the clinician is able to ascertain a tentative diagnosis and perform an arterial blood gas determination to conclude the process. Measurement of the blood gas will show whether the respiratory response to a metabolic disturbance (metabolic alkalosis or metabolic acidosis) or the metabolic (renal) response to a respiratory disturbance is as expected. The acid-base disorder could still be labeled a simple disturbance if the initial assessment of the clinical condition and the anion gap support that conclusion. Consulting the acid-base map (Fig. 14-4) will provide the expected compensatory response to each disturbance. In the case above of a patient with diabetic ketoacidosis and an initially increased [anion gap + total CO_2] concentration, the following arterial blood gases were obtained:

pH = 7.18
$P_{CO_2} = 38$ mmHg
$[HCO_3^-] = 15$ mEq/L

In pure metabolic acidosis, the ventilatory response to a $[HCO_3^-]$ lowered to 15 mEq/L would be a P_{CO_2} of 25 mmHg (Table 14-1 and Fig. 14-4). In this example, the patient shows a P_{CO_2} that is higher than the expected value of 25 for a patient with pure metabolic acidosis and a depressed HCO_3^- value of 15 mEq/L. Hence this patient demonstrates a so-called triple disturbance, metabolic acidosis (low HCO_3^-, high anion gap), a metabolic alkalosis [(HCO_3^- + anion gap increment above 12) greater than 30 mEq/L] and a respiratory acidosis (P_{CO_2} higher than expected value given the lowering of HCO_3^- level as determined from the acid-base nomogram or the formula for expected compensation). Therapy for this patient will require awareness of these various processes, since removal of a counter disturbance can induce a more severe expression of the still-present abnormality.

CHAPTER

Exercise, Integration, and Adaptation

Alfred P. Fishman

Muscular exercise, such as walking, is such a regular feature of daily life that it is usually taken for granted until something goes wrong. The range of daily activity and its limits vary greatly from person to person. The range is narrower in individuals who lead sedentary lives than in those who are active. In the athlete who regularly engages in competitive sports, the physiological adjustments are of a degree and type different from those in individuals who engage in less strenuous activities. Moreover, these functional changes are generally accompanied by structural changes in the heart and lungs (see "Adaptation" below).

In recent years, normal individuals have learned that moderate and regular exercise is both healthful and personally gratifying. However, the rewards of exercise are not confined to normal subjects. More than a few days' bed rest, such as a weeklong convalescence from an acute illness, is accompanied by a decrease in strength and physical capacity. Physical inactivity also imposes a continuing threat to persons for whom freedom of motion is limited, such as those who get about in motorized wheelchairs. In these people, physical deconditioning is inevitable unless physical exercise is deliberately incorporated into their way of life. Exercise also minimizes the risk of thromboembolism from leg veins.

Over the years, studies of the integrated adjustments during exercise led to such concepts as "fixity of the internal environment," "homeostasis," and adaptation. In addition, attention has been paid to adaptive changes such as hypertrophy and hyperplasia. This introductory chapter deals with such concepts as they apply to the physiological processes of normal subjects during exercise. Viewed from this perspective, diseases of the cardiorespiratory apparatus can be considered as failures in one or more components of the integrative and compensatory responses.

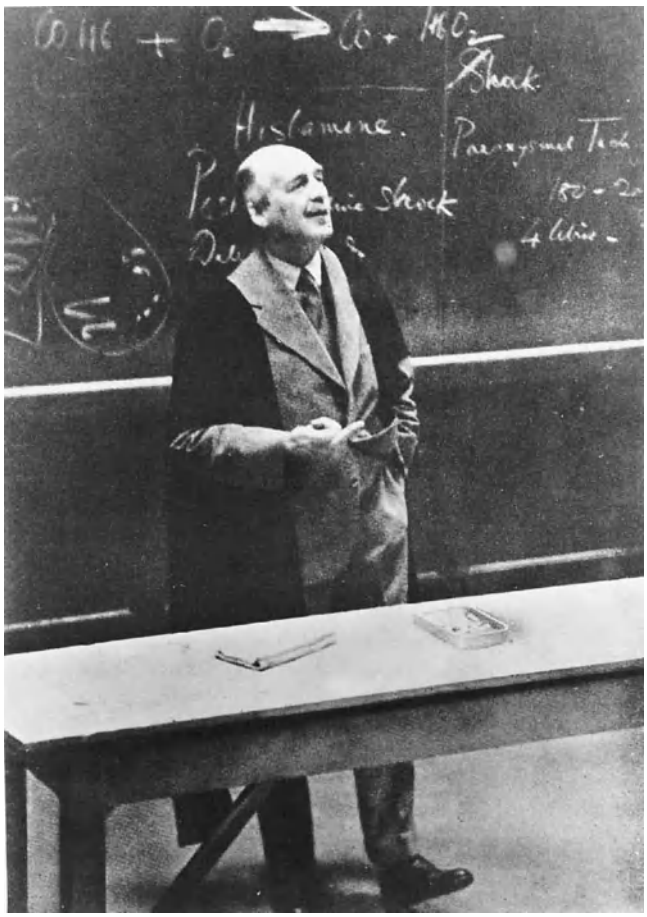

Figure 15-1 Joseph Barcroft (1872–1947) explored the integrating functions responsible for adjustments to diverse external environments, such as high altitude and fetal life. He maintained a lifelong interest in the properties of the oxygen dissociation curve and proved that oxygen entered pulmonary capillary blood by diffusion rather than by secretion.

THE INTEGRATED RESPONSE

Principles of the Integrated Response

Barcroft's classic monograph of 60 years ago, *Features in the Architecture of Physiological Function*, includes three chapters under the heading "Every Adaptation Is an Integration." One chapter deals with exercise; the other two deal with pregnancy and anoxia (i.e., hypoxia), respectively. All three are concerned with the physiological changes that make possible the successful transition from one biologic state to another (e.g., rest to exercise) (Fig. 15-1).

Barcroft's considerations of the three states led him to several generalizations about cardiorespiratory adjustments that can be paraphrased as follows: (1) after a person adjusts to a new environment or to a changed demand for oxygen, the blood gases undergo measurable changes instead of remaining constant; (2) the changes in blood gases occur in an orderly way and reverse upon return to the person's original condition or environment; and (3) the physiological adjustment is usually due to a summation or multiplication of several small changes rather than to a single major change (e.g., the cardiac output can undergo a ninefold change because of threefold variations in stroke volume and heart rate).

The Integrated Response for O_2 Uptake

The increase in energy called for by the exercising muscles has to be delivered by the heart, lungs, and blood, working as a coordinated system for the delivery of oxygen and removal of carbon dioxide. The amount of oxygen required can be quite large and impose large demands on the heart as a pump, on the transport system between the alveolar capillaries and the mitochondria, and on the ventilatory apparatus. Traditionally, the capacity to respond has been tested by progressive, steady-state exercise calibrated according to successive levels of oxygen uptake. For each level of exercise, the normal response of the cardiorespiratory apparatus has been quantified. For example, to satisfy the need for a 10-fold increase in oxygen uptake, the ventilation is expected to increase to about 20 times the resting minute volume and the cardiac output (predominantly by an increase in heart rate) to about three times the resting minute volume. These changes operate in concert with a striking redistribution of blood flow to the exercising muscles.

In 1925, Morgan and Murray, close collaborators of Barcroft and Henderson, used a four-quadrant diagram to graphically demonstrate the complex interplay in oxygen uptake by the lungs at rest (Fig. 15-2). Since then, the same type of representation has been used to depict related aspects of oxygen uptake by the lungs during steady-state exercise (Fig. 15-3). It also can be used to illustrate oxygen delivery to the exercising muscles and carbon dioxide elimination by the lungs in health and disease (Fig. 15-4).

During recent decades, the physiological parameters that make up the individual quadrants of the Morgan-Murray diagram have been extensively studied at rest and during graded exercise. For example, at consecutive levels of exercise, the cardiac output increases by a combination of an increase in heart rate and stroke volume. However, the increase in cardiac output is proportionally less than the increase in oxygen consumption. The difference between the two is made up by redistribution of the cardiac output. Thus, at the maximum rate of oxygen uptake ($\dot{V}O_{2\,max}$)—i.e., when oxygen uptake levels off despite further increases in work rate—blood flow to skeletal muscle increases from about 20 percent of the cardiac output at rest to almost 90 percent during exercise; concomitantly, the splanchnic blood flow decreases from about 25 percent of the cardiac output to about 1 percent. In addition to redistribution of the cardiac output in favor of the exercising muscles, the arteriovenous O_2 difference increases greatly; i.e., the O_2 extraction from each unit volume of perfusing blood increases. This increase in O_2 extraction is, in turn, a consequence of several physiological adjustments: an increase in the hemoglobin concentration of blood, a shift to the right of the O_2 dissociation curve due to increased release of CO_2 by the exercising muscle, and an increase in temperature of blood.

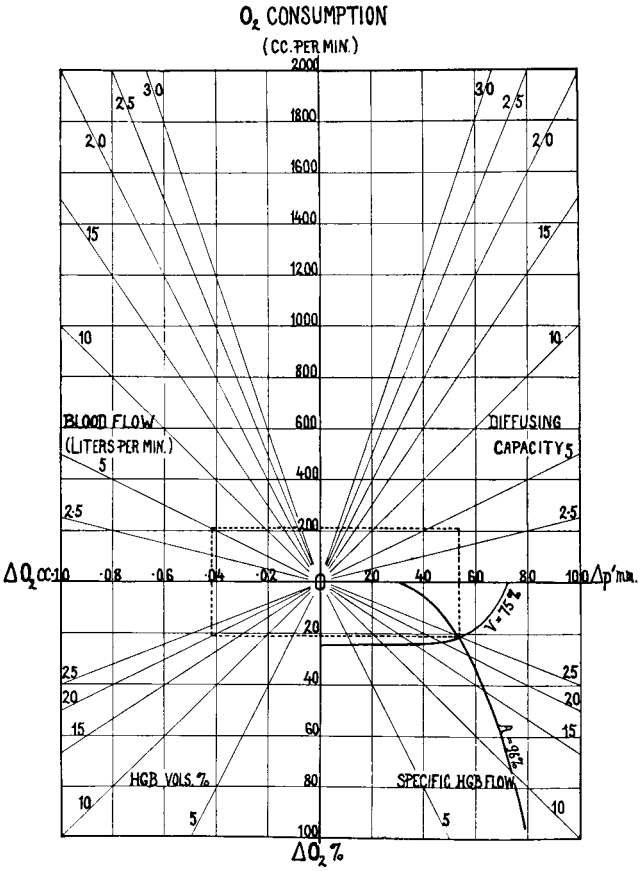

Figure 15-2 The original Morgan-Murray diagram. This diagram illustrates the linkages between physiological mechanisms at work in achieving adequate O_2 uptake by the lungs. *(From Richards DW Jr: Lawrence Joseph Henderson, in Medical Priesthoods and Other Essays. Connecticut, Connecticut Printers, 1970, p 81.)*

The circulatory component of the cardiorespiratory system imposes more of a limit on the O_2 delivery system than does the ventilation. Thus, at $\dot{V}O_2$, the cardiac output reaches almost 90 percent of the capability of the heart, whereas the ventilation is only at 65 percent of the capability of the ventilatory apparatus.

Not illustrated in graphic representations are the underlying automatic adjustments brought about by both the autonomic nervous system and local mechanisms. For example, even though muscle arteries are compressed during exercise, resulting in increased resistance to blood flow, the dramatic increase in blood flow and O_2 delivery to the exercising muscles suffices to keep pace with the increase in energy requirement. Helping to increase blood flow and O_2 delivery are vasodilation induced by the metabolic products of the exercising muscles and the modest increase in blood pressure that accompanies exercise.

Exercise Testing of the Integrated Response

Steady-state, graded exercise enables testing of the integrated response of the cardiorespiratory system, at different levels of work, in terms of power output (W) or, more conventionally, of oxygen uptake ($\dot{V}O_2$). The two are closely related. Steady state is also useful in defining the ceiling of exercise capacity in similar terms (W_{max}, $\dot{V}O_2$ max). The peak power (W_{max}) and the maximum O_2 consumption ($\dot{V}O_{2\,max}$) are among the most informative measurements obtained from a graded exercise test.

For clinical purposes, however, a standardized exercise test of the global aerobic capacity of the cardiorespiratory-muscular apparatus is often substituted for tests utilizing graded exercise. For example, in patients with chronic obstructive pulmonary disease, the 6-min walking test has been used to identify the maximum sustainable exercise. When

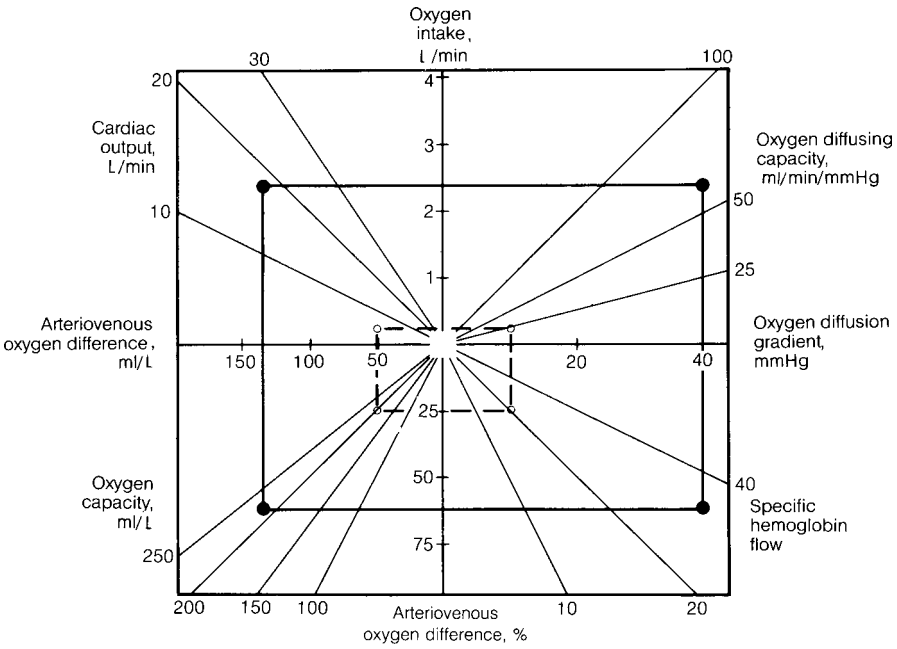

Figure 15-3 A more recent edition of the Morgan-Murray diagram, modified to show mechanisms of oxygen uptake by the lungs at rest (inner dashed rectangle) and during moderate exercise (solid rectangle). The oxygen uptake increased from 240 ml/min at rest to 2400 ml/min during exercise.

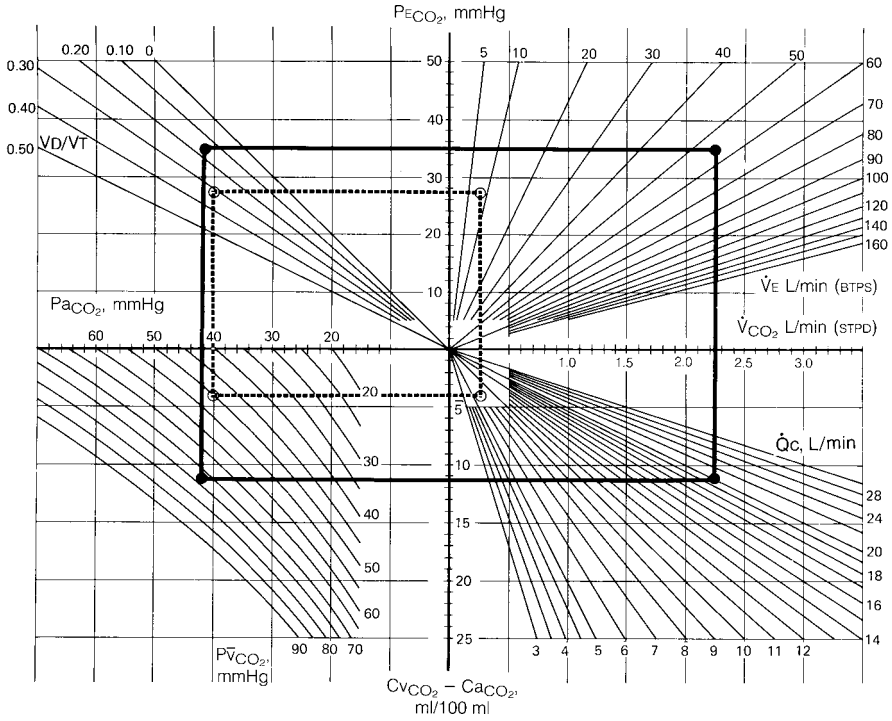

Figure 15-4 Application of the Morgan-Murray diagram to CO_2 elimination in the lungs. The inner (dashed) rectangle represents CO_2 output at a $\dot{V}O_2$ of 200 ml/min; the outer rectangle (solid line) is for a $\dot{V}O_2$ of 2250 ml/min. *(From Jones NL: Physiological basis of exercise testing, in Fishman AP (ed), Pulmonary Diseases and Disorders, 2d ed. New York, McGraw-Hill, 1988, p 235.)*

global testing is combined with specific pulmonary function tests, precise localization of the impaired structure or function can be achieved.

Anaerobic Threshold

During exercise, the rate of oxygen uptake increases predictably until a plateau is reached—i.e., the maximum oxygen uptake ($\dot{V}O_{2\,max}$). In the course of increasing exercise to the level of $\dot{V}O_{2\,max}$, as oxygen delivery to the muscles cannot keep pace with oxygen requirements, anaerobic metabolism becomes evident. As indicated in Chapter 17, at the "anaerobic threshold," serum lactate levels begin to increase when the energy requirements of exercise exceed the ability of the combined respiratory and circulatory systems to supply oxygen at a sufficiently high rate. At this juncture, ventilation increases inordinately, accompanied by decreases in blood pH and bicarbonate levels. In normal nonathletic subjects, this anaerobic threshold is reached at about 50 to 60 percent of predicted $\dot{V}O_{2\,max}$. In persons with impaired ability to transport oxygen (e.g., heart failure), this threshold occurs at a lower $\dot{V}O_2$ (expressed as a percentage of predicted $\dot{V}O_{2\,max}$).

HOMEOSTASIS AND ITS PERTURBATIONS

Homeostatic Mechanisms

For clinicians, an understanding of normal physiological processes is prerequisite for dealing with disease and with disturbances in regulatory processes. The term *homeostasis* refers to the automatic, self-regulating physiological mechanisms found especially in so-called higher animals that, after a disturbance, operate to restore the original equilibrium state of the organism. The two essential ingredients of this concept are internal stability and the integrated (coordinated) response that maintains it. Cannon (Fig. 15-5), who coined the term "homeostasis," pictured the situation in the following way: "In

Figure 15-5 Walter B. Cannon (1871–1945) incorporated the idea of stability of the internal environment into the larger concept of *homeostasis*. He appreciated the role of the autonomic nervous system in maintaining the stability of the internal environment.

Figure 15-6 Claude Bernard (1813–1878) enunciated the principle that the ability of humans and animals to function in the external environment (i.e., to maintain a "free life") is due to the stability of its internal environment (i.e., the circulating body fluids that bathe organs and tissues). *(From Fishman AP, Richards DW: Circulation of the Blood: Men and Ideas. New York, Oxford University Press, 1964.)*

Figure 15-7 Lawrence J. Henderson (1878–1942) developed seminal concepts of acid-base balance and the regulation of the neutrality of the blood based on his explorations of blood as a physicochemical system. Founder of the Fatigue Laboratory at Harvard, he created nomograms to illustrate graphically the interrelations of the major chemical constituents of the blood in normal humans and various pathological states (e.g., anemia, nephritis, diabetic acidosis).

an open system, such as our bodies represent, compounded by unstable material and subjected continually to disturbing conditions, constancy is in itself evidence that agencies are acting, or ready to act, to maintain this constancy."

Although Cannon coined the term in 1939, its roots are much older. In 1859, Claude Bernard, concerned with stability of the internal environment of the body as a prerequisite for a free and independent life in the face of a changing external environment, identified blood and lymph, the circulating body fluids, as the internal environment (Fig. 15-6). His experiments dealt with the mechanisms for ensuring this stability. The concept of blood as a critical element in the internal environment was subsequently developed by other physiologists and reached its peak of sophistication early in the twentieth century when Lawrence J. Henderson (Fig. 15-7) described the physicochemical properties and respiratory function of blood. For these classic works, Henderson drew heavily on collaborative efforts with Van Slyke's group at the Rockefeller Institute and his own group in the Fatigue Laboratory at Harvard. Henderson's monograph affords a remarkable synthesis of the composition of the blood and its biologic behavior in the transport of the respiratory gases. It deals not only with perturbations in the composition of blood in normal subjects, but also with abnormalities induced by disease (e.g., anemia, nephritis, diabetic coma).

Cannon envisaged homeostatic mechanisms as part of *The Wisdom of the Body*. His concept of homeostasis extended far beyond Bernard's ideas about the internal environment. He pictured homeostasis in the following way:

> The coordinated physiological processes which maintain most of the steady states in the organism are so complex and so peculiar to living beings—involving, as they may, the brain and nerves, the heart, lungs, kidneys, and spleen, all working cooperatively—that I have suggested a special designation for these states, *homeostasis*. The word does not imply something set and immobile, a stagnation. It means a condition—a condition which may vary, but which is relatively constant.

Restorative mechanisms per se, without intervening mechanisms to tide the body over abrupt and marked disturbances (e.g., temperature, body water, blood pressure), could not suffice to sustain the stability of the internal environment. Henderson appreciated that "the body seems to contain what may be likened to marshes or swamps into which substances may disappear and be lost to view." Aerobic metabolism illustrates the need for such "marshes." Faced with abrupt changes in ambient air or pulmonary function sufficient to elicit disease that compromises arterial hypoxemia, the body draws

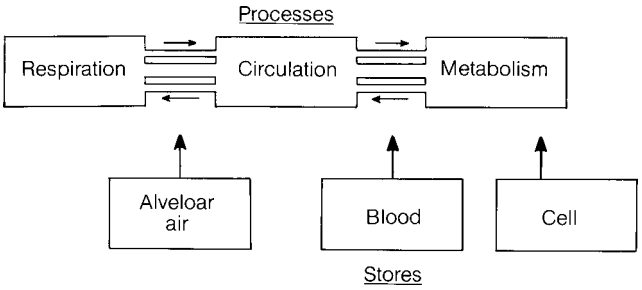

Figure 15-8 Processes and stores that maintain stable levels of P_{O_2} within cells. The alveolar air acts as a store for O_2 between ambient air and blood, serving as a tonometer of fairly stable composition. The blood, interposed between alveolar air and metabolizing tissues, has hemoglobin as the store. Within the cells are stores in the form of high-energy phosphates, dissolved O_2, myoglobin, and substrates for metabolic processes. Rearrangements in the distribution of blood by vasomotor activity determine the rate of delivery of O_2 to the different tissues. *(Modified from Weibel ER: The Pathway for Oxygen. Cambridge, MA, Harvard University Press, 1984.)*

upon oxygen-containing "swamps" to satisfy its need for oxygen. Thus, between ambient air and the mitochondrion are several distinct stores—the alveolar air, blood, and metabolizing cells. These are interposed seriatim between the processes of respiration, circulation, and metabolism (Fig. 15-8).

Disease can affect the "marshes" (stores) or the processes. With respect to the "marshes," pulmonary edema compromises oxygen uptake by replacing alveolar air with liquid; anemia limits the oxygen transport function of the blood; occlusive arterial disease can compromise oxygen delivery to the metabolizing cells. Considerations such as these prompt the idea that disease and regulatory disorders can be viewed as failure or insufficiency of normal processes and stores, components of the homeostatic system originally designed to sustain stability of the internal environment. Familiar examples of insufficiencies that compromise normal functions are arterial hypotension or abnormal hemoglobins, both of which can interfere with oxygen transport.

Homeostasis as a Feedback Process

The principles that govern man-made control systems apply equally well to the self-regulatory mechanisms of living organisms. The paradigm of a man-made control system is the regulation of temperature by means of a thermostat, which in turn is an example of a closed-loop (negative feedback) control system—one in which any deviation of the controlled output (room temperature) from the desired value automatically signals a change in input (fuel supply that generates heat) to the system in order to minimize the discrepancy between controlled output and desired output. There are two types of feedback: *negative*, which operates to the advantage of the system to minimize the original deviation in the controlled output, and *positive*, which perpetuates the deprivation, promotes instability, and runs the risk of destroying the organism unless turned off by the calling of another mechanism into play. Clearly, in a biologic system, failure of a negative-feedback system or unbridled positive feedback is capable of causing disorder or disease.

Although it is instructive to draw an analogy between man-made and living systems, it should be noted that a living system is infinitely more complex, entailing endless interplay (information transfer) among all levels in the biologic hierarchy, from cell to organ. Also, the sensory part of the regulatory apparatus is almost invariably more intricate than the effectors. Finally, the desired value ("set point") of a biologic parameter often depends on the physiological state (e.g., as dictated by the diurnal rhythm or the level of physical activity): During sleep, arterial P_{CO_2} is kept higher than during waking hours; while the subject is upright, the set point of the arterial P_{CO_2} is lower than it is while the subject is supine. Larger biologic rhythms, such as the monthly cycles in females, also are associated with different set points for the arterial P_{CO_2}.

The Bounds of Homeostatic Mechanisms

Before we consider the limitations imposed by disease, it is important to recall that the concept of homeostasis was conceived by physiologists to deal with adjustments of normal subjects to changing environments and circumstances. As a rule, considerations of homeostatic mechanisms in normal persons deal with acute or subacute adjustments. As noted above, even in normal subjects, the capacity of the cardiorespiratory-muscular system to transport, deliver, and utilize oxygen in aerobic metabolism is limited. Although compensatory mechanisms such as widening of the arteriovenous difference for oxygen can raise the ceiling, the limit, as defined by the $\dot{V}O_{2\,max}$, remains and is measurable.

A flaw or malfunction at any point in the uptake, transport, and delivery system for oxygen can lower the limit. In normal persons breathing ambient air at sea level, the weak link in the O_2 delivery system is the heart, which has only a modest capacity for increasing stroke volume. When this limitation coexists with hypoxia, as may occur at altitude, oxygen delivery (cardiac output multiplied by O_2 content) can be seriously impaired.

One special case of limitation in the aerobic capacity of the human organism under stress in a hypoxic environment has been seen in mountain climbers who have ascended to the summit of Mount Everest without supplementary oxygen. At this peak (altitude 8848 m), where the inspired P_{O_2} is about 42 mmHg, the $\dot{V}O_{2\,max}$ is at a level that barely suffices for basal metabolism. The oxygen consumption is then limited, in part, by a marked alveolar-arterial P_{O_2} gradient (attributable to diffusion limitation of O_2 uptake across the alveolar-capillary barriers) and the dependence of O_2 uptake and delivery on O_2 exchanges conducted on the steep part of the O_2 dissociation curve.

Homeostatic Malfunctioning

D. W. Richards analyzed the applicability of concepts about homeostatic mechanisms in normal individuals to patients in

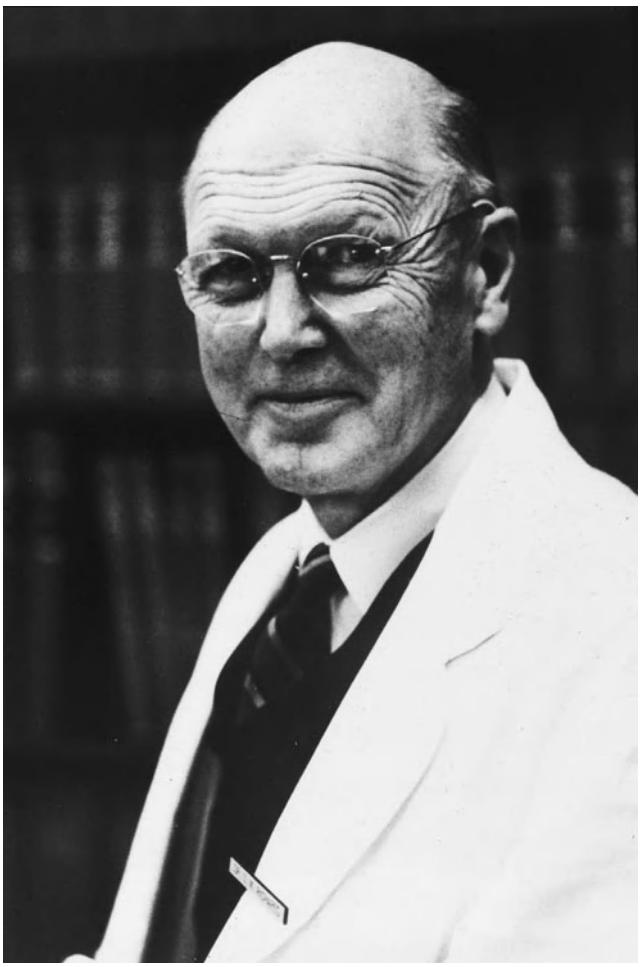

Figure 15-9 Dickinson W. Richards (1895–1973), a physician/scientist, related disturbances in homeostatic mechanisms to clinical disorders. Strongly influenced by L. J. Henderson, he shared the Nobel Prize with André Cournand and Werner Forssmann for contributing to the development of cardiac catheterization and standardization of measurements of pulmonary function.

whom the set point has been dislocated. He took into account that integrative mechanisms designed to restore the internal environment to normal levels operate within boundaries imposed by the structures and functions of the coordinating system. He recognized that diseases of the cardiorespiratory-muscular system often impose additional limits and generate distortions that may cause physiological mechanisms to undershoot or overshoot their mark or become unstable (Fig. 15-9).

Undershooting of homeostatic mechanisms is commonplace in cardiac diseases such as acute myocardial infarction, in which a low cardiac output may compromise oxygen delivery to the tissues despite other compensatory mechanisms, such as widening of the arteriovenous oxygen difference. *Overshooting* can be illustrated by renal failure in the course of the adult respiratory distress syndrome: Ischemic necrosis of the kidney can follow intense systemic homeostatic vasoconstriction to counteract systemic hypotension. *Instabilities* are exemplified by Cheyne-Stokes breathing, in which rhythmic changes in ventilation are accompanied by swings in arterial blood gas composition. These examples represent instances in which homeostatic mechanisms can miss the mark, to the detriment of the organism. In the clinical setting, well-intentioned therapeutic interventions can contribute to homeostatic malfunction. Such iatrogenic disturbances pose continuing threats in emergency or intensive care settings, in which urgency often dictates or dominates therapeutic interventions.

ADAPTATION

Adaptation signifies changes in both physiological and biochemical function and in structure that enhance performance or facilitate survival. It signifies the adjustment of an organism to its environment. In a setting in which O_2 is chronically in short supply, it entails enhancement of the O_2 delivery system coupled with redirection of metabolic activities toward sustaining oxidative functions. In doing so, it spares undue reliance on the anaerobic machinery. As a rule, adaptation is a gradual process in which anatomic changes feature prominently.

Homeostatic (physiological and biochemical) mechanisms are the first line of defense upon exposure to a threatening environment. Subsequently, structural changes come into play (e.g., muscularization of the pulmonary arteries and arterioles at altitude and right ventricular hypertrophy). When the new steady state has been achieved (i.e., when adaptation has occurred), the person at altitude can carry on the activities of daily life, including moderate exercise, about as effectively as at sea level. However, should control mechanisms, such as the sensitivity of the carotid bodies to hypoxia, fail to reset properly, maladaptation ensues. For example, Monge's disease is caused by failure to increase alveolar ventilation due to inadequate responsiveness of the carotid bodies to the hypoxic stimulus. The approach to disease in terms of malfunctioning of homeostatic and adaptive mechanisms is not confined to the cardiorespiratory-muscular system. In a similar fashion, many diseases, such as those due to hypersecretion by endocrine glands or tumors (e.g., thyrotoxicosis, Addison's disease), can be considered in terms of failure of homeostatic and adaptive mechanisms.

Adaptation may be *inherited*, as in native residents at high altitude in whom the process of natural selection, operating over the ages, has yielded a population that can exist, thrive, and reproduce in a hypoxic environment. On the other hand, adaptation may be *nonhereditary,* as in the case of the sea-level native who becomes a permanent dweller at high altitude.

Adaptation is commonly studied in people who relocate to different environments (e.g., from sea level to altitude). Upon arrival at altitude, the newcomer is tachycardic (to sustain cardiac output) and breathes rapidly. In time, these changes are succeeded by adjustments that favor O_2 uptake by

the lungs and O_2 delivery to the tissues (e.g., a left shift of the O_2 dissociation curve and increased capillary density in the muscles). Another common approach to the study of adaptation is to compare populations of animals and humans, born and raised in different environments, with respect to not only adaptive mechanisms, but also genetic influences in adaptation.

Adaptation also has been studied in people exposed to a wide variety of other chronically stressful circumstances. One large group is made up of endurance athletes who, over time, undergo biologic changes that enable them to perform optimally in competitive sports that require maximum oxygen delivery to the exercising muscles. These changes are evident both in the cardiorespiratory system and exercising muscles. The changes in the components of the cardiorespiratory system proceed at different rates: The plasma volume increases (in weeks), the pump capacity of the heart increases (in months to years), the red cell mass increases the O_2-carrying capacity of the blood (in months), the number of capillaries in skeletal muscles increases (in weeks to months), and the mitochondrial enzymes in skeletal muscle increase (in weeks).

During endurance athletic training, not only do the muscles employed in exercise undergo hypertrophy, but also the heart enlarges by combined hypertrophy and dilation, thereby raising the capacity for increasing the cardiac output. Finally, at the maximum level and intensity of the exercise, the $\dot{V}O_{2\,max}$ reaches a plateau ($\dot{V}O_{2\,max}$). Whether the heart or peripheral muscles (i.e., the mitochondria and capillaries) set the limit for maximal O_2 uptake in the endurance-trained athlete continues to be debated. However, the bulk of the evidence currently assigns the limitation to the heart rather than the number of capillaries and mitochondrial enzymes in the peripheral muscles.

Chronic respiratory disease often calls forth adaptive mechanisms that sometimes overshoot their mark. For example, polycythemia, which originates as a homeostatic response to hypoxia and serves to increase the oxygen-carrying capacity of the blood, if continued, increases the circulating blood volume. Cardiac volume and mass then increase to handle the increased circulatory load; i.e., a homeostatic mechanism has been succeeded by adaptive change in the heart. If carried to excess (the so-called "hyperexis" of D. W. Richards), venous thrombosis, on the one hand, or cardiac failure, on the other, may ensue.

Optimization and Limitation of Human Adaptation

The cardiorespiratory-muscular system operates within limits imposed by the structure and the integrated functioning of its components. The maximum oxygen uptake ($\dot{V}O_{2\,max}$) provides a measure of the limit of the capacity of this system to transport and utilize oxygen. The activities of daily life are generally conducted well below this limit. In sports, however, this ceiling is apt to be approached, usually in spurts but occasionally in sustained effort.

The capability of the cardiorespiratory-muscular system to satisfy the energy needs of the cells depends on its ability to match oxygen delivery to their aerobic needs. The system is vulnerable at many sites, particularly where respiration and circulation cross paths—i.e., in the lungs, in which O_2 is taken up from the environment and transferred across alveolar-capillary barriers into flowing blood; in the blood, which transports the oxygen to the tissues; in the tissues, in which the blood releases oxygen for diffusion into cells; and within cells, in which oxygen moves to mitochondria for oxidative phosphorylation, and which generates the high-energy organic phosphates for biologic work. Each of these sites operates within its own boundaries, which, if exceeded, could set the limit of O_2 uptake and delivery for the entire organization (i.e., the $\dot{V}O_{2\,max}$). At each site, buffer mechanisms exist: Between ambient air and the blood is the large volume of alveolar air; in the blood is the large reservoir of hemoglobin; in the muscle cells is the bank of myoglobin; and within the muscle cells are stores of high-energy phosphates. In addition to these stores, which neutralize abrupt changes in oxygen supply, compensatory mechanisms, such as an increase in heart rate to sustain oxygen delivery by increasing cardiac output are on standby alert. The autonomic nerve system plays a critical role in orchestrating the response to the call for oxygen as the energy needs increase.

In disease, adaptation to a chronic impairment may favor realignment of physiological process to compensate for a deficiency in either a component or process of the system. For example, in patients with severe kyphoscoliosis and dwarfing, a breathing pattern is adopted that minimizes the energy cost of breathing; this pattern consists of rapid frequency and small tidal volumes. However, as indicated above for homeostatic overshoot, this pattern may pay the penalty of alveolar hypoventilation, which in turn results in respiratory acidosis and arterial hypoxemia and their consequences, respiratory and cardiac failure. Thus, by adopting a respiratory pattern that minimizes the work, energy cost, and discomfort of breathing, the individual may be put at risk of losing life because of the consequences of alveolar hypoventilation.

Limitation of the adaptive potential can also vary with the disease or circumstance. For example, after lung transplantation, limitation to maximal exercise is imposed not by the heart or lungs but by abnormalities in the peripheral muscles, probably secondary to preoperative muscle disuse and atrophy.

CONCLUSIONS

Exercise is a remarkable example of the integrative and adaptive capacities of the body. Disease may impose limitations on the capacity of the body to acquire, transport, and utilize oxygen. This limitation in aerobic capacity can be tested by calibrated exercise, either graded or global, and the

malfunctioning component uncovered by a combination of clinical evaluation and pulmonary function testing.

Breathing in Exercise

Brian J. Whipp • Susan A. Ward

The increased ventilatory demands imposed by muscular exercise, and the responses to them, should not be considered in isolation. The system is a component of the complex coordinated structure configured to link the atmosphere to the mitochondria through a series of linear conductances, transferring oxygen (O_2) by means of: (1) convective flow of air into the lungs; (2) diffusional exchange into the pulmonary capillary blood; (3) convective flow of arterial blood to the contracting muscle units; and (4) the final diffusive flux into the mitochondria to serve as the terminal oxidant in the electron transport chain. This is the major mechanism of the ATP generation that directly fuels the muscular contractions. However, in order to maintain the acid-base status of the fluid milieux of the contracting muscle units within the relatively narrow range that is compatible with efficient chemical-mechanical coupling, the consequently increased carbon dioxide must be cleared at an appropriate rate along the same pathway.

To preserve alveolar, and hence arterial, O_2 partial pressure (Pa_{O_2}), the O_2 extracted from the alveoli by the increased flow of more-desaturated mixed venous blood must be replenished. The lungs must also provide diluting quantities of CO_2-free (atmospheric) air to the alveoli at rates appropriate for the increased delivery rate of CO_2 by mixed venous blood so as to maintain the stability of alveolar and arterial P_{CO_2}. However, although the function of the lung is commonly defined as that of "arterializing" the mixed-venous blood (regardless of how well the gas exchange has been effected), a better definition, in this regard, might be that its function is to "alveolarize" it. This both obviates the obvious tautology in the definition and also provides a frame of reference for quantifying the effectiveness of the exchange process; this being the alveolar-to-arterial partial pressure difference for the gas of interest.

As schematized in Fig. 16-1, there are competing ventilatory demands for: (a) alveolar PO_2 ($P_{A_{O_2}}$) and P_{CO_2} ($P_{A_{CO_2}}$) regulation when the respiratory exchange ratio (R) differs from unity; and (b) arterial P_{CO_2} (Pa_{CO_2}) and pH (pHa) regulation when the exercise results in a metabolic acidosis, i.e., a reduction of Pa_{CO_2} is necessary to provide respiratory compensation that constrains the fall of pHa. In patients with lung disease, this process is further complicated by pulmonary gas exchange inefficiencies, which result in often-marked differences between alveolar (either "ideal" or "real") and arterial gas partial pressures, which further increase the regulatory demands on ventilation ($\dot{V}_E$). Although many of the integrative aspects of the control of these regulatory processes remain to be elucidated, the general *patterns* of ventilatory response are not topics of serious dispute. These response profiles, especially their dynamics, provide clues to the elements of the control processes.

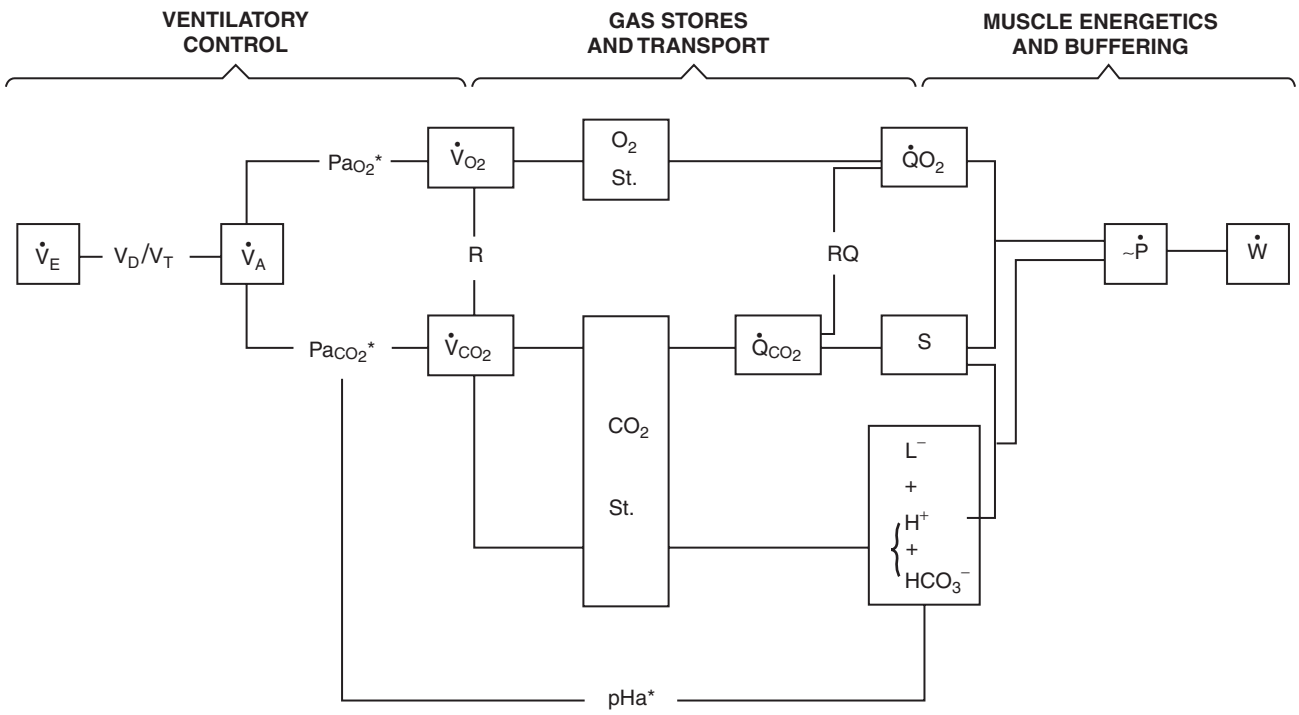

Figure 16-1 Schematic representation of physiological determinants of blood-gas and acid-base regulation in exercise. $\dot{W}$ represents the muscular power generation (i.e., work/time); ~P is the high-energy phosphate utilization rate; S is the metabolic substrate. Other symbols are standard. The regulated variables are denoted by asterisks. See text for further details. *(Reproduced with permission of Whipp BJ, Wasserman K: Blood-gas transport and acid-base, in Crystal RG, West JB (eds), The Lung: Scientific Foundations. New York, Raven Press, 1991, pp 1573–1584.)*

VENTILATORY REQUIREMENTS

We consider the primary feature of the ventilatory demands of muscular exercise to be that of arterial blood-gas and acid-base regulation; mass balance considerations therefore predominate. For example, in the steady state of moderate exercise, mean alveolar, and hence arterial, PO_2 and P_{CO_2} can be regulated at, or close to, resting levels *only if* alveolar ventilation ($\dot{V}A$) increases in *appropriate* proportion to the metabolic rate of the relevant gas. With respect to CO_2 exchange:

$$F_{A_{CO_2}} = \dot{V}_{CO_2}(STPD)/\dot{V}A(STPD) \qquad (1)$$

where

$F_{A_{CO_2}}$ = the fractional concentration of alveolar CO_2
$\dot{V}_{CO_2}$ = pulmonary CO_2 output

Note that in this equation both gas volumes are determined under the same conditions, i.e., standard temperature (0°C) and pressure (one atmosphere) dry (STPD). However, as convention has reasonably dictated that ventilatory volumes are expressed under the conditions at which they actually operate (i.e., body temperature and pressure, saturated with water vapor, BTPS), and as the partial pressure of the gas is of more interest physiologically than the concentration, then:

$$P_{A_{CO_2}} = 863 \cdot \dot{V}_{CO_2}(STPD)/\dot{V}A(BTPS) \qquad (2)$$

and

$$P_{A_{O_2}} = P_{I_{O_2}} - 863 \cdot \dot{V}_{O_2}(STPD)/\dot{V}A(BTPS) \qquad (3)$$

where

863 = the constant that corrects for these different conditions of reporting the gas volumes (at a body temperature of 37°C, saturated with water vapor) and also the transformation of fractional concentration to partial pressure
$P_{I_{O_2}}$ = inspired P_{O_2}
$\dot{V}_{O_2}$ = pulmonary O_2 uptake

However, neither $\dot{V}A$ nor the alveolar gas partial pressures in Eqs. (2) and (3) are conceptually straightforward. That is, it is difficult to validly establish a single average value for the alveolar gas tensions in a structure as complex as the lung, which has significant regional differences of alveolar ventilation-to-perfusion ($\dot{V}A/\dot{Q}$) ratios. The expedient of assigning $P_{A_{CO_2}}$ to be exactly equal to Pa_{CO_2}, as would be the case in the "ideal" lung, dispenses with this difficulty and allows $\dot{V}A$ to be computed readily from Eq. (2). However, this alveolar ventilation is figmentary. Similarly, the alveolar P_{O_2} in Eq. (3) is also that of the "ideal" lung: The "real" $P_{A_{O_2}}$ would be higher and the "real" $P_{A_{CO_2}}$ lower than the "ideal" alveolar values calculated in this manner.

Accepting these definitions, and ignoring the slight effect on P_{O_2} of the small difference between inspired ventilation ($\dot{V}I$) and $\dot{V}E$ that occurs when the respiratory exchange

ratio (R) does not equal 1, it becomes apparent from Eqs. (2) and (3) that $P_{A_{CO_2}}$ and $P_{A_{O_2}}$ can only be maintained constant during exercise if $\dot{V}_A$ changes in precise proportion to $\dot{V}_{CO_2}$ and $\dot{V}_{O_2}$, respectively. Note, however, that $\dot{V}_A$ is common to both equations, i.e.:

$$863 \cdot \dot{V}_{CO_2}/P_{A_{CO_2}} \leftarrow \dot{V}_A \rightarrow 863 \cdot \dot{V}_{O_2}/(P_{I_{O_2}} - P_{A_{O_2}}) \quad (4)$$

Therefore, alveolar ventilation cannot meet the demands of both pulmonary O_2 and CO_2 exchange under conditions in which $\dot{V}_{O_2}$ and $\dot{V}_{CO_2}$ differ. This can occur during exercise, either because of differences in substrate utilization or because of transient variations in the body gas stores. Under such conditions, $\dot{V}_E$ has been consistently demonstrated to change in closer proportion to $\dot{V}_{CO_2}$ than to $\dot{V}_{O_2}$. Pa_{CO_2} is therefore the more closely regulated variable, with alveolar and arterial P_{O_2} changing as a consequence. In normal subjects at sea level, these P_{O_2} changes only vary over the relatively flat upper region of the oxyhemoglobin dissociation curve, with little consequent effect on arterial O_2 content or saturation.

The close coupling of $\dot{V}_E$ to $\dot{V}_{CO_2}$ is perhaps most strikingly evident in their responses to a constant-load exercise of moderate intensity (Fig. 16-2, *left panel*). Following an initial $\dot{V}_E$ component (phase 1, $\phi 1$) of modest amplitude and short duration (i.e., 15–20 seconds), a more prominent slower and exponential phase 2 ($\phi 2$) component follows whose time course is very similar to but very slightly slower than that of $\dot{V}_{CO_2}$ and, interestingly, *considerably* slower than that of $\dot{V}_{O_2}$. Consequently, the rate of development of these $\phi 2$ profiles can be described by a time constant (τ), that is, the time taken to attain 63% (i.e., $(1 - 1/e) \cdot 100$) of the steady-state (or phase 3, $\phi 3$) response, or to a close approximation as 1.5 times the half-time of the response. The close matching of $\dot{V}_E$ to $\dot{V}_{CO_2}$ establishes the relative stability of Pa_{CO_2} both in the steady and transient phases of moderate exercise.

Consequently, it is more appropriate to consider the ventilatory demands of exercise using CO_2 exchange rather than O_2 exchange as the frame of reference. Note, however, that the relevant "CO_2" in this relationship is the exchange rate at the lung and *not* that of the muscle. It follows from Eq. (2) that the demands for alveolar ventilation increase as a linear function of $\dot{V}_{CO_2}$ at any "set-point" level of Pa_{CO_2}:

$$\dot{V}_A(BTPS) = 863 \cdot \dot{V}_{CO_2}(STPD)/Pa_{CO_2} \quad (5)$$

Consequently, the greater the $\dot{V}_{CO_2}$, the greater is the ventilatory requirement. However, if Pa_{CO_2} is regulated at a lower level, $\dot{V}_A$ must be appropriately higher for any given level of $\dot{V}_{CO_2}$. Nevertheless, ventilating the alveoli requires simultaneous ventilation of the dead space; i.e., the ventilatory demand is expressed through the total or minute ventilation ($\dot{V}_E$), not $\dot{V}_A$. However, as:

$$\dot{V}_A = \dot{V}_E - \dot{V}_D \quad (6)$$

or

$$\dot{V}_A = \dot{V}_E(1 - V_D/V_T) \quad (7)$$

then

$$\dot{V}_A = 863 \cdot \dot{V}_{CO_2}/Pa_{CO_2}(1 - V_D/V_T) \quad (8)$$

where

V_D/V_T = the physiological dead space fraction of the breath

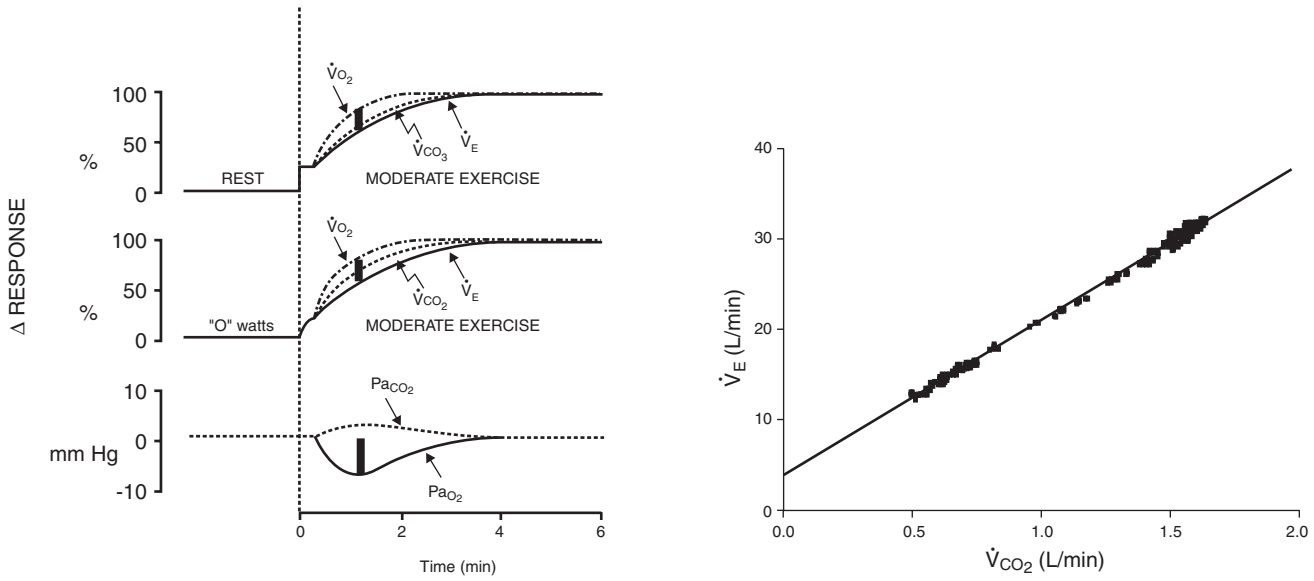

Figure 16-2 *Left.* Schematic representation of time course of O_2 uptake ($\dot{V}_{O_2}$, — · —), CO_2 output ($\dot{V}_{CO_2}$, · · · · · ·), and ventilation ($\dot{V}_E$, —) in response to a moderate work-rate step from rest *(top panel)* and unloaded pedaling *(middle panel),* with corresponding profiles of arterial P_{CO_2} (Pa_{CO_2}, · · · · · ·) and P_{O_2} (Pa_{O_2}, ———). *(Reproduced with permission of Whipp BJ, Ward SA: Int J Sports Med 1:146–159, 1981.) Right:* "Cross plot" of $\dot{V}_E$ as a function of $\dot{V}_{CO_2}$ during the on-transient of a moderate work-rate step. In both panels, note close matching of $\dot{V}_E$ to $\dot{V}_{CO_2}$.

Table 16-1

Determinants of Exercise Ventilation

	$\dot{V}_{O_2}$ (L/min)	R	$\dot{V}_{CO_2}$ (L/min)	Pa_{CO_2} (mm)	V_D/V_T	$\dot{V}_E$ (L/min)
a	1.00	0.85	0.85	40	0.2	23.0
b	1.00	0.80	0.80	60	0.5	23.0
c	1.00	0.85	0.85	50	0.2	18.3
d	1.00	1.00	1.00	30	0.5	57.6

Therefore, the ventilatory demands of exercise should be considered with respect to the three defining variables of Eq. (8):

1. The rate of pulmonary CO_2 clearance ($\dot{V}_{CO_2}$)
2. The *set-point* at which Pa_{CO_2} is regulated
3. The *physiological dead space fraction of the breath,* which represents *an* index of the *inefficiency* of pulmonary gas exchange

As shown in Table 16-1, for a range of reasonably representative values at a notional $\dot{V}_{O_2}$ of 1 L/minute, simultaneous changes in these defining variables can elicit major variations in the level of exercise $\dot{V}_E$ or potentially misleadingly similar values: a, provides a normal frame of reference; b, a subject with gas exchange abnormality (as reflected by the high V_D/V_T) and a degree of CO_2 retention, the resulting $\dot{V}_E$ being apparently normal; c, also has some CO_2 retention but, with a normal V_D/V_T, yields a relatively low $\dot{V}_E$; d, the combination of high R and V_D/V_T coupled with a low Pa_{CO_2} yields a $\dot{V}_E$ more than threefold greater than for c.

It should be noted that end-tidal P_{CO_2} ($P_{ET}CO_2$) is not a good index of either the level or pattern of change of arterial P_{CO_2}, especially during exercise; it becomes systematically greater than Pa_{CO_2} in normal subjects, by an amount that depends both on the metabolic rate and the pattern of breathing. The reason for this is that $P_{A}CO_2$ and Pa_{CO_2} fluctuate during the breathing cycle: increasing throughout expiration (chiefly as a result of continuing gas exchange, as the mixed-venous P_{CO_2} ($P\bar{v}_{CO_2}$) is greater than $P_{A}CO_2$) and decreases during inspiration. However, arterial blood is normally sampled over several respiratory cycles. Hence, the syringe value represents the mean of the Pa_{CO_2} oscillation. The end-tidal value, in contrast, is a measure of the peak of this oscillation. Consequently, $P_{ET}CO_2$ is greater than both mean $P_{A}CO_2$ and Pa_{CO_2}. As work rate (WR) and $P\bar{v}_{CO_2}$ increase, so the does the rate at which arterial and alveolar P_{CO_2} increase during exhalation, resulting in a further widening of the end-tidal to arterial P_{CO_2} difference ($P[_{ET}\text{-}a]_{CO_2}$). Naturally, when breathing frequency increases at high WRs, the shortened expiratory duration truncates the rising phase of $P_{A}CO_2$, attenuating the increase in $P[_{ET}\text{-}a]_{CO_2}$. Consequently, $P_{ET}CO_2$ should *not* be used as a direct estimator of Pa_{CO_2}, either for ventilatory control considerations or for computing the physiological dead space or cardiac output during exercise. Mean alveolar P_{CO_2}, estimated from the time average of the $P_{A}CO_2$ profile, provides a better index of Pa_{CO_2} during exercise—but only in subjects free of pulmonary disease (including pulmonary vascular disease), as maldistribution of $\dot{V}_A/\dot{Q}$ leads to mean alveolar P_{CO_2} being necessarily less and $P_{ET}CO_2$ being typically less than the arterial value.

Although arterial hypocapnia is characteristic for normal subjects during high-intensity exercise, Pa_{O_2} (at least at sea level) tends to be maintained at or close to resting levels. However, as both the ventilatory equivalent for O_2 ($\dot{V}_E/\dot{V}_{O_2}$) and "ideal" $P_{A}O_2$ increase systematically at these work rates, why does Pa_{O_2} not also increase systematically? Rather, there is a progressive widening of the alveolar-to-arterial P_{O_2} difference ($P[_{A}\text{-}a]_{O_2}$), from 5 mmHg or so at rest to as much as 40 mmHg or more in athletic subjects at high WRs.

As the topographical distributions of $\dot{V}_A$ and $\dot{Q}$ in the lung had been shown to be improved (at least for upright moderate exercise) it was assumed, seemingly reasonably, that the $\dot{V}_A/\dot{Q}$ distribution itself was also improved and that the lung exchanged gas more efficiently during exercise than at rest. Interestingly, however, the multiple inert gas technique has actually demonstrated that the dispersion of the $\dot{V}_A/\dot{Q}$ distribution is *increased* at high WRs, although with great inter-subject variability. This increased dispersion seems only sufficient to account for a relatively small component of the widening of the $P[_{A}\text{-}a]_{O_2}$. Lack of diffusion equilibrium across the alveolar-capillary membrane at these high WRs is thought to be the major contributor, even at sea level, as a result of some lung regions not having the capacity to recruit pulmonary capillary volume appropriately for the increased capillary flow. Therefore, the capillary transit time becomes insufficient for diffusion equilibrium of P_{O_2}, a mechanism exacerbated by pulmonary disease and also a major contributor to the arterial hypoxemia seen at high WRs in some highly fit subjects. However, there is also likely to be a distribution of transit times, on the basis of variations of both pulmonary-capillary lengths and diameters. Transit times longer than the critical do not further increase oxygenation; shorter ones reduce it further. Consequently, the actual hypoxemia-inducing effect begins to be manifest at WRs *less* than suggested by the *mean* transit time.

Although it has been demonstrated that intrapulmonary and intra-cardiac right-to-left shunts normally provide only a small contribution to the widened $P[_{A}\text{-}a]_{O_2}$, the reduction in mixed-venous O_2 content (especially during high-intensity exercise) affects $P[_{A}\text{-}a]_{O_2}$ more markedly for any given shunt fraction of the cardiac output ($\dot{Q}s/\dot{Q}t$) or any degree of $\dot{V}_A/\dot{Q}$ mismatch.

CO_2 Clearance

CO_2 clearance measured at the lung ($\dot{V}_{CO_2}$) only equals the CO_2 production rate in the tissues ($\dot{Q}_{CO_2}$) in the steady-state of exercise. Under these conditions R equals the metabolic

Table 16-2

Energetics of Substrate Catabolism

	RQ	$\dot{V}_{O_2}$ (L/min)	$\dot{V}_{CO_2}$ (L/min)	~P:O_2	~P:CO_2	O_2 ~:P	CO_2 ~:P
Glycogen	1.0	1.0	1.0	6.00	6.00	6.00	0.17
Palmitate	0.7	1.0	0.7	5.65	8.13	8.13	0.12
Glycogen/palmitate	1.43	1.0	1.43	1.06	0.74	0.74	1.42

Values are expressed at a particular $\dot{V}_{O_2}$ of 1L/min.

RQ. The substrates being catabolized, therefore contribute to the RQ and place fundamental demands on the pulmonary system. For example, a given rate of high-energy phosphate formation requires 6% less O_2 when carbohydrate is metabolized than when fatty acids serve as the substrate (Table 16-2). However, the carbohydrate metabolism yields 40% more CO_2 than for a typical fatty acid, leading to a greater demand for CO_2 clearance and, by extension, $\dot{V}_E$. To minimize the ventilatory demands for CO_2 clearance, fatty acids may be considered a more suitable substrate. The consequence is that alveolar and arterial PO_2 are necessarily reduced, as $\dot{V}_E$ is now low for the O_2 requirement of the task. Conversely, alveolar and arterial Po_2 are higher in subjects metabolizing carbohydrate, other things being equal.

Under non–steady-state conditions $\dot{V}_{CO_2}$ is dissociated from $\dot{Q}_{CO_2}$ as a result of transient changes in the body CO_2 stores (Figs. 16-1 and 16-2). Thus, during the on-transient of constant-load exercise, some of the metabolically produced CO_2 never reaches the lung for exchange as a result of the capacitative storage of CO_2, predominantly in the muscle. Therefore, $\dot{V}_{CO_2}$ is less than $\dot{Q}_{CO_2}$ during this phase. Because the changes in the muscle O_2 stores are trivially small with respect to those of CO_2, R *falls* transiently to reach a minimum at the point of the maximum *rate* of CO_2 storage. It subsequently rises again to equal the new metabolic steady-state RQ as the muscle P_{CO_2} stabilizes at its new and higher exercise value. As noted, although $\dot{V}_E$ during the transient is closely coupled to $\dot{V}_{CO_2}$, it changes slowly with respect to $\dot{V}_{O_2}$ (Fig. 16-2, *left*) which has a more rapid time constant. Consequently, alveolar and arterial Po_2 are reduced in the transient (Fig. 16-2, *left*). At the off-transient, the increased levels of the CO_2 stores now discharge, leading the pulmonary R to increase to levels *above* that of the metabolic RQ.

At WRs associated with a metabolic (chiefly lactate) acidosis (above the lactate threshold, θ_L), pulmonary CO_2 exchange is increased further. Additional CO_2 is produced as a result of the bicarbonate (HCO_3^-) component of the proton buffering that is formed in concert with the increased lactate at these WRs:

$$\begin{aligned} CH_3 \cdot CHOH \cdot COO^- + H^+ + NaHCO_3 \rightarrow \\ CH_3 \cdot CHOH \cdot COO \cdot Na + H_2CO_3 \\ CO_2 + H_2O \end{aligned} \qquad (9)$$

The extra CO_2 formed in these reactions is quantitatively large. For example, although the complete aerobic catabolism of one glucosyl unit of glycogen to CO_2 and H_2O yields 37 ATP molecules, its breakdown to two lactates and associated protons yields only three ATP molecules. Therefore, glycolytic flux must increase by 12.3-fold (37/3) to sustain the required ATP production rate. This leads to 24.6 mEq of lactate (2 × 12.3 mEq). Consequently, the accompanying proton production decreases [HCO_3^-] by approximately 22 mEq; i.e., HCO_3^- only accounts for 90% of this buffering. Phosphate and protein buffers provide the remainder. Of this *additional* yield of approximately 22 mM of CO_2 production, however, 6 mM replaces the CO_2 that would have been produced aerobically for this rate of ATP formation:

$$\begin{aligned} &22 \text{ mM anaerobic } CO_2 - 6 \text{ mM aerobic } CO_2 \\ &= 16 \text{ mM net } CO_2 \text{ yield} \end{aligned}$$

This represents an approximately 2.5-fold increase in $\dot{V}_{CO_2}$ – for the anaerobic component of the total $\dot{V}_{CO_2}$.

The extra *amount* of CO_2 produced under these conditions is a direct function of the *amount* of [HCO_3^-] decrease in blood and muscle compartments. Any contribution from non–HCO_3^- buffering mechanisms (e.g., phosphate and protein), although important for [H^+] regulation, does not produce extra CO_2. Consequently, the *rate* at which extra CO_2 is produced from these reactions is directly related to the *rate* at which HCO_3^- levels fall, not, it should be recognized, the *amount* of the decrease. Consequently, the more rapid the rate of rise of [lactate], the greater is the increase in $\dot{V}_{CO_2}$. This accounts for both $\dot{V}_{CO_2}$ and R (and, importantly, work rate) being appreciably higher in the period of increasing blood [lactate] during rapid-incremental exercise, compared with tests in which the WR incrementation rate is slow (Fig. 16-3).

Arterial P_{CO_2} Set-Point

Although Pa_{CO_2} is normally regulated at or near resting levels in the steady-state of moderate exercise, hyperventilation can occur transiently at exercise onset, especially in excitable subjects. This is more common in treadmill than cycle ergometry. However, as the $\dot{V}_E$ time constant ($\tau\dot{V}_E$) during the subsequent increase to the steady state is slightly longer than

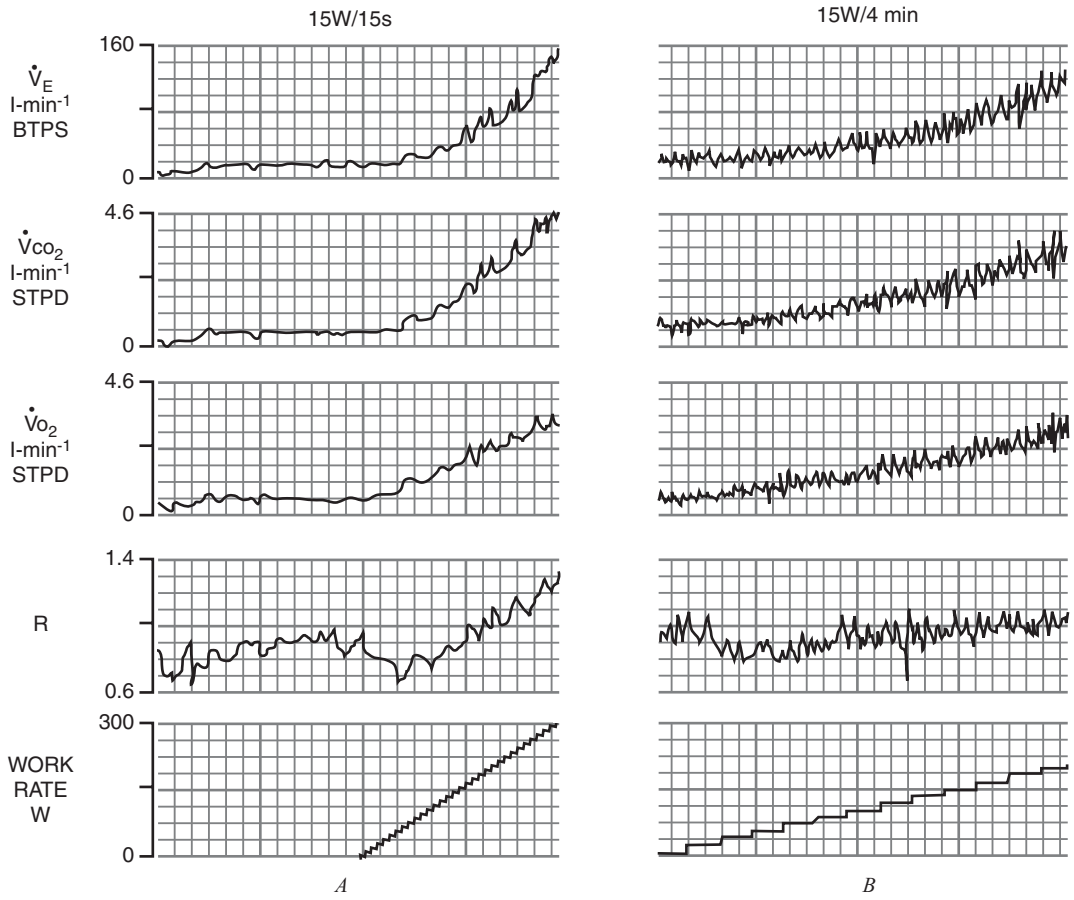

Figure 16-3 Ventilatory and pulmonary gas exchange response to a rapidly incrementing *(A)* and slowly incrementing *(B)* exercise test in the same subject, each performed to the limit of tolerance. Note that, although the peak $\dot{V}_{O_2}$ is not appreciably different in the two tests, the maximum values of $\dot{V}_E$, $\dot{V}_{CO_2}$, R, and WR are all significantly greater during the rapidly incremental test.

$\tau\dot{V}_{CO_2}$, a small and transient increase in $P_{A_{CO_2}}$ and Pa_{CO_2} is predictable and has been measured. $\tau\dot{V}_E$ seems to depend largely on the sensitivity of the subject's peripheral chemoreceptors, in humans predominantly the carotid bodies. Thus, $\tau\dot{V}_E$ is short when carotid body sensitivity is high (e.g., with hypoxia or metabolic acidemia), whereas $\tau\dot{V}_E$ is long when carotid body sensitivity is low (e.g., with hyperoxia, pharmacological suppression with dopamine or following their surgical resection) (Fig. 16-4).

Although Pa_{CO_2} appears to be a regulated variable during moderate exercise, it must be lowered by hyperventilation to constrain the fall of pHa at levels of exercise that induce a metabolic acidosis. This compensatory decrease in Pa_{CO_2} washes CO_2 out of the body stores and provides an additional source of extra CO_2 at high WRs:

$$pHa = pK' + \log\{[HCO_3^-]a/\alpha \cdot Pa_{CO_2}\} \qquad (10)$$

where

α = the CO_2 solubility coefficient that relates Pa_{CO_2} (mmHg) to CO_2 content (mM/L)

An instructive consideration of the inter-relationship among the ventilatory-related variables for pHa regulation is apparent in an alternative way of considering Eq. (10):

$$pH_a = pK' + \log\left\{([HCO_3^-]_a/25.9) \cdot (\dot{V}_E/\dot{V}_{CO_2}) \cdot (1 - V_D/V_T)\right\} \qquad (11)$$

where

$\dot{V}_E/\dot{V}_{CO_2}$ = the ventilatory equivalent for CO_2

Physiological Dead Space

The total requirement for dead space ventilation must, of course, take account of both the anatomical and alveolar dead space volumes. In healthy subjects at rest, the alveolar dead space is small and reflects, in large part, the relative underperfusion of apical alveoli. However, during exercise, the increased pulmonary artery pressure leads to a more even perfusion throughout the lung, tending to reduce the alveolar dead space. Furthermore, as the end-inspiratory expansion of the conducting airways during exercise is small compared

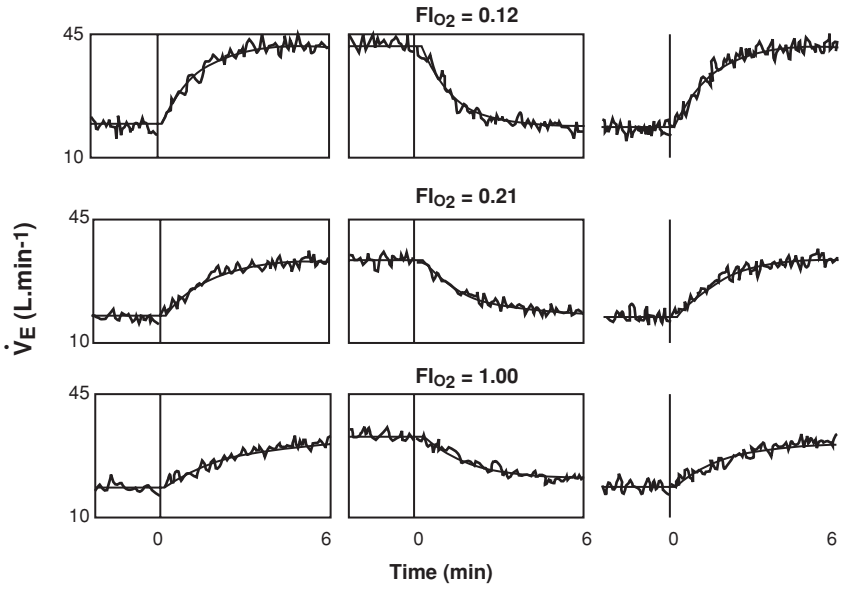

Figure 16-4 Influence of inhaled O_2 fraction (FI_{O_2} = 0.12, 0.21, and 1.00) on the time course of the phase 2 $\dot{V}_E$ response to moderate constant-load cycling (90 W) from unloaded pedaling, for a single subject. *Left panel.* On-transient responses, with the best-fit monoexponential superimposed. *Center panel.* Off-transient responses, with the best-fit monoexponential superimposed. *Right panel.* Off-transient responses (reversed) superimposed on the corresponding on-transient responses. Note that these superimposed responses are effectively indistinguishable. *(Reproduced with permission of Whipp BJ, Ward SA: Pulmonary Physiology and Pathophysiology of Exercise. New York, Dekker, 1991, pp 271–307.)*

with that of the total lung volume increase, V_D/V_T falls despite the absolute value of the dead space increasing.

Ventilation typically increases linearly with respect to $\dot{V}_{CO_2}$ over a wide WR range (Figs. 16-2 and 16-5, *right*):

$$\dot{V}_E = m \times \dot{V}_{CO_2} + c \qquad (12)$$

where

- m = the slope that has a value of approximately 25 in healthy young subjects (when $\dot{V}_E$ and $\dot{V}_{CO_2}$ are reported in L/minute)
- c = the $\dot{V}_E$-intercept, which has a value of approximately 3–5 L/minute

Therefore, it is important to recognize that the $\dot{V}_E - \dot{V}_{CO_2}$ slope alone is *not* the decisive variable with respect to Pa_{CO_2} and pHa regulation, as is apparent from Eq. (11) and also from Eq. (8), which can be rearranged as:

$$Pa_{CO_2} = 863/(\dot{V}_E/\dot{V}_{CO_2}) \cdot (1 - V_D/V_T) \qquad (13)$$

Note that two compound variables dictate the regulation, but *only* two! Therefore, $\dot{V}_E/\dot{V}_{CO_2}$ and V_D/V_T must change in a closely related pattern for Pa_{CO_2} to be regulated (Fig. 16-6); that is, the normal decrease in V_D/V_T must be closely matched by the decrease in $\dot{V}_E/\dot{V}_{CO_2}$ for Pa_{CO_2} to be regulated (Fig. 16-6*A*). Although $\dot{V}_E/\dot{V}_{CO_2}$ also typically decreases during exercise in patients with airflow limitation (Fig. 16-6*B*), it neither falls to the normal level nor is there the secondary

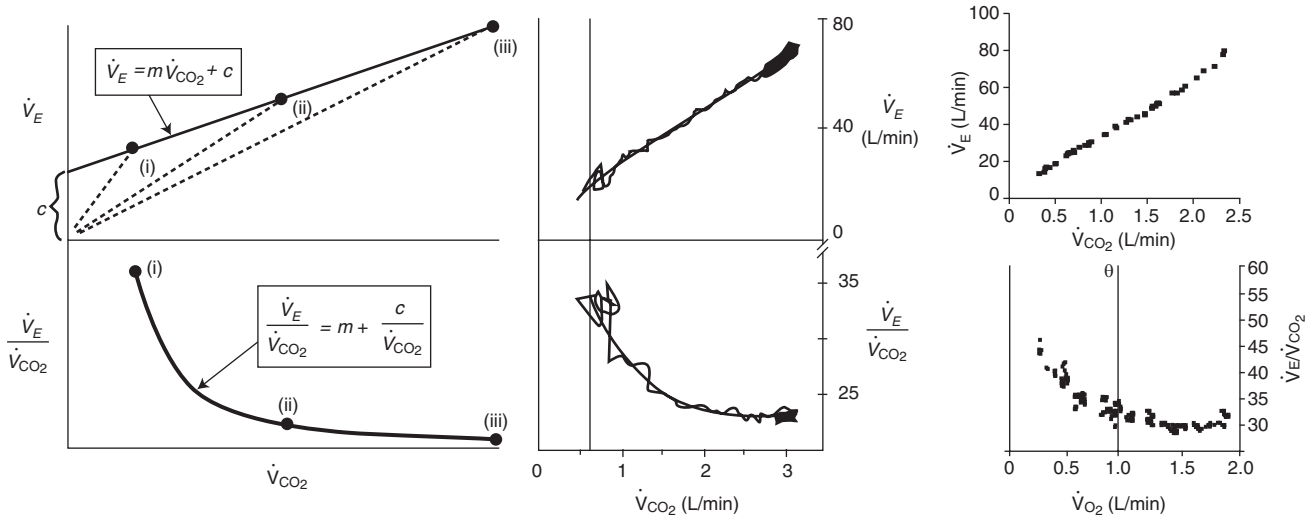

Figure 16-5 *Left.* Schematized responses of $\dot{V}_E$ and $\dot{V}_E/\dot{V}_{CO_2}$ as a function of $\dot{V}_{CO_2}$ for square-wave exercise. The dashed lines represent $\dot{V}_E/\dot{V}_{CO_2}$ isopleths at three progressively higher levels of $\dot{V}_{CO_2}$ *(below). Figure 16-6 Schematic to illustrate the interaction between physiological dead space fraction of the breath (V_D/V_T) and ventilatory equivalent for CO_2 ($\dot{V}_E/\dot{V}_{CO_2}$) as determinants of Pa_{CO_2}. To maintain isocapnia on going from rest to moderate exercise, the decrease in $\dot{V}_E/\dot{V}_{CO_2}$ must be appropriate for the fall in V_D/V_T *(normal subject, a)*. As there is little further change in V_D/V_T during high-intensity exercise, the compensatory hyperventilation is brought about by $\dot{V}_E/\dot{V}_{CO_2}$ now increasing from its reduced level; this increase is commonly not seen in subjects with airflow limitation (e.g., *b*). When V_D/V_T actually increases, Pa_{CO_2} is maintained only if $\dot{V}_E/\dot{V}_{CO_2}$ increases appropriately (e.g., *c*). See text for further consideration.

increase in $\dot{V}_E/\dot{V}_{CO_2}$ that normally occurs at high WRs (or one that is markedly attenuated). The ventilatory impairment constrains the response. The consequence is typically a modest uncompensated metabolic acidosis at maximum exercise. Similarly, the relatively sudden increase in V_D/V_T associated with the opening of a right-to-left shunt in many patients with pulmonary hypertension requires an appropriate increase in $\dot{V}_E/\dot{V}_{CO_2}$ for Pa_{CO_2} to be regulated (Fig. 16-6*C*).

Consequently, as shown in Eqs. (12) and (13) and Fig. 16-6, it is the ventilatory equivalent for CO_2 that is the crucial CO_2-linked variable with respect to Pa_{CO_2} and pHa regulation and *not* the slope of the linear $\dot{V}_E$-$\dot{V}_{CO_2}$ relationship per se. Furthermore, it is the profile of the hyperbolic decrease in V_D/V_T, consequent to the linear increase in V_D as a function of V_T (Fig. 16-5) that determines the hyperbolic decline in $\dot{V}_E/\dot{V}_{CO_2}$ over the region for which Pa_{CO_2} remains regulated, with control mechanisms that remain poorly understood.

End-expiratory lung volume (EELV) plays an important role in the ventilatory response to exercise, especially its pattern of response. The profile of EELV change during exercise is usually determined by having the subject perform a series of inspiratory capacity (IC) maneuvers during the exercise test and assuming that TLC remains unaltered. In normal subjects, EELV typically decreases by as much as 0.5 L, or more, below functional residual capacity (FRC) with increasing WR (Fig. 16-7). This not only improves the mechanical advantage of the inspiratory muscles, but also maintains a low elastic work of breathing by allowing V_T to operate over a wider "linear" range of the thoracic volume-pressure (i.e., compliance) curve (Fig. 16-7*A*). Conditions such as chronic obstructive pulmonary disease (COPD), which predispose to increased regional pulmonary-mechanical time constants, can reduce the spontaneous emptying rate to an extent that FRC is not re-attained in time for the next inhalation (Fig. 16-7*C*). EELV consequently increases (dynamic hyperinflation) with progressive increases in WR. Attempts to increase flow by further expiratory effort are typically counterproductive. The associated reduction in inspiratory capacity places increased demands on the inspiratory muscles and also reduces

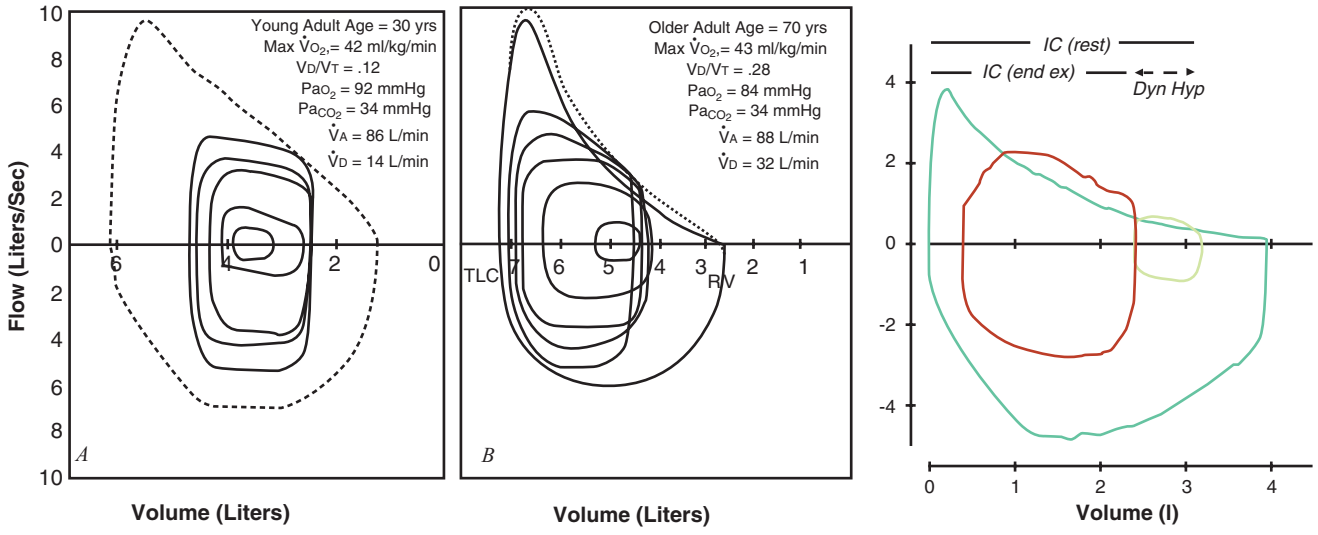

Figure 16-7 Comparison of *spontaneous* airflow-lung volume relationships at rest and during exercise with that of the *maximum* resting relationship in *(A)* a healthy "youngish" subject; *(B)* a healthy "oldish" subject; and *(C)* a patient with COPD. Note during exercise: little or no airflow limitation and a decrease in EELV in *(A)*; significant airflow limitation, an initial decrease in EELV but a subsequent increase in *(B)*; and spontaneous airflow that exceeds that achieved on the maximum maneuver and an increase in EELV in *(c)*. See text for further elaboration. (Panels A and B reproduced with permission of Johnson BD, Badr MS and Dempsey JA: Clinics in Chest Medicine 15:229–246, 1994.)

the scope for V_T increase before end-inspiratory lung volume (EILV) begins to encroach onto the flatter upper reaches of the compliance curve. In ostensibly normal elderly subjects (but with the age-related reductions of lung recoil increasing the mechanical time constant(s)), EELV has been shown to decline over the moderate WR range, but then subsequently to increase back toward, or often beyond, the resting level of FRC as the mechanical time constants become inadequate for the increased airflow demands (Fig. 16-7*B*).

VENTILATORY CONTROL

Although the postulated mechanisms of ventilatory control during exercise continue to foment considerable debate, neurogenic, chemoreflex, and circulatory-coupled processes are considered to be contributory. The challenge is to establish a justifiable control model that not only integrates these processes, but also accounts for both the dynamic and steady-state $\dot{V}_E$ responses over the range of exercise intensities. Such a model is not yet available.

Central Neural Control

As the ventilatory and cardiovascular responses to dynamic muscular exercise are initiated with little or no discernible delay, they are considered to result from neurogenic mechanisms of both central and peripheral origin.

Central Command

The cortical somatomotor command that triggers locomotion has been proposed also to influence brain stem respiratory (and cardiovascular) control centers. This has been termed "central command" of ventilatory responses, which is roughly equivalent to the magnitude of the "central command" to locomotion. Proponents of central command argue that feedback control via humoral mediation (or related to muscle contraction) need only be modest to provide a $\dot{V}_E$ response that is appropriate for the metabolic demands of the exercise.

The descending motor influences on the medullary ventilatory integrating regions include: (1) direct "irradiation" of the cortical somatomotor drive; and (2) subcortical projections from hypothalamic regions, such as the paraventricular locomotor region of the hypothalamus and the fields of Forel, and mesencephalic locomotor regions. Evidence that supports central neurogenesis derives from animal studies in which discrete focal CNS stimulation is used to activate descending central command pathways to ventilatory control regions; and also experiments in humans that attempt to dissociate the magnitude of central command from its subsequent motor outcome. For example, in conscious rats running on a treadmill, *c*-fos labeling has been used to identify activity in the hypothalamic and mesencephalic locomotor regions as well as medullary regions involved in cardiorespiratory integration. Furthermore, evidence of motor cortical involvement in the exercise hyperpnea has been provided in humans using positron emission tomography (PET) to estimate regional cerebral blood flow (indicative of regional neuronal activation). Thus, significant increases in the superomedial primary motor cortical activity (i.e., spatially consistent with the motor cortical leg region) have been demonstrated during leg exercise but not recovery. In contrast, although the activity of the superolateral primary cortical areas also increased during exercise, the activity remained during recovery. As these superolateral regions previously have been demonstrated to be associated with volitional activation of the respiratory muscles, it was concluded that this provided evidence in humans for a feed-forward component of the exercise hyperpnea, of motor cortical origin.

However, evidence from animal studies suggests that the cerebral cortex is not the sole origin of this control component. Spontaneous locomotion can be elicited in decorticate animals that is associated with prompt respiratory and cardiovascular responses. Focal stimulation (electrical or chemical) of the hypothalamic paraventricular locomotor region or the H2 field of Forel leads to locomotor activity accompanied by rapid hyperpnea, tachycardia, and arterial hypertension. Furthermore, efferent neural connections have been demonstrated from these hypothalamic sites to medullary sites of cardiovascular and respiratory control, such as the nucleus of the solitary tract (NTS), nucleus ambiguus, and dorsal vagal nucleus.

These evoked responses are essentially unaffected by muscle paralysis; hence, they appear not to depend on actual muscular contraction and increased metabolic rate. Although neural projections from the NTS to hypothalamic locomotor regions have been demonstrated (i.e., consistent with central command modulation by respiratory-related neuronal feedback), it is still not clear to what extent the hypothalamus is involved in the normal exercise hyperpnea. For example, the normal exercise $\dot{V}_E$ profile has been reported to be abolished by hypothalamic lesioning, as was also the case for the "fictive" locomotory model. However, removal of hypothalamic influences had no clear effect in other studies. Furthermore, no evidence of increased neuronal activity in these hypothalamic motor regions was found during exercise in conscious humans using PET, despite evidence of increased cortical respiratory motor activity. These hypothalamically induced $\dot{V}_E$ responses are also typically accompanied by a rapid and usually marked hypocapnia. This is not normally characteristic of humans during moderate exercise, although it does appear to be the case for many, but not all, conscious experimental animals.

Procedures designed to augment or diminish the central command for a task have also been used to characterize its role in the exercise hyperpnea. For example, selective stimulation of muscle spindles by means of high-frequency vibration applied to a contracting muscle in humans has been shown to reduce the central command required to maintain a given contractile force (i.e., the reflex facilitation of motor neurons to the exercised muscle takes over a component of force generation from central command), with the $\dot{V}_E$ response being

less than under control conditions. Similarly, stimulating an antagonist muscle led to an exaggerated $\dot{V}_E$ response. This is thought to be a consequence of the greater effort now required to sustain the force.

Other evidence seems inconsistent with the view that central command subserves the dominant component controlling $\dot{V}_E$ during exercise. Thus, the magnitude of the $\phi 1$ $\dot{V}_E$ response to exercise is not a simple function of the number of motor units recruited to generate the muscle force or of the magnitude of the central command required for their recruitment. Neither is it systematically altered over a wide range of imposed WRs. Also, when the WR increment is imposed from a background of light exercise (Fig. 16-2, *left*), the $\phi 1$ hyperpnea develops more slowly and is smaller. The initial hyperpnea is also slow when subjects initiate rest-to-work transitions in the supine position. Supporters of the central command hypothesis do not explain how body position per se would so markedly reduce this component of control. Therefore, although neurogenesis seems beyond serious challenge as the mechanism mediating the $\phi 1$ hyperpnea, the nature and functional organization of the signals themselves remain to be elucidated.

The results of sinusoidal exercise are also instructive in this regard. When WR is "forced" sinusoidally over a range of increasing input frequencies, the $\dot{V}_E$ response amplitude decreases as a close linear function of the decrease in $\dot{V}_{CO_2}$ amplitude, both in humans (Fig. 16-8) and conscious sheep. Importantly, the relationship extrapolates to the origin at high frequencies. Therefore, the ventilatory control system cannot keep up with the amplitude demands of the task at high forcing frequencies: A rapid neurogenic mechanism should! Consequently, the central command, which continues to drive the force-generating muscle units over the same WR amplitude range, either subserves a trivially small role in the exercise hyperpnea under these non–steady-state condition or these mechanisms themselves exhibit slow neural dynamics—but somehow closely proportional to those of $\dot{V}_{CO_2}$.

A servo-assisted positive-pressure ventilator has been used as a means of dissociating a subject's intrinsic ventilatory drive from the motor task. That is, the applied pressure is carefully synchronized with the respiratory cycle to take over a proportion of the normal inspiratory flow. Were the $\dot{V}_E$ to be dictated wholly by the central command, then the subject's intrinsic ventilatory drive would be expected to remain unchanged despite the external proportional-flow assistance to ventilation. Consequently, overall $\dot{V}_E$ would be expected to increase, resulting in a sustained hypocapnia. This is *not* the case, however (Fig. 16-9). Rather, a proportional compensatory reduction in the intrinsic ventilatory drive results.

Finally, if central command was a major and obligatory component of the exercise hyperpnea, then one would expect an attenuated $\dot{V}_E$ response when exercise is performed in the absence of central command. However, in subjects with clinically complete spinal cord transection, with exercise induced by direct electrical stimulation of the quadriceps muscles, both the magnitude and time course of the $\dot{V}_E$ response have been shown to be essentially normal with respect to $\dot{V}_{CO_2}$, albeit over a restricted range of metabolic response. These observations argue against a major obligatory involvement of central command in ventilatory control during moderate exercise. Rather, they reinforce the notion of redundancy of ventilatory control mechanisms during exercise.

Short-Term Potentiation

Eldridge and his associates have demonstrated that exercise activates a slowly developing neurogenic drive to ventilation in the cat, short-term potentiation or reverberation. The hyperpneic response to the abrupt cessation of afferent activity from sources such as limb muscle afferents, carotid bodies, and ventral medullary surface results in a slowly decaying exponential decrement of $\dot{V}_E$. A similarly slow decrement of $\dot{V}_E$ also can be demonstrated in humans following the abrupt cessation of volitional isocapnic hyperventilation. However, the onset of the ventilatory response in the cat is much more rapid when the stimulus is imposed; that is, the mechanism exhibits dynamic *asymmetry*. However, the reverberatory component itself is symmetrical, as evidenced by Eldridge and Gill-Kumar's cleverly designed alternate-breath stimulation study. That is, it appears that the intrinsic symmetry of the reverberatory component is masked by a direct component at the on-transient that renders the overall response asymmetrical. The exercise hyperpnea in humans, however, exhibits symmetry of the exponential $\phi 2$ $\dot{V}_E$ responses at the onset and cessation of moderate exercise. This on-off kinetic symmetry is maintained even when the $\phi 2$ $\tau\dot{V}_E$ is varied by up to fourfold (Fig. 16-4) by altered peripheral chemoreceptor gain. To date, studies addressing this issue have not been performed in the cat.

Long-Term Potentiation

In 1993, Martin and Mitchell proposed that a component (at least) of the exercise hyperpnea may be the result of long-term modulation or potentiation (LTP) resulting from repeated exposure to activity, akin to associative motor learning. They demonstrated that goats consistently overbreathed during a standard treadmill task after they had been trained to exercise repeatedly for 2 days at that level, with an additional stimulus to breathing in the form of added dead space (0.8 L). This resulted in appreciable hypercapnia (ΔPa_{CO_2} approximately + 10 mmHg) during the exercise, in contrast to the 0.5 mmHg average decrease in Pa_{CO_2} during the initial pre-training trial (i.e., hypocapnia was *not* characteristic in these goats!) and the approximately 3 mmHg decrease during the post-training trial without the added dead space. This augmented hyperpnea during exercise as a result of the hyperpneic history resolved over a period of approximately 6 hours. As the training had no effect on the $\dot{V}_E$ response to inhaled CO_2, these authors concluded that the neural mechanisms controlling the exercise hyperpnea evidence adaptability, plasticity, or "learning," possibly involving central serotonergic mediation. Evidence consistent with LTP was subsequently reported also in humans. Thus, LTP of the exercise hyperpnea is consistent with

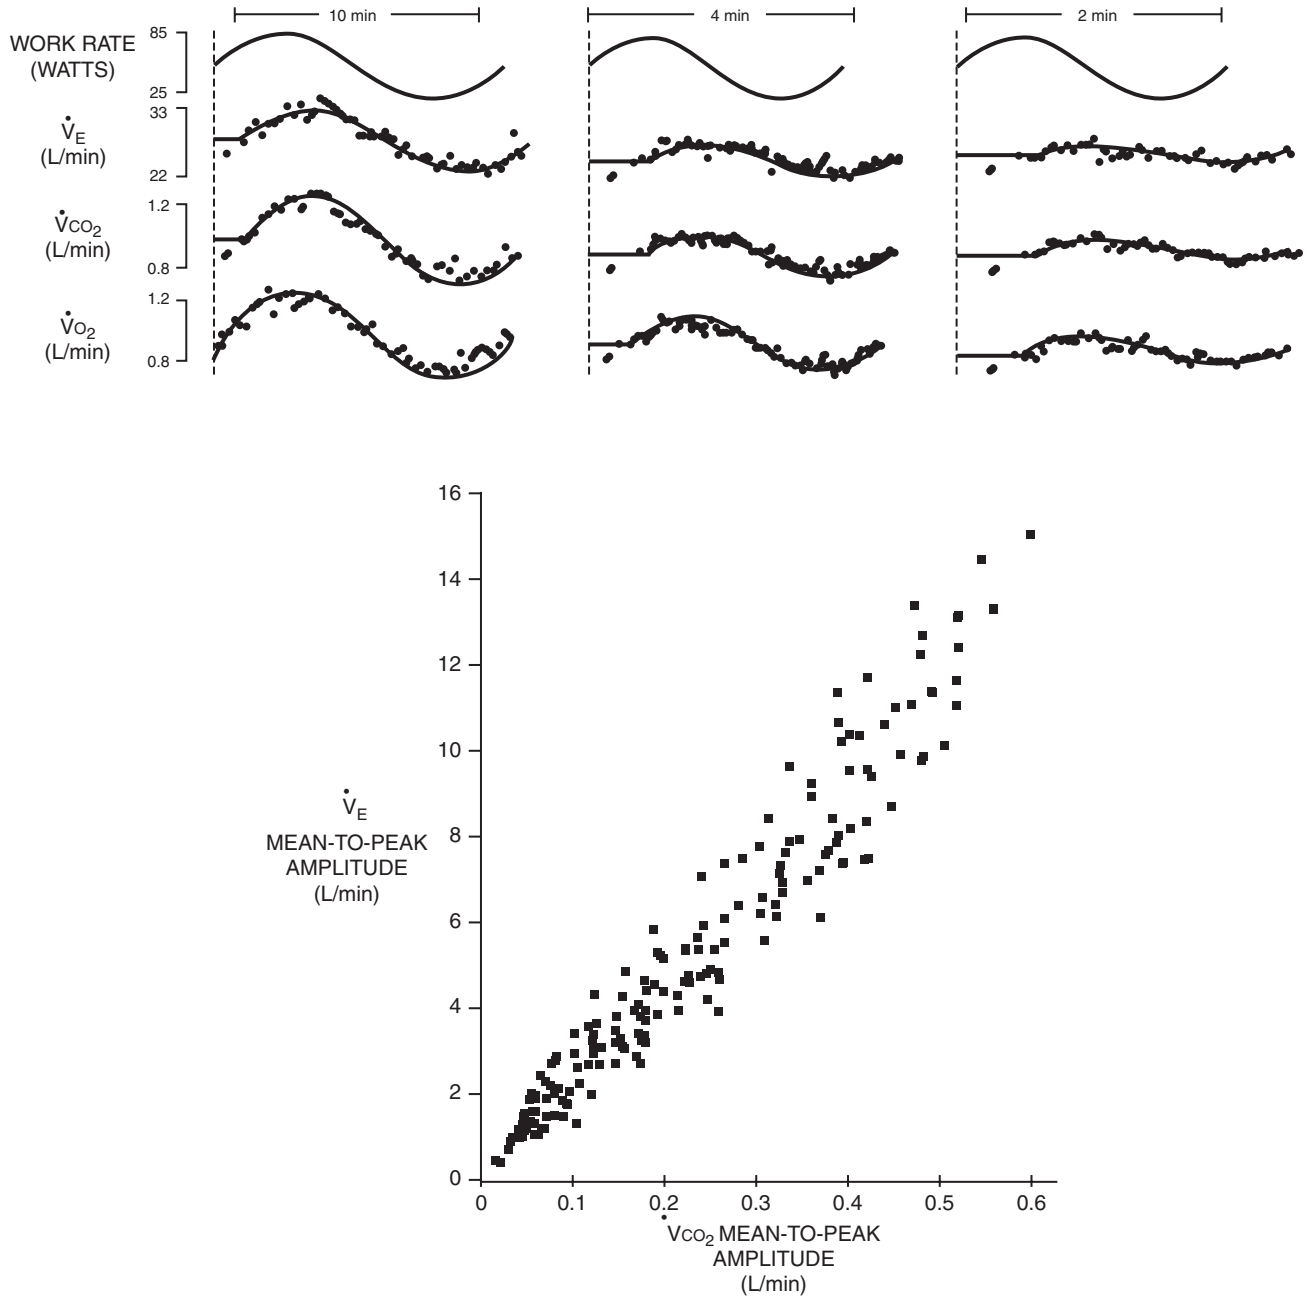

Figure 16-8 Relationship between the amplitude of $\dot{V}_E$ and $\dot{V}_{CO_2}$ in response to exercise of sinusoidally varying work rate. Note that the reduction in $\dot{V}_{CO_2}$ amplitude is matched by a proportional reduction in $\dot{V}_E$ amplitude as the forcing frequency of the work-rate sinusoid is increased, the relationship extrapolating to the origin. *(Reproduced with permission of Casaburi R, Whipp BJ, Wasserman K et al: Chest 73S:280S–283S, 1978.)*

Somjen's postulate that functionally error-free physiological control systems may operate through central nervous system control that "anticipates present and future needs on the basis of past experience."

However, evidence consistent with LTP could not be demonstrated in other studies in exercising humans. When $\dot{V}_E$ was normalized appropriately (i.e., relative to $\dot{V}_{CO_2}$) and a robust noninvasive index of Pa_{CO_2} is used (i.e., mean alveolar rather than end-tidal P_{CO_2}), the hyperpneic response following associative conditioning via external dead space was not different from control either in the exercise steady state or during the transient.

Muscle Reflex Control

There is a wide range of receptors and "free" nerve endings in skeletal muscles, the afferent projections of which have been proposed to contribute to the control of the exercise hyperpnea. For example, $\dot{V}_E$, heart rate, and arterial blood pressure all increase when the muscle contraction is induced

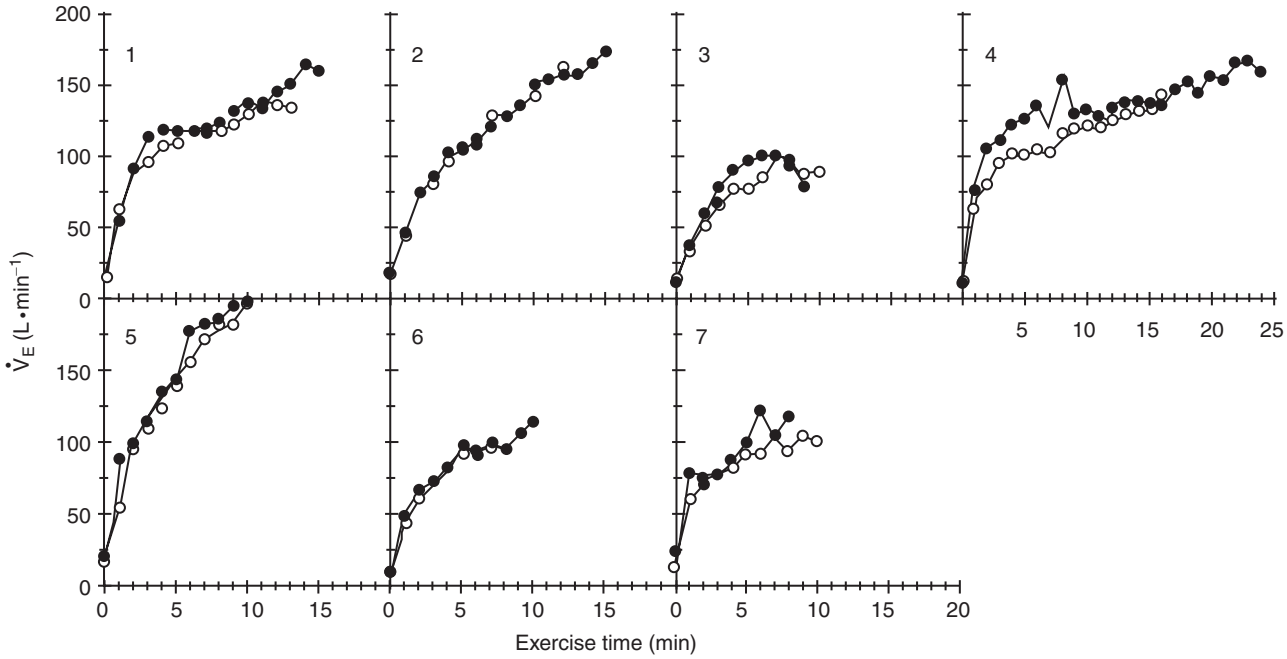

Figure 16-9 Profile of ventilatory response to high-intensity exercise in normal subjects under control conditions (○) and when the respiratory muscular demands for pressure generation were reduced by approximately one-third by means of a proportional ventilatory assist (●). *(Reproduced with permission of Krishnan B, Zintel T, McParland C et al: J Physiol (Lond) 490:537–550, 1996.)*

in experimental animals by stimulation of: (1) ventral spinal roots; (2) motor nerves; or (3) the muscles themselves. These responses are abolished by section of the dorsal spinal roots, evidence of their origin in the exercising muscles. More specifically, electrical stimulation of small-diameter group III and IV afferents (but not of the larger group I and II afferents) leads to an increase in $\dot{V}_E$, heart rate, and arterial blood pressure, which can be abolished by differential blockade of these small-diameter fibers. Other stimuli, such as local mechanical distortion and increased intramuscular pressure, also have been demonstrated to activate a sub-population of the small-diameter afferents. A second subpopulation of small-diameter afferents is responsive to humoral mediators such as intramuscular levels of potassium (K^+), lactic acid (but not lactate), bradykinin, capsaicin, and di-protonated phosphate.

However, a simple interpretation of the role of skeletal muscle metaboreception or chemoreception in the exercise hyperpnea is confounded by the consistent demonstration that when pneumatic thigh-cuffs are inflated to suprasystolic pressures at the end of exercise, the $\dot{V}_E$ response decreases *more rapidly* than normal and *not* more slowly, despite the local accumulation of exercise-induced metabolites and presumably the sustained activation of chemosensitive muscle afferents *after* the cessation of the work (Fig. 16-10). In addition, removing the influence of somatic limb afferents does not seem to impair the ventilatory response to dynamic exercise to any appreciable extent in humans—at least over the usual range of metabolic rates achieved. Furthermore, the $\dot{V}_E$ response to dynamic exercise has been shown to be essentially normal, both in normal subjects with muscle sensory blockade induced by epidural anesthesia and patients with sensory neuropathies, despite the absence of functioning afferent projections from the exercising limbs. Finally, the results of the assisted inspiration experiments described in the preceding section are relevant in this regard (Fig. 16-9). That is, the subjects' $\dot{V}_E$ was *not* significantly affected by the assist as a result of the intrinsic ventilatory drive being proportionally reduced (i.e., despite neither central command nor mechanical feedback from the exercising muscles presumably being altered). Consequently, although there appears to be little doubt that respiratory drives originate within contracting muscles, whether these represent an obligatory or necessary control component during normal volitional exercise is by no means certain.

Central Chemoreflex Control

Studying central chemoreflex function in humans is difficult owing to the inaccessibility of the receptors themselves, whose distribution is now thought to extend beyond the classical ventral medullary surface areas into higher regions of the CNS. Hyperoxic hypercapnia is commonly used to assess the "sensitivity," and in some studies, the dynamics, of the central chemoreflex; the hyperoxia is necessary to suppress peripheral chemosensitivity. However, there is no consistent evidence that central chemosensitivity is increased significantly with exercise. Patients with congenital central hypoventilation syndromes (CCHS) have impaired central chemosensitivity, with little or no $\dot{V}_E$ response in inhaled CO_2. Importantly in this regard, their $\dot{V}_E$ response to exercise was considered to be remarkably normal.

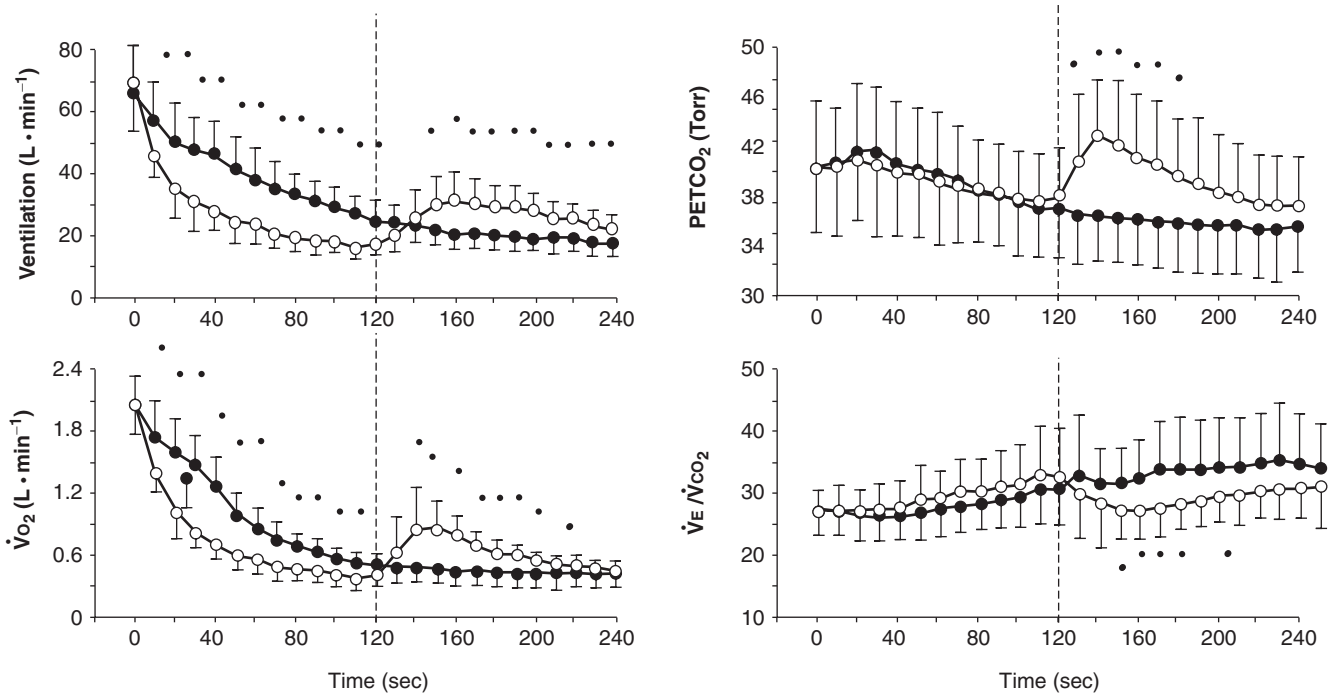

Figure 16-10 Dynamics of the ventilatory response during recovery from heavy cycle ergometer exercise in normal human subjects under control conditions (●) and when thigh cuffs were inflated to suprasystolic pressures at the cessation of exercise (○). Note ventilation decreases appreciably more rapidly with the thigh cuffs inflated. The subsequent release of the cuff pressure is marked by the dashed vertical line. *(Reproduced with permission of Haouzi P, Huszczuk A, Porszasz J et al: Respir Physiol 94:137–150, 1993.)*

The onset of the slower ϕ2 $\dot{V}_E$ response has a time delay consistent with the limb-to-lung transit time, suggestive of downstream chemoreceptor mediation. Although the ϕ1 − ϕ2 transition is prolonged with hyperoxic inspirates, it is unlikely that there is any significant involvement of the central chemoreceptors in this response, as CCHS patients demonstrate essentially normal ϕ2 $\dot{V}_E$ kinetics despite poor or absent central CO_2 chemosensitivity. However, what triggers the ϕ1 − ϕ2 transition is not known. It seems a crucial part of the puzzle.

The central chemoreceptors also appear not to play an essential role in the ϕ3 $\dot{V}_E$ control for moderate exercise. First, there is the issue of a discernible chemical stimulus: The pH of cerebrospinal fluid (CSF) remains relatively stable during the steady-state of moderate exercise. Also, despite significant increases in arterial $[K^+]$, CSF $[K^+]$ does not increase. The report that the normal $\dot{V}_E$ response to exercise in CCHS patients regulates P_{CO_2} close to resting levels (although this is often elevated in these patients) appears decisive in this regard.

Above θ_L, ventilatory compensation for the lactic acidosis results in a respiratory alkalosis in the CSF. Under these conditions, the central chemoreceptors are likely to provide *constraint* on the hyperpnea. The alkalotic CSF would not only reduce ongoing central chemoreceptor activity, but also stimulate efferent projections to the carotid chemoreceptors, which have been demonstrated to inhibit their afferent chemosensory discharge.

Interestingly, during prolonged constant-load exercise designed to produce the same degree of metabolic acidosis with markedly varying degrees of peripheral chemosensitivity, Rausch and colleagues showed a slow but systematic restoration of pHa back toward normal after its initial fall—even with hyperoxic suppression of peripheral chemosensitivity. This slow compensation might reflect a slow "leak" of H^+ ions into the CSF from blood or, possibly, a slow central chemoreflex response to the transiently elevated Pa_{CO_2} that was a consistent finding of the study. It has been suggested that this behavior may reflect, in part at least, modulation of the activity of the primary carotid-body ion channel involved in sensing changes in metabolic acidemia; possibly, a H^+ sensitive type I voltage-sensitive tandem-P-domain K^+ (TASK-I) channel.

Arterial Chemoreflex Control

It seems unlikely that the carotid bodies mediate the ϕ1 $\dot{V}_E$ response to exercise. This response is typically unaffected when hypoxic or hyperoxic gas mixtures are breathed or in subjects whose carotid bodies have been surgically resected (CBR): procedures that respectively increase, decrease and, of course, abolish carotid chemosensitivity. In contrast, the carotid bodies do appear to play a prominent role in ϕ2 $\dot{V}_E$ control. As described earlier, $\tau\dot{V}_E$ is reduced when carotid body sensitivity is increased, both in absolute terms and relative to $\dot{V}_{CO_2}$, and prolonged by procedures that reduce or

abolish carotid chemosensitivity (Fig. 16-4). Consequently, as the carotid bodies appear to modulate $\dot{V}_E$ response kinetics relative to those of $\dot{V}_{O_2}$ and $\dot{V}_{CO_2}$, they play an important role in the "tightness" with which Pa_{O_2}, Pa_{CO_2}, and pHa are regulated throughout the non–steady-state phase of exercise. For example, the faster $\dot{V}_E$ kinetics resulting from hypoxemia-increased carotid chemosensitivity reduce the magnitude of further hypoxemia during the transient.

There seems to be no dispute that the carotid bodies also provide a component of the ϕ3 $\dot{V}_E$ control, which some have termed "fine tuning." The proportional contribution of the carotid bodies to the ϕ3 hyperpnea has been estimated using the Dejours test, in which high inspired O_2 fractions are used surreptitiously to abolish abruptly any carotid body contribution to the hyperpnea. Thus, CBR subjects have no $\dot{V}_E$ decrease during the Dejours test. These tests have demonstrated that the carotid bodies normally appear to account, on average, for approximately 20% of the ϕ3 hyperpnea, although there is some concern that this may be an underestimate.

The proportional role of the various stimuli in the arterial blood during exercise, however, is unclear. Components of the oscillating CO_2-H^+ pattern, such as its amplitude and rate of change, have been proposed to provide a CO_2-linked drive to $\dot{V}_E$ in ϕ3. The carotid bodies in animals have been shown to be capable of transducing such signals into respiratory stimulation. However, whether such oscillating signals provide any significant humoral feedback for ventilatory control in exercising humans remains to be demonstrated.

The increased arterial $[K^+]$ that results from release from contracting muscle cells during exercise has been demonstrated to stimulate $\dot{V}_E$ via the carotid bodies. As K^+ does not cross the blood-brain barrier, the increased arterial $[K^+]$ apparently does not influence sites of central chemosensitivity. Consequently, the increased arterial $[K^+]$ may account for or contribute a component of the average 20% of the steady-state exercise hyperpnea mediated by the carotid bodies. However, the unaltered hyperpnea when the exercise-induced increase in $[K^+]$ is modified by propranolol infusion argues against a crucial role for $[K^+]$ as a mediator. Other known carotid-body stimuli, such as increases in the plasma levels of H^+, adenosine, osmolarity, catecholamines, temperature, and rate of change of the P_{CO_2}-H^+ oscillations also increase during exercise. These presumably also contribute to this approximately 20% of the ϕ3 hyperpnea.

It has been argued that the carotid bodies normally appear to be largely responsible for mediating the respiratory compensation for the lactic acidosis above θ_L in humans, responding to stimuli such as $[H^+]$, $[K^+]$, and catecholamines. Evidence against this view has been presented, however. Individuals deficient in the glycogenolytic enzyme myophosphorylase b (McArdle's syndrome) are constrained to exercise only at relatively low WRs as they are unable to catabolize glycogen anaerobically. These subjects have been reported to hyperventilate despite there being no metabolic acidemia at these low WRs. This suggests, to some investigators, that the compensatory hyperventilation seen in *normal* subjects above θ_L does not require a lowered pHa for its mediation. However, other mechanisms, such as apprehension, discomfort, and increased intramuscular pressure or pain can induce acute hyperventilatory *alkalosis* under some circumstances. Indeed, muscle pain is a cardinal symptom of McArdle's syndrome. Another important distinction is that respiratory alkalemia is *not* normally seen in humans performing high-intensity dynamic exercise.

In response to constant-load exercise above θ_L, the compensatory hyperventilation has been reported to be nonexistent in CBR subjects. Not only did pHa fall more for a given decrease in $[HCO_3^-]a$, but Pa_{CO_2} was higher than the corresponding control values. It has been proposed, however, that this marked reduction in the compensatory hyperventilation for the metabolic acidemia in these subjects may be a consequence of their asthmatic history rather than the absence of carotid bodies. Furthermore, despite reducing the "gain" of the carotid chemoreflex (assessed by hypoxic ventilatory responsiveness) and significantly slowing the ϕ2 $\dot{V}_E$ response to moderate constant-load exercise in humans, infused dopamine did not discernibly affect the $\dot{V}_E$ response above θ_L during ramp-incremental exercise.

In studies designed to induce a standard and more prolonged degree of metabolic acidemia during constant-load exercise (Δ standard $[HCO_3^-]$ of 5 mEq/L) in normal subjects, Rausch and associates demonstrated that hypoxia constrained the magnitude of the transient decrease in pHa, whereas hyperoxia amplified it (Fig. 16-11). However, even when carotid body chemosensitivity was suppressed by inhalation of 80% O_2, a *slow* compensatory component was still evident. Therefore, the carotid bodies in humans may be considered to play a significant, and even, dominant role in constraining pHa in response to the acute metabolic acidemia of exercise in humans. However, there are secondary—presumably central chemosensory—mechanisms that subserve a slower compensatory role. An alternative interpretation of these findings, consistent with the demonstration that $\dot{V}_E$ evidences an upward concavity at high WRs during hyperoxic incremental exercise, is that hyperoxia does not abolish peripheral chemosensitivity under these conditions. However, the absence of an early $\dot{V}_E$ response to an increased inspired CO_2 fraction in hyperoxia, both at rest or during exercise, suggests that this is not the case.

Cardio-Circulatory Reflex Control

Some investigators have proposed that a component of ventilatory control during exercise may be of cardiac or circulatory origin. Vascular distention of the heart and adjacent vasculature, for example, can elicit tachycardia and hyperpnea. Therefore, might the increased venous return of exercise contribute to the ventilatory control during exercise in humans? The relative stability of the end-tidal gas tensions and R, as a result of the close proportionality between the

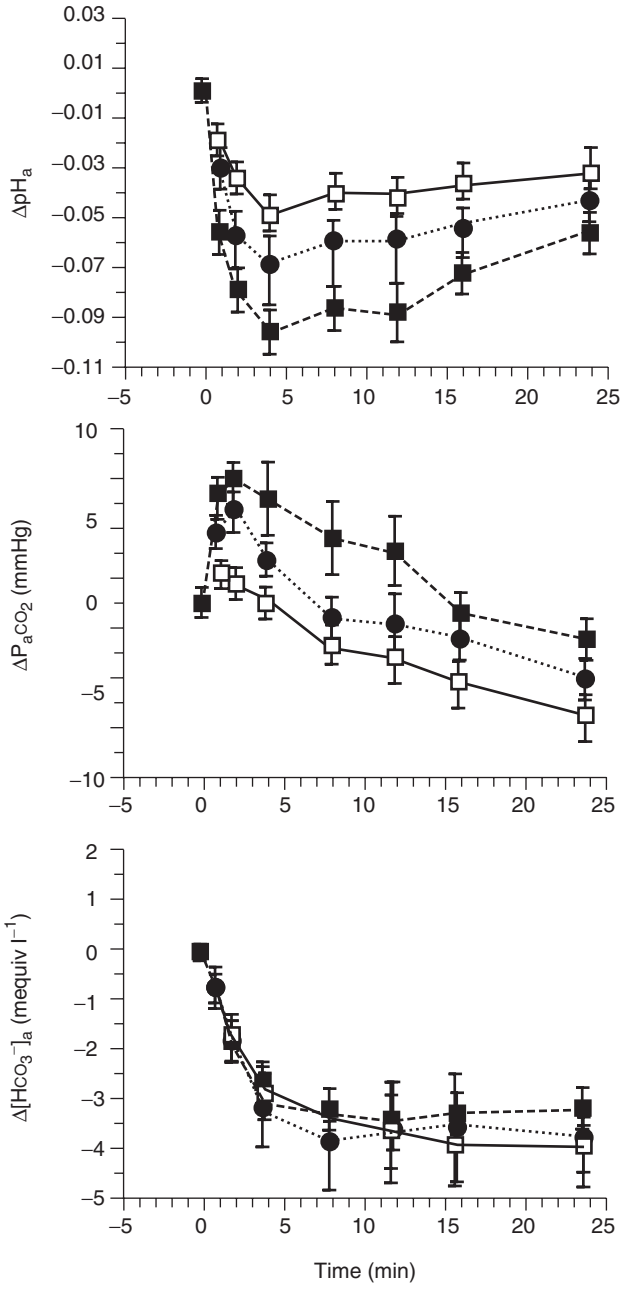

Figure 16-11 Responses of arterial pH, P_{CO_2}, and standard $[HCO_3^-]$ to suprathreshold square-wave exercise for three inspired oxygen fractions (□ = 12% O_2; ● = 21% O_2; ■ = 80% O_2), expressed as changes (Δ) from unloaded cycling. Values are means ± SEM ($n = 7$). *(Reproduced with permission of Rausch SM, Whipp BJ, Wasserman K et al: J Physiol (Lond) 444:567–578, 1991.)*

ϕ1 cardiovascular and ventilatory responses, has suggested to some investigators that there may be a component of cardiodynamic $\dot{V}_E$ control in this phase of exercise. However, evidence from several sources has questioned such a role. When the resting heart rate (and therefore cardiac output) was abruptly increased in patients with permanent demand-type pacemakers, there was no difference in the immediate $\dot{V}_E$ response amplitude compared with when heart rate was not allowed to increase, despite a clearly greater increase in $\dot{V}_{O_2}$. It is also clear that cardiac afferents do not subserve an obligatory role in the exercise hyperpnea although they can, under some circumstances, stimulate $\dot{V}_E$. Humans who have undergone cardiac transplantation and calves with an implanted pneumatically driven artificial heart have no reduction in either the magnitude or rapidity of onset of the exercise hyperpnea.

Recent studies have suggested that $\dot{V}_E$ may respond to a signal mediated by altered vascular conductance and/or tissue pressure in the exercising muscles themselves. There is evidence that some group IV muscle afferents are stimulated by venous occlusion and injection of vasodilating agents. Therefore, this proposal changes the focus of a cardio-respiratory linkage during exercise from a central circulatory control site to one more intimately related to the peripheral microvasculature and its innervation. Of course, a control link between the peripheral and pulmonary gas-exchange surfaces and breathing is intuitively attractive. However, although the mechanism itself has been clearly demonstrated, its proportional contribution to the exercise hyperpnea in humans remains to be determined.

VENTILATORY COSTS

Mechanical Costs to Respiratory Muscles

The intra-pleural pressure changes resulting from respiratory muscle contraction (P_{MUS}) serve to expand the lung and generate tracheal-bronchial airflow, with an additional small component providing lung-tissue flow and overcoming inertia. Therefore, the pressure, or power, required to overcome the total impedance of the respiratory system is given by:

$$P_{MUS} = E \cdot V + R \cdot \dot{V} + I \cdot \ddot{V} \qquad (14)$$

where

E, R, and I = the respiratory system elastance, resistance, and inertance respectively

In patients with COPD, the added cost is predominantly in the resistive component, whereas in patients with restrictive lung disease it is predominantly in the elastic component.

The relationship between $\dot{V}_E$ and respiratory muscle power during exercise is not linear. A given increment in $\dot{V}_E$ requires a larger increase in P_{MUS} at high WRs than at low WRs. Subjects who are moderately fit, however, use only 30% to 40% of their maximum available respiratory power at maximal WRs and also have a considerable breathing reserve (BR); that is, the difference between the maximum exercise $\dot{V}_E$ and that achieved volitionally during a maximal voluntary ventilation maneuver (MVV), usually measured at rest. Highly fit subjects who are able to achieve high metabolic rates and consequently high levels of $\dot{V}_E$, on the other hand, typically have a low BR at maximum exercise as the MVV is essentially unaffected by training status and fitness. A BR

that is minimal, zero, or even negative suggests a ventilatory limitation to exercise tolerance.

The mechanical cost of $\dot{V}_E$ is appreciably greater at high WRs because: (1) increased contributions from turbulence (and even inertia) when airflow is high; (2) increased elastic work of breathing, owing both to decreased lung compliance even in the tidal range (an effect ascribed to increased pulmonary blood volume) and especially as end-inspiratory lung volume reaches the poorly compliant upper region of the compliance curve at high V_Ts-the decrease in EELV, however, tends to ameliorate this effect, at least in normal subjects; and (3) the recruitment of respiratory muscles with low mechanical efficiencies at high levels of $\dot{V}_E$.

Metabolic Costs to Respiratory Muscles

These increased mechanical costs of the exercise hyperpnea require both an increased respiratory muscle work rate and respiratory muscle O_2 consumption ($\dot{Q}_{O_2}$rm). The relationship between $\dot{Q}_{O_2}$rm and $\dot{V}_E$ during exercise is not linear; rather it is concave upward, with greater increments in $\dot{Q}_{O_2}$rm being required as WR increases. Although $\dot{Q}_{O_2}$rm is small at resting levels of $\dot{V}_E$, it can be appreciable at high levels of exercise, especially in highly fit athletes. In moderately fit subjects a $\dot{Q}_{O_2}$rm of approximately 0.5 L/minute, approximately 15% of the total $\dot{V}_{O_2}$, has been reported for a $\dot{V}_E$ in excess of 120 L/minute. This is presumably even greater in athletes, who are capable of attaining appreciably higher levels of $\dot{V}_E$ at maximum exercise.

Estimation of $\dot{Q}_{O_2}$rm in humans, however, is technically difficult, as it represents such a small fraction of the whole-body $\dot{V}_{O_2}$ during exercise. A further complication results from the fact that whole-body $\dot{V}_{O_2}$ can change not solely as a result of the increased respiratory muscle work rate in tests that attempt to reproduce the exercise hyperpnea in a resting subject, but also as a result of the altered pH if Pa_{CO_2} is not maintained precisely—acute respiratory alkalosis has been shown to increase whole-body $\dot{V}_{O_2}$ by approximately 10% per 10 mmHg decrease in Pa_{CO_2}. Also, although this relationship for spontaneous breathing during exercise may be expected to be qualitatively similar to that of volitional hyperpnea at rest, there may be significant quantitative differences. The respiratory muscle recruitment patterns, their mechanical efficiencies, their operating lengths, and the metabolic cost of the $\dot{V}_E$ attained are all likely to be different.

As the respiratory muscles, like other skeletal muscles, have the potential for the O_2 demands of the task of breathing to outstrip the vascular supply mechanisms during exercise, they themselves can exercise beyond their "lactate threshold". However, the blood that flows *to* the respiratory muscles naturally cannot also flow *to* the locomotor muscles. An added inspiratory resistive load, for example, has been shown to compromise exercise $\dot{V}_{O_2}$ by this mechanism under conditions of maximum cardiac output (but not at lower levels). This is commonly (and unfortunately, in our opinion) termed "respiratory steal". The respiratory muscles "take" (they hardly "steal"!) the component of the cardiac output that is theirs by right.

SYSTEM CONSTRAINTS AND LIMITATIONS

The mechanical and metabolic costs of $\dot{V}_E$ during muscular exercise are themselves sources of *constraint* and potential *limitation* of exercise tolerance. Constraint, in this context, reflects a condition in which the $\dot{V}_E$ response is less than that of its regulatory requirement as a result of the influence of an opposing mechanism, e.g., an added resistive load. Ventilation in this case is not actually limited, as higher WRs lead to greater hyperpnea. In contrast, limitation occurs when $\dot{V}_E$ cannot increase, despite further increases in ventilatory drive. For example, maximum expiratory airflow during exercise (at a particular lung volume) becomes limited in subjects with reduced lung recoil pressure (Prec) and/or increased airways resistance (Raw), despite further increases in ventilatory drive; similarly, the achievable V_T is limited during exercise in patients with diffuse interstitial fibrosis as a result of the increased elastance.

Ventilatory Constraints

The V_T limit theoretically extends from zero to vital capacity (VC), whereas the breathing frequency extends from zero to approximately 5 Hz. Normally, however, the ventilatory system "only" operates at a V_T of approximately 50% to 60% of VC and a frequency of less than or equal to 1 Hz even during maximum exercise. The maximum airflow that can be attained, at a given lung volume, during exercise in normal subjects is that generated by a maximal forced volitional effort, i.e., that characterized by the maximum expiratory flow-volume (MEFV) relationship. At maximum exercise, the spontaneously generated expiratory flow profiles fall well below the maxima of the MEFV curve in subjects of poor or moderate fitness. However, in highly fit athletes, who are capable of generating high instantaneous airflows at their high levels of $\dot{V}_E$, these maxima may be encroached upon (Fig. 16-7).

The hypothesis that respiratory work would be minimized, at a particular level of $\dot{V}_E$, with a particular breathing frequency, is largely based on the recognition that when $\dot{V}_E$ is achieved with a high frequency and a low V_T, the flow-resistive component of the respiratory work increases. When this is accomplished with a large V_T and low breathing frequency there is an increased contribution from the elastic component of the respiratory work, as the lung volume encroaches on the flatter portion of the lung compliance curve. Exercising subjects normally seem to choose a breathing pattern at or near the optimum for minimum respiratory muscle work rate; unless, of course, this is prevented by the breathing demands of an event such as swimming.

There is likely to be turbulent constraint of airflow during exercise even in moderately fit subjects. When the inspired nitrogen is replaced by the lower-density gas helium (taking care to mask the sudden sensation of cold in the airways), there is no discernible effect when $\dot{V}_E$ is low. However, at higher levels of WR, and hence $\dot{V}_E$, replacing the nitrogen with helium, induces prompt and sustained hyperventilation. This is consistent with the removal of a constraint on $\dot{V}_E$ imposed by the turbulent component of airflow. However, the extent to which such turbulent constraint impairs the respiratory compensation for the metabolic acidemia in athletes is not clear at present.

Ventilatory Limitations

Mechanical Limitations

In moderately fit young individuals, $\dot{V}_E$ appears not to be mechanically limited during maximal exercise: (1) Such subjects can volitionally increase $\dot{V}_E$ to appreciably greater levels than those attained spontaneously at maximum exercise. (2) The ratio of maximum exercise $\dot{V}_E$ to MVV ($\dot{V}_{E_{max}}$/MVV) is relatively low (i.e., approximately 60%–70%). (3) The spontaneously generated expiratory F-V curve does not encroach on the boundaries of the MEFV curve even at maximum exercise. (4) There is also no evidence of significant respiratory muscle fatigue.

There is evidence of both ventilatory-mechanical limitation and inspiratory muscle fatigue in subjects who are more fit. For example, the spontaneous expiratory F-V curve often impacts on the envelope of the MEFV curve during maximal exercise in subjects with a maximum $\dot{V}_{O_2}$ of approximately 5 to 6 L/minute and a maximum exercise $\dot{V}_E$ of approximately 110 to 160 L/minute (i.e., 80% of MVV). Diaphragmatic fatigue has been demonstrated in such subjects both in terms of electromyographic criteria and also as reduced maximum trans-diaphragmatic pressures following exhausting exercise. Finally, there have been reports of reductions in VC, respiratory muscle strength, and endurance following exercise, but this has only been consistently observed following prolonged exercise in athletes.

In older subjects who have developed or maintained high levels of fitness, such airflow limitation has been demonstrated at lower levels of $\dot{V}_E$ during exercise (Fig. 16-7). This is predominantly caused by the age-related reduction in lung recoil reducing the maximum attainable airflow (evident as a bowing in the MEFV curve) and MVV, despite increased ventilatory demands as a result of increased V_D/V_T (Eqs (7) and (8)). However, it has been reported that even with the evidence of airflow limitation, subjects do not generate nonproductive, airway-compressive pressures that would increase respiratory work without further benefit to airflow. Rather, they generate only sufficient pleural pressures to establish the maximum flow—although this, of course, only reflects the average for the lung as a whole. There could be regions within the lung where this might occur, especially in patients with COPD.

The resting MEFV curve—and MVV—should be used with caution when deciding whether there is airflow limitation during exercise. This is because the interpretation depends on the accurate placement of the spontaneous expiratory F-V curve on the volume axis of the MEFV curve. It is more appropriate to trap an F-V display oscillographically and then perform the MEFV maneuver immediately afterward during the exercise. Furthermore, catecholamine-induced bronchodilatation can occur during exercise, which presumably accounts for the exercise MVV being greater that the resting MVV even in some normal subjects. Also, in older athletes with diminished lung recoil and airways function, and especially in patients with COPD, the maximum expiratory-*effort* F-V maneuver does not yield the optimum maximum expiratory-*flow* F-V curve.

The increased Raw and/or reduced Prec in COPD patients reduces both volume-specific maximum expiratory airflow and MVV, resulting in a reduced effective operating range for $\dot{V}_E$ during exercise. However, the ventilatory demands are typically greater than normal because V_D/V_T is high consequent to increased dispersion of $\dot{V}_A/\dot{Q}$ ratios. The ventilatory drive is also often increased consequent to arterial hypoxemia, although some patients, predominantly of the bronchitic type, can have Pa_{CO_2} levels that are higher than normal as a result of ventilatory constraint. The consequence is typically a modest uncompensated metabolic acidosis at maximum exercise.

Accordingly, during exercise, subjects with COPD commonly manifest the following:

1. Spontaneous expiratory airflows that equal or even exceed those achieved during a maximal flow-volume maneuver at a given lung volume
2. A level of $\dot{V}_E$ during maximum exercise that reaches or sometimes even exceeds the MVV determined at rest
3. An increase in end-expiratory lung volume during exercise, although this is less apparent when there is also significant inspiratory airflow impairment
4. A tendency to decrease the inspiratory duty cycle (inspiratory duration/breath duration (T_I/Ttot)) to conserve a large portion of the breath for exhalation, with T_I/Ttot falling to values as low as 0.2 in severe cases
5. Often, although not invariably, dyspnea as the cause of exercise limitation

The apparent paradox of expiratory airflow during exercise exceeding that generated during a maximal expiratory effort at rest can be explained by three factors: (1) An exercise-induced increase in circulating catecholamine concentrations can result in bronchodilatation. (2) As the fast time-constant units of the lung empty at high lung volumes during the forced expiratory maneuver from total lung capacity (TLC), the longer time-constant units empty at lower lung volumes. During the spontaneous exercise breath, the fast time-constant units now begin to empty at lung volumes that are low compared with the vital capacity breath. This results in greater

airflow at that particular generated lung volume. (3) The maximum expiratory airflow is not achieved with a maximum expiratory effort in COPD patients, especially at low lung volumes. During maximum expiratory efforts, there is typically dynamic airway compression, and even closure in some cases. This complicates appropriate "placement" of the spontaneous breath at the appropriate lung (rather than simply expired) volume with respect to the maximal maneuver.

Airflow limitation during exercise also occurs in subjects with exercise-induced asthma (EIA). Although the bronchoconstriction and reduction in forced expiratory airflow is typically manifest in the post-exercise period, it can also occur during the exercise; high-intensity exercise is a more potent causative trigger than low-intensity exercise. A bout of prior moderate exercise warm-up has been shown to ameliorate the intensity of EIA provoked by subsequent high levels of exercise. Also, many subjects with EIA can become relatively refractory to the bronchospastic effects of subsequent exercise (for a short period) after the resolution of the initial exercise-induced bronchospastic episode. However, it should be recognized that exercise-induced bronchoconstriction can also occur in subjects who do not have a history, or even recognition, of airway hyper-reactivity.

Although flow limitation at high relative WRs is most common in subjects with obstructive lung disease, it also occurs in patients with restrictive lung disease, such as diffuse interstitial fibrosis. This is because, as a result of the high lung elastance, it not only operates over such a restricted range of lung volumes, but also requires greater inspiratory muscle force development, more negative intra-pleural pressures, and greater respiratory work to produce the same inspiratory volume. Consequently, not only are the conventionally determined lung volumes reduced, but the V_T response to exercise is also typically reduced, both at a given WR and at maximum exercise. The resulting high breathing frequency and small V_T exacerbate the impaired gas exchange influence on V_D/V_T. Therefore, ventilation is typically high at a given metabolic rate. However, although V_T is relatively low during exercise, in absolute terms, in patients with restrictive lung disease, it is typically high as a fraction of the IC (measured either at rest or during exercise, as EELV does not change significantly with exercise in those with restrictive lung disease, unlike patients with COPD). Consequently, V_T/IC approaches 1.0 during heavy exercise. At maximum exercise, breathing frequency is commonly greater than 50/minute with a low, to nonexistent breathing reserve; with $\dot{V}_E$ often approximating MVV. This mechanical limitation, in addition to the effects of arterial hypoxemia, leads to dyspnea, the dominant exertional symptom in patients with restrictive lung disease.

CONCLUSIONS

Thus, although the ventilatory response to exercise is easy to measure, determining the appropriateness of its response is by no means straightforward. Its assessment should address at least four inter-related issues.

1. To what extent are the "requirements" met? This requires direct determination of the arterial blood gas and acid-base status or the use of reliable and valid estimators.
2. What is the cost of meeting these requirements? This requires an assessment of: (1) the magnitude and pattern of the $\dot{V}_E$ response used to meet the requirements; (2) by how much the alveolar and arterial gas partial pressures differ; and (3) the amount of respiratory muscle work, oxygen, and blood flow cost.
3. To what extent is the system constrained or limited? This requires determination or appropriate estimation of whether the mechanical limits of the system are achieved or closely approached. Indices of mechanical reserve, such as flow-volume and tidal volume-inspiratory capacity considerations, the maximum voluntary ventilation, breathing reserve, and even in some circumstances the maximum sustained ventilatory capacity, provide useful frames of reference.
4. How intensely is the response perceived? Useful information can be gained by the use of standardized techniques for scaling or grading the relative ease or difficulty with which the work rate or breathing is achieved.

With respect to the control of the exercise hyperpnea, we remain far from a satisfying resolution. The current congeries of mechanisms capable of stimulating ventilation under some circumstances during exercise is not sufficient. The core challenge is to establish the integrative aspects of the control that accounts for the *actual* dynamic features of the intensity-dependent responses in humans.

The Lungs in Pregnancy

Daniel B. Rosenbluth • John Popovich, Jr.

The anatomic and physiological changes of pregnancy have major pulmonary and cardiovascular consequences throughout the gravid period. Physiological values and requirements, as well as normal laboratory assessment parameters, dynamically change in preparation for fetal support and parturition. An appreciation of these changes is essential to understanding the clinical cardiopulmonary manifestations of both preexisting diseases during pregnancy and cardiopulmonary diseases that may be unique to pregnancy.

ANATOMIC CHANGES OF NORMAL PREGNANCY

Respiratory and cardiac anatomy change as a process of normal pregnancy. Basic structural changes occur in the upper and lower airways, thoracic cage, and the respiratory muscles, most notably the diaphragm.

Airways

Hyperemia, friability, mucosal edema, and hypersecretion of the airway mucosa occur throughout pregnancy. These changes are most pronounced in the upper airways, especially during the third trimester, and may be aggravated by preeclampsia, upper respiratory tract infection, or allergic rhinitis. Nasal obstruction, epistaxis, sneezing episodes, and vocal changes may occur, and these may worsen when the individual lies down. Nasal and sinusoidal polyposis is often seen and tends to recur in women with each pregnancy. Common complaints include recurrent or chronic "head colds," which are often treated with over-the-counter medications for relief. Nasal obstruction may contribute to upper airway obstruction during sleep, leading to snoring and even obstructive sleep apnea.

Clinical consequences of the anatomic changes of the upper airway may include preferential mouth breathing and intolerance of nasal cannula delivery of oxygen, if required. Nasopharyngeal obstruction may make the pregnant individual poorly tolerant of the introduction of nasogastric tubes, nasal airways, or nasotracheal tubes. Small endotracheal tubes, such as 6.0 mm or less, may be advised for nasotracheal intubations.

The anatomic changes that occur in the lower airways during pregnancy have not been characterized, but some of the mucosal changes that affect the upper airways may also occur in the central portion of the airway, such as the larynx and trachea. Nonspecific complaints of airway irritation, such as irritant cough or sputum production, may be intensified during pregnancy, often in association with functional changes in airway reactivity and/or coexistent pulmonary conditions. Other more tangible symptoms and signs of lower-airway

irritation, such as hemoptysis and wheezing, should not be considered the result of normal anatomic changes associated with pregnancy, and other etiologies for these findings should be sought.

The physiological causes of nasal mucosal changes appear to be predominantly mediated by estrogens. Estrogens increase tissue hydration and edema. They also cause capillary congestion and hyperplastic and hypersecretory mucous glands.

Respiratory Muscles and the Thoracic Cage

The enlarging uterus produces upward displacement of the diaphragm. Although the diaphragm may be elevated up to 4 cm cephalad, diaphragmatic function is not impaired. The anatomic effects of the elevation of the diaphragm are offset by an increase in the anteroposterior and transverse diameters of the thoracic cage. Diminished tone and activity of the abdominal muscles also serve to counterbalance this effect of the gravid uterus. Diaphragmatic excursion during breathing may be greater in pregnancy than during the puerperium, suggesting that breathing may be more diaphragmatic than costal during pregnancy. Progressive relaxation of the ligamentous attachments of the ribs broadens the subcostal angle by approximately 50 percent (from 68 to 103 degrees). Consequently, there is a 5- to 7-cm increase in chest circumference. These parameters, with the exception of the subcostal angle, return to pre-pregnancy values after delivery.

The shortening and widening of the thoracic cavity results in upward and lateral displacement of the cardiac apex on chest radiography. Except for the appearance of smaller lung volumes and/or positional effects, such as lordotic or rotational views, no other radiographic change should be attributed to the anatomic changes of normal pregnancy.

PHYSIOLOGICAL CHANGES OF NORMAL PREGNANCY

Profound physiological changes coincide with and may be the result of the anatomic changes needed for fetal growth and childbirth. Both respiratory and cardiovascular changes ensure the delivery of necessary oxygenated blood and other nutrients required for this process.

Respiratory Physiology

The anatomic changes induced by the enlarging uterus cause serial changes in lung volumes (Fig. 17-1). During pregnancy, the expiratory reserve volume decreases by 8 to 40 percent and the residual volume by 7 to 22 percent. As a result, there is a 10 to 25 percent decrease in functional residual capacity after the fifth or sixth month of pregnancy. This decline in functional residual capacity (FRC) is more pronounced in the supine position. Due to the counterbalancing effects of widening of the lower rib cage, attenuation of the abdominal musculature, and unimpaired diaphragmatic movement, inspiratory capacity increases. Vital capacity and total lung capacity are not substantially changed in normal healthy gravidas, although total lung capacity does minimally decrease in the third trimester. Residual volume to total lung capacity ratio is low in the third trimester.

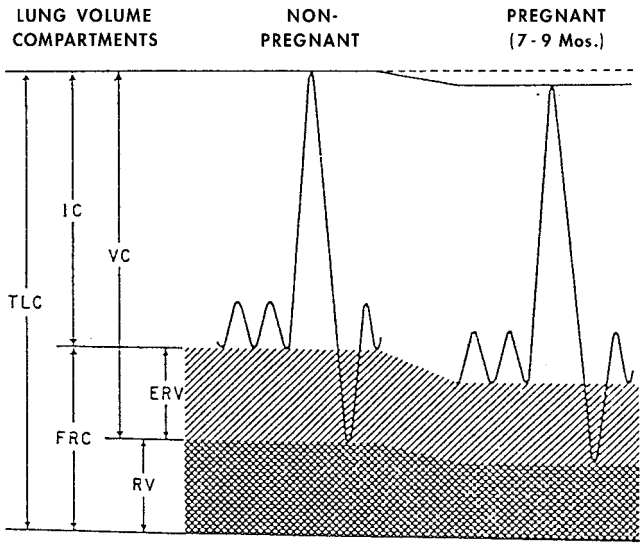

Figure 17-1 Lung volume changes associated with pregnancy. Although total lung capacity, residual volume, and expiratory reserve volume diminish, vital capacity is preserved in values similar to nonpregnant women. TLC = total lung capacity, IC = inspiratory capacity, FRC = functional residual capacity, VC = vital capacity, RV = residual volume, ERV = expiratory reserve volume. *(From Cugell DW, Frank NR, Gaensler EA, et al: Pulmonary function in pregnancy: I. Serial observations in normal women. Am Rev Tubercul Pulmon Dis 67:568, 1953.)*

In late pregnancy, airway closure may occur at a lung volume close to or greater than functional residual capacity. This phenomenon is more significant in the supine position. Increased gastric and esophageal pressure occurring in late pregnancy has been considered major factors that produce a decrease in transpulmonary pressure leading to peripheral airway collapse. An increase in lung water, resulting in a change in the elastic properties of the lungs and in the tethering small airways, may also play a role.

Tidal volume increases considerably, i.e. 30 to 35%, as a result of increased ventilatory drive. The increase in tidal volume is the predominant mechanism for the increase in minute ventilation during pregnancy, since respiratory rate either does not change appreciably or increases slightly, especially after the middle of the second trimester (Fig. 17-2*A*). Accordingly, the occurrence of tachypnea during pregnancy is an important abnormal finding that must be investigated. Maximum voluntary ventilation does not change greatly during pregnancy.

Values of FEV_1 throughout pregnancy are not significantly different from the nonpregnant condition. Nevertheless, it is not clear how pregnancy affects lower airway function. In theory, changes in maternal prostaglandin and cyclic nucleotide concentrations may affect bronchomotor tone,

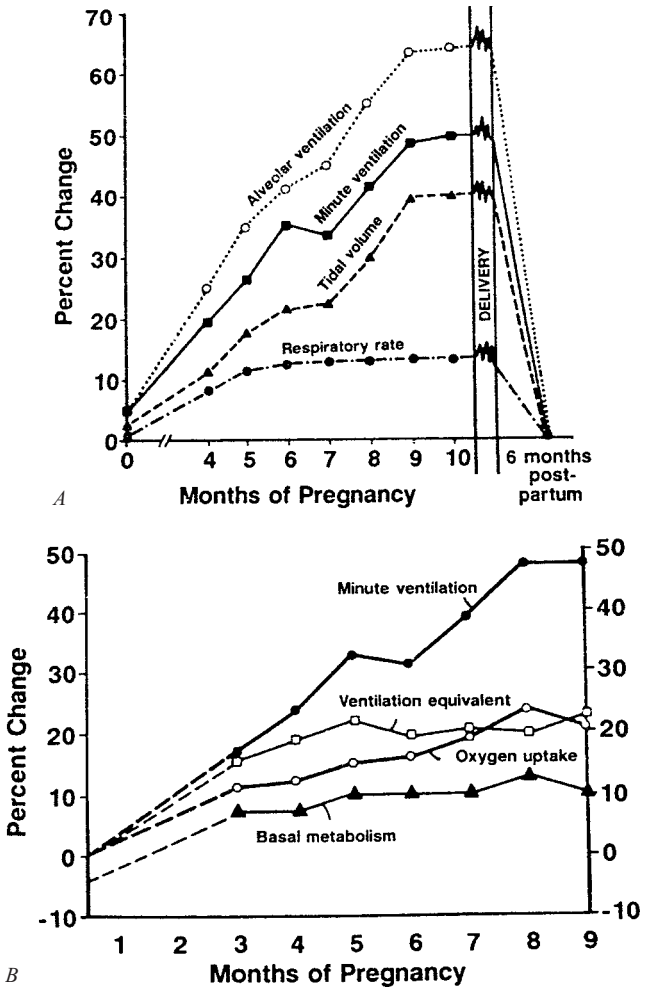

Figure 17-2 Ventilatory changes during pregnancy. *A.* The increase in minute ventilation is produced primarily by augmentation of tidal volume. This produces the significant increase in alveolar ventilation of approximately 70 percent noted at term. *(From Bonica JJ: Principles and Practice of Obstetric Analgesia and Anesthesia. Phfl adelphia, FA Davis, 1967; Cugell DW, Frank NR, Gaensler EA, et al: Pulmonary function in pregnancy: I. Serial observations in normal women. Am Rev Tubercul Pulmon Dis 67:568, 1953.) B.* Minute ventilation increases out of proportion to the increase in oxygen consumption, basal metabolism, and ventilatory equivalent. This demonstrates the physiological hyperventilation associated with pregnancy. *(From Prowse CM, Gaensler EA: Respiratory and acid-base changes during pregnancy. Anesthesiology 26:381, 1965.)*

but their effects are unclear. Progressive increases of airway conductance have been reported to occur between 6 months of pregnancy and term along with a decrease in airway resistance. However, other reports have failed to document significant changes in the function of the lower airways during pregnancy. Total pulmonary resistance, consisting of both airway and tissue resistance, is reduced by approximately 50 percent in pregnancy, most of the decrease attributable to a reduction in airways resistance. Lung compliance does not change significantly during pregnancy. Compliance of the thoracic cage decreases, as the anatomic changes in chest wall and the decrease in tone and activity of the abdominal musculature counterbalance the uterine enlargement.

In early pregnancy, the diffusing capacity is either unchanged or slightly increased. Throughout the rest of pregnancy, the diffusing capacity decreases, returning to normal or slightly lower than normal values. The relative contributions of the specific factors that affect diffusion, such as membrane diffusing capacity and pulmonary capillary blood volume, are not known.

Minute ventilation increases 20 to 50 percent before the end of the first trimester (Fig. 17-2*B*). This increase in may be explained by an increase in respiratory drive, presumably due to the effect of increased serum progesterone acting either as a direct respiratory stimulant or by increasing chemosensitivity of the respiratory center to P_{CO_2}, and an increase in the production of carbon dioxide. Carbon dioxide production and oxygen consumption increase as a result of the increase in basal metabolic rate, coupled with growth in the mass of fetal and maternal tissue and a small increase in cardiac and respiratory work. Since the increase in minute ventilation is approximately two times greater than the increase in oxygen consumption, without significant change in respiratory exchange ratio, the increased respiratory drive of pregnancy results in alveolar hyperventilation. The alveolar hyperventilation induced by altitude has been reported to be greater in pregnant women than in nongravid control subjects, again suggesting a predominant increase in respiratory drive.

Progesterone levels increase gradually during pregnancy from 25 ng/ml at 6 weeks to 150 ng/ml at 37 weeks. In normal non-pregnant women this hormone increases both the resting minute ventilation and the slope of the ventilatory response curve to changes in alveolar P_{CO_2}. Mouth occlusion pressures increase progressively during pregnancy in keeping with increasing progesterone levels. Estrogen may have an additional effect by causing an increased responsivity of the respiratory center.

The increase in minute ventilation which outpaces increases in carbon dioxide production results in a respiratory alkalosis with compensatory renal excretion of bicarbonate. As a rule, arterial P_{CO_2} falls to levels of 28 to 32 mmHg. Arterial pH is maintained in the range of 7.40 to 7.45, and plasma bicarbonate decreases to 18 to 21 mEq/L. In contrast, the acute hyperventilation during active labor and delivery superimposed on the chronic hyperventilation is not easily compensated and may produce dangerous elevations of pH, to values such as 7.6 or greater. Blunting of the increase in ventilatory drive evoked by pain and/or anxiety control can minimize this abnormality. The increase in ventilatory drive and the decrease in functional residual capacity accelerate induction and recovery from inhalational anesthesia.

Values for arterial P_{O_2} are generally greater than 100 mmHg during pregnancy. In the upright position, values for the alveolar-arterial oxygen gradient, physiological shunt, and VD/VT ratios remain similar to nonpregnant values. With the supine position, the alveolar-arterial oxygen gradient may widen, and mild arterial hypoxemia may develop, due to decrease in functional residual capacity and to increase

in closure of small airways. The decrease in functional residual capacity, the increase in closing volumes, and the increase in oxygen consumption lead to a more precipitous decline in arterial P_{O_2} in pregnant patients who are apneic or hypoventilating. Arterial P_{O_2} has been reported to decrease to 50 to 60 mmHg after 30 s of apnea during endotracheal intubation.

Exercise poses physiological challenges to the pregnant patient that may adversely affect the fetus. The oxygen reserve, which is diminished by the reduction in the functional residual capacity and the increase in oxygen consumption, may be further depleted during exercise. While some have shown that the minute ventilation is increased during exercise in pregnancy compared with nonpregnant control subjects, a recent study utilizing analysis of breath by breath gas exchange during graded exercise showed no difference in minute ventilation or maximal oxygen uptake between late gestation pregnant women and matched nonpregnant controls. Absolute oxygen consumption during exercise is primarily affected by the increase in body mass and weight that occurs with pregnancy rather than to a change in basal aerobic metabolism. During pregnancy, there is neither a significant change in the absolute oxygen cost of non–weight-bearing (e.g., cycling) exercise nor in the oxygen cost per kilogram during weight-bearing exercise.

Respiratory responses during parturition are greatly affected by stage of labor and the response to pain and anxiety. During labor, tidal volumes ranging from 350 to 2250 ml and minute ventilations from 7 to 90 L/min have been recorded. The higher values were close to the maximum voluntary ventilation and were associated with the second stage of labor, whereas the lower values were obtained in the first stage of labor while the patient was sedated. Mean alveolar P_{CO_2} measured during the contractions of uncomplicated labor in patients medicated with meperidine, nitrous oxide, and oxygen is about 32 mmHg during early labor, 24 mmHg at the end of the first stage, and 26 mmHg during the second stage. These data support the observation that the physiological hyperventilation of pregnancy that occurs during labor and delivery is independent of appreciable pain. Along with the alveolar hyperventilation, oxygen consumption during labor doubles and can even triple (e.g., to 750 ml/min) during uterine contractions. The possibility of relative hypoventilation between contractions coupled with the grave implications of fetal hypoxemia makes it reasonable to be liberal in the use of oxygen in order to keep maternal oxygen saturation at 95 percent or greater.

Sleep Disturbances

Several alterations in maternal physiology can affect breathing in pregnant women during sleep. Sleep quality is often poor. Sleep disruption can be due to leg cramps, low back pain, urinary frequency, or responsibilities relating to child care. Total sleep time and daytime sleepiness increase during the first trimester, whereas sleep time decreases and complaints of an increase in the number of nocturnal arousals increase in the third trimester. Polysomnographic studies have shown an increase in sleep latency, an increase in the amount of stage I sleep and a decrease in rapid eye movement (REM) sleep and delta sleep, as well as an increase in the number of awakenings. Although several restrictive lung factors similar to those associated with obesity are present in pregnancy, arterial oxygen saturation remains normal in pregnant women during sleep. Most sleep difficulties during pregnancy appear to relate to maintaining, rather than to initiating, sleep. The incidence of sleep-disordered breathing during pregnancy is unknown. After childbirth, most parameters of sleep quality and architecture return to pre-pregnancy values, with the possible exception of the quantity of REM sleep.

Cardiovascular Physiology

Profound changes in cardiovascular physiology occur during pregnancy (Table 17-1). Beginning around the fifth week of pregnancy and continuing into the postpartum period, cardiac output increases and peaks near term at 30 to 50 percent above normal. Multiple gestations are accompanied by greater change in cardiac output. The principal mechanisms of this change in cardiac output are increases in heart rate (maximum of 10 to 30 percent above prepartum values by week 12) and stroke volume, and a decrease (20 to 30 percent) in pulmonary and peripheral vascular resistances. Early in pregnancy the change is independent of changes in basal metabolic rate. Cardiac output is increased further by 10 to 15 percent (1 to 2 L per minute) to meet the challenges of labor and delivery. This response is principally a result of an increase in endogenous catecholamines and an increase in venous return of up to 300 to 500 ml of blood that occurs during uterine contractions. Immediately after delivery, cardiac output increases further to levels as high as 40 to 50 percent greater than values during labor, probably due to an increase in venous return and autotransfusion resulting from the contracted uterus and release of the aortocaval compression (see below) caused by the enlarged uterus. Although cardiac output remains high for the first few days after delivery, cardiac output returns to prepregnancy values over the ensuing 2 weeks.

Maternal blood volume increases progressively throughout pregnancy, beginning as early as 4 to 6 weeks of gestation and plateauing at approximately 32 to 34 weeks of gestation (Fig. 17-3). Total blood volume increases up to 35 to 50 percent above baseline (approximately 1.6 L), peaking by the third trimester. The magnitude of the increase is greater in multiparous pregnancies or multigravida mothers. The increase in blood volume provides some protection against peripartum blood loss, which averages approximately 0.6 L following uncomplicated vaginal delivery and 1.0 L following cesarean section. Plasma volume increases to a greater degree than red blood cell mass, which increases less, and more gradually, to an average increase of about 25 percent. These changes result in a decrease of hemoglobin concentration and hematocrit, producing the "physiological anemia of pregnancy." The increase in blood volume is probably determined by multiple, primarily endocrine factors, such as

Table 17-1

Central Hemodynamic Changes of Normal Pregnancy

Parameter	Nonpregnant	Pregnant*	Significance
Cardiac output, L/min	4.3 ± 0.9	6.2 ± 1.0.	$p < 0.05$
Heart rate, beats/min	71 ± 10.0	83.0 ± 10.0	$p < 0.05$
Systemic vascular resistance, (dyne/cm/s^{-5})	1,530 ± 520	1,210 ± 266	$p < 0.05$
Pulmonary vascular resistance, (dyne/cm/s^{-5})	119 ± 47.0	78 ± 22	$p < 0.05$
Colloid oncotic pressure	20.8 ± 1.0	18.0 ± 1.5	$p < 0.05$
Colloid oncotic pressure – pulmonary capillary wedge pressure (mmHg)	14.5 ± 2.5	10.5 ± 2.7	NS
Mean arterial pressure (mmHg)	86.4 ± 7.5	90.3 ± 5.8	NS
Pulmonary capillary wedge pressure, mmHg	6.3 ± 2.1	7.5 ± 1.8	NS
Central venous pressure, mmHg	3.7 ± 2.6	3.6 ± 2.5	NS
Left ventricular stroke work index, g/m/m^{-2}	41 ± 8	48 ± 6	NS

** 36–38 weeks' gestation.*

estrogen stimulation of aldosterone, non-renal renin, and atrial natriuretic factor. Chorionic somatomammotropin (a growth-hormone–like substance produced by the placenta), progesterone, and possibly prolactin probably stimulate the increase in red blood cell mass. Extracellular water increases by 1 to 2 L, which, in addition to inferior vena caval compression by the enlarging uterus and fetus, results in the peripheral edema that occurs in 50 to 80 percent of normal pregnancies.

Cardiac structure changes progressively during pregnancy. Left ventricular wall thickness increases by 28 percent, and left ventricular mass by 52 percent above baseline, resulting in a decrease in left ventricular compliance. Nevertheless, left atrial and left ventricular diastolic dimensions increase due to significant increases in filling volumes. Central venous pressure, pulmonary capillary wedge pressure, and left ventricular stroke work do not change significantly when compared with prepregnancy values. Although left ventricular end-diastolic and left atrial dimensions return to normal during the 2 weeks after delivery, left ventricular wall thickness does not return to normal for approximately 24 weeks.

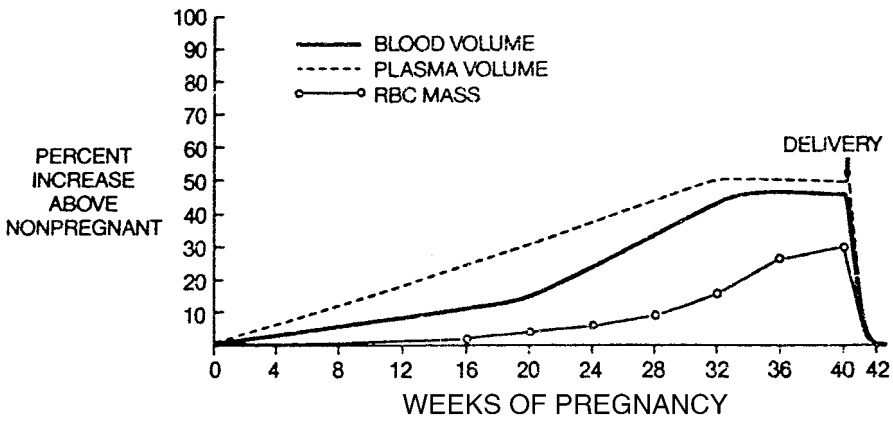

Figure 17-3 Blood volume changes during pregnancy. Plasma volume more significantly increases than red blood cell mass, especially during the first two terms. This produces the relative anemia and the hypervolemia state of pregnancy. *(From Scott AE: Anemia in pregnancy. Obstet Gynecol 1:219, 1972.)*

The changes in cardiovascular physiology during pregnancy affect maternal tolerance to preexistent cardiac disease in different ways. Thus, the increased blood volume and decreased afterload of pregnancy may cause overt heart failure in patients with stenotic lesions of heart valves or worsen right-to-left shunts in uncorrected congenital heart defects. In contrast, pregnant women with regurgitant valvular heart disease often tolerate pregnancy well.

Systemic blood pressure, especially the diastolic component, is slightly lower during pregnancy. Diastolic blood pressure reaches its nadir in the middle of the third trimester, falling by 10 to 20 percent of prepregnancy values. Subsequently, blood pressure increases to near prepregnancy levels. The mechanism for this reduction in blood pressure appears to be hormonally mediated decreases in systemic vascular resistance. Although the resultant blood pressures in the third trimester appear to be distinctly hypotensive when compared with nonpregnant patients, prenatal blood pressure records should be reviewed to ascertain the extent and the significance of the blood pressure changes associated with pregnancy, especially in patients in the second trimester. Pregnant women are susceptible to profound postural hypotension. Approximately 10 to 30 percent of women in the third trimester exhibit postural systolic hypotension. The enlarging uterus may compress surrounding vascular structures, particularly the inferior vena cava and distal aorta. The principal physiological consequence of this compression is a decrease in venous return leading to a decrease in stroke volume and cardiac output. Reflex vasovagal effects may also occur. The normal maternal compensatory response is tachycardia with vasoconstriction in the lower extremities. Care must be taken during spinal or epidural anesthesia, which causes sympathetic blockade that can prevent this normal compensatory phenomenon. Hypotension from aortocaval compression can be minimized by restoration of intravascular volume and displacement of the uterus, which is achieved by right or left lateral tilt of the pelvis.

Reductions in maternal cardiac output may have profound fetal implications. Uterine blood flow is estimated to be 10 percent of maternal cardiac output, approximately 500 ml/min. Reductions in maternal cardiac output occurring during positional changes or due to underlying heart disease may significantly impair uterine blood flow, leading to fetal distress and potential fetal loss. The low resistance nature of the uteroplacental unit makes this region highly dependent on global flow rates, and compensation by increasing vasodilation is poor when flow is impaired.

The umbilical vein supplies fetal blood, which has a P_{O_2} of 26 to 32 mmHg, an oxyhemoglobin saturation of 80 to 90 percent, a P_{CO_2} of 38 to 42 mmHg, and a pH of 7.30 to 7.35. Several factors determine the rate of transfer of oxygen across the placenta: the higher affinity of fetal hemoglobin than adult hemoglobin for oxygen, the diffusion characteristics of the placenta, and umbilical blood flow. Transfer of gas across the placenta is more limited by blood flow than diffusion. Consequently, clinical conditions that diminish maternal cardiac output and/or regional uterine blood flow, such as shock, vasoconstricting agents (epinephrine, norepinephrine, phenylephrine, or high-dose dopamine), and severe respiratory alkalosis, could have serious detrimental effects on the fetus. Likewise, any decrease in the oxygen content of maternal blood resulting from profound hypoxemia, anemia, or alterations in oxyhemoglobin saturation (carbon monoxide, severe alkalosis) could also compromise fetal health.

Dyspnea of Pregnancy

Sixty to 70 percent of normal healthy pregnant women complain of dyspnea during pregnancy even though they have no prior history of cardiopulmonary disease. These complaints commonly occur during the first and second trimester and remain stable or improve near term, suggesting that the etiology is not the mechanical burden of the enlarging uterus. Pulmonary function tests do not appear to correlate with symptomatology in this group, although one study suggested a reduction in diffusing capacity as a factor in dyspneic pregnant women. While some investigators have related the dyspnea of pregnancy to a combination of increased ventilatory drive and increased mechanical load, others have not substantiated these findings and attribute the increased dyspnea to excessive chemoreceptor sensitivity to carbon dioxide or hypoxemia.

ACUTE RESPIRATORY DISTRESS IN PREGNANCY

While preexistent cardiac and pulmonary disorders may be aggravated by pregnancy, several conditions that develop during or are specific for pregnancy need to be considered in evaluating acute respiratory distress during pregnancy. Many of these conditions, with the exception of pulmonary thromboembolic disease, pneumonia, or delivery-related pneumothorax, are attributable to the development of pulmonary edema (Table 17-2). Critical to the clinical evaluation of acute respiratory distress in pregnancy is the careful search for preexistent heart and/or lung disease, a detailed history to characterize precipitating and associated events (e.g., tocolytic therapy, aspiration, obstetrical complications), knowledge of infectious complications commonly encountered in pregnancy, and the meticulous examination of the patient and chest radiograph for findings consistent with cardiogenic failure. As a rule, causes of respiratory distress due to conditions specific to pregnancy (e.g., amniotic fluid embolism, or pulmonary edema secondary to preeclampsia or tocolytic therapy) pose little problem in clinical diagnosis. However, more complicated presentations often require invasive hemodynamic monitoring to differentiate between cardiogenic and noncardiogenic pulmonary edema. Pulmonary thromboembolism should always be strongly considered in the

Table 17-2

Differential Diagnosis of Acute Respiratory Distress in Pregnancy

Disorder	Distinguishing Features	Chest Radiograph
Venous thromboembolism	Evidence of DVT, pleuritic chest pain, positive $\dot{V}/Q$ scan, helical CT, leg dopplers, angiogram	Normal/atelectasis/effusion
Amniotic fluid embolism	Hemodynamic collapse, seizures, DIC	Normal/pulmonary edema
Pulmonary edema secondary to preeclampsia	Hypertension, proteinuria	Pulmonary edema
Tocolytic pulmonary edema	Tocolytic administration, rapid improvement	Pulmonary edema
Aspiration pneumonitis	Vomiting, reflux, fever	Focal infiltrate/pulmonary edema
Peripartum cardiomyopathy	Gradual onset, cardiac gallop	Cardiomegaly, pulmonary edema
Pneumomediastinum	Occurs during delivery, subcutaneous emphysema	Pneumomediastinum, subcutaneous air
Air embolism	Profound hypotension, cardiac murmur	Normal/pulmonary edema
Other: asthma, pneumonia, cardiac disease, ARDS	As for nonpregnant patient	As for nonpregnant patient

DVT = Deep venous thrombosis; $\dot{V}/Q$ = ventilation-perfusion; DIC = disseminated intravascular coagulopathy; ARDS = adult respiratory distress syndrome.

absence of other explanatory conditions or as a complicating process.

RESPIRATORY DISEASES IN PREGNANCY

Asthma

Approximately 4 to 8 percent of pregnant women in the United States are asthmatic and the prevalence appears to be increasing. A recent large multicenter prospective observational study failed to show an association between asthma and preterm delivery or adverse perinatal outcomes, except for a discharge diagnosis of neonatal sepsis and an increased maternal cesarean section rate in women with moderate or severe asthma. Asthma exacerbation and hospitalization rates increased with the severity of disease. Pharmacologic management of pregnant asthmatics is quite similar to management of nonpregnant asthmatics with a stepwise approach utilizing inhaled short acting beta$_2$-agonists, inhaled corticosteroids, inhaled long acting beta$_2$-agonists, and systemic corticosteroids. Although there is little published human data, animal data suggest that leukotriene receptor antagonists are safe in pregnancy. Theophylline at recommended doses is safe in pregnancy; however, its use is associated with increased side effects. Contrary to some early reports, inhaled corticosteroids are not associated with increased risks of pregnancy-induced hypertension or preeclampsia. Oral corticosteroid use in the first trimester is associated with a small increased risk of isolated cleft lip with or without cleft palate (0.1 to 0.3 percent), and may be associated with increased risks of pregnancy-induced hypertension, preeclampsia, preterm delivery, and low birth weight. However, it is difficult to separate out the effects of the medication from the effects of severe or uncontrolled asthma. The risks of poorly controlled asthma to the mother and fetus are greater than those posed by most medications (including oral corticosteroids) used to treat asthma, so all medications should be used as indicated to maintain optimal asthma control during pregnancy.

Venous Thromboembolism

The risk of venous thrombosis during pregnancy ranges from 0.5 to 3.0 per 1000 pregnancies in those without a history of thromboembolism. Prior thromboembolic disease, smoking, prior venous thrombosis, and thrombophilias are risk factors for deep venous thrombosis or pulmonary embolism (PE) during pregnancy. The risk of venous thromboembolism

is greatest in the postpartum period. Heparin prophylaxis for women with increased risk of thromboembolism during pregnancy and in the immediate postpartum period remains controversial.

Evaluation of the pregnant woman with suspected venous thromboembolism should begin with lower extremity venous ultrasound. If negative, a ventilation-perfusion (V-P) scan or helical computed tomography (CT) scan should be performed next. While helical CT is more sensitive for the diagnosis of PE, and the average fetal radiation dose appears to be less with helical CT when compared with V-P scanning, helical CT delivers about a 40 times greater radiation dose to the breast at a time when it is proliferating. Therefore the appropriate test needs to be carefully considered in each woman. Confirmed cases of venous thromboembolism during pregnancy should be managed with unfractionated or low molecular weight heparins. Coumarin should be avoided due to the risk of embryopathy.

Pulmonary Hypertension

The cardiovascular and hemodynamic changes associated with pregnancy, anesthesia, and delivery pose a severe risk to women with primary pulmonary hypertension, Eisenmenger's syndrome, and secondary pulmonary hypertension. Studies have documented maternal mortalities in these groups from 30 to 56 percent, although most of these studies evaluated patients who did not receive current vasodilator therapy. Recent case reports have documented successful use of intravenous or inhaled epoprostenol, and sildenafil in pregnant women with pulmonary hypertension; however, their long-term effect on overall pregnancy related mortality is unknown.

Sleep-Disordered Breathing

Hormonal changes of increased estrogen resulting in hyperemia and upper airway narrowing, and increased progesterone resulting in increased respiratory drive, along with other physiologic changes of sleep (decreased FRC and respiratory system compliance) predispose to alterations in sleep during pregnancy. While snoring is increased in pregnancy, and sleep-disordered breathing may worsen during pregnancy, the incidence and prevalence of sleep-disordered breathing during pregnancy are unknown. Symptoms of sleep-disordered breathing should be reviewed with women who develop pregnancy-induced hypertension or preeclampsia, and all pregnant women with symptoms of sleep-disordered breathing should be evaluated with a polysomnogram and treated with nasal continuous positive airway pressure as indicated.

Cystic Fibrosis

As survival of individuals with cystic fibrosis continues to improve, fertility and pregnancy have become important issues for many women with the condition. Maternal and fetal outcomes are satisfactory for women with good lung function and nutritional status. Pregnancy appears to have no deleterious effect on long-term survival in women with cystic fibrosis.

Aging of the Respiratory System

Edward J. Campbell

Even in individuals who enjoy apparently good health, there are measurable decrements in function of the respiratory system with age. These changes occur progressively as a healthy individual grows older and are most marked beyond 60 years of age. Cross-sectional studies show clear differences between elderly and young persons with regard to the structure and function of the components of the respiratory system (Table 18-1). However, caution must be exercised in ascribing observed changes to age alone, since the lungs are exposed to a lifetime of environmental stresses, including tobacco smoke, respiratory infections, air pollutants, and occupational exposures to dusts and fumes. Increasingly sedentary life-styles and decreasing fitness with age have marked effects, especially upon cardiovascular function. Longitudinal studies of "healthy" individuals followed to old age are essentially not available. Despite these caveats, age-related changes in the respiratory system clearly exist, although the magnitude of the changes attributable to aging alone may be somewhat uncertain. Where appropriate, methodological problems in the available cross-sectional studies are described.

Although age-associated changes can be measured easily by objective testing, it is important to note that the routine activities of healthy elderly persons are not limited by decreasing respiratory system function. However, whereas youthful persons have a marked excess of functional capacity over the amount required to meet metabolic needs at rest or with stress (physiological reserve), the respiratory system draws on this reserve as its function declines with age. Thus, the physiological reserve, especially for alveolar gas exchange, is reduced with aging. This leaves elderly individuals vulnerable to stresses, diseases, and injuries that are weathered much more easily in the young.

STRUCTURAL CHANGES IN THE LUNG

Studies of the aging lung have shown changes in shape, with increases in anteroposterior diameter that lead to a "rounding" of the shape of the lung. These changes are presumably

This chapter has been slightly modified from the version that appeared in the third edition of *Fishman's Pulmonary Diseases and Disorders.*

Table 18-1

Respiratory System: Functional Divisions and Changes with Aging

Functional Division	Components	Function	Change(s) with Aging
Conducting airways	All airways not involved in gas exchange (mouth to terminal bronchioles)	Gas movement between environment and alveolar space	Slight changes in size; calcification; glandular hypertrophy
Lung parenchyma	Gas-exchanging airways and vessels; connective tissue framework	Gas exchange between alveolar space and capillary blood	Enlarged terminal airspaces; ventilation/perfusion mismatching
Bellows apparatus	Chest wall and muscles of respiration	Provide mechanical forces for ventilation	Increased rigidity of chest wall; decreased respiratory muscle strength
Ventilatory control	Respiratory control center (pons and medulla); carotid and aortic bodies	Maintaining homeostasis by altering ventilation to match metabolic needs	Markedly decreased responses to hypercapnia and hypoxemia
Cardiovascular system	Heart and systemic vasculature	Blood transport and tissue exchange of respiratory gases	Decreased maximal heart rate and cardiac output; decreased responsiveness to hypoxemia

secondary to changes in the shape of the surrounding thoracic cage and are not thought to have functional consequences.

Conducting Airways

The conducting airways consist of the air passages from the mouth to the level of the respiratory bronchioles. Their volume comprises the anatomic dead space, and their geometry is a primary determinant of airway resistance. The larger cartilaginous airways show a modest increase in size with age, resulting in slight but probably functionally insignificant increases in anatomic dead space. Although calcification of cartilage in the walls of the central airways and hypertrophy of bronchial mucous glands is seen in advanced age, these and other changes in the extraparenchymal conducting airways appear to have little or no physiological significance.

Lung Parenchyma

After age 30 or 40, the respiratory bronchioles and alveolar ducts undergo progressive enlargement (Fig. 18-1). This change has been termed "ductectasia" because of the prominent finding of enlargement of alveolar ducts. The proportion of the lung made up of alveolar ducts increases, and alveolar septa become shortened, leading to a "flattened" appearance of the alveoli. With the change in geometry, the distance between alveolar walls (known to morphologists as the mean linear intercept, or MLI) increases, while the surface-to-volume ratio of the lung decreases. The age-related enlargement of the terminal respiratory units also produces a decrease in the percentage of parenchymal air contained within alveoli. The net result of these structural changes is that the alveolar surface area decreases by approximately 15 percent by age 70.

Pulmonary emphysema is also characterized by an increase in the size of terminal airspaces, an increase in MLI, and a decrease in surface area; however, destruction of alveolar septa with fusion of terminal airspaces is a defining characteristic of emphysema. There have been some reports of emphysematous lesions in aged lungs, but it is not certain that smokers were excluded from these studies. Since the fate of individual alveolar septa during the aging process has been somewhat controversial, some have referred to the histological changes in aged lungs as "senile emphysema." A National Heart, Lung, and Blood Institute Workshop on the definition of emphysema weighed the available evidence and decided not to include age-related changes in the lung parenchyma under the definition of *emphysema.* To simplify terms and avoid confusion, they recommended use of the term *aging lung* to apply to the uniform airspace enlargement that develops with increasing age.

CHANGES IN MECHANICAL PROPERTIES OF THE LUNGS

The lungs and chest wall are both elastic. The resting volume of excised lungs is smaller than that of the lungs contained

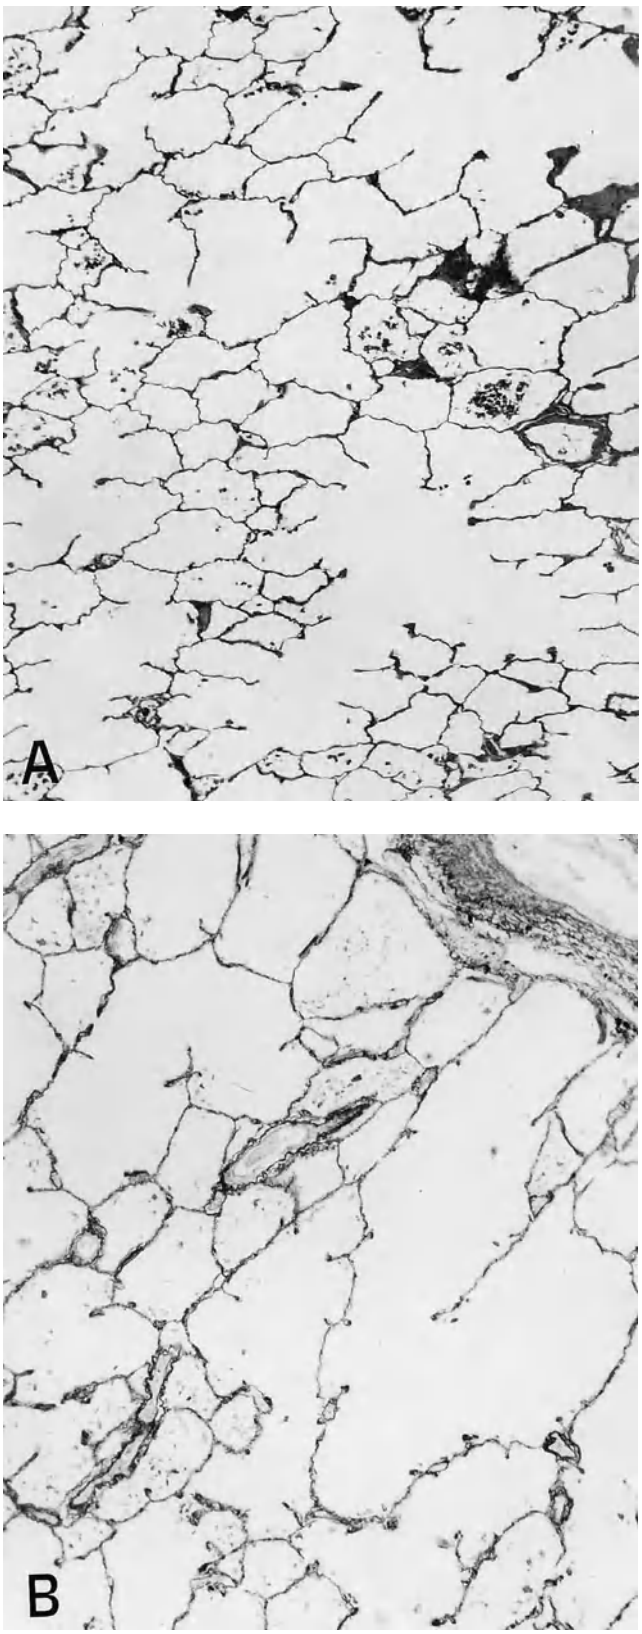

Figure 18-1 Histologic changes in the aging lung. *A*. Normal lung of a 36-year-old woman. *B*. Lung of a 93-year-old woman. In (*B*), the alveolar ducts are dilated, and shortening of interalveolar septa is observed. *(By permission of the Mayo Foundation; photomicrographs courtesy of Charles Kuhn III, M.D.)*

within an intact thoracic cage, because the lungs are held at an increased volume by the outward recoil forces of the chest wall. Thus, in the intact thoracic cage, the lungs exert an inward recoil force. The retractile force of the lungs, or "elastic recoil," can be measured during life by estimating the pleural pressure with an esophageal balloon at progressively decreasing lung volumes from total lung capacity to functional residual capacity, when the airways are open and there is no air flow. The negative pleural pressure is generated by the lungs' elastic recoil forces.

The pressure measurements may be displayed on a pressure-volume diagram (Fig. 18-2). Figure 18-2 compares, at the same volume, the elastic recoil pressures of a young man, a normal elderly adult, and a patient with emphysema. The normal elderly individual and the patient with emphysema both have a greater decrease in elastic recoil pressure than does a young person. This is reflected in the leftward shift of their pressure-volume curves. This loss of elastic recoil is the physiological hallmark of emphysema. However, emphysema is characterized by a much greater loss of elastic recoil than is caused by aging alone.

There has been some disagreement regarding the effects of aging on lung compliance (Δ volume/Δ pressure;

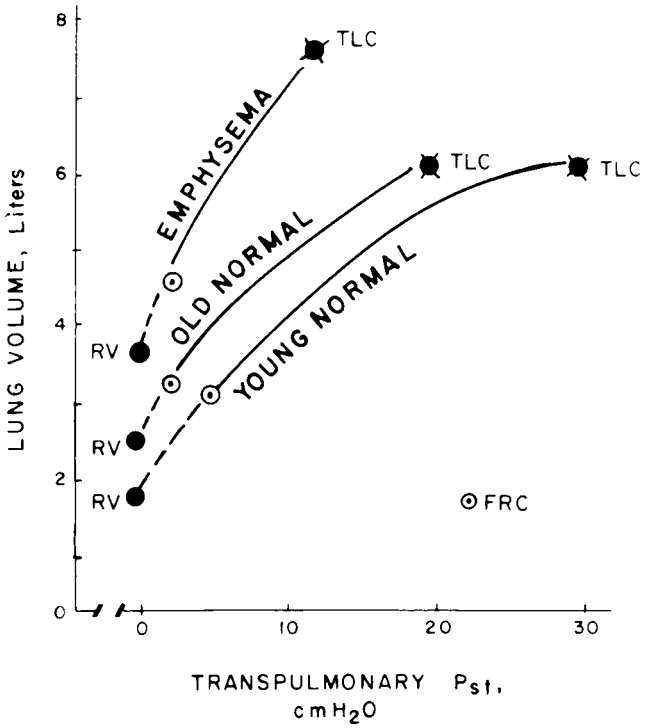

Figure 18-2 Static pressure-volume curves of the lungs. Static recoil pressure, expressed as transpulmonary pressure measured at various lung volumes, is plotted against lung volume on the ordinate. Note that at any lung volume, the recoil pressure is less in the aged individual than in the young, normal control, resulting in a pressure-volume curve that is shifted upward and to the left. For comparison, a curve for a patient with emphysema is shown. In emphysema, recoil pressures are reduced much more, and lung compliance (the slope of the pressure-volume relationship) is clearly abnormal. *(From Pride NB: Bull Eur Physiopathol Respir 10:103–108, 1974, with permission.)*

i.e., the slope of the pressure-volume relationship, Fig. 18-2). The question is whether there is a parallel leftward shift of the pressure-volume curve with aging (no change in compliance), or, instead, a steeper slope in addition to a shift (indicating an increase in compliance), as seen in emphysema. In aged individuals, the static pressure-volume curve is slightly steeper and is more concave in relation to the pressure axis. However, there is general agreement that changes in lung compliance with aging are not physiologically significant.

Two forces in the lung parenchyma are responsible for producing the elastic recoil of the lungs. The greatest part of the elastic recoil forces is provided by the surface tension at the curved air-fluid interface of the small airways and alveoli. The second retractive force is that produced when the fibrous skeleton of the lung (primarily the elastic fibers) is stretched.

Changes in Surface Forces

Most of the loss in lung recoil with age is likely to be related to the decrease in lung surface area with age. The loss of surface area that accompanies aging can be expected to reduce the area of gas-liquid interface, resulting in a decrease in the surface tension forces and, ultimately, a decrease in the total elastic recoil of the lung. Whether it is due to loss of air-liquid interface or to changes in lung structural macromolecules (see below), the reduced elastic recoil has important consequences for the function of the intraparenchymal airways and, ultimately, on alveolar gas exchange and forced expiratory flow (see "Pulmonary Function Tests," below).

Changes in Structural Macromolecules

Elastic fibers, which are composed in large part of an extremely hydrophobic, highly cross-linked, and very elastic macromolecule (elastin), form a continuous skeleton that follows the airways and pulmonary vessels and extends to a fine meshwork in the alveolar septa. These fibers are thought to contribute substantially to lung elasticity. Analysis of whole lungs has revealed that the elastin content actually increases (rather than decreases) with age. More recent evidence indicates that the increase in lung elastin with age is accounted for by an increase in pleural elastin; parenchymal elastin does not change.

Careful studies of the elastic fibers in the lung parenchyma have shown that they are remarkably stable following postnatal lung growth. Certain biochemical changes in very long-lived proteins (change of amino acids into their mirror-image structures, or racemization) provide a type of "biological clock" that permits an estimate of the time that has elapsed since the proteins were synthesized. Because of the constraints of the protein synthetic mechanisms, only L-amino acids are incorporated into newly synthesized proteins. With the passage of years at body temperature; however, there is a readily measurable accumulation of D-aspartic acid. When all of the lung proteins are examined together, minimal D-aspartic acid is found. In purified lung elastin,

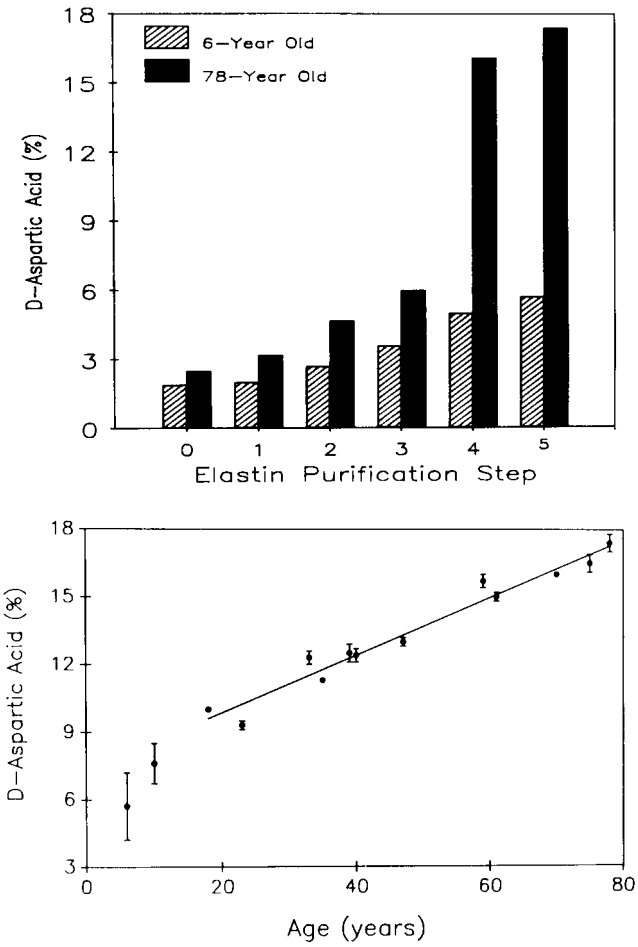

Figure 18-3 Longevity of human lung parenchymal elastin, as evidenced by in vivo racemization of aspartic acid. *Top panel.* Each pair of bars shows results from two individuals with greatly differing ages at time of death. Step 0 of elastin purification represents whole lung parenchyma, while step 5 is purified elastin. D-Aspartic acid detected in the 6-year-old specimen can be attributed to racemization that occurs during the analytical procedures, whereas the difference in prevalence of D-aspartic acid between the young and old individual has resulted from racemization in vivo. Note that results from whole-lung hydrolysates (step 0) are similar for both specimens, reflecting their composition of proteins, having predominantly rapid turnover. However, purified elastin from the oldest specimen has racemized extensively in vivo, indicating that it was synthesized many decades before death. *Bottom panel.* D-Aspartate in elastic fibers is shown as correlated with age at death. The relationship of D-aspartic acid to the age of the subject indicates that parenchymal elastin is markedly persistent after its synthesis. The data for elastin agree well with results for other very long lived proteins. *(From Shapiro SD, Endicott SK, Province MA, et al: Marked longevity of human lung parenchymal elastic fibers deduced from prevalence of D-aspartate and nuclear weapons–related radiocarbon. J Clin Invest 87:1828–1834, 1990, with permission.)*

however, there is an age-related accumulation of D-aspartic acid, indicating that lung elastin is turning over very slowly if at all (Fig. 18-3). It has also been possible to estimate lung elastin turnover by measurement of the incorporation into elastic fibers of carbon 14 (^{14}C) from atmospheric nuclear

weapons testing. For example, individuals who completed their postnatal lung growth prior to the nuclear age show no excess ^{14}C in their lung elastin, indicating absence of new elastin synthesis. In contrast, an appropriate excess of ^{14}C is found in the lung elastin of individuals whose lungs were growing in the post–weapons testing era. Modeling of the radiocarbon data indicates that the "mean carbon residence time" in elastin is 74 years.

Taken together, the amino acid racemization and radiocarbon data indicate that lung parenchymal elastin is stable over the human life span, and it appears that the elastin content of the lung parenchyma not only does not change with age, but the individual fibers persist for at least many decades. The remarkable longevity of lung elastic fibers raises the strong possibility that these connective tissue structures provide a metabolically inert scaffold for the structure of the lung. This may explain the appearance of structural abnormalities in the lung parenchyma (such as pulmonary emphysema) when the elastic fibers are injured.

Other studies of lung elastic fibers have shown changes in the location and orientation of individual fibers with age as well as changes in the cross-linking of elastin. Thus, some authors have suggested that remodeling of the lung architecture may occur without replacement of elastic fibers. In any case, at the present time, the age-related changes in connective tissue do not provide a sufficient explanation for the decrease in elastic recoil forces observed in the elderly.

Studies of lung collagen have failed to show a consistent change in its quantity during aging. Although human studies have not been done, studies in rodents and birds suggest that lung collagen fibers, like elastic fibers, are very long-lived. Finally, although some qualitative changes in collagen during aging have been described (decreases in solubility and increases in intermolecular cross-links), these appear to have no relationship to changes in lung elastic recoil.

Changes in Chest Wall

There is good evidence that the chest wall becomes more rigid with advancing age. As may be seen in Fig. 18-4, the static pressure-volume curve of the chest wall is shifted to the right and is less steep with increasing age. The articulations of the ribs with the sternum and spinal column may become calcified, and the compliance of the rib articulations decreases. The changes in rib articulations may be compounded by the development of kyphosis due to osteoporosis. The decreasing compliance of the chest wall demands greater work from the respiratory muscles. For example, in a 70-year-old person, approximately 70 percent of the total elastic work of breathing is expended on the chest wall, whereas this value is 40 percent in a 20-year-old.

Figure 18-4 also demonstrates that the compliance of the total respiratory system decreases with age because the decrease in lung elastic recoil is outweighed by the changes in the mechanical properties of the chest wall.

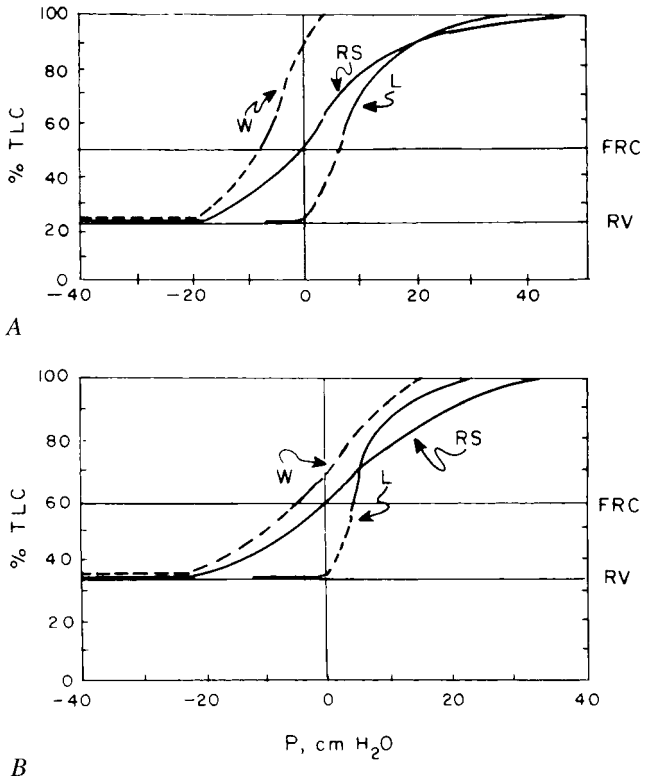

Figure 18-4 Static compliance relationships of the components of the respiratory system. (L = lungs; W = chest wall; RS = total respiratory system.) *A*. A 20-year-old man. *B*. A 60-year-old man. Note that the static compliance of the chest wall is substantially decreased (reduced slope) in the older individual, while functional residual capacity (the resting volume of the respiratory system, or the point at which the pressure gradient across the respiratory system is zero) increases. As in Fig. 18-2, it is also apparent that the static recoil pressure of the lungs is reduced in the older subject. *(Based on data from Mittman C, Edelman NH, Norris AH, et al: Relationship between chest wall and pulmonary compliance and age. J Appl Physiol 20:1211–1216, 1965; Turner JM, Mead J, Wohl ME: Elasticity of human lungs in relation to age. J Appl Physiol 25:664–671, 1968, with permission.)*

CHANGES IN MUSCLES OF RESPIRATION

Age-related changes in nonrespiratory skeletal muscle include decreased work capacity due to alterations in the efficiency of muscle energy metabolism, atrophy of motor units, and electromyographic abnormalities. Based upon lessons learned with other skeletal muscles, it appeared likely that age-related abnormalities in respiratory muscles also would be found.

An early study by Black and Hyatt appeared to confirm age-related decrements in respiratory muscle function by measuring maximal inspiratory pressure (PI_{max}) and maximal expiratory pressures (PE_{max}) in 120 normal individuals (both smokers and nonsmokers) between the ages of 20 and 70. Maximal respiratory pressures in females were 65 to 70 percent of those in males. No significant age-related changes were observed in individuals under the age of 55. Trends toward reduced maximal respiratory pressures with age were

seen in both genders and with both PI_{max} and PE_{max}. With the numbers of males studied, the change with age in PI_{max} was not statistically significant for male gender.

More recently, McElvaney and coworkers came to a different conclusion in a similar study of 104 healthy individuals over the age of 55. They found large variation in maximal respiratory pressures from individual to individual (as had Black and Hyatt), but no significant correlation with age. In contrast, in a third population of 160 healthy individuals who ranged in age from 16 to 75 years, Chen and Kuo found significant gender differences in maximal respiratory pressures as well as trends toward decrements with age for both PI_{max} and PE_{max} in both genders. The age-related change in PE_{max} in males was not statistically significant with the sample size studied. When the 40 individuals of both genders in the youngest age group (16 to 30 years) were compared with the 40 individuals in the oldest group (61 to 75 years), the decrement in PI_{max} was 32 to 36 percent, while the decrement in PE_{max} was 13 to 23 percent. Representative findings for maximal respiratory pressures in women are illustrated in Fig. 18-5.

Chen and Kuo also measured inspiratory muscle endurance against a resistive load, and found significant decrements with age. Physically active men had greater inspiratory muscle endurance than sedentary men.

In summary, it appears that when populations of healthy individuals of widely differing ages are studied, moderate age-related decrements in respiratory muscle strength and endurance can be found. These studies usually define *healthy* only by the absence of disease and do not control for physical activity. They are complicated by marked interindividual variability, and longitudinal studies have not been reported. Continuous respiratory muscle activity may have a training effect that leads to better preservation of respiratory muscle function when compared with other skeletal muscles. Finally, physical activity may have an additional training effect that enhances inspiratory muscle endurance in all age groups.

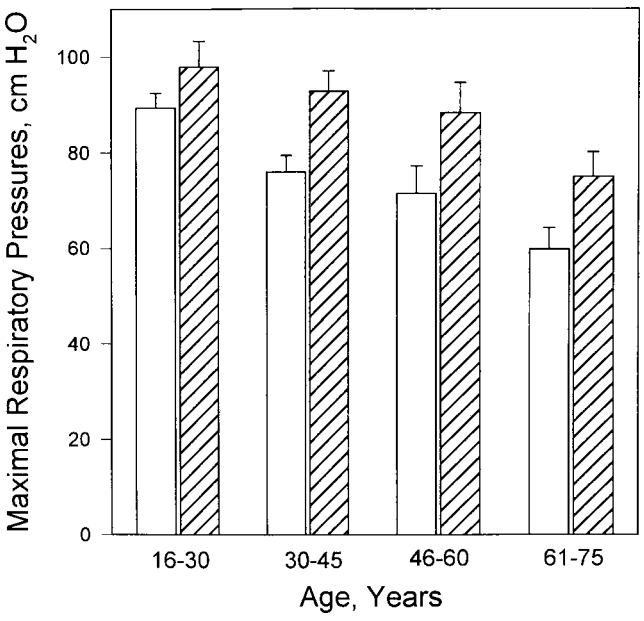

Figure 18-5 Representative variations in maximal respiratory pressures with age among women. Inspiratory and expiratory measurements were made at residual volume and total lung capacity, respectively. Maximal inspiratory pressure (*open bars*) and maximal expiratory pressure (*hatched bars*). Error bars are standard errors of the mean. Although quantitatively moderate, variations with age were statistically significant for both measurements. *(From Chen H-S, Kuo C-S: Relationship between respiratory muscle function and age, sex, and other factors. J Appl Physiol 66:943–948, 1989, with permission.)*

CONTROL OF BREATHING

In young individuals, minute ventilation is matched to metabolic demands. As a result, arterial blood gas values remain stable throughout a wide range of activities from rest to strenuous exertion, while oxygen consumption and carbon dioxide production are varying widely. Similarly, when the efficiency of gas exchange is diminished by lung disease or congestive heart failure, appropriate increases in minute ventilation minimize the resulting hypercapnia and/or hypoxemia in healthy young individuals. The ventilatory control system is described in detail in Chapter 11.

Ventilatory control mechanisms are typically tested by stressing the respiratory system, by inducing either hypoxemia or hypercapnia while monitoring ventilatory parameters (and often cardiac parameters as well). Such tests have shown striking differences between young and elderly individuals in both ventilatory and cardiac responses.

Diminished Ventilatory Response to Hypercapnia

Kronenberg and Drage compared the ventilatory responses to hypercapnia in eight young (mean age, 25.6 years) and eight elderly (mean age, 69.6 years) individuals. During the tests, the subjects were asked to rebreathe 5 percent CO_2 while their $P_{A_{O_2}}$ was held above 200 mmHg by supplemental oxygen to eliminate hypoxic ventilatory drive. Measurements were made while $P_{A_{CO_2}}$ was allowed to rise to 65 mmHg. Although there was considerable individual variation and some overlap between the groups, the elderly individuals had a significantly diminished ventilatory response to hypercapnia, measured as the slope of the relationship between ventilation and $P_{A_{CO_2}}$.

Diminished Ventilatory Response to Hypoxia

When Kronenberg and Drage measured the ventilatory response to hypoxia at constant CO_2, they found even more striking differences between the young and elderly subjects (Fig. 18-6). For example, the ventilatory response to a $P_{A_{O_2}}$ of 40 mmHg was uniformly smaller in the older subjects, and there was no overlap between the groups. The mean minute ventilation at a $P_{A_{O_2}}$ of 40 mmHg was 40.1 and 10.2 L/min in the young and old groups, respectively.

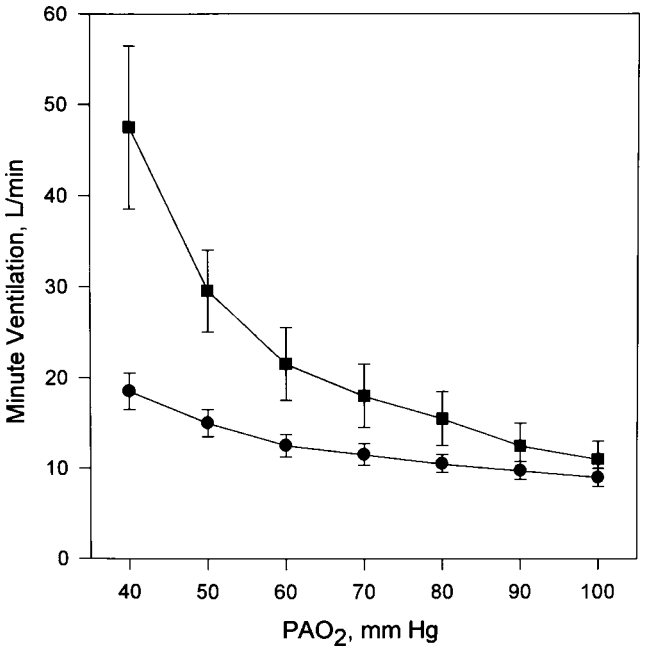

Figure 18-6 Variations with age in ventilatory responses to hypoxia. Eight normal men aged 64 to 73 (squares) and eight controls aged 22 to 30 (circles) were subjected to isocapnic progressive hypoxia by a rebreathing method. Data values are means, with standard errors of the mean shown by the error bars. Note that the ventilatory responses differ strikingly between the elderly individuals and the controls. *(From Kronenberg RS, Drage CW: Attenuation of the ventilatory and heart rate responses to hypoxia and hypercapnia with aging in normal men. J Clin Invest 53:1812–1819, 1973, with permission.)*

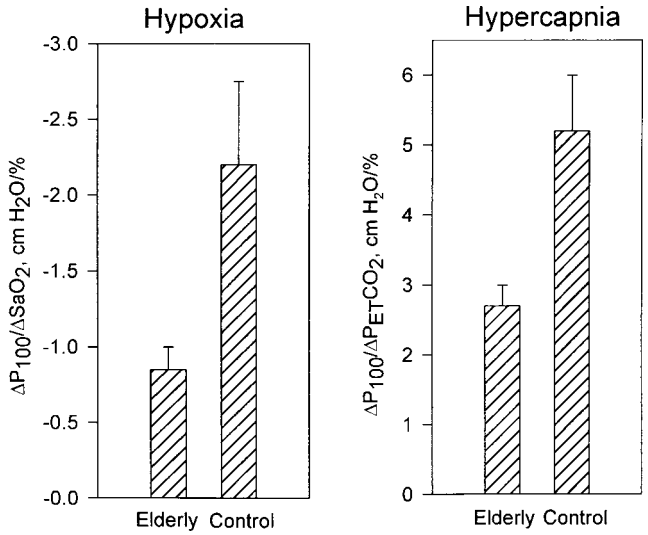

Figure 18-7 Variations with age in occlusion pressure responses to hypoxia and hypercapnia. Data shown are slopes of relationships between occlusion pressure responses and either Sao_2 or end-tidal P_{CO_2}; error bars are standard errors of the mean. Elderly individuals had significantly diminished occlusion pressures in response to both hypoxia and hypercapnia. Both differences were significant, with $p < 0.01$. *(From Peterson DD, Pack AI, Silage DA, et al: Effects of aging on the ventilatory and occlusion pressure responses to hypoxia and hypercapnia. Am Rev Respir Dis 124:387–391, 1981. with permission.)*

Diminished Occlusion Pressure Responses

Peterson and colleagues confirmed the above observations and have shown that the differences in responses of elderly subjects to both hypercapnia and hypoxia are due to a lesser increase in tidal volume while the ventilatory rate increases normally. Since this observation could be caused by differences in respiratory muscle strength or increases in chest wall stiffness, the authors also measured airway occlusion pressures, which are valuable indices of respiratory drive that are not affected by respiratory muscle strength or respiratory mechanics. The measurement (P_{100}) is the negative pressure at the mouth, measured 100 ms after the start of inspiration against an occluded airway. The occlusion pressure responses to both hypoxia and hypercapnia (Fig. 18-7) were significantly reduced in the 10 elderly subjects studied by Peterson (mean age, 73.3 years) when compared to nine young control subjects (mean age, 24.4 years). Although the elderly individuals had reduced respiratory muscle strength (mean, 24 percent lower maximal static inspiratory pressure), the differences in occlusion pressure persisted when normalized for these differences.

In summary, the reduced responsiveness in tidal volume to either hypoxemia or hypercapnia with age is apparently due to a reduced responsiveness of ventilatory drive or neural output from the respiratory center. It has not been determined whether the diminished ventilatory drive results from altered chemoreceptor function or from altered function of the respiratory center. Kronenberg and Drage favor altered receptor function based on their observation that elderly subjects responded to an alveolar oxygen tension of 40 torr with only an 11 percent increase in heart rate, whereas the young subjects responded with a 34 percent increase.

Respiratory Load Compensation and Dyspnea

Reflex compensation for a change in respiratory mechanical load (as in lung disease, changes in posture, and mouth versus nose breathing) normally serves to maintain ventilation constant during the change. Akiyama and colleagues measured responses to inspiratory flow-resistive loading in young and elderly individuals and found significant differences. In the young control group, inspiratory loading resulted in an increase in P_{100} at each level of induced hypercapnia, such that inspiratory loading did not change the ventilatory response to hypercapnia when compared with unloaded responses. In marked contrast, the P_{100} in the elderly group did not change when an inspiratory load was applied. In the absence of a compensatory change in ventilatory drive, ventilatory responses to hypercapnia were reduced during inspiratory loading in the elderly group.

At each level of P_{CO_2}, the intensity of perceived dyspnea in response to inspiratory loading was greater in the elderly than in the control group. Thus, the sensation of dyspnea was intact or enhanced in the elderly subjects, while their

compensatory responses were reduced. This suggests the possibility that elderly individuals may complain of greater dyspnea than younger individuals with similar pathophysiological deterioration.

PULMONARY CIRCULATION

Invasive physiological studies of pulmonary artery catheterization have typically been biased by including only subsets of patients whose signs and symptoms led to referral for heart catheterization and who, therefore, may not be representative of a "healthy" cohort. Further, age-related changes in the pulmonary circulation are difficult or impossible to separate from changes due to heart disease or age-related changes in cardiac function.

Ehrsam and colleagues reported a retrospective analysis of right heart catheterization studies performed in 125 asymptomatic subjects who ranged from 14 to 68 years of age. Small increases in right atrial, pulmonary artery, and pulmonary artery wedge pressures observed in the highest age group disappeared when values were adjusted for sex, weight, and height. No significant age-related changes were found in cardiac output, stroke volume, or oxygen uptake. Age explained 10 percent or less of the total variation in the hemodynamic and pressure variables when assessed by multiple regressions. During supine exercise with a bicycle ergometer, however, pulmonary artery and wedge pressures increased with age, particularly in subjects over age 45. The changes were highly significant, with age accounting for 12 to 30 percent of the total variation when assessed by multiple regressions. Finally, pulmonary artery resistance showed a highly significant increase with age, whether measured at rest or during exercise, with age contributing 12 to 27 percent to the total variation in pulmonary artery resistance. Although the cohort studied were all asymptomatic and ambulatory, it is possible that silent coronary artery disease was present in some of the subjects, and the prevalence of coronary artery disease can be expected to increase with age. Moreover, younger patients tended to be referred for evaluation of a heart murmur, whereas the older patients were referred for "pulmonary investigation" that included coin lesions, hilar lymphadenopathy, "previous pulmonary infiltrates," and smoke inhalation. Cigarette smoking history was not discussed. Thus, it is not certain that the younger and older patients were strictly comparable.

More recently, Davidson and Fee reported the results of right-heart catheterization at rest in 47 normal subjects who were free of coronary disease and had normal left ventricular systolic function. Smokers were included. The investigators found highly significant but quantitatively modest age-related increases in mean pulmonary artery pressure, pulmonary vascular resistance, and pulmonary/systemic vascular resistance ratio, but they found no age-related differences in pulmonary artery wedge pressure. The authors felt that the most likely explanation for the age-related changes in pulmonary artery pressure and pulmonary vascular resistance was a primary abnormality of the pulmonary vascular bed, but they could not exclude effects of subtle abnormalities in left ventricular function.

In summary, studies of pulmonary hemodynamics with aging are limited by retrospective design, bias in patient selection, and potential effects of smoking. Minor increases in pulmonary vascular resistance and age-related increases in pulmonary artery wedge pressure during exercise have been reported. These age-related changes may not be physiologically significant.

PULMONARY FUNCTION TESTS

Lung function and exercise capacity decline with age in concert with numerous other physiological, morphological, and biochemical changes. Descriptions of "normal" age-related changes are confounded by an increasing prevalence of disease, chronic illness, medication use, and an increasingly sedentary life-style. Further, chronological age only approximates physiological age; the two often differ significantly. Chronological age is, therefore, an imperfect measure for indexing changes with senescence. While it would be desirable to isolate the effects of "normal aging" (aging in the absence of disease), it is essentially impossible to do so. The best studies to do so are longitudinal, tracing change with time, because they avoid the obvious biases of cross-sectional studies. Longitudinal studies, however, have methodologic problems and biases of their own, the most obvious being that the healthy elderly represent a healthy survival population. If, as a group, they have better than average lung function, they would not represent the general population of elderly people well.

Lung Volumes

Figure 18-8 illustrates typical lung volume changes with aging based on cross-sectional studies. With the exception of vital capacity, the effect of aging on lung volumes is based on cross-sectional rather than longitudinal data because there are almost no longitudinal studies of static lung volumes. Total lung capacity (TLC), the volume of air in the lungs at the end of a maximal inspiration, is marked by the point at which the recoil pressure exerted by the respiratory system is exactly counterbalanced by the maximal inspiratory pressure generated by the respiratory muscles. Since both the compliance of respiratory system (lung and chest wall combined) and maximum inspiratory pressure fall with aging, TLC might also be expected to fall. However, in seven cross-sectional studies of TLC summarized by the European Coal and Steel Community, four of the studies in men and three of those in women did not find a significant age coefficient. The remaining studies found only small declines in TLC with age, on the order of −8 to −19 ml/year. When these study results were combined into average equations, no significant age coefficients were reported for either men or women. McClaran and colleagues

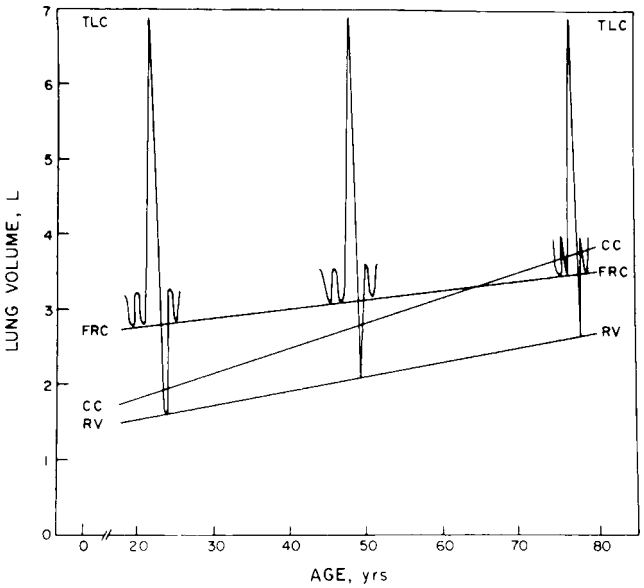

Figure 18-8 Schematic illustration of lung volume changes with age based on cross-sectional studies in seated individuals. (TLC = total lung capacity; FRC = functional residual capacity; RV = residual volume; CC = closing capacity.) Although not labeled, vital capacity (VC) is TLC minus RV. The most consistent changes are an increase in RV and a decrease in VC. *(From Peterson DD, Fishman AP: Aging of the respiratory system, in Fishman AP (ed): Update: Pulmonary Diseases and Disorders. New York, McGraw-Hill, 1992, pp 1–17, with permission.)*

measured lung volumes twice in 18 healthy, fit men. The first measurement was at a mean age of 67 and the second was 6 years later. Although average TLC fell 25 ml/year, the change was not statistically significant. The study was small and the interval was short.

In summary, current cross-sectional studies suggest that TLC either does not decline with age or declines very slowly. It is interesting to speculate on the possibility that cross-sectional studies of TLC might be confounded because they typically index TLC to both age and height. Height declines with aging, and maximum height during a life span appears to increase with successive generations. The authors believe that longitudinal studies of TLC with age are likely to show small but significant declines with age.

Both slow and forced vital capacity (FVC) decline with age, more rapidly in men than women. Average decrements in vital capacity per year vary considerably; in cross-sectional studies, declines range from 21 to 33 ml/year in men and 18 to 29 ml/year in women. Theoretically, longitudinal studies should provide better estimates of the effect of aging on lung function. Ware and colleagues, in a study containing both longitudinal and cross-sectional computations, found cross-sectional falls in FVC for men and women to be −34 and −27.8 ml/year, respectively. The longitudinal estimates were −40 ml and −31.3 ml/year, respectively. This study contradicts the generally held concept that longitudinal studies show smaller declines in FVC than cross-sectional studies. Currently, it is not certain whether longitudinal studies are all that much different from cross-sectional studies in describing declines in FVC and forced expiratory volume in 1 s (FEV_1). Longitudinal studies tend to show an acceleration in the rate of loss in FVC and FEV_1 as age advances.

Cross-sectional studies of residual volume (RV) and the RV/TLC ratio consistently show increases with age. In the young, RV, the volume of air in the lungs at the end of a maximal expiration is the volume at which the outward static recoil pressure of the respiratory system is counterbalanced by the maximal pressure exerted by the expiratory muscles. In older subjects, expiratory flow never completely reaches zero and the determination of RV is made partly by the length of time an individual can maintain expiratory effort. Other factors leading to an increased residual volume with aging include loss of lung recoil, decreased chest wall compliance, decreased expiratory muscle force, and increased small airway closure (air trapping) in dependent lung zones. Time of exhalation and increase in air trapping are probably more important than changes in lung and chest wall compliance in explaining the increase in RV with aging.

Functional residual capacity (FRC) is also determined by the balance of the elastic recoil forces of the lung and chest wall; but, in this instance, the equilibrium occurs at the end of a quiet (unforced) exhalation. Since lung recoil falls and the chest wall stiffens with age, one would expect FRC to increase. Cross-sectional studies, however, show inconsistent results, with most showing no change in FRC with aging. Studies that find an increase in FRC with aging show a small positive age coefficient on the order of 7 to 16 ml/year. McClaran's longitudinal study found FRC to increase 40 ml/year, but, again, the change was not significant. Despite the conflicting data, it is generally believed that FRC increases with aging.

Loss of lung recoil also changes the volume at which airway closure occurs. When adults exhale fully, small airways close in the region of the terminal bronchioles in dependent lung zones. The lung volume at which this closure begins is measured as closing volume or, if it is added to residual volume, closing capacity. Closing volume increases linearly with age from about 5 to 10 percent of TLC at age 20 to about 30 percent of TLC at age 70. The loss of lung elastic recoil, a possible decrease in the recoil of the intrapulmonic airways, and decreases in small airway diameter probably explain most of the change in CV.

Closing volume encroaches on tidal volume by about age 44 when subjects are supine and about age 65 when they are seated (Fig. 18-8). Airway closure during tidal breathing explains part of the decrease in arterial oxygen tension ($P_{A_{O_2}}$) observed with aging and may contribute to an aging-related increased frequency dependency of compliance.

Airflow

While essentially all expiratory flows measured during a maximum expiratory maneuver decrease with age, the declines are most evident at lower lung volumes (Fig. 18-9). Nunn and colleagues, in a study of 225 male and 228 healthy female nonsmokers, reported a modest, nonlinear decrease in peak expiratory flow (PEF) with aging (Fig. 18-10), which reached

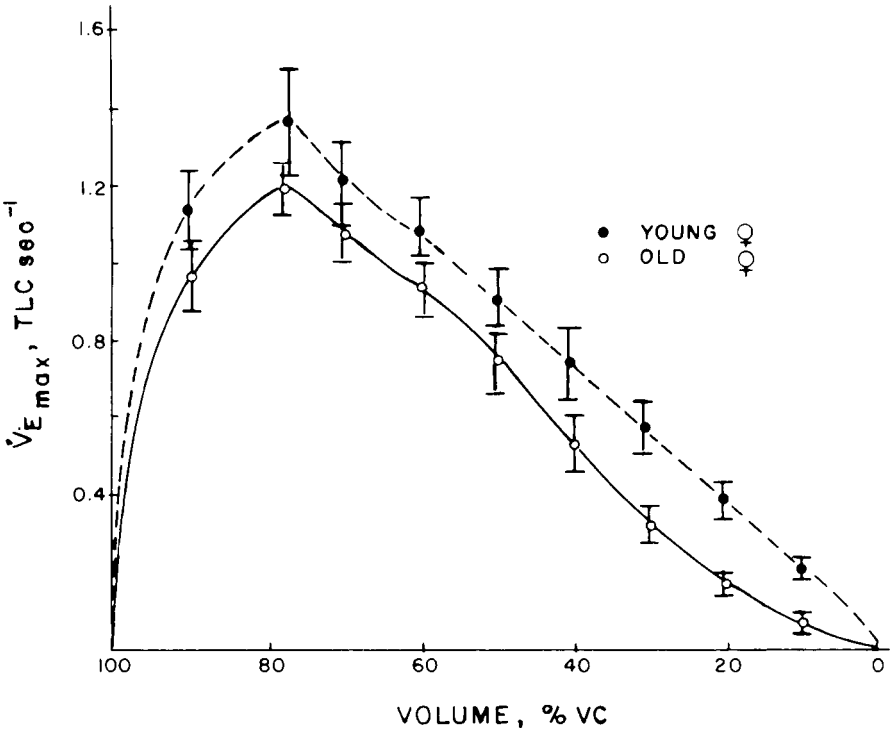

Figure 18-9 Illustrative maximal flow-volume curves for healthy "elderly" women (mean age, 63 years) and healthy young women (mean age, 25 years). Although all flows tend to be reduced with aging, the reduction in flow is most evident at lower lung volumes, where the flow-volume curve is clearly concave to the volume axis. *(From Peterson DD, Fishman AP: Aging of the respiratory system, in Fishman AP (ed): Update: Pulmonary Diseases and Disorders. New York, McGraw-Hill, 1992, pp 1–17, with permission.)*

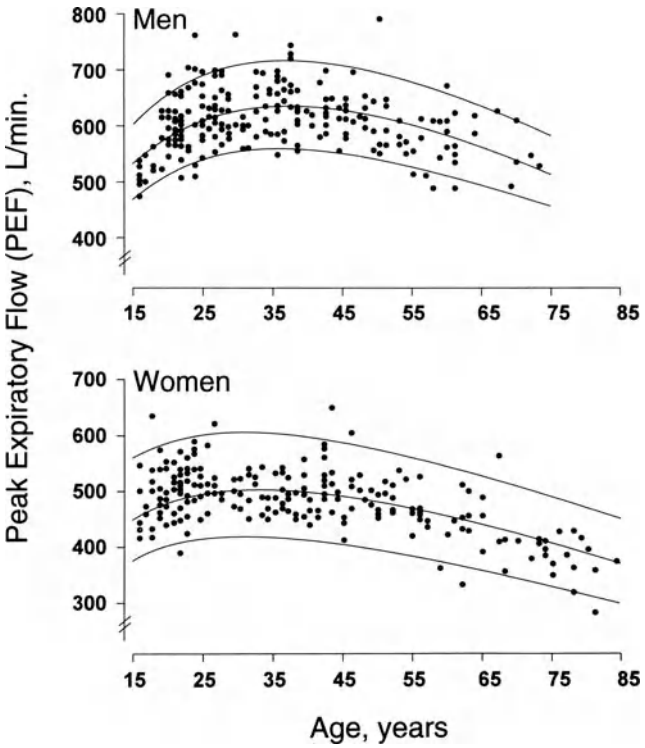

Figure 18-10 Changes in peak expiratory flow in 225 males and 228 females who were healthy nonsmokers. The center line is a regression curve representing mean data and the boundaries are 90 percent confidence intervals. *(From Nunn AJ, Gregg I: New regression equations for predicting peak expiratory flow in adults. Br Med J 298:1068–1070, 1989, with permission.)*

a high point at age 30 to 35; decline became evident at about age 45. After age 50, the average decline in men was about 4 L/min per year, about 2.5 L/min per year for women.

Figure 18-11, from Paoletti et al., illustrates changes in FEV_1 during growth, maturation, and senescence. Changes in FVC are similar. In one model of aging, FVC and FEV_1 increase progressively during the growth phase until about age 12. In the maturation phase (during adolescence) there is an acceleration of these increases. Increases in FVC and FEV_1 are seen up to about age 20 years in women and about 25 years in men; increases in lung volumes occur even after somatic growth ceases. There appears to be a plateau phase where there is little or no change in FVC or FEV_1 prior to the onset of a decline. However, Robbins and colleagues demonstrated that, while the plateau correctly represents average data, lung function is often increasing or decreasing in individuals (Fig. 18-12). Their study confirms the suspicion that the "plateau" phase represents the merging of slower maturation-related increases in FVC and FEV_1 in some subjects, with subtle decreases in others. In the decline phase, there appears to be acceleration in the rate of loss of FVC and FEV_1 as age progresses. An accelerated rate loss at older ages is, however, not found in all studies. The rate of decline in FVC and FEV_1 with age tends to be greater: (1) in men; (2) in taller individuals; (3) in individuals with larger baseline values; and (4) in individuals with increased airway reactivity.

Airways Resistance

Total airway resistance measured at FRC does not change with aging. Since upper airways increase and smaller airways decrease in size with aging, it is likely that peripheral airway

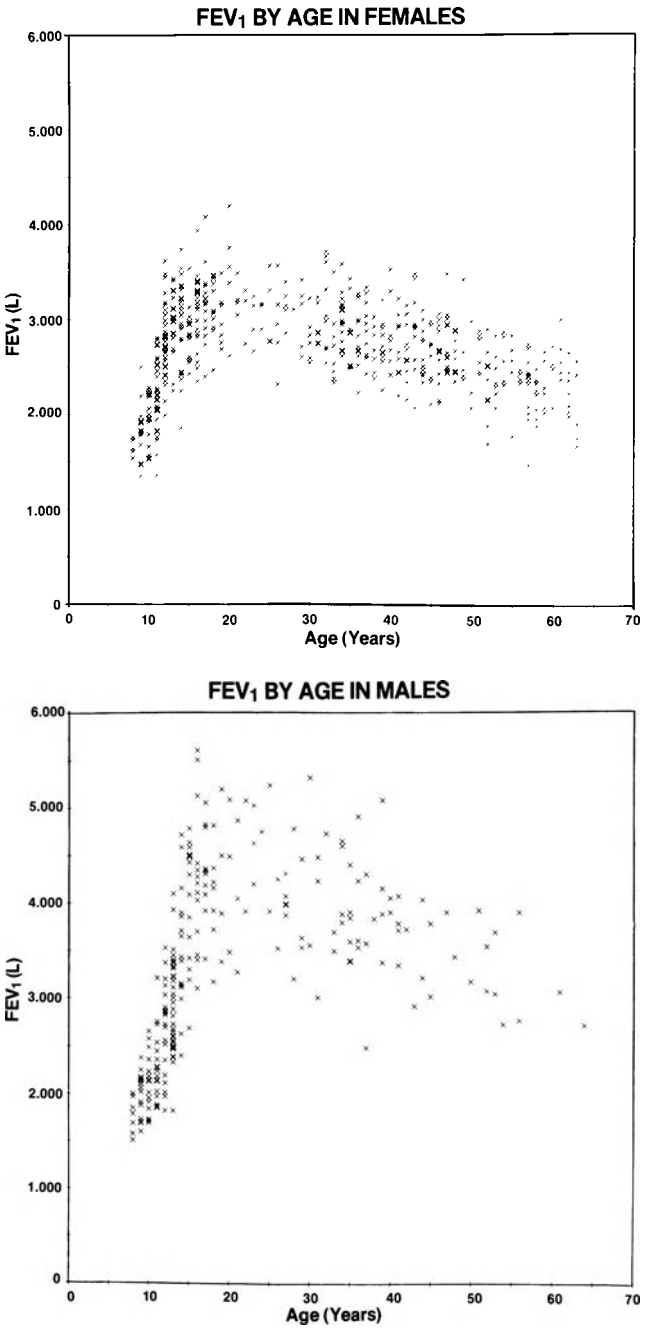

Figure 18-11 Change in FEV_1 with age from a cross-sectional study of 538 females and 263 males selected as ''normal" from a larger study of 3289 subjects. Changes in FVC are similar. *(From Paoletti P, Pistelli G, Fazzi P, et al: Reference values for vital capacity and flow-volume curves from a general population study. Bull Eur Physiopathol Respir 22:451–459, 1986, with permission.)*

resistance increases and central airway resistance decreases. That total airway resistance does not change with aging may be a function of the counterbalancing of these two opposite changes. However, since about 90 percent of total airway resistance resides in the upper airways, significant changes in peripheral airway resistance might not be readily reflected in total airway resistance. Significant increases in peripheral airway resistance with age also would be consistent with the more dramatic decreases in maximum flow observed at low lung volumes.

Gas Exchange

The carbon monoxide diffusing capacity (D_{LCO}), also known as transfer factor (T_{LCO}), declines with age. Earlier cross-sectional studies report a linear decline in D_{LCO} of about −0.2 ml CO/min per mmHg per year for men and −0.15 mL CO/min per mmHg per year for women. These declines are roughly 0.5 percent per year. In a large representative sample of U.S. adult men, Neas and Schwartz found an almost identical linear fall in D_{LCO}. In women, however, they found a nonlinear, quadratic decline in D_{LCO} with age. After age 47, the nonlinear component was not significant and the decline in D_{LCO} was identical to that in the earlier studies. The decline in D_{LCO} with age did not vary with race.

The decline in D_{LCO} with age is not explained by increased nonhomogeneity of gas distribution. Measured D_{LCO} falls as alveolar P_{O_2} increases and venous hemoglobin concentration falls. Neither alveolar P_{O_2} nor hemoglobin concentration varies enough with age to explain the aging decline in D_{LCO}. The magnitude of the decline in D_{LCO} corresponds fairly well to the magnitude of the known aging-related decrease in the internal surface area of the lung.

The components of D_{LCO} are membrane diffusing capacity (Dm) and pulmonary capillary blood volume (Vc). Both Dm and Vc decrease with age. In a cross-sectional reference value study of 54 male and 36 female healthy nonsmokers, the declines in Dm and Vc with age were found to be linear. Membrane diffusing capacity fell at about 0.6 percent per year in both men and women. Pulmonary capillary blood volume fell at about 0.3 percent per year.

Although alveolar oxygen pressure ($P_{A_{O_2}}$) remains constant with age, arterial P_{O_2} (Pa_{O_2}) decreases and the alveolar-arterial oxygen tension gradient ($P_A - a_{O_2}$) increases with aging (Fig. 18-13). The decline in Pa_{O_2} with aging is more pronounced when subjects are studied in a recumbent as contrasted with an upright position. The most likely explanation for the decline in Pa_{O_2} with aging is increased mismatching of ventilation to blood flow ($\dot{V}E/\dot{Q}$) as airway closure begins to occur during tidal breathing. Increased $\dot{V}E/\dot{Q}$) mismatching with aging is also associated with an increase in physiological dead space. Hypoventilation does not contribute to the age-related fall in Pa_{O_2}, since Pa_{CO_2} and pH do not change with age (Fig. 18-13).

EXERCISE CAPACITY

Peak $\dot{V}O_2$ ($\dot{V}O_{2\,peak}$) and maximum work capacity decrease with aging in both sedentary and active individuals. $\dot{V}O_{2\,peak}$ (L/min) increases until about age 20. Declines are evident at about age 25 in both men and women and continue at about 1 percent per year (Fig. 18-14). If one expresses $\dot{V}O_{2\,peak}$ as a function of body weight (L/kg per min), the decline is evident

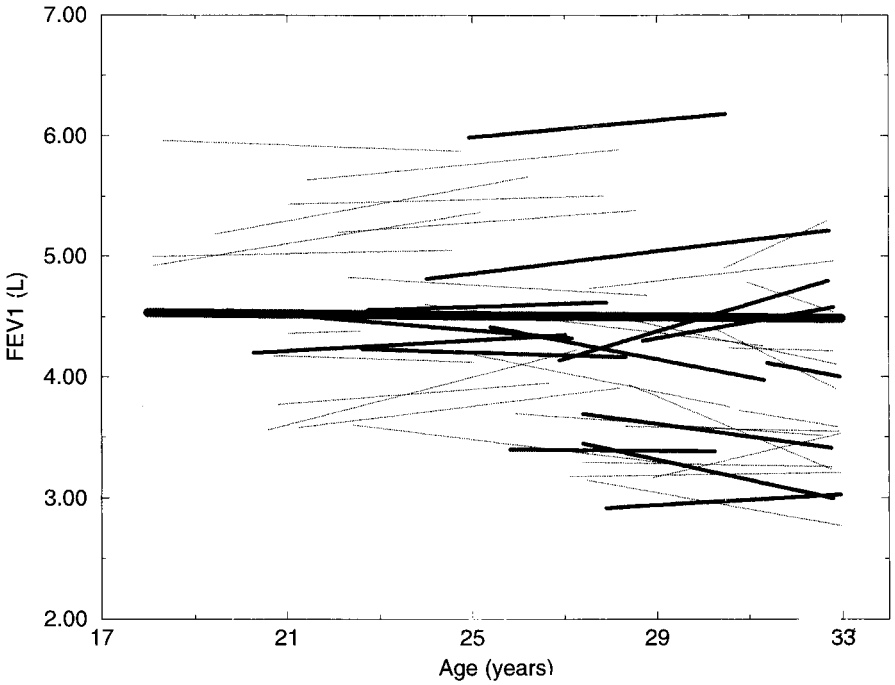

Figure 18-12 Predicted FEV_1 trajectories from 44 men based on linear regressions of longitudinal data. Nonsmokers (fine lines) and smokers (dashed lines). The heavy line is based on the entire group's data. While the group's data show no change with age, data for individuals show both increases and declines with age during this time period, when a plateau in lung function was theorized to occur. *(From Robbins DR, Enright PL, Sherrill DL: Lung function development in young adults: Is there a plateau phase? Eur Respir J 8:768–772, 1995, with permission.)*

much earlier, perhaps in the first decade of life. The magnitude of the decline in $\dot{V}O_{2\,peak}$ tends to be greater in longitudinal than in cross-sectional studies and occurs roughly twice as fast in sedentary than in physically active persons. Most but not all studies report linear declines in $\dot{V}O_{2\,peak}$ with age, even though a nonlinear decline would be expected based on the number and type of variables that affect exercise capacity.

The decline in exercise capacity with age occurs as a result of normal aging but is accelerated by life-style issues. Aging is associated with significant changes in body configuration. Specifically, there is an increase in total body weight, primarily representing an increase in fat mass, since fat-free mass (mostly muscle mass) decreases with aging. The changes are most pronounced in sedentary persons. Muscle mass decreases, with a preferential atrophy of type II muscle fibers, and is associated with a decrease in muscle capillarization and oxidative activity. Muscle strength decreases on the order of 2 percent/year from ages 20 to 70. Variables associated with loss of exercise capacity with aging are listed in Table 18-2.

While exercise capacity declines with aging, it is also clear that the ability to respond to exercise conditioning is well maintained even at very advanced ages. Elderly individuals respond to both endurance and resistive training

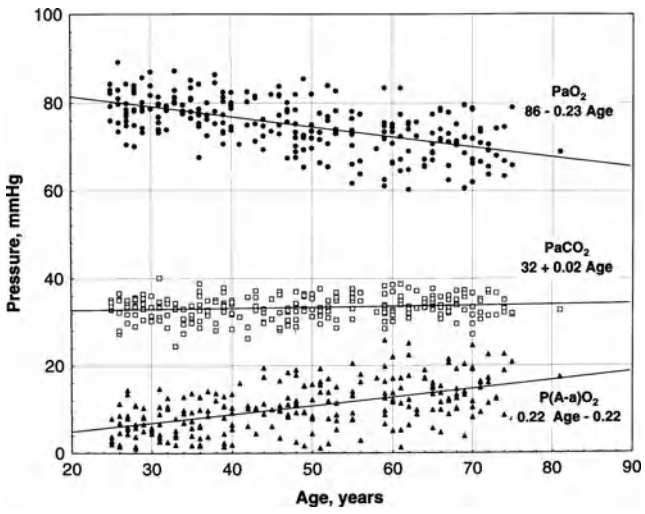

Figure 18-13 Change in Pa_{O_2}, Pa_{CO_2} and A–a gradient [$P(A–a)_{O_2}$] with age. Data were obtained from 200 healthy men and women living in Salt Lake City, UT (altitude = 1400 m). Sea level data would be similar, with a small upward shift in Pa_{O_2} and Pa_{CO_2}.

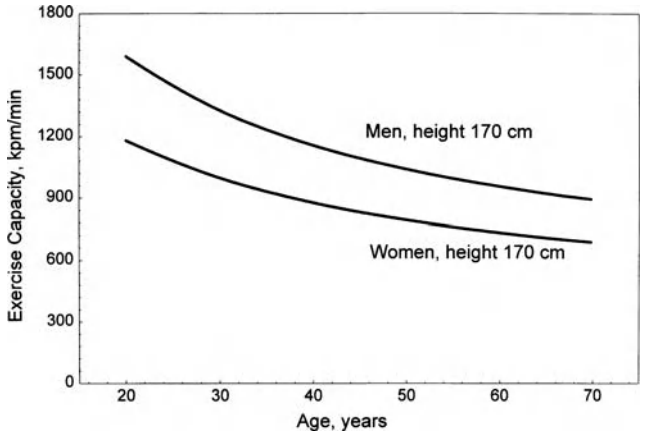

Figure 18-14 Decline in maximum exercise capacity with age. Exercise capacity declines nonlinearly with age. Maximum work capacity correlates strongly with peak oxygen uptake. *(From Jones NL, Summers E, Killian KG: Influence of age and stature on exercise capacity during incremental cycle ergometry in men and women. Am Rev Respir Dis 140:1373–1380, 1969, with permission.)*

Table 18-2

Variables Associated with a Decline in Exercise Capacity with Age

Variable	Comment
Decreased muscle mass	These changes especially affect $\dot{V}O_2$ calculated per kg of body weight
Increased fat mass	
Decreased cardiac output oxygen	As a result of the decreased cardiac output and maximal $C(a-\bar{v})O_2$, delivery and extraction are reduced; decreased cardiac output is a major contributor to the age-related decline in exercise capacity
Decreased maximal stroke volume	
Decreased maximal heart rate	
Decreased maximal $C(a-\bar{v})O_2$ difference	
Decreased maximum voluntary ventilation	
Increased ventilation at each workload	At each workload, older individuals breathe more and work harder for each breath than younger persons; however, the effect is small and contributes little to the decline in exercise capacity with aging
Increased oxygen cost of breathing	
Sedentary life-style	Life-style issues play a large role in the rate at which exercise capacity is lost with age; the good news is that, like other deconditioned groups, the elderly respond very well to exercise training
Decreased training intensity in active persons	
Decreased willingness to work to maximal level during tests	

with improvements similar in magnitude to those seen in the young. There are equivalent increases in $\dot{V}O_{2\,peak}$, muscle mass, capillarization of muscle tissue, muscle oxidative activity, and general muscle strength.

SLEEP

Sleep complaints from elderly patients present a difficult problem for the clinician, who must determine whether the complaints are related to the normal aging process, sleep hygiene issues, or the presence of pathology. Problems with sleep are widespread among elderly persons, with 25 to 40 percent complaining about sleep difficulties. There is no evidence to confirm the widely held belief that the need for sleep declines with age. However, sleep quality decreases, and the frequency of various primary sleep disorders increases. The most common age-related change in sleep pattern is a striking increase in the number of nocturnal awakenings, resulting in lower total sleep time and lower sleep efficiency (total sleep time/time in bed). Whether or not sleep latency changes with aging is equivocal. The amount of time spent in stage 1 non–rapid eye movement (NREM or light) sleep tends to increase with age. The decrease in total sleep time at night is associated with an increase in unwanted daytime naps. Disrupted sleep in the elderly is, in large part, explained by medical and psychological issues and the lack of structured physical and social activity during the day. Chronic illnesses, nocturia, medication and alcohol use, periodic leg movements, bereavement, and depression also play a role. Not surprisingly, the elderly are more likely to use sedatives or hypnotics; their use is more frequent in elderly women than in elderly men. While hypnotics and sedatives are occasionally necessary, their chronic use may contribute to sleep disruption and aggravate certain sleep disturbances, such as sleep apnea. Increased autonomic activity, increased sensitivity to external stimuli (which may increase arousals as a result of environmental factors),

decreased exposure to outdoor light, inactivity, and daytime napping also play a role in sleep disruptions in the elderly. Alterations in endogenous circadian rhythms for variables like temperature and cortisol or thyroid-stimulating hormone (TSH) levels may also contribute to sleep disruption in the elderly.

However, the neural system that regulates sleep is, like most other systems, subject to the "normal" aging process, and sleep disruption occurs in the elderly in the absence of any pathological process. The amount of stages 3 and 4 sleep (slow- or delta-wave sleep) declines with aging, although some argue that the aging decline is mostly a technical issue related to how delta-wave amplitude is defined. Changes in slow-wave sleep appear to be evident early, perhaps by 20 years of age. Arguments have been made both for and against declines in the amount of REM sleep with age. The persistent controversy about REM sleep and aging suggests that if REM sleep does change with aging, the magnitude of decline is so small that it does not overwhelm the confounding factors in studies.

Sleep disorders such as sleep apnea and restless legs syndrome, with periodic limb movements, appear to be more prevalent in older persons, and they are also more marked among nursing home residents than the independent elderly. For example, using an apnea index of five per hour as a threshold, one study found evidence of sleep apnea in 42 percent of elderly nursing home residents, in contrast to 24 percent of the independent elderly. Some argue that sleep disorders are associated with less morbidity and mortality in the elderly, but the data are inconsistent and remain inconclusive.

INTERPRETING PULMONARY FUNCTION TESTS IN THE ELDERLY

Several issues complicate the interpretation of lung function tests in the elderly. The elderly are not well represented in most reference value reports; the number of subjects usually falls off significantly after age 60. The number of subjects over age 80 is usually so small that mean values calculated from regression equations are essentially an extrapolation of the data for younger persons. This means that the average or "predicted" value may not be as representative for the elderly as it is for middle-aged persons. The fall in sample size with aging likely reflects the reduced total number of candidates for participation and the larger number of individuals who fail screening criteria. In reference value studies, individuals are screened so as to be free of symptoms and illnesses that alter lung function. These selection criteria may eliminate more older than younger candidates because of their increased prevalence of illness. Also, test quality is carefully standardized. Cognitive impairment may compromise test quality. As a result, older individuals may have more difficulty meeting test quality criteria, increasing their likelihood of exclusion and potentially increasing the variability of reference data for the elderly. In summary, the selection processes may make the older individuals who participate in reference studies less representative of the individuals who present for clinical lung function testing.

These same issues also affect the limits applied to determine whether a tested individual is within the "normal" range. Limits are often defined assuming that the distribution of data is gaussian. Although tests of this assumption are sparse, there is reason to suspect that it is more likely to fail in the elderly. Even when the "normal" range is defined using methods that avoid assumptions about data distribution, data from the elderly are often lumped with those of younger subjects. The result may be an erroneous "normal" range. These reference value issues all suggest that increased caution should be used in interpreting lung function tests in the elderly. This caution is especially important for those over age 80 and in any elderly person whose data lie near the limits of a "normal" range.

CHAPTER

Pulmonary Defense Mechanisms against Infections

Herbert Y. Reynolds • Jack A. Elias

The atmosphere that we breathe is more than just "air." In reality, it is a complex mixture of ambient gases and environmental particulates to which virus- and bacteria-containing droplets can be added when respiratory secretions are coughed or sneezed out by others. Moreover, normal humans frequently aspirate secretions from the upper respiratory tract, particularly during sleep. The respiratory system must recognize and eliminate these unwanted elements in inspired air to keep pulmonary structures free of infection, yet not overreact inappropriately to every stimulus. This is accomplished by local mechanisms and innate immune defenses spaced along the entire respiratory tract to protect it. The fact that the normal lower respiratory tract is infection-free despite its constant exposure to foreign antigens and infectious agents is testimony to the efficiency of these defense mechanisms. The evolving appreciation of direct associations between aging and breakdowns of these host defenses and resultant pulmonary diseases emphasizes the need for all physicians to be familiar with these critical protective processes.

Components of the defense system are spaced along the entire respiratory tract, from the point of air intake at the nose and lips or mouth to the level of oxygen uptake at the alveolar surface. The conducting airways functionally extend from the nares down to the respiratory bronchioles and include the nasal turbinates, epiglottis, larynx, pharyngeal lymphoid tissue (Waldeyer's ring), and other anatomic barriers. Fourteen generations of dichotomous airway branching of the respiratory tree, as bronchi and bronchioles, in this segment cause the airstream flow to decelerate and deflect the particles it contains onto the mucosal surface, trapping them in airway mucus. In this location, inhaled particulates and infectious agents also interact with other locally produced proteins, such as secretory immunoglobulin A (IgA). Resulting ciliary clearance or coughing efficiently removes these particulates from the respiratory tree. Beyond the respiratory bronchioles, other noncellular host defenses remain important in protecting the alveolar units (Fig. 19-1). These defenses are in the lining material fluid of the alveoli, which contains

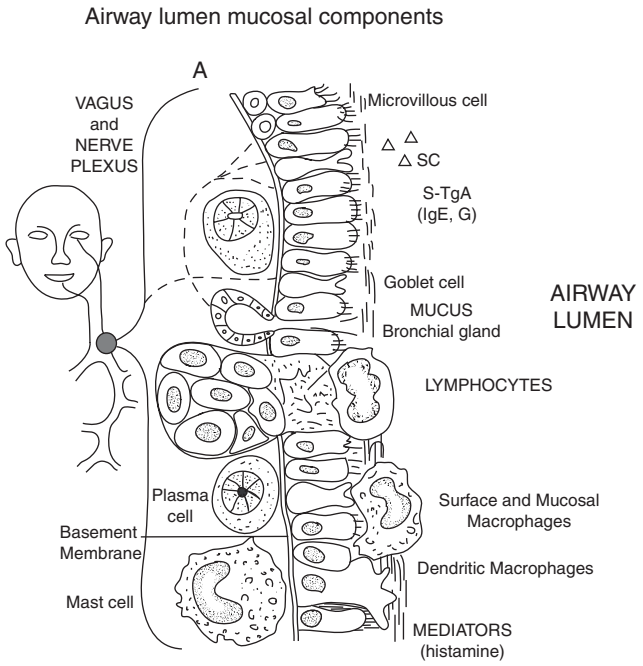

Figure 19-1 Airway lumen mucosal components. A portion of the conducting airway surface is enlarged (A) and depicts the mucosa and its submucosal structures. The pseudostratified ciliated epithelium has a covering layer of mucus (produced by goblet cells and bronchial glands) and fluid that contains various proteins, including immunoglobulins and secretory component. A few surface cells may be present, such as lymphocytes (from bronchial-associated lymphoid aggregates) and macrophages. Among the epithelial cells are absorptive microvillous brush cells and the dendritic cells, concentrated near lymphoid aggregates or in the respiratory bronchiole area, whose cellular processes interdigitate with the mucosal surface. In addition, the epithelial cells can produce proinflammatory cytokines that influence mucosal swelling and permeability. In the submucosa below the basement membrane, plasma cells and mast cells reside that secrete local immunoglobulins (such as IgA) and mediators (such as histamine). Interacting with all of these glandular and cellular networks are nerves, exerting their control through neuropeptides, and by adrenergic and cholinergic nerve fibers. A rich bronchial arterial vascular supply also exists. *(Modified from Reynolds HY: Pulmonary host defenses-state of the art. Chest 95(Suppl):223–230, 1989, with permission.)*

surfactant apoproteins and glycoproteins such as fibronectin, immunoglobulins such as IgG opsonins, and complement (properdin factor B), which are active against aerosolized, inhaled particles or microorganisms.

Alveolar macrophages are the principal phagocytic and scavenger cells on alveolar surfaces. Particulates and microbes that evade other host defense mechanisms and arrive on the alveolar surface are efficiently removed by these roaming cells. When further assistance is required, an inflammatory reaction can be initiated, which attracts polymorphonuclear neutrophils (PMNs) and other vasomediators and humoral immune elements from systemic sources.

At all levels of the respiratory tract, specific and nonspecific defense mechanisms exist to protect respiratory structures. The nonspecific mechanisms, as noted above, include the mechanical barriers, cough, mucociliary elevator, and macrophage phagocytosis, which behave similarly regardless of the inhaled particulate. They also include aspects of the innate immune response, such as the inflammation triggered by Toll-like receptors (TLR). In contrast, prior contact with a microbial agent or a sensitizing substance can induce antigen-specific cellular or humoral immune responses, activating adaptive or acquired immunity. The latter includes the production of secretory IgA antibody in the airway, which prevents mucosal adherence, and IgG opsonins that facilitate phagocytosis. Such responses help the lung deal more efficiently with these agents and substances on rechallenge in the future.

In summary, the integrated action of diverse pulmonary defense mechanisms along the respiratory tract acts to remove or neutralize microorganisms, particulates, and noxious gases that are inhaled or aspirated into respiratory structures. Many are mechanical barriers and reflex actions that are concentrated in the naso-oropharynx and along the conducting airways. There is also phagocytosis, which occurs in the alveoli and airways. These are surveillance mechanisms that function mechanically and can be activated by nonspecific (nonimmunologic) or immunogenic stimuli. In addition, several augmenting mechanisms exist that enhance the responsiveness of this defense system and make it flexible and adaptable. Crucial in this regard are the pathways of innate immunity and the ability of dendritic-type macrophages in the lung to mount antigen-specific immune responses (humoral and cellular)—adaptive immunity—and a local inflammatory reaction. This allows components in plasma and blood cells to bolster local defenses in the airways and alveoli. A more in-depth review of these innate defense mechanisms follows. Also in the "Suggested Reading" section, several reviews by the authors and others provide more details about this actively expanding topic.

SPECIALIZED REGIONAL DEFENSES

Nose and Oropharynx

Inhaled air passes through the nose or mouth back to the glottis and into the extrathoracic portion of the trachea before it enters the thorax. With nasal breathing, air is filtered and conditioned for humidity and body temperature as it flows over the nasal turbinates and mucosa of the posterior pharynx. With nasal obstruction or ventilatory requirements for exertion that exceed about 20 to 30 L/min, mouth breathing occurs. Inhaled air then may pass into the trachea without optimal filtering and climatic conditioning.

The nose provides formidable barriers to inhaled particulates. The nasal hairs help to exclude large particles, and materials greater than 10 μm in diameter that bypass the hairs impact upon the nasal mucosa. Sneezing (or blowing) then has the effect of coughing and provides high-velocity ejection from the mucosal surface. For substances that attach to the nasal mucosa, production of large quantities of watery secretions helps to wash off the surface (rhinorrhea).

Mucociliary clearance is also operant in the nasal cavity. "Downspouts" leading from the ears, lacrimal glands, and sinus cavities provide numerous points for the addition of fluid to the nasal secretions. However, these drainage systems also contain vulnerable points that are prone to blockage. The complex plumbing found in the nose works well if there is good gravitational flow and orifices stay open. If not, sinusitis, otitis media, parotid gland obstruction, and occluded tear ducts result. In some diseases, dryness of secretions (sicca syndrome) is problematic.

Several substances in nasal secretions help control bacteria or viruses. Prominent in this regard are lysozyme and immunoglobulins, especially secretory IgA (SIgA) which bathes mucosal surfaces. The nose and upper airways are contiguous immunologically with the lower airways and have been studied extensively. Nasal secretions, like those from other external or mucosal surfaces, are rich in IgA, which is synthesized locally by submucosal plasma cells. Free secretory component (SC) can also be detected in nasal wash fluid. Of the nasal immunoglobulins, SIgA is the major source of antibody, accounting for approximately 10 percent of the total protein content of nasal washings. IgG is present in smaller amounts. IgE probably is not secreted by normal, nonatopic people. Only in people with allergic rhinitis will IgE antibody be substantial. The usual specificity of IgA antibody is antiviral. After nasal immunization of normal subjects with various viral or mycoplasmal vaccines, many experimental studies have shown that appropriate neutralizing IgA antibody can be elicited. Although these antibodies are protective against homologous and live microbial challenge, the duration of protection is often brief, and the antibody titers diminish rapidly unless repeated exposure occurs.

In the oral cavity, the tongue sweeps against many surfaces during chewing and swallowing. This should make it difficult for bacteria to persist in these locations. However, bacteria adhere to buccal squamous cells, and many accumulate in crevices around teeth and gums and colonize dental plaque. Many kinds of bacteria are present: aerobes and anaerobes, spirochetes, gram-positive and gram-negative species, and some that specialize in making dental plaque and causing tooth decay. A common feature of host defense in the mouth and nose is the plentiful amount of SIgA in secretions that bathe each area. The parotid glands and probably the submandibular salivary glands secrete IgA as their principal humoral immune substance; this immunoglobulin accounts for 12 to 15 percent of the total protein in their secretions. In this fluid, albumin represents about 10 percent of the protein, but IgG is barely detectable (under 1 percent). In parotid fluid, IgA is found in monomeric and dimeric forms, and free secretory component can be detected as well. Thus, normal nasal and parotid (or salivary) secretions have about the same composition of immunoglobulins. As with the nasal immune system, it has been possible to manipulate SIgA in the mouth to produce antibodies against certain cariogenic strains of streptococci that will subsequently prevent bacterial adherence to teeth—the immune exclusion function of SIgA antibody. The importance of a vaccine approach for augmenting dental defenses has yet to be fully determined.

Host defenses in the nose and mouth serve as a reminder that the upper portion of the respiratory tract has features in common with the lower part, particularly at the mucosal surfaces. They also demonstrate that infections in the nose, sinuses, ears, teeth, and gums may have ramifications for the diagnosis or successful treatment of illness in the lower respiratory tract. As examples, aspiration of anaerobic bacteria in oral secretions or dental plaque contributes to lung abscess formation; chronic sinusitis can be present with cystic fibrosis, dyskinetic ciliary syndromes, and dysgammaglobulinemia; atopic diseases can manifest with rhinitis, sinusitis, and asthma; and control of asthma symptoms often requires vigorous treatment of concomitant sinus infection.

Conducting Airways

Bridging the upper airway (nose, oropharynx, and larynx) and the alveolar air-exchange area distal to the terminal bronchioles are the conducting airways (Fig. 19-1). Mucociliary clearance and coughing are the principal means of cleansing the mucosal surfaces of these airways. SIgA antibodies also prevent epithelial attachment of certain bacteria and viruses to the ciliated and nonciliated airway epithelial cells. The branching structure of the airways also causes airborne particulates to impact against the mucosa, enhancing the efficiency of mucociliary clearance. Bronchial-associated lymphoid aggregates are present, especially around branching points. This segment is susceptible to many diseases—e.g., epithelial cell infection with viruses or bacteria such as *Bordetella pertussis, Chlamydia pneumoniae,* or *Mycoplasma pneumoniae;* inflammation, edema, and bronchoconstriction in asthmatic syndromes; chronic infection in bronchiectasis; irritation from noxious gases; and lung cancer.

The conducting airways mucosa is coated to a depth of 5 to 100 μm with a mucous gel-aqueous sol complex viscous fluid, which has a low pH (6.6 to 6.9). This is secreted by bronchial glands, goblet cells, and Clara cells (nonciliated bronchiolar secretory cells found in the terminal bronchioles). Airway surface liquid is also derived from transepithelial acid-base flux across the bronchial epithelium. Special proteins, such as SIgA and SC, can be added locally along airways by immunoglobulin-secreting plasma cells and epithelial cells. Antimicrobial factors such as lysozyme, lactoferrin, cathelicidin, and defensins are present.

About half of the mucosal epithelial cells have beating cilia that propel secretions up the respiratory tree. Periodic coughing can assist the process. An intact mucosal lining and overlying mucous layer, containing mucin glycoproteins and proteoglycans, provide a protective barrier or blanket that prevents inhaled particulates from penetrating or sticking to the respiratory surface. This seems to be an important component of host defense. Bacteria and other infectious agents may transiently colonize the airways, but mucociliary clearance effectively removes them. Tight junctions between epithelial cells also limit the passage of macromolecules into

the submucosa, and microvillous brush cells may help clear fluid. A number of circumstances can alter these protective barriers, making this portion of the respiratory tract susceptible to disease. They include (1) malnutrition, which affects the integrity of mucosal epithelial cells and enhances bacterial adherence; (2) cigarette smoke and noxious fumes, which disrupt the anatomy of epithelial junctions and enhance the passage of airway substances into areas that are usually inaccessible; and (3) some bacteria, which elaborate proteolytic enzymes that may break down IgA, promoting selective colonization and persistence in matrix-enclosed biofilms that help avoid innate immunity and create chronic infections.

Lymphoid tissue is present along the entire respiratory tract, but the level of organization of the lymphoid tissue varies greatly. A ring of lymphoid structures are situated in the naso-oropharynx. Lymphoid nodules may occur in the mucosal surface of large and medium-sized bronchi and are particularly numerous at points of airway branching. On the airway side, these submucosal follicles are covered by a layer of flattened, nonciliated surface epithelium, which is often observed to be infiltrated with lymphocytes. These bronchial-associated lymphoid tissues (BALT) bear some resemblance to gut-associated lymphoid tissues (Peyer's patches), and are part of the body's overall mucosal-associated lymphoid network (known as MALT) that is important in mucosal immunity. Whereas BALT is easily demonstrated in some rodents and rabbits, subhuman primates and humans have decidedly less obvious amounts of this lymphoid tissue, and it may not be as relevant to airway defenses as initially thought, especially in adults.

Loosely organized collections of lymphocytes (lymphoid aggregates) are concentrated in the distal airways, especially at the bronchoalveolar junctions at the interface between the ciliated epithelial cells of the terminal bronchioles and the alveolar lining cells. These aggregates provide an opportunity for close interaction between lymphoid cells and inhaled antigens that have been deposited in the lower respiratory tract. Antigens and microbes may adhere to surface macrophages or dendritic cells imbedded in the mucosa where immune processing or elimination occurs. Bacteria such as *Pseudomonas aeruginosa* may become enmeshed in a biofilm containing their exopolysaccharides, which can interfere with macrophage or dendritic cell elimination of them and contribute to airway colonization and persistence. Also, in the vicinity of the respiratory bronchioles, lymphatic channels begin that might provide these lymphocytes with a route to draining lymph nodes (hilar nodes) where immunologic responses develop.

Respiratory Bronchioles

Anatomically, lung structure changes at the level of the respiratory bronchioles, which are inserted between the distal conducting airways and the acinar units (alveolar ducts and alveoli) of the air exchange surface. They functionally separate the upper and lower respiratory tracts. This segment can be a bottleneck or choke point for airflow, but it is the last surface to capture small airborne particulates and microbial or antigenic debris before entering the alveolar space; adaptive immune responses can begin here. Several structural changes occur: the single-layer cuboidal epithelial surface flattens and differentiates into alveolar type I cells that primarily cover the alveolar lining surface; mucus-secreting cells disappear, although goblet cells can be found in cigarette smokers; and another secretory cell type becomes prominent, the Clara cells. Pulmonary brush cells with a tuft of squat microvilli are found in this area, especially in rodent species, and may be involved with chemosensing or trapping inhaled particles and pollutants, or with regulating fluid and solute absorption. Dendritic macrophage-like cells, which may constitute 1 percent of the cells in the surface of this segment, are present to capture and process antigens. Lymphatic channels form to collect the lymphatic fluid emerging from the interalveolar interstitial spaces. The changeover from the bronchial arterial blood supplying the conducting airways to the pulmonary artery-capillary blood flow structure that surrounds the alveoli also occurs, which is necessary for aeration.

The Alveolar Spaces

Defenses in the airways (Fig. 19-2) eliminate most particles and microbes inspired into the lungs. As a result, the airways distal to the major bronchi are probably sterile in normal subjects. However, some particles of small size and special geometry can elude the airway mucosal mechanisms and reach the air-exchange surface of the alveoli. When this occurs, another set of host defense mechanisms must take over. Microbial clearance and the removal of other antigenic material from alveoli depend on cellular and humoral factors such as the lipoproteins, immunoglobulins, and complement factors in the alveolar lining fluid and phagocytic cells such as alveolar macrophages and PMNs.

Inhaled microbes are an appropriate example. If a bacterium of critical size (0.5 to 3 μm in diameter) is deposited in an alveolus, it is likely to make contact with the alveolar wall and roll along in about 0.2 μm of alveolar lining fluid, pH 6.9, which is a combination of a watery subphase with an overlying film of surfactant secreted by type II pneumocytes. In the process, a microbe encounters several substances that can inactivate it and assist in its eventual phagocytosis. These substances include a variety of soluble lipoprotein substances, IgG, complement factor (C3b), and nonimmune opsonins, such as high-molecular-weight fibronectin fragments. The lipoproteins in the form of surfactant are secreted by type II pneumocytes, and surfactant proteins A and D have opsonic effects through binding of surface carbohydrates, which promotes antibacterial activity against staphylococci and rough colony strains of some gram-negative rod bacteria. The immunoglobulins are principally of the IgG class. They account for 5 percent of the total protein in alveolar fluid, with subclasses IgG1 and IgG3 being the most important and lesser concentrations of monomeric and secretory forms of IgA being noted. These immunoglobulins can develop specific opsonic antibody activity for the bacterium. The complement components, especially properdin factor B, interact with the

bacterium and can trigger the alternative complement pathway, thereby lysing the microbe directly. One or all of these interactions can prepare the bacterium for ingestion by an alveolar macrophage. Although alveolar macrophages avidly phagocytose some inert particles, they ingest viable bacteria with considerably less enthusiasm. Coating or opsonizing the organisms will enhance phagocytosis appreciably as studied in an in vitro culture system. The nonimmune opsonins nonspecifically enhance this process. The immunoglobulins are capable of enhancing alveolar macrophage phagocytosis in an antigen-specific fashion, and the C3b complement fragment can function in concert with IgG to enhance or amplify this process.

Phagocytosis, the ingestion of particulate matter by cells, is divided into two phases: receptor attachment of the particle to the cell surface and internalization. Attachment of the particle to the surface of the phagocytic cell is essential before ingestion occurs. Although binding occurs randomly, it is greatly enhanced by opsonization of the particle by antibody (especially IgG) or a component of the complement system, C3b. Opsonin-dependent phagocytosis is mediated by receptors on the cell surface for the Fc component of the opsonizing immunoglobulin or complement. Specific receptors for the Fc portion of IgG (Fcγ) (IgG3 and IgG1 primarily) and for the third component of complement (C3b) are present on human monocytes and alveolar macrophages. Receptors for IgA are also found on alveolar macrophages.There is evidence that the number and function of these receptors can be modulated by lymphocyte-derived cytokines such as interferon-γ (IFN-γ). Ingestion of membrane-bound particles occurs via a process that is energy-dependent as the plasma membrane of the ingesting cell surrounds the bound particle, enclosing it in an endocytic vesicle. This is followed by the activation of a number of well-developed mechanisms that operate to kill internalized pathogens.

Following internalization of bacteria, the fate of alveolar macrophages is not certain. They are long-lived tissue cells that can survive at least for several months and presumably are capable of handling repeated bacterial and other microbial challenges (reusable phagocytes). Because they are mobile cells, they can migrate quickly to other alveoli through the pores of Kohn, or move to more proximal areas of the respiratory tract (to the region of the respiratory bronchioles) for elimination from the lungs by the mucociliary escalator. In addition, macrophages may gain entry into lung lymphatics at the same location and be carried to regional lymph nodes. This exit gives them access to systemic lymphoid tissue and is important in initiating cellular immune responses. Undoubtedly, macrophages are also instrumental in degrading antigenic material and presenting it in an appropriate manner to local T lymphocytes as part of innate and adaptive immunity in the lung.

Increasingly, attention is being given to the immune effector role of macrophages. The alveolar macrophage has a dual role in the respiratory tract—one as a phagocyte to dispose of debris, process foreign antigens, and kill ingested microorganisms and a second as an effector cell to initiate immune and inflammatory responses. Alveolar macrophages are usually successful in inactivating inhaled microorganisms. As a result, clinical disease and pneumonitis rarely develop after day-to-day exposures. However, if a sufficiently large bacterial inoculum reaches the lower respiratory tract, or if particularly virulent microorganisms are inhaled, the macrophage system can be overwhelmed. By the secretion of proinflammatory chemotactic factors such as the chemokine family cytokines, alveolar macrophages then recruit PMNs and other cells to the lung, and pneumonitis develops. Also, airway epithelial cells can generate proinflammatory cytokines to assist with PMN attraction.

Gram-negative rod bacteria provide an interesting example. Some complement components, particularly factor B, are present in small amounts in bronchoalveolar fluids. The bacterial endotoxin in the gram-negative rod bacteria can directly activate the alternative complement pathway—leading to the formation of C5a, which is a potent stimulus for PMN chemotaxis. Also, the inflammatory response may activate the kinin system; this results in generation of kallikrein, which has chemotactic activity, and bradykinin, which is capable of increasing vascular permeability. The latter allows for the seepage of fluid and other humoral and bioactive substances from the intravascular compartment into the alveoli. Another mechanism of inflammation emanates from the alveolar macrophage itself. Following phagocytosis of opsonized bacteria or other forms of activation, proinflammatory chemokines are synthesized and secreted by macrophages that will attract PMNs and other cells. Several substances with chemotactic activity have been found to be produced by human alveolar macrophages. These include interleukin-8 (IL-8), macrophage inflammatory protein-2 (MIP), monocyte chemoattractant protein-1 (MCP-1), tumor necrosis factor (TNF), and lipoxygenase pathway metabolites of arachidonic acid, namely leukotrienes. Leukotriene B_4 (LTB_4) is one of the most important of these.

Inflammation is the ultimate host response to contain common bacteria that reach the alveolar space. This response can be activated in several ways: (1) directly by microbes or substances such as lipopolysaccharide (endotoxin) that can activate the complement cascade, probably via the alternate complement pathway; (2) through the generation of phlogistic factors from the kallikrein and bradykinin pathways; and (3) from the effector cell function of macrophages. It is also known that other airway cells, such as epithelial cells, elsewhere in the respiratory tract, can produce chemokines like IL-8 and that this can stimulate inflammation in other sites (bronchitis).

Special interest has focused on the macrophage-secreted proinflammatory chemokines, a family of cytokines that can stimulate cellular motion (chemokinesis) and promote directed migration of different populations of responder cells (chemotaxis). These populations are primarily PMNs in the acute inflammatory responses. Lymphocytes, monocytes, and eosinophils are also recruited in the chronic phase of pneumonia, chronic inflammatory disorders such as hypersensitivity pneumonitis and sarcoidosis, and atopic and eosinophilic syndromes. Investigation has elucidated the cellular mechanisms whereby CXC chemokines activate and

initiate the migratory process of PMNs. An extensive review of the literature is summarized to say that this process involves a number of cell surface adhesion molecules, found on endothelial cells (adhesion molecule ICAM-1, L- and P-selectins and integrins) and granulocytes, that bind to one another. At sites of inflammation mediators such as IL-1, TNF, and IFN-γ induce or augment the expression of these adhesion molecules. As a result, intravascular PMNs slow down, roll along, deform, and then anchor on the endothelium. They then enter the interstitium via traversing capillary endothelial cells, which contract or pull apart to allow a gap through which PMNs pass, and plasma fluid can leak, and the cells emerge through the alveolar type I pneumocyte lining barrier into the alveoli. Microvillous brush cells may also absorb fluid or regulate ion-solute flux.

Eventually, all pneumonic responses run their course. If the host is successful in containing the infective microbes or particles that initially incited the host response, resolution usually occurs. Resolution can be passive, resulting from the removal of the initiating agent. Resolution can have an active phase as well. In the active phase, signals must go out to begin the healing and resorption phases that will restore the lung to normal respiratory function and architecture. Less is known about active resolution of inflammation. A platelet-derived substance, sphingosine 1-phosphate (S 1-p) may help restore the endothelial barrier by reducing PMN infiltration and vascular leak, as found with endotoxin injury. Moreover, cytokines such as transforming growth factor-β, IL-6, IL-10, and the IL-1 receptor antagonist released by macrophages and possibly other cells are believed to be important mediators of this process. As such, they provide a view of potential anti-inflammatory therapies of the future.

Lymphocytes in the Alveolar Space

When cells are retrieved from the alveolar surface by bronchoalveolar lavage (BAL), approximately 7 to 10 percent of the respiratory cells are lymphocytes. Some characteristics of these cells are given in Table 19-1. Two major populations of lymphoid cells are recognized, those that depend on the thymus gland for differentiation (T cells) and those that differentiate independently of the thymus in the bone marrow (B cells). The T and B lymphocytes are indistinguishable by usual morphologic criteria but can be differentiated by membrane surface markers. They are also functionally distinct, with T cells playing an important role in cell-mediated immunity and cell-mediated cytotoxicity while the B cells serve as precursors for cells that synthesize immunoglobulins and, hence, antibody molecules that are the basis of the humoral immune response.

As shown in Table 19-1, approximately 70 percent of the lymphocytes in lavage fluid are T cells and approximately 5 percent are B cells. The ratio of T to B cells in lavage fluid is roughly that of peripheral blood, although in blood more circulating B cells are usually identified (approximately 15 percent). Approximately 1 to 5 percent of lung lymphocytes seem to be able to release or secrete class-specific immunoglobulin. Enumeration of these cells has found that IgG- and IgA-secreting cells are much more numerous than IgM-producing cells. Natural killer lymphocytes make up about 5 to 8 percent of lung lymphocytes. As they do not express T-cell receptors or surface immunoglobulins for specific antigens, they can respond in an antigen-independent way to help contain viral infections and are thus important in innate immunity. With phenotypic markers, T cells can be divided into two principal groups. The CD8 cells usually have a suppressor-cytotoxic phenotype. The CD4 cells usually have a helper-inducer phenotype and thus are also called T-helper (TH) cells. In the BAL fluid from normal subjects there is a greater percentage of CD4 cells, with approximately 45 percent of the total T cells expressing this surface marker. In contrast, approximately 25 percent of lung T cells express the CD8 phenotype. In lung lavage fluid, the ratio of these subtypes of T cells is approximately 1.5 to 2:1, which is approximately the same ratio found among peripheral blood lymphocytes.

As noted, most of the T lymphocytes in the alveoli are CD4-positive. When activated, these TH cells are capable of producing regulatory cytokines that in turn modulate the function of other immune and structural cells. Recent studies suggest that there are at least two subsets of CD4 TH

Table 19-1

T-Lymphocyte Subgroups in Lung Lavage Fluid from Normal Subjects

Fluid	Cell Count $\times 10^6$	Lymphocytes (%)	T Cells (%)	CD4 (T Helper) (%)	CD8 (T Suppressor) (%)
Lung lavage*	$10 \pm 4^{\dagger}$	7 ± 1	73 ± 5	46 (35–55)	25 (18–32)
Blood				48 (40–60)	28 (22–40)

* *Cells from 300-ml lavages of six normal nonsmokers.*

† *Mean ± SEM; range observed in parentheses.*

cells, T-helper–1 (TH1) and T-helper–2 (TH2) cells. These cell populations have different functions based on the different array of cytokines that they produce. The TH1 cells secrete IFN-γ and IL-2, which activate macrophages and play a major role in cell-mediated immunity. The TH2 cells produce IL-4, IL-5, and IL-6, which stimulate B lymphocytes to produce immunoglobulins and, by their production of IL-10 and IL-13, suppress monocyte/macrophage activity and cell-mediated immune responses. Thus, TH2 cells play a particularly important role in generating tissue eosinophilia and stimulating IgE production, processes that are extremely important in atopy, allergic asthma, and other inflammatory pulmonary disorders. IL-2, formerly called T-cell growth factor (TCGF), is among the most important T-cell–regulating cytokines. It is produced by activated T cells and acts in an autocrine or paracrine fashion to stimulate TH1 cells and TH2-cell precursors. IL-2 can also activate killer T cells. A few killer lymphocytes can be identified among alveolar T cells, but these cells seem to be dormant in normal subjects until stimulated. Lastly, IL-2 can stimulate B lymphocytes to differentiate into plasma cells that synthesize various classes of immunoglobulins. This is a mechanism by which local production of immunoglobulin in the lung can occur. In all cases, the effects of IL-2 are mediated by the multimeric IL-2 receptor, a component of which is the Tac-surface ligand. The expression of the IL-2 receptor is highly regulatable, and the expression of the Tac antigen can be used as a marker of T-cell activation.

Most T cells have T-cell receptors with alpha and beta subunits (α/β T-cell receptors). In the normal lung, a lesser number of T cells have gamma and delta T-cell receptors. The function of these cells is poorly understood. They may, however, play an important role in mucosal immunity, since they are increased in atopic allergic subsets.

Alveolar macrophages and lymphocytes have the capacity to produce many cellular mediators (cytokines) that in turn affect each other as well as other inflammatory, structural, and immune effector cells. This dynamic and complex interaction is illustrated in Fig. 19-2, which reviews dendritic cell, alveolar macrophage, and lymphocyte interactions in the airways and alveolar milieu. Monocyte precursors from the blood differentiate into mature macrophages under the influence of vitamin D metabolites and undoubtedly other stimuli and become long-lived, aerobically metabolizing alveolar phagocytes. Their principal activity is to cleanse the alveolar surface and ingest debris that accumulates or microbes aerosolized into the lungs. In the process, the macrophages may become "activated" and are then capable of secreting an enormous array of enzymes and cytokines. These moieties can affect the function of resident cells of the lung such as lymphocytes or epithelial cells. In addition, the release of proinflammatory chemokines attracts PMNs, lymphocytes, monocytes, and other cells into the alveoli. Of particular note are LTB_4, IL-8, TNF-α, MIP-1α, MCP-1, and IL-1. When secreted by activated macrophages (especially in active lung forms of sarcoidosis) IL-1 may attract T lymphocytes to the lungs.

In the other direction, activated TH cells can produce several monokines that affect macrophage function. Such a substance is migration inhibition factor, which immobilizes macrophages engaged in phagocytosis. Of special interest is IFN-γ, which activates macrophages, increasing their expression of membrane receptors, which in turn enhances macrophage phagocytic uptake. IFN-γ also has other functions that promote cellular immunity. Almost mutually exclusive sets of chemokines can be induced by TH1 immune responses (IL-12 and IFN-γ) and by TH2 cells (IL-4 and IL-13) toward infectious challenges. The scheme shown in Fig. 19-3 may help to explain certain derangements found in a number of lung diseases that have excessive or deficient secretion of cytokines and feature changes in the relative proportions of macrophages and lymphocytes. Examples of

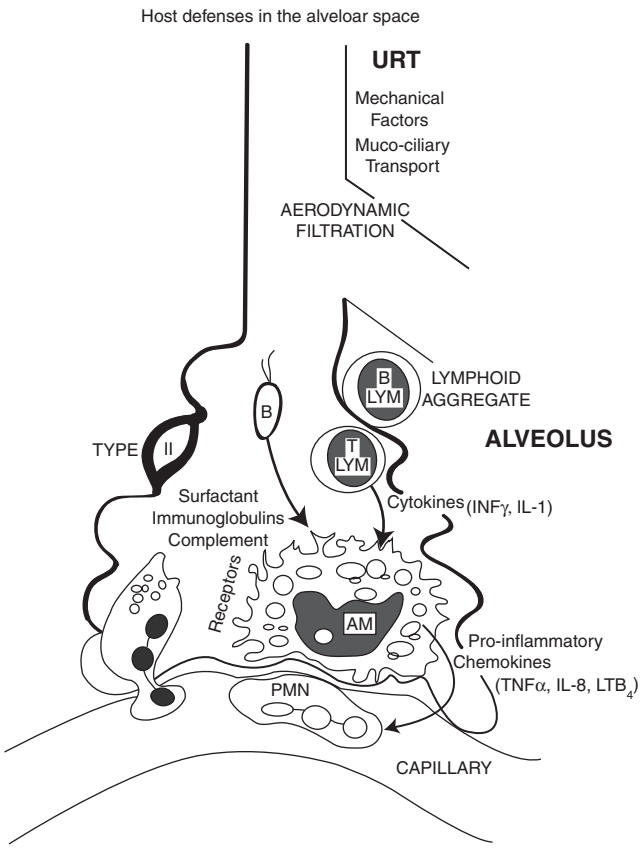

Figure 19-2 Host defenses in the alveolar space. Bacteria (B) that escape clearance mechanisms in the upper respiratory tract (URT) can reach the alveolus (represented by an enlargement of one). Most of the alveolar surface is lined by type I epithelial cells with pulmonary microvillous brush cells interspersed, and type II cells positioned in the corners that secrete surfactant. A variable amount of interstitial space separates the epithelium from the capillary endothelium where sequestered PMNs and platelets reside. A bacterium deposited in an alveolus may encounter at least three different but coordinated sets of innate immunity immunologic materials and cells that can destroy it: opsonins, both IgG and surfactant proteins A and D, or complement factors that facilitate phagocytosis or create a lysis of the microbe; activated macrophages stimulated by cytokines produced by nearby lymphocytes; and other inflammatory phagocytic cells, usually PMNs attracted into the alveolar space by proinflammatory chemokines produced locally by macrophages and epithelial cells. *(Modified from Reynolds HY: Respiratory infections may reflect deficiencies in host defense mechanisms. Dis Mon 31:1–98, 1985, with permission.)*

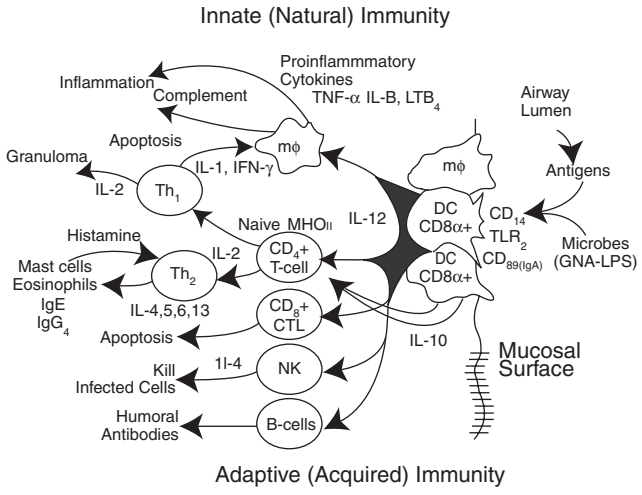

Figure 19-3 Major immunity pathways. Within the body, mucosal surfaces are positioned at initial intake and contact points to ''meet" external substances that enter with inhaled air, ingested food and liquids, or reproductive secretions. Mucosae in the nose, airways, and gastrointestinal and genital tracts must discriminate between pathogens and harmless microbes or possible toxins and essential nutrients, and then respond quickly to exclude, tolerate, or initiate immune responses.

Respiratory host defenses balance two important immune mechanisms created for dealing with airway microbes or other entering antigens: (1) an innate or quick reaction response producing inflammation as an end point (bronchitis or pneumonitis), and (2) a more deliberate approach through stimulation of lymphocytic pathways that creates a versatile and adaptive response involving specific T-cell activity and/or production of immunoglobulins (antibodies). Foreign substances or microbes or their exoproducts (lipopolysaccharide from gram-negative rod bacteria) that enter the airway lumen and adhere to the mucosa will be picked up by macrophages (M) or dendritic cells (DCs). Toll receptor recognition and attachment are important, and dealt with in a variety of ways. Phagocytic uptake and intracellular killing of bacteria might suffice, or recruitment of PMNs may be needed through secretion of proinflammatory cytokines by macrophages, creating pneumonitis for example. Later, active resolution of inflammation requires inhibition of PMN influx (suppress chemotaxis) and cellular cleanup (apoptosis). Alternatively, DCs (or macrophages) can process antigens, present these to major histocompatibility complex (MHC) compatible but naïve CD4+ cells, facilitated with the stimulatory cytokine IL-12; IL-2 produced by CD4+ T cells can direct TH1 lymphocytes to develop and proliferate. In turn, TH1 cells can produce IL-1 and IFN-γ that can stimulate macrophages for the inflammatory pathway, or induce clonal expansion of CD4+ lymphocytes that contribute to building granulomata for containment of certain microbes or particles.

Returning to the DC-antigen–presenting cell process involving the CD4 cells, another subset of DCs (or macrophages) can produce IL-10, an inhibitory cytokine that promotes the TH1 response preferentially in normal subjects and suppresses the TH2 cellular pathway. However, pending the allergic status of the host (atopy) and/or the particular antigen present, TH2 lymphocytes can be stimulated and in turn produce IL-4, 5, 6, and 13 cytokines that culminate in allergy (asthma and allergic rhinitis) with stimulation of mast cells and then eosinophils and production of reaginic antibodies (IgE, IgG 4). The TH2 immune response is also effective against certain parasites. *(From Reynolds HY: Modulating airway defenses against microbes. Curr Opin Pulm Med 8:154–165, 2002.)*

such cellular imbalances include sarcoidosis, hypersensitivity pneumonitis, and acquired immunodeficiency syndrome (AIDS).

DEFECTS IN HOST DEFENSES THAT CAN BE ASSOCIATED WITH RESPIRATORY INFECTIONS

Infection can occur everywhere along the respiratory tract—upper airways (nose, sinuses, ears, and oropharynx), conducting airways (trachea and bronchi down to the respiratory bronchioles), or the alveolar area. Although exposure to a virulent microorganism or to a large inoculum, if inhaled or aspirated into the lungs, may cause illness in a normal person, recurrent or chronic infections may point to deficiency or malfunction of a particular component of the host defense system (Table 19-2). A number of situations associated with frequent respiratory infections serve as examples. Endotracheal tubes give direct access to the lung but, in so doing, bypass the larynx and the other upper-airway protective structures. Patients with depressed consciousness or with postoperative chest or abdominal pain become infected because of their inability to cough and clear airway secretions. In addition, patients with viral infections have an increased incidence of bacterial superinfection. The cause of this association appears to be multifactorial, including the ability of these infectious agents to damage ciliated epithelial cells and diminish the clearance of airway secretions; also viruses and other microbes can infect alveolar macrophages, diminishing their bactericidal activity. In combination, these host defense defects are believed to contribute to the frequent association of influenza infection and staphylococcal superinfection.

Ultrastructural defects in the cilia located on the apical edge of the airway epithelial lining cells cause mucociliary dysfunction. As a result, the removal of mucus and respiratory secretions is depressed, and recurrent infections and bronchiectasis occur. The constellation of multiple upper and lower respiratory infections and bronchiectasis should raise the possibility of a ciliary dyskinesis syndrome. Infertility, especially in males, may be associated, and the evaluation of this problem may bring the respiratory symptoms to the physician's attention. With age, ciliary beat frequency decreases and might be a factor in greater susceptibility to lung infections in the elderly.

A variety of γ-globulin abnormalities are associated with recurrent infection. In patients with hypogammaglobulinemia, the lack of opsonic antibody can promote infections with encapsulated bacteria. Several common bacteria that colonize the airways of patients with chronic bronchitis and chronic obstructive pulmonary disease (*Streptococcus pneumoniae, Haemophilus influenzae,* and *Neisseria*) can also produce a specific IgA protease that cleaves the IgA heavy chain in its hinge region adjacent to the Fc portion. By this mechanism, these bacteria could inactivate a substantial portion

Table 19-2

Pulmonary Host Defenses

Component	Possible Impairment Defect	Related Impact or Infection
Conducting airways		
Mechanical barriers (larynx, etc.)	Bypassing barriers with an endotracheal tube or tracheostomy	Aspiration, direct aerosol of microbes into airway
Mucociliary clearance (cough)	Intrinsic structural defect in cilia; ciliotoxic infections	Stagnant secretions, coughing, bronchiectasis, sinusitis, pneumonitis
Bronchoconstriction and mucosal edema	Hyperactive airways; asthma	Poor removal of secretions; excessive secretions
Local immunoglobulin coating—secretory IgA	IgA deficiency or functional deficiency from breakdown by bacterial IgA1 proteases	Sinopulmonary infections; abnormal colonization with bacteria
Iron-containing proteins (transferrin, lactoferrin)	Iron deficiency	May not inhibit certain bacteria (*Pseudomonas, Legionella*)
Alveolar space		
Other immunoglobulin classes (opsonic IgG)	Acquired hypogammaglobulinemia; selective IgG2 and IgG4 deficiency	Sinopulmonary infections; pneumonia with encapsulated bacteria
Alternative complement pathway activation	C3 and C5 deficiency	Recurrent infection possible
Surfactant (protein)	Decreased synthesis; acute lung injury	Loss of opsonization activity; alveolar collapse (atelectasis)
Alveolar macrophages	Subtle effects from immunosuppression; cannot kill intracellular microbes	Propensity for intracellular microbes and *Legionella* infections; poor containment of *Mycobacteria* spp
Polymorphonuclear granulocytes	Absent because of immunosuppression; intrinsic defects of motility; lack of chemokine stimulus	Poor inflammatory response, associated with gram-negative bacillary infection and fungi (*Aspergillus*)
Augmenting mechanisms		
Initiation of immune responses (humoral antibody and cellular immunity)	Immunosuppression	Inadequate SIgA or IgG antibody available (more susceptible to viral, mycoplasmal, and bacterial infections)
Generation of an inflammatory response (influx of PMN granulocytes, eosinophils, lymphocytes, and fluid components)	Generally reflects status and supply of PMN granulocytes; impaired adherence to endothelium	Inadequate inflammatory response, recurrent infection

Source: Modified from Reynolds HY: Respiratory infections may reflect deficiencies in host defense mechanisms. Dis Mon *31:1–98, 1985.*

of the secretory IgA coating the conducting airways and gain better access to the ciliated epithelial cells for attachment. While this mechanism is somewhat theoretical, associations between deficiencies in IgG and recurrent infection are well documented. Particularly important are the associations between deficiencies of IgG subclasses IgG2 and IgG4, alone and in combination with IgA deficiencies and chronic inflammation and bronchiectasis. Presumably, an absence of these subclasses denies phagocytic cells potential opsonic antibody, thereby diminishing membrane receptor attachment of opsonized particles or bacteria and subsequent phagocyte ingestion. Clinically, establishing the diagnosis of an IgG deficiency is quite important because, in contrast to many other immunodeficiencies, replacement preparations of IgG are often available for these patients.

Cytotoxic antineoplastic chemotherapy and other forms of immunosuppression also compromise host defenses in a major way. A major side effect of these therapies is granulocytopenia, which prevents the mobilization of PMNs and creates a poor inflammatory reaction.

HOST DEFENSES IN THE APPROACH TO PATIENTS WITH PULMONARY DISEASE

As noted above, normal hosts can develop respiratory infections or inflammation as a result of exposure to particularly virulent agents or a large inoculum of aerosolized particulates. In others, respiratory infections are associated with obvious clinical features that compromise pulmonary defenses (Table 19-2). Occasionally, however, the physician is confronted with a relatively young person who has an unexpected number of respiratory problems that seem inappropriate. The illness can manifest as recurrent infection or poorly controlled allergic rhinitis, asthma, frequent sinusitis, recurrent nasal polyps, and/or bouts of otitis media. Because the severity of these respiratory problems may not seem great, the physician may not initially suspect that something unusual is present. The propensity for infection may not have been obvious in childhood but became apparent as the patient reached adolescence or adulthood. Although genetic defects usually are manifested in infancy, minor forms of host deficiency, creating antibody deficiency diseases, may not be recognized until later in life. Cystic fibrosis (adult onset), selective absence of IgG subclass immunoglobulins, structural ciliary defects, and IgA deficiency are the principal diseases that should be considered in this differential diagnosis. Recurrent sinopulmonary infections are an important clue to all these syndromes.

The physician should be prepared to examine such a patient thoroughly. A detailed history will immediately provide important information about affected siblings, infertility, or a striking change in respiratory health that makes an acquired abnormality likely. Preliminary screening tests are a complete blood count and quantitative serum immunoglobulins, and perhaps pulmonary function tests, even if the chest radiograph is normal in appearance; also indicated may be microbial cultures of respiratory secretions and analysis of the electrolytes contained in a sample of sweat or nasal potential difference measurements. Mucoid strains of *Pseudomonas aeruginosa* and elevated sweat chloride values can be noted in cystic fibrosis. Other useful secondary-level screening tests are quantitation of subclasses of IgG; secretory IgA as sampled in parotid fluid or nasal wash samples; subtyping of blood lymphocytes; measurement of antibody responses to protein and/or polysaccharide antigens; search for genetic mutations of the cystic fibrosis transmembrane conductance regulator (CFTR); assessment of ciliary clearance with an aerosolized, isotopic tracer; nasal mucosal biopsy for electron-microscopic ultrastructural analysis of cilia; sperm motility in males of appropriate age; and documentation of bronchiectasis by high-resolution computed tomographic scans of the chest. A thorough evaluation by an otolaryngologist is also often helpful because of the recurrent sinusitis, otitis media, and nasal polyps that might be present.

Alternatively, certain forms of pneumonia point to possible deficiencies in lung cells such as alveolar macrophages, lymphocytes, or PMNs. As opsonization of certain encapsulated bacteria is necessary for optimal phagocytosis by macrophages and PMNs, the lack of appropriate IgG antibodies against pneumococci, *Haemophilus* species, *Klebsiella pneumoniae,* and staphylococci may contribute to infections with these common bacteria. However, other causes of pneumonia may reflect abnormal lymphocyte function and cell-mediated immunity. Infection with *Legionella* bacteria is an example. After an infection with *L. pneumophila,* the host develops specific IgM and IgG serum antibodies. These antibodies, in the presence of complement, do not create a lytic state that is sufficient to kill the bacteria. However, they do behave as opsonins to ensure that the *Legionella* organisms can attach and be ingested by various phagocytic cells, including PMNs, blood monocytes, and alveolar macrophages. Once inside the phagocytes, *Legionella* multiply and eventually can kill and disrupt the host cells. When alveolar macrophages are activated with IFN-γ these stimulated phagocytes will inhibit the growth of the bacteria. This may be the result of the ability of IFN-γ to down-regulate the transferrin receptors on these cells, thereby limiting the accumulation of intracellular iron which is an essential metabolite for *Legionella.* Support for this concept comes from experiments with an experimental *Legionella* pulmonary infection rat model, in which administration of intratracheal IFN-γ reduced intrapulmonary replication of the bacteria, improving host defenses.

Another example of defects at the level of the lymphocyte is AIDS, in which the human host is infected with human immunodeficiency virus (HIV) that destroys CD4 TH lymphocytes. These patients experience recurrent respiratory infections with diverse organisms, including viruses (cytomegalovirus or herpes simplex), *Pneumocystis carinii, Mycobacterium tuberculosis, M. avium-intracellulare,* fungi such as *Cryptococcus* species, and *Toxoplasma gondii* and *Legionella.* These infectious agents have a common feature of residing in macrophages or similar cells as facultative intracellular organisms. One reason why a patient with AIDS has trouble with this group of infections relates to the relative imbalance of lymphocytes found in the alveoli, as sampled by BAL of the lung. Normal values for T lymphocytes have been given in Table 19-1. From subjects with AIDS, the recoverable alveolar lymphocytes reflect a decrease in the CD4 TH cells from HIV infection, offset by an increase in the suppressor-cytotoxic species of T lymphocytes. Although alveolar macrophages normally exist in an environment where they can be activated sufficiently to kill or control microbes of this sort, the CD4 deficiency in lungs of patients with AIDS compromises this activation process. This causes an impressive defect in cell-mediated immunity and the ability of macrophages to contain or kill organisms such as *Pneumocystis* or mycobacterial species.

Lymphocyte- and Macrophage-Mediated Inflammation in the Lung

Frederic F. Little • Kevin C. Wilson • Jeffrey S. Berman • David M. Center

The lung receives a flow of foreign infectious and noninfectious antigens on the tide of airflow. Like the gut, genitourinary tract, and skin, the lung is one of the interfaces of the sterile body with the environment. The lung immune defense system and inflammatory mechanisms are poised to deal with this role. This chapter considers the inflammatory and immune roles of two key cells of hematopoietic origin, the lung lymphocyte and the lung macrophage.

While these two cell types interact extensively and might even be considered codependent in many situations, they represent two very different arms of the inflammatory response. The macrophage, as a phagocytic cell, is of ancient phylogenetic lineage. It is the sentinel of the innate immune system. As such, it is not antigen specific, but it is triggered by many inflammatory stimuli through both specific and pattern recognition receptors. Lymphocytes are present only in vertebrates and represent a significant refinement in the inflammatory response by the ability to recognize specific antigens and discriminate between self and non-self.

Macrophages or macrophage-associated dendritic cells (DCs) are required for optimal presentation of antigens to lymphocytes, and for optimal lymphocyte activation and cytokine production. Conversely, macrophage microbicidal function and release of arachidonate and oxygen metabolites is influenced by cytokines produced by activated T lymphocytes and phagocytosis is markedly enhanced by antibodies produced by B lymphocytes. The cooperation between these two cell types represents a cornerstone of lung defense against noninfectious antigen challenge or microbial infection. Another chapter deals with acute lung inflammation mediated by neutrophilic leukocytes. This chapter presents a brief overview of the macrophage and lymphocytes in the human lung, their function and interactions, and a synthesis of their role in lung inflammation and disease.

We will assume a basic knowledge of immunology. However, an explanation of the terminology used in this chapter is appropriate. Many surface receptors expressed by immunologic cells have had multiple names based on different functions. In the past 30 years these terms have been grouped together in a series of standardized "clusters of differentiation" (CD) for the purpose of standard nomenclature. A list of the CD markers referred to in this chapter, other names used for them, and their putative functions are included in Table 20-1.

Table 20-1

Cluster of Differentiation (CD) Antigens and Surface Molecules

Name/CD Designation	Function
CD1	Accessory molecule for antigen presentation on APCs
Sheep RBC receptor/CD2	Accessory molecule for T lymphocyte activation, adhesion receptor (ligand LFA-3)
T3/CD3	Signaling subunit of TCR
αβ TCR	T cell receptor for antigen
γδ TCR	Alternate form of the T-cell receptor for antigen
CD4	T-cell coreceptor (ligand MHC class II); marker for helper/inducer cells
CD8	T-cell coreceptor (ligand MHC class I); marker for cytotoxic cells
CD11a,b,c	α chains of the β2 integrin; CD11a (LFA-1); CD11b (Mac-1/CR3); CD11c (CR4)
CD14	Macrophage receptor for lipopolysaccharide
CD18	β_2 integrin chain
CD25	p55 IL-2 receptor; T-cell activation antigen (Tac)
HLA-DR	Class II MHC; expressed on APC's; activation antigen for T cells
CD28	Accessory molecule for T-lymphocyte activation (ligands B7-1, B7-2, and CTLA-4)
CD29	Common beta chain of the β_1 integrins
VLA-1-6/CD49a-f	Adhesion molecules; α-chains of the β_1 integrins (ligands ECM proteins)
VLA-4/α4β1 integrin	Adhesion molecule (ligand VCAM expressed on endothelium, fibronectin)
α4β7 integrin	Adhesion molecule (ligand VCAM, fibronectin)
HML-1/αEβ7 integrin	Adhesion molecule (ligand epithelial cell carbohydrate antigen)
ICAM-1/CD54	Cell adhesion molecule for cell-cell interaction (ligand LFA-1/CD11a/CD18)
B7-1, B7-2/CD80	Accessory molecule for T-cell activation; ligand CD28
CD95/Fas	Receptor for Fas ligand, induction of apoptosis
VCAM/CD106	Adhesion molecule expressed on activated endothelium (ligand α4 integrins)
CCR3	Chemokine receptor (CKR) for CCL11/eotaxin
CCR4	CKR for CCL17/TARC (thymus and activation-regulated chemokine)
CCR5	CKR for CCL4
CCR7	CKR for CCL21/SLC (secondary lymphoid-tissue chemokine)/TCA-4 (T-cell activation-4)

Notes: Abbreviations: CD = cluster of differentiation; RBC = red blood cell; TCR = T-cell receptor; VLA = very late activation antigen; LFA = lymphocyte function–associated antigen; APC = antigen presenting cells; MHC = major histocompatibility complex antigen; CR = complement receptor; ECM = extracellular matrix; ICAM = intercellular adhesion molecule; VCAM = vascular cell adhesion molecule; CCR = chemokine CC type receptor; CCL = chemokine CC–type ligand.

LYMPHOCYTES IN THE LUNG

In the normal lung lymphocytes are distributed in one of four compartments (Fig. 20-1). The compartments include lymphocytes at the epithelial surface (LES), including those in the bronchoalveolar space; lymphocytes associated with the epithelium in lymphoid aggregates (also known as bronchus-associated lymphoid tissue; BALT); interstitial and intraepithelial lymphocytes (IL); and an intravascular pool. The presence of BALT in normal human lung is controversial; it is clear that BALT is present in the setting of infection and possibly with chronic airway inflammation. Each compartment has a distinct phenotypic and functional repertoire. It is not yet clear whether there is a sequential influx of lymphocytes from the blood/intravascular pool to interstitium or BALT and finally to the epithelial surface, or whether lymphocytes are destined to reside in one or another of these pools from the time of maturation and/or activation. The absence of afferent lymphatics to the lung dictates that the intravascular pool is the original source of lymphocytes destined to one of the pulmonary compartments. The exact nature of influx and turnover of normal lung lymphocyte populations is not clear; however, the identification of organ and lung specific homing chemotactic cytokines (chemokines) with selective distribution of their cognate receptors raises the possibility that the origins of the populations of each compartment are distinct, and for inter-compartmental trafficking to occur there must be site-specific signals that alter the chemotactic receptor repertoire in situ.

Lymphocytes at the Epithelial Surface

Lymphocytes at the epithelial surface (LES) and intraepithelial lymphocytes are best studied as lymphocytes from the bronchoalveolar space that are easily recovered from the lung using bronchoalveolar lavage (BAL). In normal non-smoking individuals, lymphocytes make up only about 5 to 15 percent of the 10^5 cells found per milliliter of BAL fluid; lymphocyte numbers may increase dramatically during an inflammatory response. LES differ markedly from blood lymphocytes suggesting either a selection bias or organ specific maturation process that occurs between blood and lung (Table 20-2). Approximately 70 percent of LES are T cells; the CD4/CD8 ratio of T cells is approximately the same as in the blood, although with a larger scatter among individuals. Over 70 percent of BAL T cells are of the previously activated memory type as determined by expression of a low molecular weight form of the leukocyte common antigen CD45 (CD45RO); and many have been chronically activated as shown by expression of the $\alpha 1 \beta 1$ integrin. The balance of BAL T-cells are naïve, based on their expression of one of the chemokine receptors CCR7, which identifies cells that have not come into contact with their cognate antigen. LES are more likely than blood T cells to express the activation antigen HLA-DR, and CD8+ (cytotoxic/suppressor) LES are more likely to express

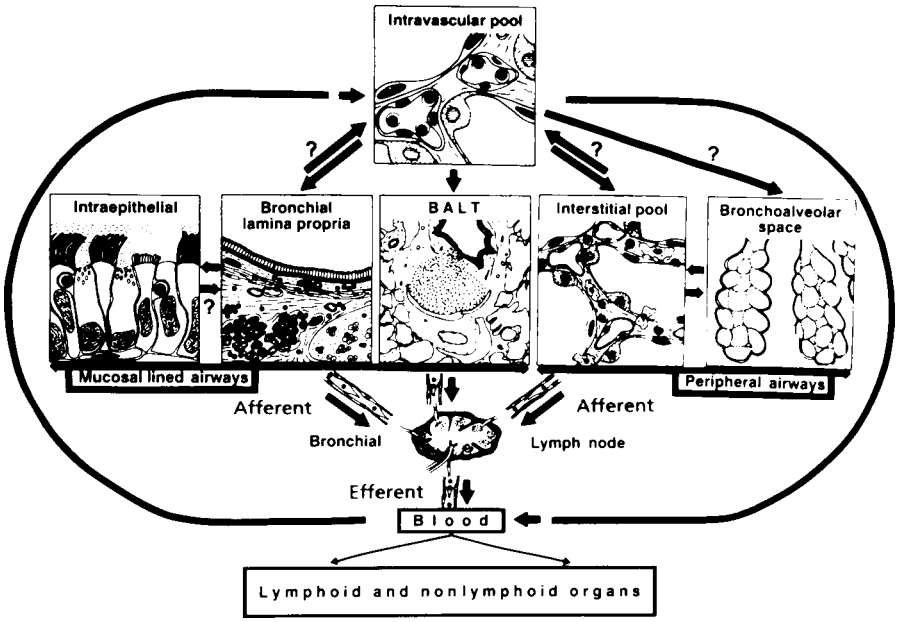

Figure 20-1 Lymphocytes are found in the lung in distinct sites. These include lymphocytes at the epithelial surface (including those at the bronchoalveolar surface); the interstitial and intraepithelial lymphocytes, bronchus-associated lymphoid tissue (BALT), which are centers of airway antibody production; and an intravascular pool. Lymphocytes travel from lymph nodes to blood and into lung via interaction with lung endothelial cells. Hypothesized trafficking from one pulmonary compartment to another is indicated by arrows. Some lymphocytes from these various compartments may be able to exit the lung back to lymph nodes, and others become effete and die. For further explanation see text. *(Reproduced from Pabst R: The immune system of the respiratory tract, in Busse W, Holgate ST (eds), Asthma and Rhinitis. Cambridge, MA, Blackwell Scientific, 1994, pp 415–425, with permission.)*

Table 20-2

Characteristics of Lung Lymphocytes*

Location	Number	Cell Type	Comments
Epithelial surface	10^4/ml BAL; Approx 10^8 total	CD4/CD8 ratio = blood 70% T cells >90% memory cells 40% express $\alpha_E\beta 7$ integrin (70% of CD8+) Memory CTL NK phenotype present, decreased function	Specialized for interaction with epithelial cells. First line of defense?
BALT	? If present in normal human lung	B cells in center T cells scattered in center and surrounding follicle	Local antigen sampling and antibody production
Interstitium	10^7/gm lung tissue Approx 6×10^9 total	CD4/CD8 ratio < blood >90% memory T cells Bulk of NK activity	With intravascular, equal to total blood lymphocyte pool
Intravascular	?Characteristics in human	?	Possible mobilizeable cells poised for lung entry

Note: Abbreviations: ELF = epithelial lining fluid; BAL = bronchoalveolar lavage; CD = cluster of differentiation; CTL = cytotoxic T lymphocyte; BALT = bronchus-associated lymphoid tissue.

**For a review, see Ainslie MP, McNulty CA, Huynh T, et al. Characterisation of adhesion receptors mediating lymphocyte adhesion to bronchial endothelium provides evidence for a distinct lung homing pathway. Thorax 57:1054–1059, 2002.*

markers associated with cytotoxic cell function. An unusual population of memory cytotoxic cells that lack the accessory molecule CD28 has also been described in normal LES. In rodent lung the majority of T cells express the gamma-delta T-cell receptor, and account for up to 20 percent of resident (whole lung) pulmonary T cells in normal mice; a percentage that is markedly upregulated with infection. By contrast, the vast majority of human T cells at the epithelial surface are alpha-beta+. The function of the small population of gamma-delta LES T cells in humans remains unknown, but functional similarities to homologous mouse cells suggest that their primary role is in regulating the primary immune response. There are a variable number of natural killer (NK) (including NK-T) cells in this compartment as might be expected in an area of microbial and antigen assault. However, the bulk of NK activity in the lung is found in the interstitial population. B cells are also present in the LES population derived by BAL. They have been documented to produce antibodies of all types, with their primary role being to provide mucosal immunity through the secretion of IgA. It is unknown whether there are selected B cell populations among LES.

The source and fate of these T and B cells are unknown. It seems reasonable to hypothesize that epithelial surface T cells (and other lung T cells) emerge from the circulation, perhaps proliferate locally and differentiate further while in the lung, and then die or recirculate. Appearance of labeled blood T cells in LES has been documented in animals, as has the reverse. The predominant memory phenotype of epithelial surface and interstitial T cells strongly suggests that such differentiation occurs before entry into the lung.

Many LES adhere to and interact with airway epithelial cells through the expression of a unique adhesion molecule (HML-1/αeβ7 integrin). This integrin is expressed on 40 percent of LES (60 percent of CD8+ cells are HML-1+ while fewer CD4+ cells express it) and on intestinal lymphocytes, but only rarely on blood or lung interstitial lymphocytes. It is likely that local influences, such as epithelial derived cytokines like transforming growth factor beta-1 (TGFβ1), result in the expression of this molecule on LES. Epithelial cells are directly stimulated by bacteria to release specific chemokines and cytokines [e.g., IL-8, MIP2α (CXCL2), MIP3α (CCL20), IL-7, IL-15] depending on the organism and pathogenicity. These ligands can bind surface chemokine and cytokine receptors on adjacent LES, suggesting that these cells are not necessarily effete or dying cells that are present in the airway only to be cleared by the mucociliary escalator and expectorated. Rather, they include a specialized lymphocyte population involved in the surveillance of the airway and interaction with epithelial cells. The possibility that LES reenter the interstitium and lymphoid tissue has been confirmed experimentally in the rat. In addition to their interaction with airway epithelial cells, LES directly interact with mucosal DCs, whose phenotype

directs further T-cell phenotype evolution (see Lymphocyte Activation in the Lung, below).

LES can be stimulated to proliferate, produce cytokines and antibodies, and perform cytolytic functions. However, they are in general hyporeactive in proliferative or antibody responses to antigen or mitogens when compared with blood T cells or even when memory T cells in lung interstitium. The reason for this is not known, but may relate to immunosuppressive influences in the airways, including alveolar macrophages (AM), local production of TGFβ1, the immunosuppressive activity of pulmonary surfactant lipids or proteins, and the possible presence of other immunomodulatory cytokines such as IL-10 and IL-16.

Bronchus Associated Lymphoid Tissue

BALT is the term applied to localized subepithelial collections of lymphocytes in the airways, and is a secondary lymphoid tissue analogous to other types of mucosa-associated lymphoid tissue. BALT is present in normal rodent airway and increases in amount with age. Current evidence suggests these structures are uncommon or absent in adult humans but are present in childhood and may appear and proliferate in response to infection or chronic inflammation. These data suggest that antigen, infection-induced cytokine production, or some other stimulus is required for the development of these lymphoid aggregates in humans, perhaps through the development of "high" venular endothelium (HEV, characteristic of lymphoid tissues) which facilitates lymphocyte exit from the post capillary venule.

BALT is similar to gut associated lymphoid tissue (GALT; e.g., Peyer's patches) in appearance, association with epithelium and a blood vessel; presence of specialized cuboidal or (HEV) characteristic of lymphoid tissues; and a specialized thinned overlying epithelium facilitating antigen entry from the bronchial lumen and exit of lymphocytes and lymphocyte products. Immunohistochemistry has revealed a preponderance of B cells staining with IgM, IgG, and IgA, with a scattering (approximately 20 percent) of T cells, especially CD4+ helper cells within and surrounding the aggregate. BALT lacks organized germinal centers found in other secondary lymphoid tissue. The resemblance of BALT to GALT, as well as the similarity of lymphocyte recirculation patterns from lung and gut associated lymphoid tissue, has suggested to some authors that these structures represent a common mucosal immune system. In this paradigm, recirculating blood lymphocytes exit into these structures, which provide an efficient exposure to antigens sampled from the environment. Activated memory cells are then a source of local antibody production, and they may disperse through the circulation to other mucosal sites to provide dissemination of immunologic memory.

Despite observations that have been made in rodents, several issues continue to limit what we can infer about BALT function in humans: its near absence in normal human airways and limited presence in experimental animals, primarily observed in pathogen-free colonies.

Interstitial Lymphocytes

Lymphocytes are rarely seen in histologic sections of normal human lung, and there are no established techniques to study these cells as an exclusive, pure population. However, several investigators have prepared lymphocytes from human lungs extensively washed to remove airway surface cells using minced tissue and enzymatic digestion. The resulting population of pulmonary infiltrating lymphocytes in normal humans appears to be distinct from lymphocytes recovered from normal BAL. Specifically, approximately 20×10^6 mononuclear cells were found per gram of wet lung tissue; of these 70 percent were lymphocytes, of which 90 percent were CD2+ T lymphocytes. There was enrichment for memory T cells similar to that seen in LES, but the CD4/CD8 ratio among interstitial lymphocyte (IL) T cells was lower than that seen in blood or LES. Memory T lymphocytes from the interstitial compartment can be stimulated to produce cytokines, and proliferate in response to IL-2 despite a decreased proliferative response to mitogens. Most if not all NK activity in the lung has been localized to the interstitial compartment. The exact origin, fate, and function of interstitial lymphocytes are not known.

Intravascular Lymphocytes

The presence of this lymphocyte pool has been convincingly shown in animals, especially the pig. Experimental data include lung perfusion studies showing the continued slow elution of lymphocytes from lung following elimination of red blood cells. The presence of an intravascular lymphocyte pool in humans has not been directly confirmed. However, labeled lymphocytes injected into humans are "held up" in the lung whether injected intravenously or intra-arterially. These data confirm the more recently detected presence of homing receptors on the surface of lymphocytes that match cognate organ specific chemokine expression. Therefore, this phenomenon likely represents margination of lymphocytes in capillaries due to adhesion molecule interactions. Complete phenotypic characterization of this pool in the human is unknown, as is the size and role of this pool in populating interstitial or epithelial lymphocytes.

Lymphocyte Recruitment to the Lung

Lymphocytes are recruited to extravascular sites through a complex process involving adhesion to endothelial cells (EC), release from adhesion, transendothelial migration, interaction with cellular matrix, and response to locally produced chemoattractants. This sequential process is characterized by an initial capture step that is mediated by selectins and integrins, followed by arrest/activation mediated by chemokine and cytokine receptors and other integrins. The role of chemokines has emerged as central to the regulation of tissue-specific lymphocyte homing and retention. These are low-molecular-weight proteins that share a cysteine repeat motif (e.g., C-C or C-X-C), near the N-terminus. As a class, these proteins have cationic charge, and therefore bind

heparin. Chemokine function is mediated through cognate seven transmembrane-spanning receptors. There is significant promiscuity between chemokine receptors and their ligands, such that any specific chemokine may have several ligands and vice versa. Because of their physicochemical properties, the chemokines may bind to heparinlike regions of endothelial cell membrane receptors, preventing dilution of locally produced chemoattractant signal by blood flow and facilitating concentration gradients, a phenomenon known as haptotaxis. The chemokines have been shown to enhance both adhesion to endothelial cells and endothelial transmigration of multiple leukocyte types including T-cell subsets and monocytes. Recently the chemokines have also been found to act as accessory growth factors for T lymphocytes. While CXCL15 (lungkine) appears to be selectively expressed in mouse lung, there does not appear to be a unique human lung specific lymphocyte directed chemokine profile. However, certain chemokines (see below) are preferentially expressed in Th2- and Th1-type immune responses in the lung.

The interaction of adhesion molecules expressed on blood T cells with complementary adhesion molecules on EC is the critical first step to T-cell emigration from the blood. This step is closely regulated at the level of expression of adhesion molecules by T cells at different stages of development, and by transiently increased adhesion molecule function following T-cell activation. Similarly, expression of adhesion molecules by EC may be increased markedly by organ site and location, or proinflammatory cytokines, especially tumor necrosis factor (TNF)-α, IL-1, and interferon-γ (IFN). Treatment of EC with these cytokines markedly alters the adhesiveness of EC for leukocytes, including certain subsets of T cells. The result of such EC activation by local production of cytokines or other factors is that the exit of T cells from the blood is not random, but rather is restricted to sites such as lymphoid tissues, mucosal sites, or tissue sites of inflammation.

The specific events involved in T-cell transendothelial migration have been dissected at the cellular level, while their characterization in human lung is incomplete. T lymphocytes first appear to "roll" along the endothelium, an interaction that requires loose adhesion via T-cell $\alpha 4\beta 1$ integrin/endothelial VCAM-1 and P-selectin/PSGL-1. A signal is required to produce formal "capture" via other integrin molecules, particularly lymphocyte LFA-1 ($\alpha L\beta 2$ integrin) interaction with ICAM-1 or other ligands on endothelium. This latter signal enhances the avidity of integrins for ligand, strengthening adhesion. Other interactions, including decay of integrin affinity, homotypic interaction of T cell and endothelial PECAM (CD31) at endothelial cell junctions, and release of matrix-degrading enzymes, permit release of firm adhesion and T-cell migration into matrix. Preliminary evidence in TH2 cell migration suggests that this step is mediated by T-cell CCR3/endothelial CCL11 and CCR4/CCL17, respectively.

T cells are constantly recirculating from blood to tissue and back, with an average half-life in the blood of only about 18 h. In addition, the sites of migration in vivo appear to be quite different for naïve/virgin cells, as opposed to previously activated memory cells. Due to high level of CCR7 expression, naïve cells preferentially traffic to lymphoid tissue where they are likely to encounter antigen, while memory cells traffic to non-lymphoid tissues such as skin or lung.

The normal lung vasculature may have unique properties that facilitate the retention of circulating lymphocytes. Whether injected intravenously or intra-arterially, labeled lymphocytes are held up in the lung disproportionately in comparison with other organs. Thus, this is not just a "first-pass" clearance effect from capillary passage. Several investigators have found that antibodies to adhesion molecules, particularly lymphocyte function–associated antigen (LFA)-1, decrease lymphocyte retention in the lung. However, capillary size may determine trapping of activated cells since cytoskeletal changes occurring coincident with activation reduce cellular deformability; this has been shown to be a significant force in the lung trapping of activated neutrophils and monocytes. Lymphocytes also become larger, and lose deformability with activation, but the role of this process in lung retention of lymphocytes is not yet defined.

Lymphocyte chemoattractants represent another step in the regulation of the exit of adherent or trapped T cells from the capillary circulation. As noted earlier, varied T-cell chemoattractants have been described that are relevant to the lung, many of which also alter the growth and activation of T cells. A partial listing of known chemoattractants may be found in Table 20-3. In lung diseases multiple T-cell chemoattractants have been found in BAL or tissue specimens, including the chemotactic growth factors IL-2, IL-16, insulin-like growth factor I, the C-X-C chemokine IL-8 (CXCL8), and the C-C chemokines macrophage chemotactic protein (MCP)-1 (CCL2), RANTES (CCL5), and macrophage inflammatory protein (MIP)-1α (CCL3). IL-2 is presumed to be of lymphocyte origin while IGF-1 and IL-16 have multiple potential cellular sources, including T cells, eosinophils, and epithelial cells. The chemokines likewise have multiple cellular origins, including macrophages, endothelial cells, and epithelial cells. It also has been noted that CXCL9, 10, and 11 appear to be important in Th1 responses in the lung, but their expression may relate more to induction by gamma interferon rather than a lung-related phenomenon.

Lymphocyte Function in the Lung

Lymphocytes in the lung serve four major functions: (1) antibody production; (2) cytotoxic activity, including lysis of virally infected cells, cells which have bound antibody, and tumor cells; (3) cytokine production; and (4) immune tolerance. These functions are summarized in Table 20-4.

Antibody production in the lung by B lymphocytes serves to bind antigen and facilitate inactivation of bioactive material and phagocytosis by macrophages. Mucosal IgA is of particular interest in its active transepithelial transport to the bronchial lumen. Antibody production by lung B cells has been extensively studied in mouse lung. Following challenge,

Table 20-3

Lymphocyte Chemoattractants*

Interleukins	**Activation Stimuli**
IL-1	Antibody to T-cell receptor (T cells)
IL-2	Anti-surface immunoglobulin (B cells)
IL-6	Phorbol esters
IL-10	
IL-15	
IL-16	
Chemokine Chemoattractants	**Growth Factors**
CXCL8/IL-8	Insulin
CCL5/RANTES	IGF-1
CCL3/MIP1-α, CCL4/MIP-1β	TGFβ1
CCL2/MCP-1, CCL8/MCP-2, CCL7/MCP-3	
CXCL10/IP-10	
CL11/eotaxin	
Matrix Proteins	**Miscellaneous Chemoattractants**
Laminin	Lysophosphatidylcholine
Fibronectin	fMLP, mycobacterial lipoarabinomannan
Amyloid protein AA	Casein/denatured protein

Note: Abbreviations: IL = interleukin; RANTES = regulated activated normal T cells expressed, secreted; MIP = macrophage inflammatory protein; MCP = monocyte chemotactic peptide; IGF = insulin-like growth factor; TGF = transforming growth factor.

**Not a complete listing. For reviews see Barnes PJ, Cosio MG: Characterization of T lymphocytes in chronic obstructive pulmonary disease.* PLoS Medicine *1:e20, 2004, Kallinich T, Schmidt S, Hamelmann E, et al: Chemokine-receptor expression on T cells in lung compartments of challenged asthmatic patients. Clin Exp Allergy 35:26–33, 2005; Pober JS: Warner-Lambut/Parke-Davis award lecture. Cytokine-mediated activation of vascular endothelium. Physiology and Pathology. Am J Pathol 133:426–433, 1988.*

antigen is removed to regional lymph nodes by motile phagocytic cells (macrophages and DCs) where optimal activation of T and B cells occurs. Activated cells relocate into the circulation and migrate into the lung at areas of inflammation and local antibody production results. Re-challenge with antigen results in a more rapid local response derived from resident memory cells. While the duration of pulmonary memory lymphocytes is unknown, systemic B lymphocytes can persist for over 100 days in the absence of antigen, as is the case with memory CD4+ and CD8+ T cells.

The lung contains multiple types of cytotoxic cells, including NK cells (not antigen restricted), antigen-restricted cytotoxic cells, and cells exhibiting antibody-dependent cytotoxicity. One unusual aspect of lung cytotoxic cells is the preeminence of CD3+ cytotoxic T cells with NK activity (non-antigen receptor-mediated killing of tumor cell targets). This is in contradistinction to the blood, where the majority of cells expressing NK activity are CD3–. NK activity is found in the interstitial compartment of lung T cells; NK cells are phenotypically present among LES, but have been found to be functionally impotent.

Cytokine production by lung helper T cells (TH) has emerged as a major focus of investigation in lung inflammation. In contrast to antibody production by B cells, T cells produce cytokines. A broad range of cytokines have been documented to be produced by lung T cells in inflammatory disease (Table 20-4). In general, the complexion of the inflammatory response correlates with the cytokines produced by T cells, suggesting that T cells orchestrate many inflammatory responses.

Activated T-helper (TH) cells produce a distinct spectrum of cytokines. The repertoire of a single T cell to produce cytokines appears to be limited and stereotyped, depending on the circumstances of activation. According to data accumulated in mice, virgin T cells produce mainly IL-2 in response to activation. After proliferation and switch to memory cell phenotype, T cells produce one of two major clusters of cytokines, either TH1 (interferon gamma, IL-2) or TH2 (IL-4, IL-5, IL-10, IL-13), and share mutually exclusive transcriptional programs, regulated by the transcription factors T-bet and GATA-3, respectively. In humans this distinction between phenotypes has not been as predictable as in the mouse, and IL-10 may be produced by either TH1 or TH2 cells. These two phenotypes roughly conform to polarized expressions of cell-mediated immune responses: granuloma formation with activation of mononuclear phagocytes and production of opsonizing IgG2 antibody (TH1); or optimal antibody response including IgE formation, often with associated eosinophilia (TH2).

Certain immune responses are dominated by either a TH1 or TH2 response, while others are mixed. For example, in human asthma T cells producing TH2, cytokines predominate, but IFN-γ–producing cells are found in the airways suggesting a mixed response. In contrast, granulomas at sites of tuberculin reactions in skin show evidence for production of IFN-γ and IL-2 but not IL-4. In leprosy or leishmaniasis, an ineffective host reaction is associated with a TH2 response, and an effective granulomatous response is associated with a TH1 response; treatment of ineffective responses to leishmania with IFN-γ has been reported to increase the efficacy of chemotherapy. In sarcoidosis, airway and granuloma cells, particularly activated CD4+ (HLA-DR+) T cells, have been found to produce both IL-2 and IFN-γ, suggesting the predominance of a TH1 response. There is considerable cross regulation of TH1 and TH2 subsets even after commitment to production of these cytokines, leading to the general concept that the character of an immune response as well as its termination may depend on the sequential predominance of TH1 or TH2 responses. Indeed, the functional distinction

Table 20-4

Function of Lung Lymphocyte Subpopulations*

Cell Type	Function	Secreted Products
TH1 cell	Antiviral and antifungal defense, granuloma formation, CMI, Graft rejection	IL-2, IFN-γ, IL-3, IL-6, IL-12, IL-16, GM-CSF, TGFβ1
TH2 cell	Allergic inflammation, antiparasite defense	IL-2, IL-4, IL-5, IL-9, IL-10, IL-3, IL-13, IL-16, GM-CSF, TGFβ1
TCTL	Antigen-restricted lysis of viral- or mycobacteria-infected macrophages or epithelia; lysis of fungi, tumor cells	TH1 cytokines, perforin, IL-4
T reg cell (various phenotypes)	Peripheral tolerance Maintenance of immature DC	IL-10, TGF-β1
NK cell	Non-antigen–restricted lysis of tumor cells	IL-2
B cell	Antibody production	IgM, IgG subtypes, IgE, IgA, IL-10

Note: Abbreviations used: TH1 = T-helper type 1; TH2 = T-helper type 2; CTL = cytotoxic T lymphocyte; NK = natural killer cell; IL- = interleukin-; CMI = cell-mediated immunity; GM-CSF = granulocyte-macrophage colony stimulating factor; TGFb1 = transforming growth factor beta 1; DC = dendritic cell.

between TH1 and TH2 cells is less distinct in humans than it is in the mouse.

The role of T cells (and T-regulatory cells in particular) in mediating mucosal tolerance is directly related to their interaction with mucosal DCs. The mechanism of action of Treg cells is incompletely understood and the phenotypic classification of these cells is evolving. The majority of studies examining the regulatory potential of T cells in inflammatory lung disease have been in ex vivo manipulation, depletion, and adoptive transfer experiments in the mouse. The evidence for intraparenchymal (i.e., mucosal or interstitial) Treg cells is not direct, but their requirement for maintenance of peripheral tolerance in the lung and the systemic inducibility of tolerance to inhaled antigen provide the basis for their speculated presence in the epithelium. In addition, intratracheal treatment of mice with the immunomodulatory cytokine IL-16 elicits an expansion of lung CD4+CD25+ T cells.

Lymphocyte Activation in the Lung

T lymphocytes are designed to require specific (antigenic) signals for activation, restricting their involvement in inflammation to situations in which antigen overwhelms the mucociliary escalator and macrophage and neutrophil defenses. Lymphocytes are activated following engagement of an antigen receptor of remarkably fine specificity. This receptor is unique to a given lymphocyte clone, and is generated by recombination of gene segments in the antibody (for B cells) or T-cell receptor genes. B-cell receptors consist of single membrane-spanning antibody molecules of the same specificity as the B cell, whereas T-cell receptors consist of a heterodimeric receptor (dimers of alpha and beta or gamma and delta chains). The T-cell receptor is highly antigen specific and has structural homology to the immunoglobulin molecule. Lymphocytes are activated by cross-linking of membrane antibody by antigen (B cells) or engagement of the antigen receptor by antigen bound to major histocompatibility complex (MHC) molecules on the surface of so-called antigen presenting cells (APC) also known as accessory cells. APC provide many "accessories" for T-cell activation, including: (1) a source of MHC molecules to which antigen can bind; (2) internalization and "processing" of antigen, including protease digestion into antigenic fragments; (3) multiple cell adhesion molecules that bind to complementary adhesion molecules on T cells and serve to strengthen T cell–accessory cell interactions and transduce activation signals required for optimal lymphocyte activation; and (4) production of cytokines that amplify activation, including IL-1.

APC in the lung includes pulmonary macrophages of all varieties; however, DCs and Langerhans' cells are most efficient in this function (see below). These cells express important "accessory" cell adhesion molecules important to accessory cell function, including ICAM-1, LFA-2, LFA-3, and the CD28 ligands B7-1, B7-2, and CTLA-4. Other cells that

may be induced to express Class II MHC molecules may also act as weak accessory cells. Such cells include local B cells, epithelial cells, smooth muscle cells, and fibroblasts. Uncommitted naïve T cells require intense accessory cell interaction in order to be activated by antigen, while previously activated (memory) T cells require less accessory cell input and might be influenced by interaction with such weak accessory cells. Due to naïve CCR7+ T cells' inability to cross post-capillary venules, most lung T cells are memory cells, which suggests that the relatively weak lung accessory cells may indeed play a role in T-cell activation in the lung inflammatory response (Table 20-5).

As discussed earlier, the lung has proved to contain major immunosuppressive elements that may serve to prevent inappropriate or excessive T-cell activation in an area of the body characterized by constant antigen exposure. These influences include surfactant lipids, which have been shown to inhibit T-cell activation, proliferation, and cytokine production; basal production (perhaps by epithelial cells) of the potent immunosuppressive cytokine TGF-β1; and an inhibitory effect of alveolar macrophages. These inhibitory effects may be moderated, reduced, or increased in various disease states. The role of dendritic cell phenotype and degree of maturation in directing activation versus tolerance in T cells is emerging as a key determining step in pulmonary T-cell differentiation. DCs can be broadly described as activating or tolerogenic; this distinction appears to be related to the maturity of the dendritic cell and functionally to the presence of costimulatory molecules on the cell surface (e.g., CD80, CD86, CD40). Typically, DCs process inhaled antigen and migrate to draining lymph nodes to present antigen to naïve T cells. (The role of BALT in this process is unknown, see earlier discussion.) Thereafter, the nature and concentration of processed antigen determines the fate of cognate T-cells: TH1, TH2, or Treg. Presumably, TH cells that have encountered Ag in secondary lymphoid tissue acquire cell surface markers that direct homing and permit post-capillary emigration to lung interstitium and epithelium, either as regulatory or effector cells. There is evidence that the communication between DC and T cells is not exclusively toward T cells; differentiated T cells communicate with local DC via cytokines and cell surface markers to alter DC phenotype. This phenomenon has been described in a mouse diabetes model, and proposed in murine allergic airway inflammation. In light of the emerging central role of DCs in immunologic lung disease and growing knowledge of their plasticity, future directions will likely approach modulating DC phenotype and function as targets for therapy.

Lymphocyte Clearance and Death in the Lung

The means by which lymphocytes exit the lung or are cleared during homeostasis or following an inflammatory response is largely unknown. It is not known how long memory T or B cells reside in the lung in any of the compartments, nor is the extent of lymphocyte exit from the lung via lymph to nodes or to the circulation. However, it is clear from studies in the mouse that programmed cell death, or apoptosis, is involved in the termination of antigen-induced inflammatory responses. In lymphocytes, this energy requiring form of cell death leading to the fragmentation of the nucleus and DNA may result from one of three events: (1) "neglect" or absence of stimulation; (2) stimulation out of context, or without the appropriate second signals (e.g., CD28 or matrix interactions); or (3) signaling via Fas (CD95) engagement with Fas ligand. Such regulation of cell death appears to be critically important for the termination of an immune response once antigen has been cleared, preventing the accumulation of activated lymphocytes.

MACROPHAGES IN THE LUNG

Macrophages reside in many organs. However, they are especially prominent in the lung and perform many functions.

Macrophages ingest inhaled particles or antigens and are then removed on the mucociliary escalator. They also serve as "professional" antigen presenting cells, traveling to regional lymph nodes where they sensitize T and B lymphocytes. Lung macrophages release a variety of cytokines and biologically active arachidonate metabolites that influence the function of nearby cells, including T cells, B cells, endothelial cells, and fibroblasts. Finally, macrophages ingest microorganisms and, when stimulated, kill them using a variety of means, including toxic oxygen metabolites and nitric oxide.

Macrophages or macrophage-like cells are found in several lung compartments, including the epithelial lining fluid, interstitium, epithelium, and intravascular compartment. These cells have varying functional repertoires and are typically categorized as alveolar macrophages, interstitial macrophages, DCs, Langerhans' cells, blood monocytes, or blood macrophages, respectively. Each of these cell types, their recruitment, and their activation will be discussed.

Macrophage Types

Alveolar Macrophages

Derivation of AMs from blood monocytes was initially suggested by an experiment in which the quantity of AM declined 20 to 30 days after bone marrow ablation despite in situ proliferation and increased cell stability. It has since been established that AM derive from blood monocytes and that differentiation is regulated by the tissue microenvironment. The molecular details of differentiation from blood monocyte to AM remain largely unknown.

If quantity implies importance, then one would surmise that AMs play an essential role in the lung's defense against foreign invaders. Found in airspaces throughout the lung, it is estimated that macrophages make up 90 percent of cells found in the alveolar spaces of both smokers and nonsmokers. The absolute quantity of AM, however, is approximately fourfold greater in smokers than nonsmokers. The increased quantity of alveolar macrophages in smokers is likely due to both recruitment of blood monocytes from the bone marrow and their differentiation into alveolar macrophages. In one study, alveolar macrophages were exposed to ambient particles and their supernatant collected. The supernatant promoted transit of monocytes through the bone marrow and their release into the circulation. Analysis of the supernatant revealed large amounts of inflammatory mediators including granulocyte-macrophage colony-stimulating factor (GM-CSF), macrophage colony-stimulating factor (M-CSF), macrophage inflammatory protein (MIP)-1beta (CCL4), monocyte chemotactic protein (MCP)-1 (CCL2), interleukin (IL)-6, and ICAM-1. Many of these mediators are known to increase monocyte turnover in the bone marrow and enhance their recruitment into peripheral tissues.

AMs have a diverse repertoire of functions. Importantly, AMs are the first line of defense against inhaled antigens and pathogens. As such, they have well-developed phagocytic activity that is enhanced when activated by opsonization or inflammatory signals (e.g., IFN-γ). Activated AMs release more inflammatory mediators and have superior microbial killing than their unstimulated counterparts. It is impossible to accurately assess the phagocytic and microbicidal capabilities of AM compared with other lung macrophages because many of the accessible AM may have been depleted of a portion of their functional capabilities due to previous activation. In general, smaller AM are more efficient at phagocytosis and microbial killing than large AM. The smaller AM may represent younger, recently emigrated phagocytes and the larger AM may represent previously activated AM.

AM release a variety of inflammatory mediators including arachidonate products, cytokines, and enzymes (Table 20-6). These mediators impact extracellular matrix, fibrin deposition, and the function of leukocytes and lung cells at sites of inflammation. Many also play key roles in the pathogenesis of lung diseases. As an example, IFN-γ inducible protein 10 (IP-10; CXCL10), monokine induced by IFN-γ (Mig; CXCL9), and IFN-inducible T-cell α chemoattractant (I-TAC; CXCL11) are released by alveolar macrophages and stimulate the release of matrix metalloproteinases −9 and −12 in emphysema.

Table 20-6

Cytokines and Other Bioactive Substances Released from Lung Macrophages*

Arachidonate Metabolites	**Cytokines**	
Thromboxane A_2	IL-1	
PGE_2, D_2, $F_{2\alpha}$	IL-1RA	IL-10
LTB_4	IL-6	IL-12
5-HETE	TNF-α	IL-15
	IFN-α/β	MIF
Reactive Oxygen Metabolites	**Nitric Oxide**	
Superoxide anion (O_2^-)	Constitutive	
H_2O_2	Inducible?	
hydroxyl radical (OH^-)		
Enzymes		
Metalloproteases		
Elastase		
Procoagulant activity		

** Not a complete listing. Abbreviations: Tx = thromboxane; PG = prostaglandin; LT = leukotriene; HETE = hydroxy tetraenoic acid; MIF = macrophage migration inhibitory factor; IL- = interleukin; TNF = tumor necrosis factor; IFN = interferon; MIF = migration inhibition factor.*

Am Rev Respir Dis 139:393–400, 1989; Johnston RB Jr: Current concepts: Immunology. Monocytes and macrophages. N Engl J Med 318:747–752, 1988; Kremlev SG, Umstead TM, Phelps DS: Effects of surfactant protein A and surfactant lipids on lymphocyte proliferation in vitro. Am J Physiol 267:L357–L364, 1994

A wide array of receptors is expressed by AMs, of which most mediate AM activation, migration, or phagocytosis. Perhaps most important are the toll-like receptors that are pattern recognition receptors for microbial cell walls lipids, DNA repeats, and other components of infectious agents. They provide the recognition function of the innate immune system that links to CD14 and subsequent inflammatory cytokine release (e.g., IL-1, IL-6, TNFα secretion). These cytokines are essential in controlling infection with intracellular organisms such as *Mycobacterium tuberculosis*. For example, AMs express toll-like receptor-2, which, when activated, induces killing of intracellular *Mycobacterium tuberculosis*. MARCO is a scavenger receptor expressed by AMs that facilitates phagocytosis of unopsonized particles. In the absence of MARCO, pulmonary infection and inflammation are markedly increased. Other receptors expressed by AMs include chemokine receptors, cytokine receptors, Fc receptors that recognize opsonizing antibodies, complement receptors that facilitate phagocytosis, lectin receptors, bacterial endotoxin (CD14) receptors, and mannose receptors (Table 20-7).

Under certain circumstances, AMs function as antigen-presenting cells and facilitate memory T lymphocyte activation. This ability is enhanced in disease states such as HIV, transplant graft rejection, and sarcoidosis. In alternative situations, AM may impact the immunologic synapse to suppress T-lymphocyte activation. This supposition is corroborated by one animal model in which AM depletion enhanced lymphocyte activation, suggesting that AMs can suppress T-lymphocyte activation in normal lung homeostasis.

Interstitial Macrophages

Interstitial macrophages are a population of macrophages found in the interstitium of the lung instead of the airway lumen. They may be precursors of AMs in transit from the vasculature to the air spaces. Little is known about human interstitial macrophages because they are not readily accessible for study.

Dendritic Cells and Langerhans' Cells

DCs are potent APCs that reside within airway epithelium. Like alveolar macrophages, they likely originate in the bone marrow, travel via the blood (0.5 percent of blood mononuclear cells are DCs), then translocate into tissue. Although chemokines and other factors like IL-16 that are chemotactic for DCs have been identified, the precise stimulus for translocation of lung DCs is unknown. DCs are most numerous in large airway epithelium and decrease in quantity as the airways become smaller. Histologic sections along the long axis of airways have revealed a meshwork of DC processes ideal for antigen sampling and interaction with T cells. A similar meshwork is found in BALT in the mouse. It is unknown whether DCs proliferate in the lung.

DCs are highly mobile and travel from the airway to regional lymph nodes, where they interact with lymphocytes. DCs are tenfold to 100-fold more potent than monocytes at presenting antigens to naïve T lymphocytes. DCs express cell surface proteins that are essential for antigen presentation and lymphocyte activation, including MHC, cell-cell adhesion molecules (e.g., ICAM/CD54, LFA-3/CD58, and β1 and β2 integrins), CD4, and the CD28 ligands. Specialized DCs with distinctive infoldings of the plasma membrane called Langerhans' cells also exist in the lung, especially

Table 20-7

Ligands Recognized by Alveolar Macrophage Receptors*

Immunoglobulins (Fe Receptors)	**Complement Receptors for**
$IgG1$, $IgG2_a$ (murine)	C3b, iC3b, C4b, C3d, C5a
IgG2b, IgG3 (murine)	
IgG1, IgG3 monomers (human)	
IgE, IgA (murine, human)	
Protein, Cytokine, and Matrix Receptors	**Lipoprotein Receptors for**
Fibronectin R	Low-density lipoprotein
Fibrin R	Beta-very-low-density lipoprotein
Lactoferrin R, transferrin R	
GM-CSF R	
IFN-γ R, IL-2 R, IL-4 R, IL-1 R, IL-1RA	
Insulin	
Chemotactic factor receptors	
Other Receptors and Adhesion Molecules	**Lectin Receptors for**
Class II MHC (HLA-DR, -DP, -DQ)	α-Linked galactose residues
CD4	N-acetylgalactosamine residues
β_2 Integrins (CD18; CD11a, b, c)	N-acetyl galactosamine residues
β_1 Integrins (CD29; CD49a,b,c,e,f)	α-Linked fucose residues
CD54 (ICAM-1)	N-acetylneuraminic acid residues
CD14 (lipopolysaccharide receptor)	Mannose residues (mannose receptor)

* *Not a complete listing.*

those of smokers. Like DCs, Langerhans' cells are potent antigen-presenting cells but are less efficient at phagocytosis, microbial killing, and cytokine secretion compared with macrophages.

The importance of DCs to the pathogenesis of lung diseases was highlighted by a murine model in which CD11+ DC depletion during an allergen trial resulted in abrogation of the characteristics of an asthmatic response eosinophilic inflammation, goblet cell hyperplasia, and bronchial reactivity. Their role with T-cell education in the lung was discussed earlier.

Blood Monocytes and Intravascular Macrophages

As discussed above, blood monocytes are likely the precursors of both lung macrophages (alveolar and interstitial) and intravascular macrophages, with differentiation being directed by the microenvironment. This is supported by the observation that blood monocytes can be induced in vitro to express receptors characteristic of AM over a period of days if cultured in the correct microenvironment. The average monocyte spends 1 to 3 days in the circulation and then exits the circulation to differentiate into a macrophage. During inflammation, translocation from blood to tissue increases.

Intravascular macrophages are found within the vasculature of the lung. They are located in postcapillary venules, strongly adherent, and face the flow of blood. Like interstitial macrophages, these cells are not readily accessible and, therefore, are difficult to study. They are presumed to act as intravascular inflammatory sentinels, ingesting antigens and releasing mediators in response to inflammatory stimuli that reach the lung via the blood.

Recruitment of Monocytes and Macrophages

Monocytes are motile cells that adhere to endothelial cells and then migrate with extraordinary efficiency. Monocyte adherence to endothelial cells is promoted by the monocyte "rolling" along vascular walls to increase the likelihood that its β2 integrins (αLβ2, αMβ2, and 4β1) will bind the endothelial cell selectins. Following adhesion, translocation into the lung parenchyma occurs. Once the monocytes have entered the tissue, they differentiate into interstitial macrophages and continue to migrate via their β1 integrins. Both differentiation and migration are influenced by local tissue-specific factors including chemokines, cytokines, matrix components, complement fragments, antigens, and interactions with other cells.

Monocytes respond to a variety of chemotactic influences including complement fragments (e.g., C5a), bacterial peptide f-MLP, leukotriene B4, and the chemokines CCL2, CCL3, CCL4 and CXCL8 (IL-8). The importance of chemokines for monocyte migration is illustrated by a study that investigated the impact of CCR2 (the receptor for CCL2; MCP-1) deletion in a murine model of pulmonary granulomatous inflammation. Following deletion, there was marked decrease in granuloma size and a dramatic decrease in the level of interferon gamma in draining lymph nodes. These findings suggest that CCL2 is vital for monocyte/macrophage migration to sites of inflammation.

Motility of AMs and DCs has also been studied. When labeled DCs and AMs are introduced into the airways, DCs but not AMs are readily found in draining lymph nodes, suggesting that DCs are far more motile than AMs. DC migration is likely chemokine-mediated. In one set of experiments, interleukin-13 (IL-13) and IFNγ were administered intranasally, resulting in increased numbers of DCs accumulating in draining lymph nodes, similar to the experiment previously described. Compared with untreated mice, the treated mice had more expression of chemokines, including CCL5, CCL2, and CCL7 (MCP-3). In addition, chemokine receptor expression was increased including CCR2, CCR5, and CCR10.

Activation of Lung Macrophages

A major feature of tissue macrophages is its ability to be "activated." Activation of macrophages is a key event in the inflammatory cascade in the lung and defines a functional state characterized by extrusion of pseudopodia and an increase in cell size and membrane ruffling. Examples of stimuli that interact with receptors on the macrophage's surface to induce activation include antigen-antibody complexes (via the macrophage's Fc receptors), complement fragments (via the macrophage's complement receptors), and cytokines (e.g., interferon-γ). When activated, macrophage phagocytosis, receptor expression, and production of toxic oxygen metabolites are markedly enhanced. The activated macrophage is a secretory cell, releasing cytokines, toxic oxygen metabolites, and enzymes. Finally, antigen presentation is optimized in activated macrophages but increased expression of class II MHC.

Activated macrophages are prominent in many lung diseases. While it is unclear whether macrophage activation is a cause or result of lung disease, it is probably both. As an example, in emphysema, macrophage activation is initiated by cigarette smoke exposure and results in the release of inflammatory mediators and by products that are toxic to lung parenchyma. These inflammatory mediators, in turn, activate additional macrophages, establishing a vicious cycle of macrophage activation and parenchymal lung destruction.

LYMPHOCYTE-MACROPHAGE INTERACTIONS IN THE LUNG

The interactions between lymphocytes and macrophages, and their effects on lung inflammatory cells and lung inflammation are summarized in Fig. 20-2. Lung macrophages and lymphocytes each perform important functions and influence the differentiation and function of a large variety of cells.

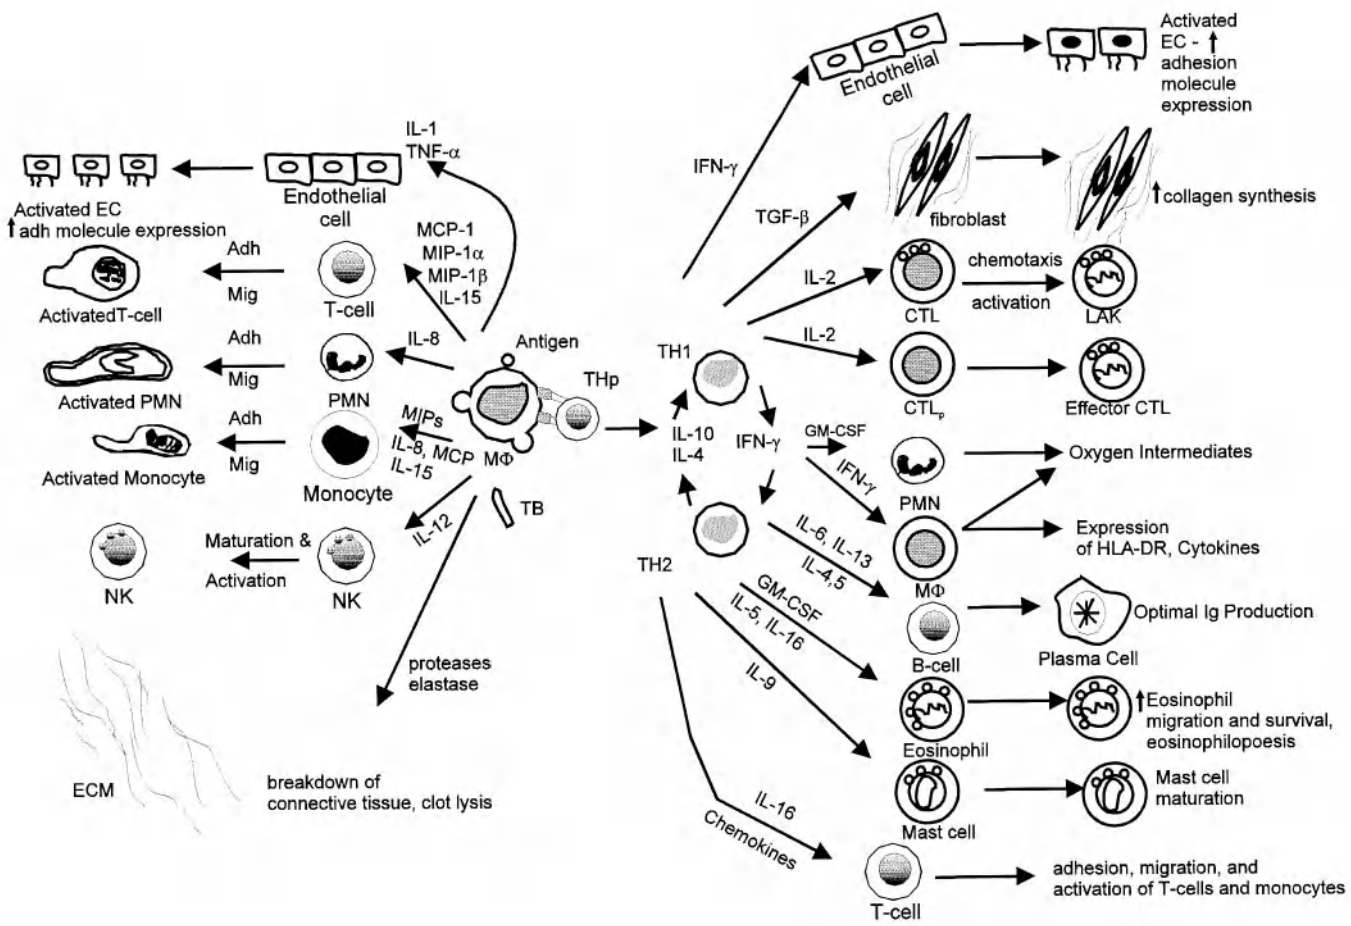

Figure 20-2 Lymphocyte and macrophage interactions in lung inflammation. Lymphocytes and macrophages interact directly and indirectly to influence lung inflammation. These interactions are complex, as illustrated by this diagram, which contains a necessarily incomplete sampling of these processes. Lymphocytes and macrophages interact directly in the process of lymphocyte activation; macrophages also are immunosuppressive in some circumstances. Activated T lymphocytes express a broad range of cytokines that interact with a variety of effector cells; B lymphocytes produce antibodies. T lymphocytes also may interact with infected epithelial or phagocytic cells or with tumor cells to effect cell lysis. Macrophages similarly produce a large number of cytokines that alter the functions of a variety of cells. Macrophages also release arachidonate metabolites, reactive oxygen species, nitric oxides, and a large number of proteases that alter the function of surrounding cells, kill invading microorganisms, and degrade matrix proteins. See text for further explanation. *(Adapted from Agostini C, Chilosi M, Zambello R, et al: Pulmonary immune cells in health and disease: Lymphocytes. Eur Respir J 6:1378–1401, 1993, with permission.)*

Lung macrophages and lymphocytes also interact via direct cell-cell contact during T-cell activation and are greatly codependent.

AM and related cells are the initial sentinels of the innate immune response, phagocytosing and eliminating invading antigens and microbes. After interaction with microbial invaders, and especially in conditions of overwhelming invasion, lung macrophage activation via toll-like receptors and CD14 and other receptors (Table 20-7) results in the release of inflammatory mediators that activate adhesion molecule expression on endothelial cells, and promote the migration and activation of blood leukocytes including polymorphonuclear leukocytes (PMNs), monocytes, lymphocytes, and eosinophils (left half of Fig. 20-2). Rapid induction of selectin molecules stored in Weibel-Palade bodies of endothelium results in the rolling adhesion of neutrophils and monocytes. Migration of these leukocytes may be rapidly modulated by rapid release of arachidonate products such as LTB4, bacterial products themselves such as the peptide f-MLP, complement fragments, and chemokines. More time is required for optimal expression of adhesion molecules that enhance lymphocyte entry, especially VCAM and expression of the chemokine chemoattractant cytokines. One exception is the release within hours of IL-16 from epithelium or resident T cells in response to mast cell–derived histamine.

Interaction of resident or infiltrating T cells with antigen-presenting cells (mainly DC, Langerhans' cells, and

monocytes) results in optimal T-cell activation with resultant production of cytokines that act upon a variety of cytokine-receptor bearing cells (right half of Fig. 20-2). This results in the activation of endothelium, optimal B-cell production of antibody, generation of cytotoxic effector T cells, and (depending on the nature of the cytokines produced) a delayed-type hypersensitivity or granulomatous (TH1-cytokine) or allergic (TH2-cytokine) immune response. Fibrosis or repair also may be influenced by the production of neutral proteases by AM, or the elaboration of the fibrogenic cytokine TGFβ1 by T cells or other cells depending upon the TH skewing. Of particular interest for the future are the ways the lung macrophage–lymphocyte inflammatory access is "turned off." The networks responsible for control of inflammation to prevent lung damage are likely to be as complex as those that initiate the inflammatory responses in infectious and noninfectious lung diseases.

Overall, the mammalian lung is uniquely poised to protect the sterile environment of the lower respiratory tract and its essential gas exchange units through the presence of a complex network of monocyte/macrophage and lymphocytes selectively sequestered in various anatomic compartments. Together they coordinate early innate responses to microbial infection and subsequent specific acquired immune responses (e.g., to viruses) that have evolved to protect the organ. Of particular interest in certain noninfectious or autoimmune lung diseases is the similarity of inflammatory responses to those in response to infections in which the consequences are deleterious rather than beneficial. Thus, understanding ways to control lung innate and acquired immune responses will be essential in developing appropriate therapies for inflammatory lung diseases. Unfortunately, the converse is also true. Individuals treated with antibodies to TNFα to control the inflammation of rheumatoid arthritis or inflammatory bowel disease are at risk for reactivating latent *Mycobacterium tuberculosis* infections, an infectious disease clearly controlled by early innate and late acquired immunity. More detailed understanding of these processes, how to regulate them quantitatively, and how to replace essential elements is clearly needed to adjust the balance in individuals whose immune systems are compromised or in those whose immune systems are overwhelmed by infection or self-antigens.

Mast Cells and Eosinophils

Edward S. Schulman • Peter H. S. Sporn

For more than a century physicians have noted a clear connection between mast cell (MC) activation and the subsequent appearance of eosinophils both within the circulation and in tissues. Only recently, however, have basic insights been gained into the mechanisms of this cellular collusion. In keeping with this association, human mast cells and eosinophils are considered together in this chapter.

Mast cells and eosinophils were discovered in the 1870s by the same observer, Paul Ehrlich. He noted that some cells stained in a peculiar fashion when incubated with standard aniline dyes such as toluidine blue and alcian blue. He used the term *metachromasie* or *metachromasia* to describe the peculiar color modifications that occurred and the term *Mastzellen,* meaning "well fed" or "fattened" in German, to describe what we now call MC. Interestingly, this latter term is now known to be a misnomer, since mast cell cytoplasmic granules are not phagocytosized but rather synthesized during cell growth and again during regranulation. Ehrlich also noted that some cells stained intensely when incubated with the acidic dye eosin. As a result, these cells were called *eosinophils.* Studies of these two cell types, over the ensuing years, have provided great insight into their roles in biology. They have also highlighted the differences that exist in these cells among different species and their heterogeneity even within a single species and even within single organs.

MAST CELLS

The capacity of strategically localized human MC to rapidly release a panoply of powerful chemical mediators makes this cell a unique member of the body's immune response network. Although most frequently discussed in the context of hypersensitivity immune responses, MC are also known to participate in normal physiological processes including gastric acid secretion, angiogenesis, and lipid clearance. Increasing evidence supports a role in the innate immune response, especially serving bacterial defense. Mast cells also participate in nonallergic pathophysiological processes such as inflammatory bowel disease, arthritis, scleroderma, tumors, interstitial pulmonary fibrosis, angiogenesis, and atherosclerosis. Over the years, basophils have been confused with MC in a number of contexts. This confusion is due, in part, to a number of similarities between the cells, including the shared expression of FcRI (high-affinity receptor for Fc fragment of IgE), release of preformed histamine, and metachromatic staining. However, MC are mononuclear cells and are almost exclusively localized to tissues. In contrast, basophils are circulating polymorphonuclear cells that are found occasionally in tissue reactions, including the late-phase allergic response. In addition, significant differences in the two

cell populations exist in cell lineage, ultrastructure, mediator release biochemistry, mediator profiles, pharmacology, and surface antigenicity.

Anatomic Localization

Mast cells are present in all organs but are particularly abundant in the nose, skin, gastrointestinal tract, and lung. They reside primarily near blood vessels, within the adventitia of arteries, and also near lymph vessels and nerves. Estimated concentrations of human lung MC (HLMC) range from 500 to 4000 mm^{-3}. In nonasthmatics, HLMC localize to submucosal connective tissues and not epithelium or smooth muscle. Though data in asthmatics are conflicting as to whether numbers are increased vs. nonasthmatics, MC localize to three critical sites: bronchial epithelium, airway mucous glands, and within smooth muscle. Mediator release from the small numbers of HLMC within the epithelium may subserve initial antigen recognition and also be strategically placed to respond to nonantigenic signals, including hyperosmolarity, as well as "endogenous" mediators, including extracellular adenosine and adenosine 5′ monophosphate (ATP). In the case of aeroallergens, permeabilization resulting from epithelial mast cell mediators enhances further antigen penetration to deeper airway smooth muscles and mucous glands, which in turn, promotes bronchoconstriction and mucous secretion, respectively. The finding of HLMC within the smooth muscle layer appears to be a common finding in asthmatics. It is an uncommon finding in nonasthmatics and in patients with eosinophilic bronchitis. In the lung periphery, abundant MCs reside within small airways and in the alveolar septa, within a few microns of the alveolar lumen. The small numbers of MC in bronchoalveolar lavage (BAL) fluid ($\leq$0.1 percent of all cells) likely result from epithelial shedding.

Origins of Mast Cells

Mast cells are believed to be derived from the multipotential hematopoietic stem cell. Tryptase-negative mast cell–colony-forming cells leave the marrow and circulate with a surface phenotype that is CD (cluster of differentiation) 34+, c-kit (CD117)+, LY−, CD14−, and CD17−. The progenitors home in a tissue-specific manner where they undergo differentiation, maturation, and synthesis of granule proteases in response to microenvironmental factors, including chemokines from fibroblasts, endothelial cells, airway smooth muscle cells, and possibly T cells. The microenvironmental factor most critical in chemotaxis, differentiation, adhesion, proliferation, maturation and survival is stem cell factor (SCF or c-kit ligand), the ligand for the c-kit tyrosine kinase receptor. This receptor is expressed on the MC surface throughout its life span.

Mast Cell Heterogeneity

Striking differences in the morphology, T-cell dependence, resident proteoglycans, and responsiveness to secretagogues and drugs have been described in human MC. The ontogeny of this heterogeneity, as well as the differing roles these MC play in physiology and disease remain speculative.

The most commonly recognized system for classifying human MC is based on the expression of protease profiles as determined by immunohistochemical staining using monoclonal antibodies. According to this system, the serine proteinase tryptase (T) is expressed in virtually all human MC, and a subset, predominantly in the submucosa of the gut and in the skin, also express chymase (C) and multiple other proteases. Those that express tryptase alone are classified as the MC_T type, and those with additional proteases, as the MC_{TC} type. Because significant numbers of both types can be found in the same organ (e.g., lung), tissue location alone cannot dictate the protease type. In the lung, only 8 to 35 percent of MC are MC_{TC}, 1 percent are MC_C, and the remainder are MC_T. The protease system does follow some rules of distribution and function. MC_T are preferentially localized at mucosal surfaces, within airway smooth muscle, in areas of T-cell infiltration and are reduced in immunodeficiency syndromes. The MC_{TC} phenotype does not appear immune related. As detected by immunohistochemical staining, the MC_{TC} subtype more selectively expresses interleukin (IL)-4 (85 percent MC_{TC} vs. 15 percent MCT). IL-5 and IL-6 are almost exclusively restricted to the MCT subtype.

HLMC diameters vary between 8 and 18 μm with the majority being 12 to 15 μm. Histamine contents of 2.5 pg to 10.0 pg/MC vary directly with cell diameter. HLMC densities vary from 1.053 g/ml to 1.123 g/ml with the majority (67 percent) between 1.077 and 1.088 g/ml. These diameter and density-based subtypes also are distinct with respect to mediator content and function. MC location also subserves function: Airway and parenchymal MC differ in their releasibility. At the ultrastructural level, marked heterogeneity has been described (see Morphology). Last, at least two types of proteoglycans are present in HLMC: chondroitin sulfates, predominantly chondroitin sulfate E, and heparin. HLMC are both positive and negative for the heparin-sensitive dye berberine sulfate, whereas stomach MCs synthesize exclusively chondroitin sulfate E and not heparin.

Morphology

All MC are mononuclear cells with heterogeneous cytoplasmic granules (Fig. 21-1). A variety of granule-filling patterns occur within individual cells: scrolls, crystals, particles (the least seen in pure form), and combinations (mixed). The appearance of individual patterns can be influenced by cross section. Granules are outlined by a perigranular membrane. Cell membranes are outlined by short, narrow surface folds.

Morphology of Degranulation and Regranulation

Following IgE-mediated (anaphylactic) activation, granules swell and their perigranular membranes fuse to form canaliculi that open through multiple pores to the cell exterior. Within 20 min of activation, granular matrix materials solubilize within these intracytoplasmic channels and

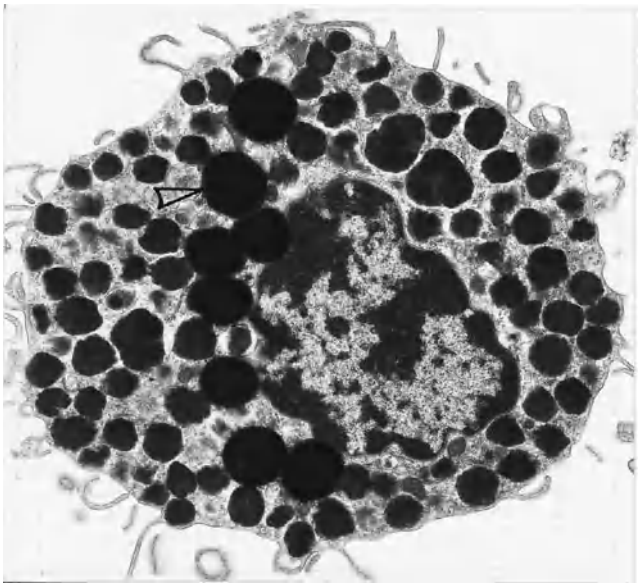

Figure 21-1 Ultrastructure of the human lung mast cell after purification. The mast cell is a mononuclear cell packed with multiple dense cytoplasmic granules that vary in size and shape. Eight electron-dense lipid bodies (open arrow) are bunched near the nucleus (× 15,000). *(Reproduced with permission from Dvorak AM: Recovery of human lung mast cells from anaphylactic degranulation utilizes a mixture of conservation and synthetic mechanisms, in Galli SJ, Austen KF (eds),* Mast Cell and Basophil Differentiation and Function in Health and Disease. *New York, Raven, 1989, p 124.)*

empty. In HLMC, only rarely is extrusion of nonsolubilized granules observed. Lipid bodies, which are electron-dense nonmembrane-bound organelles, remain adjacent to these channels. They appear to serve as repositories of arachidonic acid and occasionally release lipid into the degranulation channels. In vivo, a process termed "piecemeal degranulation" is more frequently observed than anaphylactic degranulation. This process involves the budding of small vesicles from granule membranes and their movement to the cell surface. Piecemeal degranulation may be more typical of the ongoing MC release observed in chronic asthma.

Depending on the extent to which an individual cell has degranulated, one of two predominant types of regranulation are observed individually or in combination. In partially degranulated cells, the channel (formerly perigranular) membranes are reutilized, and regranulation events resemble degranulation in reverse. In cells with more complete degranulation, the channel membranes are placed in continuity with the plasma membrane and externalized. This results in the appearance of elongated, activated cell surface folds. These excessive folds can be internalized or shed. Shedding results in cells that are initially small (7 μm), but then enter a rapidly expanding recovery cycle to produce a fully mature cell.

Activation

Immunological activation of MC is the mechanism most studied. It results from antigen cross-linking of antigen-specific cell surface IgE molecules and subsequent aggregation of the high-affinity receptors (FcεRI) to which they are attached. Receptor dimerization is the minimum cross-linkage requirement for IgE-mediated activation. In vitro, immunological activation can be achieved using antibodies directed against human IgE or the FcεRI-receptor itself. The mechanism(s) involved in chronic HLMC activation characteristic of asthma are not known but likely may reflect low-level allergen activation. Recent evidence contends that monomeric IgE alone, in the absence of antigen, can also induce prolonged mediator release.

Non–IgE-mediated release triggers of MC are also well characterized. In general, the profile of agents that degranulate MC from human intestine and synovium is similar to that of HLMC but different from skin MC. These non–IgE-mediated secretagogues include ionophores, hyperosmolar stimuli, and "histamine-releasing activities" derived from human alveolar macrophages. The purified anaphylatoxin C5a, an active trigger of human basophils and dermal MC, is generally inactive in HLMC, although CD88, the receptor for C5, has been reported in the MC_{TC}. Consistent degranulators of dermal but not HLMC include substance P, morphine, polyamines such as 48/80, and SCF. Even within lung compartments, responsiveness to triggers may vary. Compound 48/80 is reported to degranulate BAL MC, whereas those from lung parenchyma are minimally responsive. To date, neuropeptides have been shown to be inactive in degranulating HLMC. Last, expression in both mouse MC and human progenitor–derived MC of several innate pattern recognition receptors, including the Toll-like receptor-2 (TLR2) and TLR4, has been reported. The expression of TLR and effects on activation of HLMC are as yet poorly defined.

Modulators of Activation

Although not acting as direct release triggers, a number of endogenous chemicals in the MC microenvironment can influence activation. Extracellular ATP and its breakdown product, adenosine, are potent modulators of HLMC degranulation, although neither directly activates HLMC in vitro. In asthmatics, aerosolized adenosine induces bronchoconstriction, an effect not observed in other groups of pulmonary patients or normals. The ability of antihistamines to inhibit this response has directly implicated activation of allergically primed airway MC by adenosine. Components of the local connective tissue matrix such as fibronectin also modulate MC reactivity.

Biochemical Analysis of HLMC Activation

Elegant studies defining the biochemical events following IgE-mediated activation have been performed in rodent MC or cell lines. Evaluations of similarities and differences in HLMC activation await future investigations. Two receptors for IgE have been identified. The high affinity IgE receptor (FcεRI) on MC and basophils is expressed in a tetrameric form ($\alpha\beta\gamma 2$) and on antigen presenting cells is present in a trimeric form ($\alpha\gamma 2$). The Fc fragment of IgE binds to the α-chain of FcεRI. Expression of the β-chain amplifies signaling. A low-affinity

IgE receptor (FcεRII; CD23) is present on B cells but not on MC or basophils. Serum IgE levels correlate with basophil expression of FcεRI, likely indicating a role for IgE in stabilizing the FcεRI on the cell surface. As noted above, receptor dimerization is the minimum cross-linkage requirement for antigen-mediated allergen activation through the FcεRI. Following receptor aggregation, multiple signal transduction pathways are activated. Since FcεRI possesses no inherent tyrosine kinase activity, critical to the sequential activation are two tyrosine kinases, lyn which is associated with the β chain and syk. Lyn binds to the β chain associated immunoreceptor tyrosine-based activation motifs (ITAMs), which are phosphorylated after FcεRI aggregation. For degranulation to proceed, syk then binds to the γ-chains–linked ITAM, which are also phosphorylated after receptor aggregation. The lyn-syk driven pathway directly or indirectly stimulates tyrosine phosphorylation of several adapter proteins, including the transmembrane adaptor molecule linker for activation of T cells (LAT) among others. Also activated are phospholipase C-γ1 and PLC-γ2. In this context, at 2 minutes following FceRI aggregation, extracellular calcium influx occurs, which is a prerequisite for degranulation to proceed over the next 5 to 20 min. Other "early-phase" granule-associated and lipid mediators (e.g., arachidonate metabolites) are also released over 20 min. Over the ensuing 1 to 24 h, mRNAs for select cytokines are generated followed by their protein synthesis and release.

Chemical Mediators

The clinical expression of MC–mediated responses may reflect the individual mediators or in certain instances, the interplay of the multiple mediators these cells release (Table 21-1). The temporal sequence of their release appears critical to the development of both the early and late phase responses after antigen challenge (Fig. 21-2). Certain mediators are virtually unique to MC (e.g., tryptase, chymase, heparin), and others are shared with one or more other cells (e.g., histamine, leukotriene (LT) C_4, and IL-5).

Mediators released within minutes after activation are divided into preformed, or secretory, granule-associated mediators (e.g., histamine) and non-preformed, or newly synthesized mediators (e.g., lipids). It is now known that tumor necrosis factor alpha (TNFα) may be both preformed and newly synthesized. Other cytokine mediators, including IL-5 and IL-13, are only detected over hours and may be critical to the evolution of the "late-phase" response.

Table 21-1

Human Mast Cell and Eosinophil Mediators

	Mast Cells	Eosinophils
Granule-associated (performed) mediators	Histamine Heparin Chondroitin-sulfate E TNFα	MBP ECP EDN EPO CLC protein
Enzymes	Tryptase Chymase Cathepsin-G Elastase Carboxypeptidase-A	EPO CLC protein Collagenase MMP-9 Indoleamine 2,3-dioxygenase
Acid hydrolases	β-hexosaminidase β-glucuronidase Arylsulfatase	β-glucuronidase Arylsulfatase B
Lipid mediators (nonpreformed)	PGD_2 LTC_4 LTB_4 PAF Thromboxane-A_2	LTC_4 15-HETE 5-oxo-ETE PAF
Cytokines	IL-4, IL-5, IL-13 IL-6, IL-8 TNFα TGF-β bFGF	IL-1α, IL-2, IL-3, IL-4, IL-5, IL-6, IL-8, IL-10, IL-12, IL-13, IL-16, IL-17 GM-CSF TNFα TGF-α TGF-β SCF NGF PDGF VEGF
Chemokines		RANTES MIP-1α MCP-4 Eotaxin
Reactive oxygen products	None detected	$O2^-$, H_2O_2, OH· HOBr, HOCI

Preformed Mediators

Histamine

Histamine measurements have served as a classic marker of MC-mediated events. The pleiotrophic effects of histamine are mediated through the differential expression, regulation, and distinct intracellular signals evoked by four distinct receptors, H1, H2, H3, and H4. The actual role of histamine in asthma remains less clear, although levels in bronchoalveolar lavage fluid are many-fold higher in asthmatics, and plasma levels rise three- to fivefold following airway antigen challenge. Most histamine-induced allergic repiratory reactions are mediated via the H1 histamine receptor subclass, producing enhancement of vascular permeability, mucous production, initiation of neurogenic reflexes, and bronchial smooth muscle contraction. The reasons for the marginal value of the H1 receptor-blocking drugs in asthma may be due to high local tissue concentrations of histamine that exceed the inhibitory capacity of these agents and/or the redundancy of histamine actions with the multiple other mediators that are released.

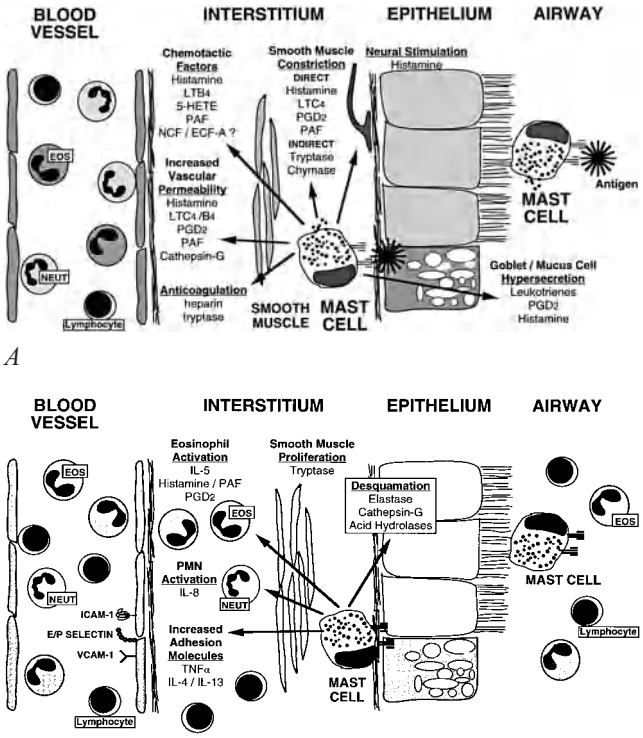

Figure 21-2 Effects of mast cell mediators in the early- and late-phase responses following airway allergen challenge. *A.* Early phase: Mediators are released within minutes following antigen cross-linking of allergen-specific IgE on the cell surface. Mechanisms of the initial airflow obstruction that persists for 30 to 60 min include smooth muscle constriction, edema formation due to increased vascular permeability, nerve stimulation, and mucus hypersecretion from both goblet cells and submucosal glands. *B.* Late phase. Within hours, the effects of newly synthesized and released cytokine mediators along with delayed effects of early-phase mediators produce recurrent airway obstruction. Mast cell mediators and cytokines can increase the expression of adhesion molecules on endothelial cells, both recruit and activate leukocytes (particularly eosinophils), contribute to epithelial desquamation, and stimulate smooth muscle proliferation.

Proteoglycans

Mast cell proteoglycans serve as the major determinant for the metachromatic tinctorial properties of the cell and form the granule backbone to which other preformed mediators, including histamine and neutral proteases, are bound. HLMC synthesize heparin and chondroitin sulfate E proteoglycans in roughly a 2:1 ratio. In humans, heparin appears to be unique to MC. In addition to anticoagulant activity, heparin possesses both anti-inflammatory and immunoregulatory properties. Heparin may limit allergic responses in the skin, nose and lung and exert protective effects on exercise-induced asthma. The inhibitory effects may be related to the extracellular binding and inhibition of multiple mediators, including histamine and cytokines.

Chemotactic Factors

Within hours of MC activation, airway inflammation (the late-phase response) at the tissue level is characterized by the infiltration of leukocytes. This response is principally eosinophilic but also contains neutrophils and, over time, lymphocytes. Chemotactic mediators may be derived directly from MC and/or other cells through secondary stimulation. Early-phase MC-derived eosinophilic chemotactic activities include leukotriene B_4 (LTB_4), platelet activating factor, and histamine. HLMC robustly express IL-8, which along with LTB4, attracts neutrophils. A high-molecular-weight (750 kDa) chemotactic factor for neutrophils (NCF-A) can measured in the blood of sensitive asthmatics following antigen, may actually represent a small MC-derived lipid (e.g., LTB_4) bound to a high-molecular-weight carrier. Mast cells are responsive to chemokines released from other cells. Airway smooth muscle secretes a number of chemotactic factors including CXCL9, -10 and -11 that can serve as ligands for CXCR3 expressed by HLMC.

Proteases

Large quantities of neutral proteases are contained within MC and constitute the predominant protein component of the secretory granule. The proteases include tryptase, chymase, cathepsin-G, carboxypeptidase A, and elastase.

Tryptase is the predominant neutral protease of the MC granule. It is a tetramer that is stabilized by its association with proteoglycan. The concentration of tryptase in pulmonary MC is 11 pg/MC. Since the concentrations of tryptase in circulating basophils (α tryptase, see below) are negligible, responses characterized by the presence of histamine but not tryptase at the reaction site or in the circulation implicate mediation by basophils and not MC. Two forms of tryptase (α and β) have been identified. The α tryptase is constitutively secreted in an inactive form and reflects systemic MC burden. The active β form is packaged in the secretory granule and acutely rises in anaphylactic reactions. Postulated roles for tryptase in pathophysiology remain to be established. Described actions include the degradation of the neuropeptide vasoactive intestinal peptide (VIP), mitogenic effects on smooth muscle and epithelial cells, and inactivation of procoagulant proteins.

Chymase is associated with heparin in a manner similar to tryptase. The role of chymase in asthma and other disorders is not clearly defined. Chymase may play a role in tissue remodeling. Substrates include angiotensin I, converting it to the angiotensin II, VIP (inactivates), substance P, bradykinin, and kallidin (inactivates). Other activities include activation of matrix metalloprotease and stimulation of tissue neutrophilia and eosinophilia.

Cathepsin G is a neutral protease with chymotryptic specificities. The concentration of cathepsin-G in HLMC is roughly 100 to 700 ng/10^6 cells. An elastase released from HLMC appears to be identical to human neutrophil elastase. A measurement of 40 to 170 ng/106 cells assumes all HLMC contain this enzyme, although it may be localized to a HLMC subset. Among carboxypeptidases, the MC carboxypeptidase A, a metalloexopeptidase, is unique. Granule-associated acid hydrolases include β-hexosaminidase, β-glucuronidase, and arylsulfatase.

Nonpreformed Mediators

Arachidonic acid metabolites are generated within minutes of MC activation and play a crucial role in the early phases of the asthmatic response. Cyclooxygenase metabolism in MC generates large quantities of prostaglandin (PG) D_2 and a small quantity of thromboxane A_2. PGD_2 is the most potent bronchoconstrictor of the cyclooxygenase metabolites. Additional actions of PGD2 include induction of chemotaxis in eosinophils, basophils, and TH2 cells; increase in capillary permeability and vasodilation. Although all tissue MC generate PGD2, not all generate significant quantities of 5-lipoxygenase products (e.g., lung > skin). The major 5-lipoxygenase pathway products of HLMC are LTC_4, and LTB_4, with lesser quantities of 5-HETE. In IgE-mediated human lung challenges, MCs constitute the major source of released LTC_4.

Platelet activating factor *(PAF)* is an early phase phospholipid bronchoconstrictor that consists of a family of molecules. In contrast to the other lipid mediators, MCs appear to retain PAF intracellularly or demonstrate rapid reuptake of any that may be released.

HLMC synthesize and release TH2-type cytokines, including IL-5, and -13, which are felt to be central to the evolution of the late-phase response. Additional multifunctional cytokines, including IL-3, -6, -8, transforming growth factor beta (TGFβ), basic fibroblast growth factor (bFGF) and TNFα, are also synthesized by HLMC. In general, cytokine protein products are released over a 1- to 24-h period following allergic activation. Interleukin-4, a cytokine that virtually defines TH2 immunity, is immunolocalized to HLMC, which are rich in surface IL-4 receptors. However, generation of IL-4 mRNA and protein release has been reported by some, but not all, investigators. TNFα, stored preformed within MC granules is in a unique position to exert diverse host defense effects in allergy and innate immunity. Recent studies suggest that increased expression of TNFα within HLMC may play a role in asthmatic airway inflammation and correlates with asthma severity.

Amphiregulin, a member of the epidermal growth factor family, is secreted following FcεRI-mediated activation. Its effects include increasing mucin gene expression, which may contribute to the epithelial cell metaplasia and mucous hypersecretion of asthma.

Pharmacologic Modulation of Mast Cell Function

Only a limited number of pharmacologic agents have been tested in vitro on HLMC activation-secretion. In general, these agents have been tested on human parenchymal MC rather than those in bronchi or resident in BAL. The common classes of antiallergic and/or antiasthmatic drugs used in clinical practice have received most evaluation. To date, the β-agonist pharmacologic agents, as typified by fenoterol and salmeterol, are reported to be among the most potent global inhibitors of HLMC mediator release with concentrations that inhibit histamine release by 50 percent (IC_{50}) of $\leq 10^{-8}$M. Less effective inhibitors include the theophylline-like phosphodiesterase inhibitor isobutylmethylxanthine ($IC_{50} = 0.5$ mM) and PGE_2 ($IC_{50} = 10^{-5}$M). Although widely touted as "MC stabilizers," disodium cromoglycate and nedocromil sodium poorly inhibit purified HLMC histamine release. Inhibition of BAL MC activation by these agents is reportedly more striking.

The effects of glucocorticosteroids on MC are diverse, including both stimulatory and inhibitory effects on the transcription of select genes. Release of early-phase mediators (e.g., histamine, LTC_4) in vitro and acute airway responses in vivo are unaffected by short pretreatment (up to 24 h) with these drugs. In contrast, IgE-mediated generation of TH2-type late-phase cytokine mRNA and protein (e.g., IL-5, -13) are suppressed ($IC_{50} = 10^{-8}$ to 10^{-9}M).

FK-506, a macrolide that binds to a specific binding protein, inhibits HLMC mediator release at low concentrations (0.1 to 300 nM). Cyclosporin A, which binds to cyclophilin, and auranofin, an orally absorbable gold compound, both inhibit HLMC mediator release.

Specific inhibitors of leukotriene generation include direct 5-lipoxygenase enzyme inhibitors, such as A-60477 (Zileuton), and indirect inhibitors, such as MK-886, which bind to a protein termed *5-lipoxygenase activating protein* (FLAP). Interestingly, PGD_2 release is markedly enhanced by FLAP inhibiton. This phenomenon has been termed a *reverse shunt effect.* Generally, 5-lipoxygenase pathway inhibitors do not affect HLMC histamine release. Cyclooxygenase-1 inhibition plays a critical role in a certain subset of "aspirin-sensitive" asthmatic patients (see below). Agents such as indomethacin potently inhibit HLMC PGD_2 generation ($IC_{50} = 5.5 \times 10^{-10}$M) while producing significant enhancement of LTC_4 release.

Mast Cells in Pulmonary Disease

Mast cells have been implicated in a variety of pulmonary disorders based, to a great extent, on their presence in increased numbers and/or percentages in diseased tissues and the recovery of increased concentrations of MC-derived mediators, particularly histamine, in BAL fluid. Implicated pulmonary disorders include asthma, idiopathic pulmonary fibrosis, sarcoidosis, extrinsic allergic alveolitis, and chronic bronchitis.

Asthma

At baseline, even very mild asthmatics show evidence of MC degranulation in bronchial mucosa and increased histamine content in BAL. Analysis of BAL in allergen-challenged atopic subjects and asthmatics demonstrates increased release of histamine, tryptase, and PGD_2. Increased numbers of lumenal MC are also noted and correlate with mediator content, airflow obstruction, and bronchial hyperresponsiveness. In general, asthmatic MCs exhibit ultrastructural evidence of degranulation. In nonfatal asthma, there is a significant increase of MC within airway smooth muscle and mucosal gland stroma. Multiple redundant MC mediators likely contribute

to increased mucous gland secretion and smooth muscle constriction. Following chronic corticosteroid treatment, allergic reactions are diminished in association with depletion of MC in both the epithelium and submucosa.

Although much attention has been given to IgE-mediated mechanisms of asthmatic airway activation, it is likely that multiple other MC-triggering mechanisms operate under a variety of immunologic and environmental conditions. One mechanism proposed for exercise-induced asthma (EIA) relates to airway cooling and the generation of hyperosmolarity on the airway surface leading to MC degranulation.

Up to 10 to 20 percent of asthmatics are intolerant of aspirin and other nonstructurally related nonsteroidal anti-inflammatory drugs (NSAIDs). The potential role for MC in this disorder remains controversial. Support for MC involvement includes the demonstration of a neutrophil chemotactic activity following challenge and that indomethacin pretreatment of human airway tissues results in increased LTC_4 generation following IgE-mediated stimulation.

Fibrosis

The cellular composition of diffuse fibrotic reactions includes striking increases in MC numbers. Mast cells synthesize and release important mediators of fibrosis, including TGFβ and hFGF. The hypothesis that MC and their mediators are critical to the development of fibrotic reactions is supported by animal models in which MC hyperplasia has been a constant finding in pulmonary fibrosis induced by bleomycin, ionizing radiation, and asbestos. Bronchial remodeling with subepithelial fibrosis is also a prominent feature of the asthmatic airway. It is not clear whether MC proliferation and activation drive and/or are secondary to the fibrotic process. The latter mechanism could be effected through fibroblast generation of SCF, producing MC proliferation, chemotaxis, and inhibition of apoptosis.

EOSINOPHILS

While eosinophils are considered leukocytes, in actuality, like MC, they reside primarily in the tissues. Indeed, the ratio of tissue to blood eosinophils is estimated to be 100:1 or greater. Under normal circumstances, the major resident population of eosinophils is in the lamina propria of the gastrointestinal tract. Eosinophils are also present in the thymus, as well as the uterus and developing mammary gland in females. In the absence of disease, very few eosinophils are found in the lung. On the other hand, large numbers of eosinophils traffic to the lungs and other tissues in the setting of allergic diseases, helminthic parasite infections and certain other pathological states.

Eosinophil Development

Eosinophils develop in the bone marrow from hematopoietic stem cell precursors. The immediate eosinophil precursor is a common eosinophil-basophil progenitor. Specific differentiation to the eosinophil lineage involves coordinated expression of the transcription factors, GATA-1, PU.1, and C/EBP. Among these, GATA-1 plays a central role, since GATA-1–deficient mice completely lack eosinophils, without loss of other hematopoietic lineages. The cytokines, interleukin-3 (IL-3), granulocyte-macrophage/colony-stimulating factor (GM-CSF) and interleukin-5 (IL-5) stimulate growth and differentiation of eosinophils in the bone marrow. IL-5, the only one of these that is eosinophil-specific, plays an essential role in stimulating bone marrow production of eosinophils and triggering their release into the circulation. IL-5 is produced by lymphocytes and endothelial cells in the bone marrow, as well as by lymphocytes and parenchymal cells in the lung and other tissues. The importance of IL-5 in eosinophil production is demonstrated by the fact that transgenic mice overexpressing IL-5 develop profound blood and tissue eosinophilia. On the other hand, IL-5 knockout mice have markedly reduced numbers of eosinophils at baseline, and fail to develop eosinophilia in response to allergen sensitization and challenge. These and other findings provided the impetus for development of therapeutic anti-IL-5 monoclonal antibodies, which have been studied in asthma, as discussed below.

Morphology and Structure

The mature human eosinophil has a diameter of 12 to 17 μm, slightly larger than the neutrophil. The nucleus is usually bilobed, and the cytoplasm contains characteristic granules that stain yellow-pink with eosin. The distinctive features of eosinophil granules can be seen clearly by electron microscopy (Fig. 21-3). Primary granules, which appear during the promyelocytic stage of development, are round, membrane-limited structures that contain Charcot-Leyden crystal (CLC) protein. Secondary or specific granules appear later during eosinophil differentiation. These are more numerous and appear as oval or elongated membrane-bound structures with a dense crystalline core and less dense matrix. The secondary granule core contains major basic protein, while other granule proteins are in the matrix. Lipid bodies are non–membrane-bound, lipid-rich organelles that localize arachidonic acid-metabolizing enzymes and serve as sites of eicosanoid synthesis.

Granule Proteins

Eosinophils contain a number of cationic granule proteins that have toxic effects on parasitic helminths and RNA viruses, as well as on host cells. In addition, a variety of other proteins, including enzymes and cytokines, are stored in and released from eosinophil granules. Major basic protein (MBP), a highly basic protein that accounts for more than half of eosinophil granule protein mass, is found in the crystalline core of specific granules. MBP is synthesized as a preproprotein, which is cleaved to a 13.8-kD highly cationic molecule during eosinophil maturation. The pro-peptide, which is

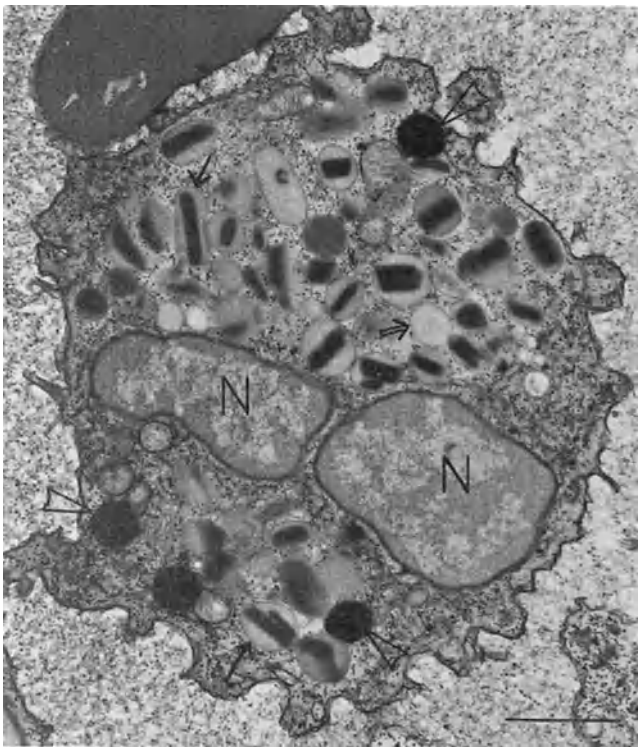

Figure 21-3 Ultrastructure of a mature human blood eosinophil. The bilobed nucleus (N), specific granules (closed arrows), primary granules (open arrow), lipid bodies (open arrowheads), mitochondria, and irregular surface processes are seen. Dark cytoplasmic particles represent glycogen. *(Reproduced with permission from Dvorak AM, Ackerman SJ, Weller PF: Subcellular morphology and biochemistry of eosinophils, in Harris JR (ed),* Blood Cell Biochemistry 2, Megakaryocytes, Platelets, Macrophages, and Eosinophils. *New York, Plenum Press, 1991, p 239.)*

anionic, is thought to protect the developing eosinophil from the toxic effects of the highly cationic mature MBP. Low levels of MBP are expressed in basophils, consistent with their close lineage relationship to eosinophils. MBP is directly toxic to larvae of *Schistosoma mansoni*, *Trichinella spiralis*, and other helminths, supporting a role in host defense against parasites. Several lines of evidence have suggested that MBP could be an important mediator of asthma. MBP inhibits ciliary function and is toxic to bronchial epithelial cells. When administered to the airways of monkeys, MBP caused transient bronchoconstriction followed by persistent bronchial hyperresponsiveness. In addition, MBP was shown to bind to and inhibit M2 muscarinic receptors, increasing vagally mediated bronchoconstriction in guinea pigs. Despite these observations, a critical role for MBP in asthma pathophysiology was thrown into doubt by a recent report that mice deficient in MPB showed no attenuation of airway histopathological changes or airway hyperreactivity in an allergen-induced asthma model.

Eosinophil cationic protein (ECP) and eosinophil-derived neurotoxin (EDN) are both highly basic proteins found in the matrix of specific granules. ECP and EDN are homologous proteins (67 percent amino acid sequence identity), the result of gene duplication, that are also similar to human pancreatic ribonuclease (RNase) A. Indeed, both ECP and EDN are active RNases, with the ability to inactivate RNA viruses, such as respiratory syncytial virus (RSV). EDN was initially described as a neurotoxin that causes severe damage to myelinated neurons, a property possessed by ECP, as well. This activity may account for the neurological abnormalities seen in patients with hypereosinophilic syndrome and CSF eosinophilia. Like MBP, ECP and EDN are both helminthotoxic. Levels of ECP are elevated in blood, bronchoalveolar lavage fluid, and sputum in patients with asthma, and have been found to correlate with disease activity. For this reason, ECP levels in blood or sputum are often monitored in asthma clinical trials as a means of assessing response to treatment.

Eosinophil peroxidase (EPO) is another highly basic protein found in the matrix of specific granules. EPO is a unique peroxidase, expressed only in eosinophils. In the presence of H_2O_2, EPO oxidizes halide ions to form highly reactive hypohalous acids. Bromide is the preferred substrate, leading to hypobromous acid (HOBr), an extremely potent oxidant that damages DNA and other critical cellular targets. EPO plus H_2O_2 and halide ions can kill multiple parasites, bacteria, mycobacteria, and also MC and tumor cells. The potential role of EPO in asthma has been explored in mice with targeted deletion of the EPO gene. In this study, despite a marked reduction in bromo-oxidation of lung proteins, EPO deficiency did not result in any attenuation of allergen-induced airway inflammation or bronchial hyper-responsiveness.

CLC protein localizes to the primary eosinophil granule, and is also expressed in basophils. CLC protein belongs to the galactose-binding lectin family (galectins). Also known as galectin-10, CLC protein avidly binds the sugar mannose. CLC protein also possesses weak lysophospholipase activity. Thus, it may protect cells from potentially toxic lysophospholipids generated at sites of inflammation, or it may degrade surfactant lysophosholipids and contribute to atelectasis. The true role of CLC protein remains to be determined.

Eosinophils also contain within their granules various other enzymes, including β-glucuronidase, arylsulfatase B, and matrix metalloproteinase-9 (MMP-9), as well as preformed cytokines and chemokines, that all can be released in regulated fashion, as discussed further below.

Chemical Mediators

Lipid Mediators

Upon stimulation, eosinophils produce large quantities of the 5-lipoxygenase–derived eicosanoid, LTC_4. Synthesis of LTC_4 in eosinophils occurs in cytoplasmic lipid bodies and at the nuclear membrane. Following secretion, LTC_4 is converted extracellularly to LTD_4 and LTE_4. These cysteinyl leukotrienes act through $cysLT_1$ and $cysLT_2$ receptors to cause bronchoconstriction, stimulate mucus secretion, promote synthesis of Th2 cytokines, and contribute to airway remodeling. The ability to block these effects underlies the beneficial actions of cysLT receptor antagonists and leukotriene synthesis

inhibitors in asthma. Other biologically active lipids produced in substantial quantities by eosinophils include 15-HETE, 5-oxo-ETE, and platelet-activating factor (PAF). However, the roles of these products in asthma and other eosinophil-associated diseases remain unclear.

Cytokines and Chemokines

Classically, eosinophils were considered as terminal effector cells of inflammatory responses, acting by secretion of granule proteins and the acute release of other mediators. More recently, however, it has been recognized that eosinophils synthesize an array of cytokines and chemokines, equipping them to participate in immunoregulation. The major cytokines and chemokines known to be expressed in eosinophils are listed in Table 21-1. Interestingly, a number of these factors have autocrine or paracrine effects on eosinophils themselves. For instance, IL-3, GM-CSF, and IL-5, which may be produced by various cells in the lung and other tissues, and by eosinophils themselves, inhibit apoptosis and enhance eosinophil survival. In another example, IL-16, a product of eosinophils and other cells, triggers rapid eosinophil release of RANTES, which generates autocrine signals that augment release of LTC_4 and IL-4. A number of cytokines and chemokines synthesized eosinophils are stored within granules. When cells are stimulated, these preformed cytokines are released by a regulated process involving piecemeal degranulation, which is described further below.

Eosinophil-derived cytokines likely contribute to regulation of inflammatory responses in eosinophil-associated diseases and may drive specific pathophysiological responses. For example, elaboration of Th2 cytokines would be expected to amplify allergic responses, and may be important in host defense against parasites and in pulmonary fibrosis. TGF-α released by eosinophils is a potent stimulus for synthesis of mucins by airway epithelial cells, which contributes to asthma and other eosinophilic airway diseases. Also, there is accumulating evidence linking eosinophil-derived TGF-β with airway remodeling in asthma and with pulmonary fibrosis. However, a clearer understanding of the roles of eosinophil cytokines in human diseases must await clinical studies with pharmacologic agents designed to target specific cytokines or cytokine receptors.

Reactive Oxygen Metabolites

Like neutrophils, eosinophils synthesize superoxide anion (O_2^-) and H_2O_2 through the action of NADPH oxidase. Notably, NADPH oxidase components are more highly expressed and more readily activated in eosinophils than neutrophils, endowing stimulated eosinophils with a greater capacity to produce O_2^- and H_2O_2. As discussed previously, eosinophils produce HOBr through the action of EPO on bromide and H_2O_2. In a reaction involving HOCl and O_2^-, EPO also catalyzes formation of hydroxyl radical ($OH^\cdot$), the most reactive of all oxygen metabolites. As noted, EPO-derived oxidants kill parasites and other microorganisms, and thus may be important for host defense. By contrast, EPO appears not to play a key role in allergic airway disease in mice. The importance of eosinophil-derived oxidants in human health and disease is at present uncertain, and requires further study.

Eosinophil Recruitment

Current knowledge about the mechanisms of eosinophil recruitment into tissues is based largely on studies of asthma and allergic diseases, but these mechanisms may operate in other eosinophilic disorders as well. The initial step in eosinophil recruitment involves *priming*, which converts the resting cell to an adhesive, migratory and activation-sensitive phenotype. Priming likely results from exposure to IL-3, IL-5, and GM-CSF in the circulation, particularly in allergic individuals, in whom these cytokines are elevated. TNF-α and eotaxin may prime eosinophils as well. Once primed, eosinophils make contact with the blood vessel wall and undergo *rolling*, mediated by E- and P-selectins on endothelial cells, which can be up-regulated by IL-1 and TNF-α, and L-selectin that is constitutively expressed on the eosinophil. Rolling can activate eosinophil integrins, which mediate tight adhesion through high-affinity binding to endothelial cell adhesion molecules. The eosinophil integrins, VLA-4 (α4β1 or CD49d/CD29) and CD11b/CD18, and their respective endothelial counterligands VCAM-1 and ICAM-1, comprise the most important binding pairs responsible for firm adhesion to the vessel wall. IL-4 and IL-13 increase VCAM-1 expression on endothelial cells. Since its binding partner, VLA-4, is expressed on eosinophils, but not neutrophils, this represents a mechanism for selective eosinophil recruitment to sites of allergic inflammation. Integrin-mediated firm adhesion is followed by diapedesis, or transmigration across the endothelium. Eosinophils are further activated by endothelial transmigration, which also increases their ability to survive. Based on in vitro studies, eosinophils can probably survive in tissues for 2 weeks or longer.

Upon entering tissue, eosinophils shift from β_1- to β_2-integrin–dominated interactions under the influence of chemokines such as eotaxin-2, and migrate along chemoattractant gradients. Multiple factors are known to be chemotactic for eosinophils, including PAF, LTB_4, complement factors C3a and C5a, GM-CSF, IL-3, IL-5, IL-16, and the chemokines RANTES, MIP-1α, MCP-3, IL-8, eotaxin, eotaxin-2, and eotaxin-3. Among these, IL-5 and the eotaxins are the most highly selective for eosinophils. For this reason, they have been considered as potential therapeutic targets, and clinical trials of monoclonal antibodies directed against IL-5 in patients with asthma have recently been reported. The results of these studies are discussed below.

Eosinophil Activation and Degranulation

The priming process required for eosinophil recruitment also represents the initial phase of eosinophil activation. IL-5 is probably the most important cytokine for priming of eosinophils in vivo. IL-5 binds to heterodimeric receptors on the eosinophil surface, consisting of a ligand-specific α

chain and common β chain that is also used in the receptors for IL-3 and GM-CSF. Binding of IL-5 to its receptor triggers a variety of intracellular signaling cascades, which enhance multiple eosinophil functions, including the response to chemotactic factors, integrin-mediated adhesion, agonist-stimulated LTC_4 and superoxide generation, phagocytosis, and helminthotoxic activity. IL-3 and GM-CSF are capable of enhancing these functions, as well. As noted earlier, IL-5, IL-3, and GM-CSF also enhance eosinophil survival. The effects of all three cytokines are antagonized by glucocorticoids, which also induce eosinophil apoptosis. Other factors that have been shown to prime eosinophils include TNF-α, nucleotides such as ATP, and chemokines such as eotaxin and RANTES.

Priming of eosinophils in the circulation is enhanced in patients with asthma and hypereosinophilic states, resulting in greater functional responses when blood eosinophils from such individuals are studied in vitro, in comparison to cells from normal controls. In vivo priming has also been demonstrated in eosinophils obtained by bronchoalveolar lavage following antigen instillation into the lungs of allergic subjects (segmental allergen challenge).

Eosinophils express a panoply of surface receptors that can mediate cell activation. These include receptors for immunoglobulins (IgA, IgG, and IgE), complement components (C3a and C5a), eicosanoids (LTB_4, cysteinyl leukotrienes, and PGD_2) and PAF, and numerous cytokines and chemokines. Priming can up-regulate cell surface expression of specific receptors, and may induce new expression of receptors not normally present on resting eosinophils, e.g., the high-affinity IgE receptor FcεRII (CD23). Ligand binding to many of these receptors triggers responses that include degranulation, lipid mediator synthesis, and generation of reactive oxygen species. Various ligands activate distinct signaling cascades within the cell, resulting in stimulus-specific differential activation of eosinophil effector functions.

As in MC, the principal mode by which granule-associated proteins are released from human eosinophils is piecemeal degranulation. This process involves secretion of specific granule contents in discrete packets, without granule-to-granule or granule-to-plasma membrane fusion. An eosinophil undergoing piecemeal degranulation in vitro is illustrated in Fig. 21-4. Electron microscopic studies reveal that piecemeal degranulation is associated with the development of complex vesiculotubular networks within emptying granules. Recent data indicate that intracellular cytokine receptors within granules and secretory vesicles play a key role in transporting and guiding selective secretion of their cognate cytokines. Regulation of these events also involves SNARE family transport docking and vesicle fusion proteins. These mechanisms allow for stimulus-specific, selective, and sequential release of cationic granule proteins, such as MBP and multiple stored cytokines and chemokines.

Besides piecemeal degranulation, the secretion of whole granules, referred to as compound exocytosis, has been described. This process also involves SNARE docking and fusion proteins. Finally, cytolytic degranulation is a term used to account for the presence of cell-free eosinophil granules seen in tissue in certain eosinophilic diseases. Whether this is a regulated process or the result of eosinophil necrosis at sites of inflammation is not known.

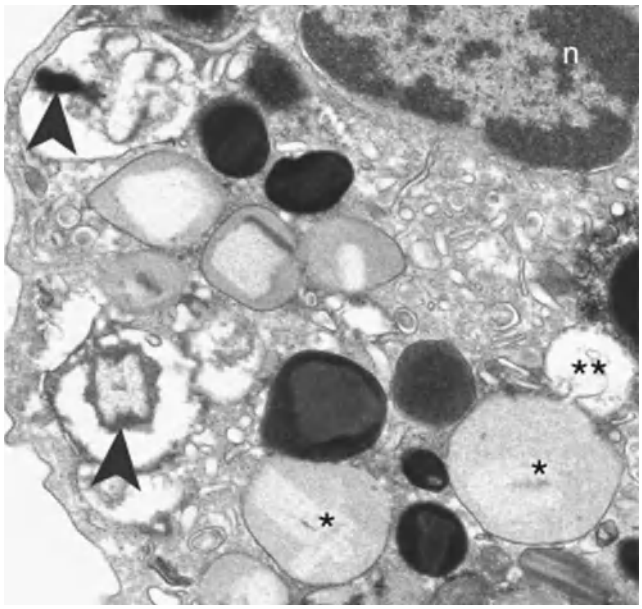

Figure 21-4 Ultrastructure of a human blood eosinophil activated in vitro with eotaxin. Specific granules undergoing piecemeal degranulation exhibit lucent areas in their cores, matrices, or both. Granules with residual cores (arrowheads), reduced internal electron density (*) and membrane empty chambers (**) are shown. *(Reproduced with permission from Melo RCN, Perez SAC, Spencer LA, et al.: Intragranular vesiculotubular compartments are involved in piecemeal degranulation by activated human eosinophils. Traffic 6:866-879, 2005.)*

Mast Cell--Eosinophil Interactions

Since shortly after their discovery, it has been recognized that MC and eosinophils home to many of the same tissues, particularly in the setting of allergic and other inflammatory conditions. Not surprisingly, therefore, researchers have identified a variety of cooperative interactions between the two cell types. For example, the eosinophil granule proteins MBP and ECP can trigger histamine, PGD_2, and cytokine release from human MC. Eosinophils also produce important MC survival and activation factors, such as SCF and nerve growth factor (NGF). Conversely, MC-derived TNF-α induces eosinophil GM-CSF release and autocrine survival enhancement, while MC tryptase induces eosinophil IL-6 and IL-8 secretion. Also, the MC mediators histamine and PGD_2 have been shown to augment synthesis of LTC_4 in human eosinophils. Not all MC-eosinophil interactions are proinflammatory, however, as it has recently been reported that MC tryptase can cleave and inactivate the eosinophil chemokines eotaxin and RANTES. Thus, MC and eosinophils communicate bidirectionally in complex ways that may amplify or potentially modulate the inflammatory response.

Eosinophils and Host Defense

Many years ago, histopathological evidence of eosinophils surrounding dying helminths in tissue biopsy specimens led to the hypothesis that eosinophils play a role in the immune response to multicellular parasites. Subsequently, it was demonstrated that, in the presence of antibodies or complement, eosinophils can kill parasites in vitro, as can purified eosinophil granule proteins. Further support of a role for eosinophils in host defense against helminths came from epidemiological studies that correlated high eosinophil counts with resistance to post-treatment reinfection with *Schistosoma* spp. in humans. Moreover, some recent studies of experimental helminth infections in mice depleted of eosinophils by IL-5 neutralization or gene targeting have indicated that IL-5 and eosinophils are important for protective immunity against a variety of parasites, although the results are not all consistent. Other recent studies of mice deficient in eotaxin or CCR3 (the receptor for eotaxin and related chemokines) have also demonstrated that eosinophils are important for clearance of parasites in vivo. Thus, while some uncertainty remains, substantial evidence supports the concept that eosinophils have a role in protective immunity against helminths and participate in their elimination.

As noted earlier, human ECP and EDN are both RNases, and can inactivate RSV in vitro. Mouse eosinophils also express RNases with the ability to inactivate murine pneumonia virus, a major pathogen in rodents that is closely related to RSV. These observations suggest a role for eosinophils in defense against infection with RNA viruses. In vivo viral infection studies utilizing animals in which eosinophils are pharmacologically or genetically manipulated are needed to further our understanding of this important area.

Recent investigations have demonstrated that eosinophils can process antigen, express major histocompatibility complex II (MHC-II) and co-stimulatory molecules, and function as antigen-presenting cells. Eosinophils within the airway lumen can migrate to regional lymph nodes where they stimulate antigen-specific T-cell proliferation. In addition, eosinophils metabolize tryptophan via the enzyme indoleamine 2,3-dioxygenase to kynurenines, which contribute to Th2 skewing of immune responses by promoting selective apoptosis of Th1 cells. The degree to which these eosinophil immunoregulatory functions contribute to host defense and allergic or hypersensitivity responses is currently unknown.

Eosinophil–Disease Associations

Peripheral blood eosinophilia and eosinophilic lung inflammation are common in a variety of pulmonary conditions, including those listed in Table 21-2. The clinical manifestations and treatment of these disorders are discussed in detail elsewhere in this textbook.

Among eosinophilic lung diseases, asthma is by far the most common and most well studied. Over the years, much evidence has accumulated supporting a key role for eosinophils in asthma pathogenesis. This includes findings that eosinophils and their specific products (e.g., ECP) increase in the airway lumen and airway wall during spontaneous exacerbations and following experimental allergen challenge. Sputum eosinophil numbers and ECP levels also correlate with asthma severity. Eosinophil mediators, including MBP and other granule proteins, induce characteristic features of asthma, such as epithelial damage and bronchial hyperreactivity. When asthma improves, either spontaneously or in response to treatment, eosinophils and their products decline. Corticosteroids, the most effective therapy for asthma, have potent anti-eosinophil effects. Finally, a treatment strategy directed specifically at reducing sputum eosinophils resulted in significantly better asthma control than treatment based on standard asthma guidelines. Despite this large body of evidence, the importance of eosinophils was thrown into question by the finding that treatment of mild asthmatics with an anti–IL-5 monoclonal antibody reduced blood and sputum eosinophils markedly, but did not alter bronchial hyperresponsiveness. However, it was subsequently shown that the anti–IL-5 monoclonal antibody used only depleted eosinophils in bronchial tissue by about 50 percent, indicating that neutralization of IL-5 alone may be insufficient to eliminate eosinophils from the airway. This notwithstanding, the IL-5 antibody did reduce deposition of extracellular matrix proteins in the airways, confirming both a role for eosinophils in airway remodeling and a therapeutic benefit of anti-IL-5 treatment in asthma. Additional new evidence supporting a critical role for eosinophils in allergic airway disease comes from animal studies in which the eosinophil lineage was selectively eliminated using two different genetic strategies. These important studies showed

Table 21-2

Eosinophilic Lung Diseases
Asthma
Allergic bronchopulmonary aspergillosis/mycosis
Allergic angiitis and granulomatosis (Churg-Strauss syndrome)
Simple pulmonary eosinophilia
Chronic eosinophilic pneumonia
Acute eosinophilic pneumonia
Helminthic infections
Drug hypersensitivity reactions
Hypereosinophilic syndrome

that eosinophils were required for airway mucus accumulation, bronchial hyperreactivity, and peribronchiolar collagen deposition in an allergen-induced asthma model in the mouse.

Hypereosinophilic syndrome (HES) is a rare disorder characterized by persistent blood eosinophilia (>1500/μl for at least 6 months) and eosinophil-induced organ damage or dysfunction, without evidence for other known eosinophilic disorders. Pulmonary involvement is seen in 50 percent of cases. Corticosteroids are the first line of treatment for HES. A subset of HES patients bears a fusion gene, *FIP1L1-PGDFRA*, which produces a constitutively active tyrosine kinase that drives eosinophil hyperproliferation. The tyrosine kinase inhibitor, imatinib mesylate (Gleevec®), is useful in treatment of these patients. Others with HES have been reported to respond to anti–IL-5 monoclonal antibodies.

In addition to the disorders listed in Table 21-2, eosinophils may play a role in the pathogenesis of several pulmonary diseases not normally thought of as eosinophilic in origin. Among these is idiopathic pulmonary fibrosis, in which elevated numbers of eosinophils in BAL fluid have been associated with a poor prognosis. This is consistent with in vitro and animal data demonstrating the ability of eosinophils to promote tissue fibrosis. Another example is cystic fibrosis, in which increased levels of cationic eosinophil granule proteins correlate with worse pulmonary function, presumably due to toxic effects of these proteins on lung cells.

Pharmacologic Modulation of Eosinophils

Corticosteroids have been the mainstay of pharmacotherapy for eosinophilic disorders for many years. Corticosteroids induce apoptosis of eosinophils, both directly and by inhibiting formation of the pro-survival cytokines, IL-5, IL-3, and GM-CSF. This leads to rapid reductions of circulating and tissue eosinophils and clinical improvement in the majority of treated patients. Leukotriene receptor antagonists and the anti-IgE monoclonal antibody omalizumab are two other classes of drugs used to treat asthma and allergic diseases that have been shown to reduce circulating eosinophil counts and cause eosinophil apoptosis. Of course, none of the foregoing classes of drugs are specific for eosinophils, so the degree to which their anti-eosinophil activities contribute to their beneficial effects is uncertain. Specific anti-eosinophil therapeutics, such as the anti-IL-5 monoclonal antibodies discussed above, remain investigational at the time of this writing. Other specifically eosinophil-directed agents in development include monoclonal antibodies and small molecule inhibitors of the integrin VLA-4, the selectins, and the chemokine receptor CCR3.

Antibody-Mediated Lung Defenses and Humoral Immunodeficiency

David N. Weissman • Kenneth S. Landreth • Nevin W. Wilson

Immunoglobulin (Ig) plays a key role in both respiratory tract host defense and the pathogenesis of respiratory disease. These unique protein products of B lymphocytes are composed of a highly variable amino acid sequence at the amino terminal end of the molecule that conforms to a broad array of antigens; and a highly conserved carboxy terminus that interacts with other components of the immune system to effect antigen clearance from the body. For that reason, appropriate Ig responses participate in clearance of antigens from the lung and minimize injury responses that are caused by antigen deposition in that tissue. In contrast, inadequate, or inappropriate, Ig responses can allow or even cause life-threatening lung injury. This chapter reviews the development of B cells, which are the cells with the unique capacity to produce antibody; how antibody responses to antigen are generated; some of the physical and functional characteristics of Ig; unique features of pulmonary antibody immunity; and humoral immunodeficiency syndromes relevant to the lung.

OVERVIEW OF B LYMPHOCYTE BIOLOGY

Definition of Antibody

Ig is a member of the Ig superfamily of adhesive proteins. Ig heavy-chain and light-chain genes are present in all cells; however, Ig genes are only expressed in B cells, because only in B cells do the genes undergo a series of structural rearrangements that permit expression of their gene products. B lymphocytes express Ig both as integral cell membrane receptors and as secreted proteins. Production and secretion of Ig by B cells in response to antigen is the hallmark of a humoral immune response. Antibodies are Ig that bind specifically

to stimulating antigen. In vivo antibody production normally results from the combined activation of a number of B-lymphocyte clones that respond and produce antibodies to different antigenic determinants, or epitopes, on the same antigen.

Development of B Lymphocytes in the Bone Marrow

B lymphocytes, like all other circulating leukocytes, derive from a pool of blood-forming stem cells in hematopoietic tissues. Embryonically, committed hematopoietic progenitor cells destined to give rise to B lymphocytes are first detectable at 9 weeks of gestation in the developing liver of humans, deriving from stem cells that first appear in the periaortic splanchnopleure surrounding the heart. B-lymphocyte progenitor cells undergo a temporal migration and subsequently appear in the developing spleen and bone marrow. B-lymphocyte production in postnatal humans resides in the bone marrow and requires continual renewal from hematopoietic stem cells throughout life to maintain immunocompetence. In the marrow, the tempo of B-lymphocyte production is regulated by cytokines produced by hemopoietic stromal cells and extramedullary cytokines that circulate through the marrow spaces. B-cell precursors are retained in the bone marrow in part via the CXCR4 chemokine receptor and the chemokine CXCL12.

The steps involved in the differentiation and commitment of stem cells to form B lymphocytes can be characterized based on the progressive rearrangements of immunoglobulin genes and associated expression of immunoglobulin molecules that occur. Immunoglobulin molecules expressed after differentiation of B cells are made up of two identical protein heavy chains and two identical protein light chains (Igκ or Igλ) that are encoded by separable gene families. Immunoglobulin heavy-chain genes reside on chromosome 14 and immunoglobulin light chains are derived from either the Igκ-locus on chromosome 2 or the Igλ locus on chromosome 22. The unique expression of either κ or λ gene products by an individual B lymphocyte is genetically regulated and known as light chain isotype allelic exclusion.

The initial stages of differentiation of B lymphocytes occur independently of antigen in the bone marrow (Table 22-1). Ig heavy-chain and Ig light-chain transcription in B lymphocytes requires somatic recombination and repair of the germline genetic material that encodes immunoglobulin prior to protein transcription. The variable domain of the heavy chain is encoded in three sets of genes, the variable (V), diversity (D), and junctional (J) genes, which must be physically rearranged to result in expression of Ig heavy-chain protein. Similarly, the variable region of the Ig light-chain protein is encoded in two sets of genes, the V and J genes, which are likewise rearranged to allow transcription of functional

protein. The rearrangement of DNA to join V, D, and J heavy-chain exons and V and J light-chain genes (or exons) also results in elimination of unused V, D, and J sequences and noncoding stretches of DNA or introns. The many possible variable regions resulting from these random rearrangements confer a broad range of potential antigen specificities to the mature Ig molecules. Additional diversity results from introduction of additional nucleotides (P and N nucleotides) at the junctions between gene segments during the process of recombination.

Ig V-region genes are located 5′ of constant regions. After successful recombination, rearranged VDJ or VJ variable regions are transcribed in a unit that also includes the constant region of Ig. The constant regions on the nucleotide sequence remain separated from VDJ and VJ segments in the primary transcript of RNA and formation of a mature mRNA transcript requires removal of this noncoding RNA by post-transcriptional RNA processing in the cell. Newly formed B cells are capable of expressing mature mRNA transcripts for both IgM and IgD. This is accomplished by producing a single primary RNA transcript containing both μ and δ constant regions. This initial primary mRNA for immunoglobulin heavy chain is then processed to remove intervening sequences and exons for the entire coding sequence of either μ or δ constant regions. Newly formed B cells initially produce only mature IgM transcripts; however, within 24 hours, coexpression of IgD occurs on individual B cells by this mechanism. Contact with bone marrow stromal cells plays a key role in stimulating B lymphocytes with successful Ig gene rearrangements to survive and divide. Marrow stromal cells produce a set of cytokines that affect the tempo of B lymphocyte production, including interleukin-7 (IL-7), c*kit*-ligand (or stem-cell factor), insulinlike growth factor-1 (IGF-1), and FLT-ligand. IL-7 is the primary proliferative cytokine for developing lymphocyte precursors, and c*kit*-ligand, IGF-1, and FLT-ligand potentiate the effect of IL-7 on these cells. Absence of specific receptors for these cytokines or failure to express B linease specific intracellular signaling molecules like B-cell–specific tyrosine kinase *Btk*, which are activated by cytokine exposure may result in failure of stem cell differentiation into the B-lymphocyte pathway, or failure to appropriately produce (or respond to) IL-7, c*kit*-ligand, or IGF-1 and lead to humoral immunodeficiency.

The process of Ig gene rearrangement is random and generates B cells producing immunoprotective antibodies as well as potentially harmful self-reactive cells and cells without protective value. These B cells must be inactivated or removed. In the bone marrow, immature B cells expressing surface IgM that is self-reactive to cell surface components are removed by induction of programmed cell death, or apoptosis (clonal deletion), and immature B cells expressing IgM that binds soluble self-antigens are rendered unresponsive (clonal inactivation; anergy). B lymphocytes without protective value that are not stimulated by cognate antigen within 1 week die by apoptosis. Anergic B lymphocytes are unable to be stimulated in the periphery, and thus are also rapidly eliminated by apoptosis.

B-Cell Differentiation and Antibody Responses in Secondary Lymphoid Tissues

Newly formed B cells expressing IgM on their cell surfaces exit the marrow and circulate through peripheral secondary lymphoid tissues, such as spleen, lymph nodes, or mucosa-associated lymphoid tissues. Migration to secondary lymphoid tissues is in part mediated by production of the chemokines CCL19, CCL21, and CXCL13 by these tissues. Recirculation of B cells to secondary lymphoid tissues throughout the body increases the chance that relevant B-cell responses are generated wherever foreign antigen penetrates into the body. Unless stimulated in these secondary lymphoid tissues by cognate antigen, recirculating newly formed B cells have a limited life span of only a few weeks. B lymphocytes encountering appropriate antigen in peripheral lymphoid tissues during the responsive period after expression of surface IgM are activated, enlarge, and prepare to enter the cell cycle. However, these activated B cells require additional signals for continued response and cell division.

Most antigens, including proteins, are thymus dependent. To mount antibody responses to thymus dependent antigens, B cells require help from antigen-specific T cells in secondary lymphoid tissues such as lymph nodes. T cells can be activated to provide B-cell help in two ways. Antigen can be presented to T cells in lymph nodes antigen presenting cells (APCs) such as dendritic cells that carry antigen from tissues to draining lymph nodes. Alternatively, B cells serve as APCs, presenting antigen directly to T cells. In either case, antigen is presented in the form of antigen-derived peptides bound to cell surface proteins encoded by major histocompatibility complex (MHC) class II genes. The specific interactions between peptide:MHC class II complexes on an APC and antigen-specific TCRs on a $CD4^+$ T cell trigger the T cell to make membrane and secreted molecules that drive B-cell proliferation and differentiation. One such T-cell surface molecule is CD40-L, which is a member of the TNF family. CD40-L binding to CD40 on the B-cell surface results in intracellular signaling necessary for B cells to enter the cell cycle. This interaction is essential for B-cell responses to thymus dependent antigens, as demonstrated by the effect of absent CD40L function in the X-linked hyper-IgM syndrome. Thus, regardless of the type of APC stimulating T cells, direct contact between T cells and B cells is necessary for effective T-cell help. Interactions between B and T cells also stimulate T cells to secrete a variety of B-cell stimulatory cytokines, such as IL-2, IL-4, IL-5, and IL-6.

During an antibody-mediated immune response, individual B cells alter the isotype of antibody that is produced via a process termed isotype switching, e.g., cells producing IgM and/or IgD switch to producing IgE or one of the IgG or IgA subclasses. Isotype switching involves translocation of the V_HDJ_H gene to a position immediately 5′ to one of the constant gene regions coding for heavy-chain isotypes other than IgM or IgD; 5′ to each heavy chain constant region gene (except the *δ* gene) lie repetitive DNA sequences called *switch regions*. Switching occurs by recombination between the switch

regions, with deletion of intervening DNA and requires the presence of an inducible enzyme, activation-induced cytidine deaminase (AID). In addition to being needed for isotype switching, AID also increases the diversity of antibody V regions through a process termed *somatic hypermutation*. AID deaminates cytosine to uracil in expressed Ig genes. Subsequent DNA repair results in point mutations. Isotype switching occurs during B-cell proliferation and does not occur in nondividing plasma cells. Ability of the same heavy-chain variable gene segment to become associated with different heavy-chain constant gene segments provides a mechanism for use of a single antigen-binding specificity by different Ig heavy-chain classes. No isotype switching occurs in light chains.

Isotype switching is regulated by T lymphocytes and T-cell–derived cytokines. T cells affect isotype switching in B cells both through cell surface interactions, such as those between CD40-L on T cells and CD40 on B cells, and by secreting cytokines. Cytokines alone are not sufficient to induce isotype switching in proliferating B cells but must act in concert with B-cell activators such as LPS, antigen-receptor cross-linkers, or activated T cells. Cytokines appear to act by selectively inducing transcriptional activation of the constant heavy (C_H) genes that encode the Ig class that is subsequently induced. C_H gene activation, in turn, makes switch regions accessible to switch recombinases and induces the enzyme AID. Different cytokines can preferentially induce switching to specific isotypes. For example, in humans, IL-4 and IL-13 are able to promote isotype switching and production of IgE and IgG4; IL-10 may act as switch factor for IgG1 and IgG3 production; gamma-interferon (IFN-γ) supports IgG2 production; and transforming growth factor-beta (TGF-β) induces IgA production.

Because of their differing patterns of cytokine secretion, polarization of the CD4+ T cells providing B-cell help into T-helper 1 (Th1) and T-helper 2 (Th2) phenotypes has a profound impact on isotype switching. For example, Th2 polarization, associated with prominent production of IL-4 and and IL-13, favors class switching to IgE and IgG4. Th1 polarization, associated with IFN-γ production, antagonizes this effect. Because dendritic cells play a key role in regulating Th1/Th2 polarization, they are also important in determining patterns of isotype switching in vivo. Similarly, because NK cells (through secretion of IFN-γ) and NKT cells, eosinophils, and mast cells (through secretion of IL-4) regulate the function of dendritic cells, they also likely play an important role.

Successsful stimulation of B cells by antigen in the secondary lymphoid tissues can lead to several possible outcomes. Some of the activated B cells in lymph nodes and spleen can proliferate and differentiate directly into low-affinity IgM producing plasma cells. Plasma cells are efficient producers and secretors of antibody. Antibody secretion is the result of alternative splicing of the heavy-chain mRNA resulting in expression of a hydrophilic carboxy terminus, rather than the hydrophobic carboxy terminus of membrane-bound immunoglobulin. Other activated B cells migrate into a primary lymphoid follicle to form a germinal center. The chemokine receptor CXCR5 plays an important role in this process. Within the germinal center, somatic hypermutation of variable regions leads to affinity maturation, or the selection of B cells with surface immunoglobulins having the highest affinities for antigen. Both class switching (described above) and somatic hypermutation require the B lymphocyte specific enzyme AID (described above).

Cells that survive the process of affinity maturation can migrate to other sites in the secondary lymphoid tissue and bone marrow and complete their differentiation into plasma cells. Alternatively, they can develop into memory B cells. Memory B cells are long lived. They recirculate through the body in a fashion similar to naive B cells, but require only intermittent stimulation for survival and are much more easily activated by antigen to differentiate into plasma cells and engage in secondary antibody responses that develop more quickly and are stronger than primary antibody responses. Thus, memory B cells can provide enhanced protective immunity when an antigen is re-encountered.

MARGINAL ZONE AND B1 B CELLS

In addition to the conventional "B2" B cells described in the preceding, based on work in rodents, two other populations of B cells are also recognized. Marginal zone B cells and B1 B cells are thought to play important roles in generating antibody responses to T-independent antigens. These are generally nonprotein antigens such as polysaccharides. T-cell involvement is not absolutely required for antibody responses to these antigens.

Marginal zone B cells arise from immature B cells that migrate to the spleen but differentiate differently than conventional B cells. Differentiation into marginal zone B cells is proposed to result from the combination of weak B-cell receptor activation and other signals. This cell population localizes to the marginal zone of the spleen adjacent to B-cell follicles. In humans, marginal zone B cells have been considered particularly important for antibody responses to T-independent type 2 multivalent antigens such as pneumococcal, meningococcal, and *H. influenzae* capsular polysaccharides because the spleen is required for these responses. In addition to splenectomy, age less than 2 years (when the marginal zone is immature and poorly organized in humans) is associated with poor antibody responses to these antigens.

Much of what is known about B1 B-cell subpopulations comes from studies of the immune system of mice. B1 B cells appear to be produced during embryonic development in the fetal liver and omentum and are subsequently maintained throughout life as replicating cells primarily in the peritoneal and pleural cavities, where they are the major B-cell population. In the mouse, B1 B cells express a unique cell surface protein, CD5, but CD5 is not required for their development or function. However, in the past, B1 B cells often were referred to as CD5+ B cells. B1 B cells express little or no IgD. The variable regions of antibodies produced by B1 B cells are less diverse than those of conventional B cells. They tend to produce low affinity antibodies to nonprotein

antigens such as polysaccharides. B1 B cells also appear to play an important role in producing "natural antibodies" that arise spontaneously without prior infection or defined immune exposure (such as hemagglutinins).

IMMUNOGLOBULIN STRUCTURE AND FUNCTION

Immunoglobulins are expressed in five unique heavy-chain isotypes encoded in the immunoglobulin heavy-chain gene complex. Each heavy-chain isotype or class has unique structure and properties (Table 22-2). The basic structure of immunoglobulin is a protein complex composed of two identical immunoglobulin heavy chains and two identical immunoglobulin light chains held together by intrachain disulfide bonds. An immunoglobulin monomer has an approximate molecular weight of 160,000 kD. This immunoglobulin monomer has two antibody binding sites, composed of the amino terminal ends of both heavy and light chains, and a single carboxy-terminal Fc region. (The name derives from the historical observation that it could be crystallized.) By binding to Fc receptors on cells, Ig can confer antigen specificity and can modulate cell function through either activation or inhibition. The Fc region of Ig is also able to interact with other immune system components, such as complement.

IgM

Immunoglobulin M is the first immunoglobulin isotype expressed on newly formed B cells and is expressed as both a cell surface protein and a circulating immunoglobulin making up approximately 10 percent of total plasma Ig. Circulating IgM is a pentamer of IgM molecules, polymerized by a unique B-cell–derived J-chain protein. The approximate molecular weight of pentameric IgM is 960,000.

IgM is the most effective complement-fixing immunoglobulin class and the 10 antigen binding sites on the pentameric form make it a good agglutinating antibody. It is the first antibody to be produced in an immune response. IgM is well suited to bind to and eliminate particulate antigens and microorganisms from the intravascular compartment.

IgD

Immunoglobulin D is expressed primarily as a cell surface receptor, making up less than 1 percent of total plasma immunoglobulin. Although IgD is thought to function in B cell signaling and activation, its unique function remains unknown.

Table 22-2

Structural and Functional Characteristics of Human Immunoglobulin Classes*

	IgM	IgD	IgG1	IgG2	IgG3	IgG4	IgA1	IgA2	IgE

IgG

Immunoglobulin G is the major circulating plasma immunoglobulin class, making up some 70 to 75 percent of total detectable circulating antibody. IgG is also expressed as a cell membrane immunoglobulin, primarily on memory cells. Circulating IgG is found as a monomer of approximately 150,000 molecular weight and in humans can be subdivided into four subclasses each with a unique heavy-chain structure (serum concentrations of IgG1 > IgG2 > IgG3 and IgG4).

Considerable functional differences exist among the four subclasses. For example, differing antigenic stimuli induce differing IgG subclass responses. In general, polysaccharide antigens evoke a predominantly IgG2 response systemically, whereas protein antigens induce IgG1 and IgG3 responses. IgG4 responses appear to evolve with chronic antigen exposure. The subclasses also differ in their ability to fix complement with IgG1 and IgG3 > IgG2 in this respect. IgG4 does not fix complement.

IgG subclasses also differ with regard to ability to bind Fcγ-receptors (FcγRs). Types of FcγRs include FcγRI; FcγRII-A, B1, and B2; and FcγRIII. These receptors are found on many cell types, including neutrophils, monocytes, macrophages (including alveolar macrophages), eosinophils, platelets, NK cells, and other lymphocytes. By binding to Fc receptors, IgG can mediate a number of functions including phagocytosis, endocytosis, antibody-dependent cell cytoxicity, inflammatory cell activation, and release of inflammatory cell mediators. FcγRIII binds IgG1 and IgG3 with equal strength. For the other FcγRs, IgG1 binds most strongly, IgG3 and IgG4 bind with intermediate strength, and IgG2 binds most weakly. FcγRI is the only FcγR capable of binding monomeric IgG with high affinity. It is expressed mainly on mononuclear phagocytes. FcγRIII can also bind monomeric IgG but with moderate affinity. It plays an important role in antibody-dependent cell cytotoxicity mediated by NK cells. FcγRII receptors bind monomeric IgG poorly but do bind IgG in aggregates or immune complexes. FcγRII-B1 and B2 are inhibitory receptors that help control the activation of naïve B cells, mast cells, macrophages, and neutrophils. Their cytoplasmic tails contain immunoreceptor tyrosine-based inhibition motifs (ITIMs), which mediate this inhibitory activity.

Another type of Fc receptor is termed the neonatal Fc receptor (FcRn) or the Brambell receptor (FcRB). FcRn has two roles, to protect IgG from catabolism and engage in IgG transport. In humans, it likely plays an important role in antenatal transport of IgG from mother to young. FcRn is expressed in several human epithelial tissues, including lung, kidney, and intestine. FcRn-mediated transport of IgG across rat alveolar epithelial cell monolayers is fivefold greater in the apical-basal than in the basal-apical direction. Transport via this receptor may be relevant to the human respiratory tract, given that a fusion protein consisting of erythropoietin and the Fc domain of IgG1 administered by aerosol was better able to penetrate the lungs of non-human primates and reach the circulation than was native erythropoietin.

IgA

Humans produce more IgA than any other immunoglobulin class. The major role of IgA is mucosal immunity. Although IgA is a major constituent of external secretions, it constitutes only about 20 percent of plasma immunoglobulin. In humans, 88 percent of circulating IgA is in monomeric form with the remainder in polymeric form. Dimeric IgA polymerized by J chain is the predominant IgA polymer. As compared to circulating IgA, which is mostly monomeric and derived from bone marrow B cells, most IgA in secretions is dimeric, associated with J chain, and derived from mucosal B cells. Two subclasses of IgA exist—IgA1 and IgA2. Circulating IgA and IgA in secretions differ in IgA subclass composition, with the IgA2 subclass constituting a lesser proportion (about 20 percent) of circulating IgA and a greater proportion (approaching 50 percent) of IgA in secretions. Thus, IgA2 may be particularly important for mucosal immunity, especially in view of its resistance to bacterial proteases specific to the hinge region of IgA1 produced by certain pathologic strains of *Streptococcus pneumoniae, Haemophilus influenzae, Neisseria gonorrheae,* and *Neisseria meningitidis.*

Polymeric IgA is actively secreted onto mucosal surfaces by epithelial cells, which express a polymeric immunoglobulin receptor (pIg-R) on their basolateral surfaces (Fig. 22-1). After binding of polymeric IgA to the pIg-R, the IgA-pIg-R complex is endocytosed into intracellular vesicles that transport the complex to the apical (luminal) surface of the epithelial cell. The complex is cleaved with release of the polymeric IgA onto the mucosal surface by exocytosis, still bound to a cleavage fragment of the pIg-R known as secretory component (SC). Polymeric IgA bound to secretory component is termed secretory IgA (sIgA). Binding of secretory component probably prolongs IgA half-life by increasing resistance to proteolysis. sIgA on the mucosal surface is mostly derived from locally produced, not plasma-derived, IgA.

Mucosa-associated lymphoepithelial tissue (MALT), where precursors of IgA-producing cells are generated in response to antigen and T-cell regulation, is a key site for mucosal IgA production. These lymphoid tissues—which include Peyer's patches and other gut-associated lymphoid tissue (GALT), bronchus-associated lymphoid tissue (BALT), and nasal-associated lymphoid tissues (NALT) like the palatine and nasophyaryngeal tonsils—are covered by specialized epithelium facilitating uptake and processing of antigen from the mucosal lumen. They are also supplied with high endothelial venules (HEVs) facilitating entry of circulating lymphocytes from the vasculature.

Factors in MALT such as T cells and cytokines promote development of antigen-specific B cells committed to IgA production. These cells leave MALT and recirculate to mucosal surfaces, where they are subjected to further immunoregulatory signals, causing both local proliferation and terminal differentiation to IgA plasma cells. MALT has been considered

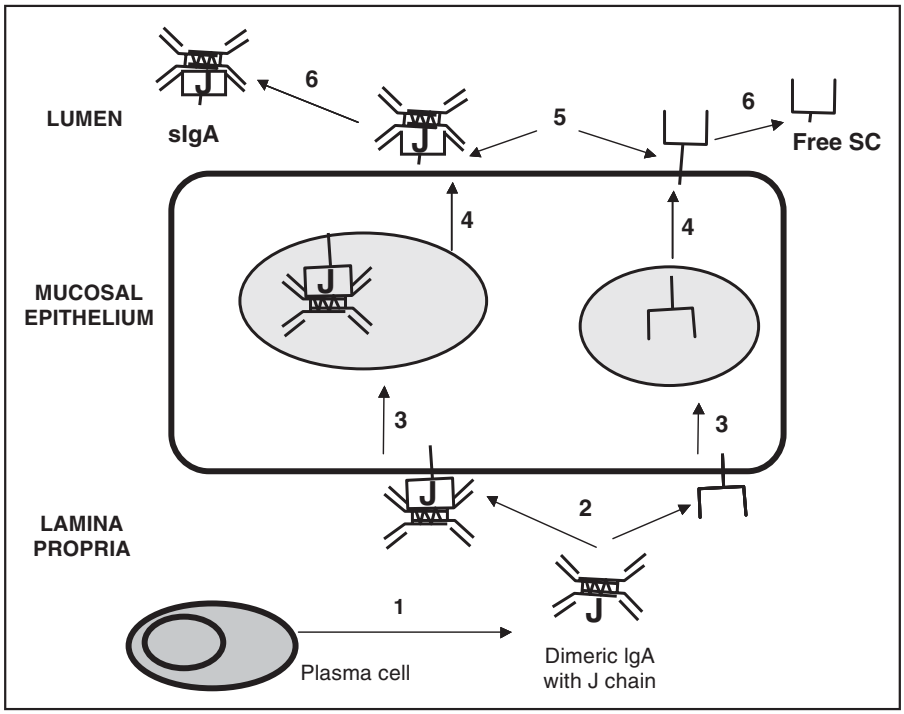

Figure 22-1 Active secretion of secretory IgA (SIgA) and free secretory component (SC) onto mucosal surfaces via the polymeric immunoglobulin receptor (pIgR). An epithelial cell is depicted with the apical surface at the top and basolateral surface at the bottom. *1.* Dimeric IgA (dIgA) is produced by plasma cells in the lamina propria. *2.* Some pIgR molecules on the basolateral surface of the epithelial cell bind dIgA (left) and others do not (right). *3.* The dIgA-pIgR complex (left) and unbound pIgR (right) are packaged into transcytotic vesicles. *4.* Vesicles are transported to the apical epithelial surface. *5.* The extracellular, ligand-binding portion of pIgR is proteolytically cleaved. *6.* SIgA, consisting of dIgA bound to the cleaved, extracellular fragment of pIgR, is released onto the mucosal surface (left); free SC, or the unbound extracellular fragment of pIgR, is also released (right). Diagram is adapted from Kantele A: [Mucosa: The first specific immune defense system in the body]. *Duodecim* 108:2088–2096, 1992. a key component of the common mucosal immune system, as immunocytes generated in MALT are capable of migrating to distant mucosal surfaces and producing IgA at these sites. For example, immunocytes generated in GALT can migrate to breast and secrete IgA into breast milk. However, recent studies have shown fundamental differences in the patterns of cell adhesion molecules involved in migration of cells to GALT and BALT. Binding of lymphocytes to HEV from BALT is dependent on lymphocyte expression of the integrin $\alpha_4\beta_1$ and HEV expression of VCAM-1. In contrast, binding of lymphocytes to HEV from GALT is dependent on lymphocyte expression of $\alpha_4\beta_7$ and HEV expression of MAdCAM-1. These findings suggest a mechanism for differing migratory patterns of cells generated by respiratory mucosal immune responses from that of cells generated by mucosal immune responses in the gut.

IgA is less able to induce inflammation via Fc interactions than IgM or IgG. One of IgA's key functions is immune exclusion and/or neutralization of bound antigens (Fig. 22-2). An Fc receptor for IgA, FcαR1 (CD89), is expressed on monocytes, macrophages, neutrophils, and eosinophils. It binds monomeric IgA and promotes phagocytosis and killing of IgA-opsonized bacteria.

IgE

Immunoglobulin E (IgE) constitutes only a minuscule fraction of the total antibody in human serum. However, the biologic effects of IgE are not mediated by free antibody, but rather by IgE bound to cell surface receptors. The high-affinity receptor for IgE (FcεRI) binds IgE via its Fc portion and is expressed constitutively by mast cells and basophils and by eosinophils after activation by cytokines. IgE bound to FcεRI is responsible for immediate hypersensitivity reactions such as occur in asthma and allergic rhinitis. Cross-linking of cell surface IgE bound to FcεRI by multivalent antigen triggers degranulation of mast cells and basophils, resulting in rapid release of stored mediators such as histamine. IgE cross-linking also leads to synthesis and secretion of cytokines that subsequently attract and activate inflammatory cells, leading to the "late-phase response." On eosinophils, FcεRI can mediate IgE-dependent killing of parasites.

IgE also binds to a low-affinity receptor, FcεRII (CD23). Unlike other Fc receptors, FcεRII is not a member of the immunoglobulin superfamily. It is found on a broad range of cell types including B cells, activated T cells, monocyte-macrophages (including alveolar macrophages), eosinophils,

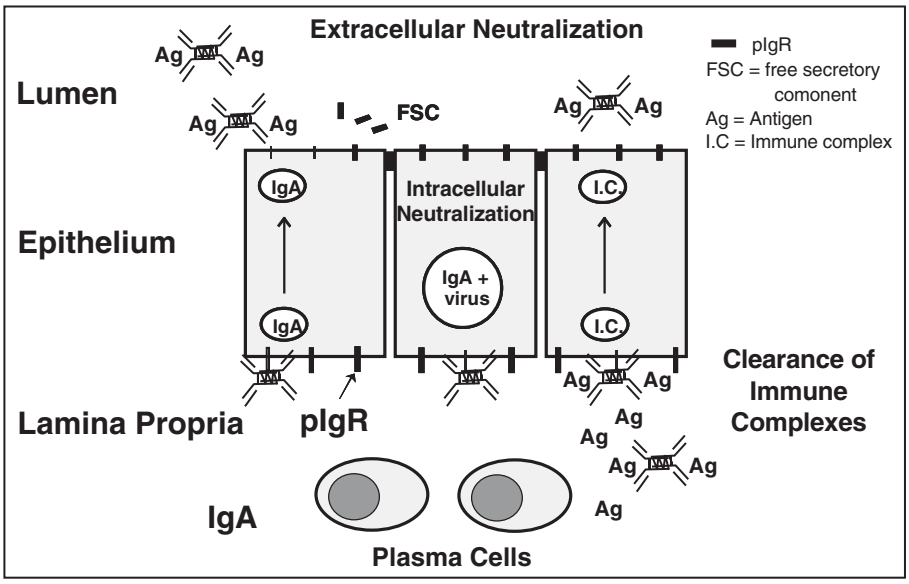

Figure 22-2 Neutralization and removal of antigen by polymeric IgA in both intracellular and extracellular compartments of the mucosa. Epithelial cells are depicted with apical surfaces at the top and basal surfaces at the bottom. *Left cell:* Secretory IgA is secreted into the mucosal lumen, where it binds to microbial pathogens and either neutralizes them or excludes them from the mucosa by preventing them from binding to the mucosal epithelium. *Middle cell:* During transcytosis, the dimeric IgA (dIgA)-polymeric immunoglobulin receptor (pIgR) complex is able to bind and neutralize intracellular pathogens. *Right cell:* Active transport via pIgR removes dIgA-antigen immune complexes from the lamina propria and secretes them into the mucosal lumen. *Diagram is adapted from: Mazanec MB, Nedrud JG, Kaetzel CS, et al.: A three-tiered view of the role of IgA in mucosal defense.* Immunol Today *14:430–435, 1993. Reproduced with permission from Pal K:* Regulation of Polymeric Immunoglobulin Receptor by Reovirus Intestinal Epithelial Cells. Morgantown, WV, West Virginia University (doctoral thesis), 2006.

platelets, follicular dendritic cells, and thymic epithelial cells. FcεRII also has important immunoregulatory functions both with and without IgE binding. Binding of IgE to FcεRII on B cells inhibits IgE synthesis. Murine antigen–induced airways inflammation is negatively regulated by FcεRII and is exacerbated in its absence. Thus, IgE and its receptors mediate a broad range of biologic activities.

ORIGINS AND FATE OF RESPIRATORY TRACT IMMUNOGLOBULINS

There are several sources for respiratory tract Ig. Passive transudation (diffusion) from the vascular compartment across lung tissue is an important source. The rate of transudation is dependent on several factors, including plasma Ig concentration, "resistance" to diffusion, and effective Ig size. Transudation rate may be elevated during increased permeability states such as inflammation.

Another source of respiratory tract Ig is local production by B cells within lung tissue. By far the most active site for Ig production is the bronchial mucosa, although under certain conditions, Ig production also can be demonstrated in other compartments of the lung, such as the parenchymal interstitium and within the airways. After synthesis, Ig reaches airways lumina by either passive diffusion across epithelial barriers or, in the case of polymeric IgA and IgM, by active transport through epithelial cells via the pIg-R.

Assessment as to whether Ig in respiratory secretions are serum derived or locally produced has often been performed by standardizing Ig concentrations to proteins that are purely serum-derived, such as albumin. Using this approach, similar Ig/albumin ratios at both sites are interpreted as evidence for passive transudation of Ig from blood to lung. Increased Ig/albumin ratio in respiratory secretion relative to blood is interpreted as evidence for local antibody production (although active transport of Ig also could result in this finding). A limitation to this approach is that Ig are larger than albumin, so the lung is less permeable to Ig. For this reason, use of Ig/albumin ratios to standardize data may lead to overestimation of Ig proportion derived from serum.

Relative to production, far less is known about the fate of respiratory tract Ig. It is likely that inflammatory conditions associated with increased epithelial permeability and the presence of endogenous and bacterial proteases increase Ig clearance and contribute to pathology.

ANTIGEN-SPECIFIC PULMONARY ANTIBODY RESPONSES

Pulmonary antibody responses have been evaluated in a number of animal species using models based on instillation of antigen into the lower respiratory tract. In general, exposure of the lung to low doses of antigen is not sufficient to induce a primary antibody response, even after repeated antigen

exposures. These low doses of antigen appear to be cleared by nonspecific defense mechanisms, such as mucociliary clearance and nonspecific phagocytosis. Induction of an antibody response requires a dose of antigen sufficient to overwhelm nonspecific clearance mechanisms and induce pulmonary inflammation, leading to translocation of antigen from the lung to the draining lung-associated lymph node (LALN). Dendritic cells play an important role in antigen uptake, transport, and presentation in the LALN. LALN are the primary site for induction of an antibody response to intralobar antigen. Antibody-forming cells (AFCs) generated in LALN are then released into efferent lymphatics and blood. AFC reach the lung parenchyma from blood. Nonspecific pulmonary inflammation promotes recruitment of AFC from blood to lung, regardless of antigen specificity or lymph node of origin. Findings in humans are consistent with this sequence of events.

In addition to recruiting AFC to the lung, localized antigen exposure leads to recruitment and/or production of immune memory cells only in the immunized lung lobe. These cells are able to function locally and manifest their presence in several ways. First, they confer the ability on immunized and challenged lung to mount AFC and antibody responses to far lower doses of antigen than can induce these responses in previously unimmunized lung lobes. Second, after local challenge with a given dose of antigen, they allow previously immunized and challenged lung lobes to mount AFC responses of markedly greater magnitude than occur after antigen instillation in previously unimmunized lobes. Finally, in the dog model, B cells recruited to and/or produced in the lung interstitium are able to produce antibody for years after localized immunization and challenge. Thus, primary antibody responses induced in the lung by intrapulmonary deposition of antigen are mediated by B cells recruited from regional lymph nodes via the circulation. Subsequent local antigen exposure can result in antibody responses that are compartmentalized within the lung and mediated by memory cells recruited to and/or produced in the pulmonary interstitium.

Recent work in mice has shown that BALT is also a site in which T-cell, B-cell, and antibody responses to antigen can be generated. Mice lacking spleens, lymph nodes, and Peyer's patches formed inducible BALT (iBALT) in response to infection with intranasal influenza virus. iBALT contained structures necessary to mount immune responses, including B-cell follicles centered around networks of follicular dendritic cells and interfollicular regions containing dendritic cells and T cells. iBALT was also equipped with HEV, a key structure through which immune cells migrate from the circulation. iBALT was the site of vigorous T- and B-cell responses to influenza, including specific IgG responses. These responses were protective and cleared infection. Thus, iBALT is an inducible lymphoid tissue that can generate local pulmonary immune responses independently of conventional draining LALN. iBALT may represent an adaptive local pulmonary response to antigen overload, such as in COPD, in which progression of COPD is strongly associated with percentage of airways with lymphoid aggregates containing follicles.

IMMUNOGLOBULIN MEASUREMENT IN THE HUMAN LUNG

Immunoglobulins are prominent protein constituents of normal respiratory secretions, with IgG, IgM, and IgA accounting for approximately 20 percent of total protein in bronchoalveolar lavage (BAL) fluids. IgG and IgA are the Ig present in greatest concentrations, with the relative content of IgA progressively decreasing and IgG progressively increasing as one moves from oral cavity to alveolus. In canines, saliva IgA concentrations exceed IgG concentrations, whereas in tracheal and bronchial washings IgG concentrations exceed those of IgA (with higher proportions of IgA in the more proximal tracheal washings). Similarly, in humans the ratio (by weight) of IgG to IgA in nasal washings has been reported at about 1:3 as compared to 2.5:1 in lung lavage obtained via a bronchography catheter. Thus, the relative contribution of IgA to respiratory tract host defense appears greater proximally than distally; the reverse is true for IgG.

Because of ease of sample collection, most measurements of Ig levels in the human lung have been performed using BAL fluid. Bronchoalveolar lavage samples both conducting airways and the alveolar surface. Levels of IgG, IgM, and IgA have been reported in a large multicenter study that used a standardized BAL technique to collect samples. In 76 never-smokers, mean BAL IgG, IgA, and IgM concentrations were 5.9, 6.2, and 0.2 μg/ml, respectively. Current smoking significantly increased mean BAL IgG and IgM concentrations to 10.2 and 0.23 μg/ml, respectively (62 subjects studied). Mean BAL IgA concentrations were unaffected by smoking (5.9 μg/ml).

Data were also presented for serum and BAL Ig/albumin ratios for all 184 subjects studied (including an ex-smoker group). Mean IgG/albumin and IgM/albumin ratios were significantly lower in BAL than in serum, suggesting that these Ig were largely serum derived. In contrast, mean IgA/albumin ratios documented were significantly greater in BAL than in serum, suggesting that a significant proportion of BAL IgA was locally produced.

Respiratory Tract IgA

As noted, BAL data support local production and active secretion of total IgA into the human respiratory tract. The various forms of IgA also have been evaluated in human BAL. With regard to relative proportions of monomeric and polymeric forms, approximately 84 percent of BAL IgA is polymeric sIgA. With regard to IgA subclass levels, IgA2 constitutes 10 to 20 percent of total IgA in blood and about 30 percent of total IgA in BAL. Free secretory component also can be recovered by BAL. SC recovery ranges from less than 25 to 500 μg per BAL. Of interest is that SC recovery is markedly decreased in about 20 percent of smokers, perhaps as a result of epithelial dysfunction.

Immunohistologic studies have documented sites of IgA production and secretion in the human lung.

IgA-producing plasma cells are most abundant in the glands and lamina propria of the major bronchi but also are found in small bronchi, bronchioles, and alveolar septa. The proportion of IgA plasma cells producing IgA2 is somewhat greater in bronchial mucosa (26 to 33 percent) than in bone marrow or peripheral lymph node (10 to 20 percent), but less than in large bowel mucosa (about 60 percent). As staining for SC is also most intense in the bronchial glands (in glandular epithelial cells), bronchial glands appear to be particularly important sites for production and transepithelial secretion of IgA. SC and IgA associated with J chain also have been demonstrated in bronchiolar nonciliated epithelium and type II alveolar cells, so IgA production and secretion also appears to occur at other sites, including the lower respiratory tract.

Respiratory Tract IgG

As noted, respiratory tract IgG is serum derived to a far greater extent than is IgA. However, some variation in the level of local production has been noted among the IgG subclasses. All IgG subclasses have been identified in human BAL. In healthy nonsmokers, the various subclasses constitute the following percentages of BAL IgG: IgG1, 65 percent; IgG2, 28 percent; IgG3, 1.8 percent; and IgG4, 1.3 percent. Based on albumin ratios, IgG1 and IgG2 appear to reach the airways lumen primarily by passive transudation, IgG4 originates to a significant degree from local antibody production, and demonstrable local IgG3 production occurs only in some individuals. Smoking is associated with increased levels of IgG1 in both serum and lavage and evidence for increased local production of IgG3 (based on BAL and serum IgG3/albumin ratios).

Using immunostaining techniques, IgG-producing cells have been identified in human bronchial mucosa and are present in relatively greater proportions than at other mucosal surfaces, such as the intestine. Unlike IgA-producing cells, IgG-producing cells in bronchial mucosa do not localize to glandular areas.

In contrast to IgA, whose main role is immune exclusion, the main role of respiratory tract IgG appears to be immune elimination of foreign antigens penetrating the respiratory mucosal barrier. Immune elimination is facilitated by interactions with Fc receptors on inflammatory cells such as neutrophils, monocytes, macrophages, and NK cells, as well as interactions with soluble factors such as the complement system.

Respiratory Tract IgE

IgE appears to be locally produced in the human respiratory tract. In healthy nonsmokers, mean BAL IgE concentrations have been reported to be 9.1 ng/ml, with mean IgE/albumin ratios significantly greater in BAL than in serum, suggesting local IgE production. Healthy smokers' mean BAL IgE concentrations appeared elevated at 14.0 ng/ml, but the study lacked sufficient power to document statistical significance. Based on albumin ratios, IgE production also appeared to be occurring in the lungs of smokers.

IgE bound to histamine-containing cells can also be identified in the human lung by BAL. Over 95 percent of such cells obtained during the late-phase response to segmental challenge with antigen are basophils.

PATHOLOGY INDUCED BY RESPIRATORY TRACT IMMUNOGLOBULIN

The Gell and Coombs classification system is dated, but still useful. It classifies immune-mediated tissue injury into four types. Types I to III are antibody mediated and type IV is cell mediated. Type I, or allergic, responses are mediated by IgE. Types II and III responses are usually mediated by IgG or IgM, with activation of either complement-mediated or phagocytic effector mechanisms. Type II responses are the result of antibodies directed against cell surface– or matrix-associated antigen. Type III responses are directed against soluble antigens with tissue damage caused by responses to immune complexes. All three types of tissue injury can occur in the lungs and respiratory tract.

A common pulmonary disease associated with type I injury is atopic asthma, in which IgE plays a prominent role. An example of a disease causing type II injury is Goodpasture's syndrome in which autoantibodies against basement membrane collagen type IV activate complement and recruit inflammatory cells, leading to necrotizing hemhorragic interstitial pneumonitis. Type III injury mediated by immune complexes may contribute to the pathogenesis of hypersensitivity pneumonitis.

Elevated BAL Ig levels are noted in a variety of pulmonary diseases, including interstitial diseases such as hypersensitivity pneumonitis, idiopathic pulmonary fibrosis, and sarcoidosis as well as acquired immunodeficiency syndrome (AIDS). It is often unclear whether increased Ig levels are of pathogenic importance or simply a marker of some other underlying disease process. For example, BAL IgG2/IgG1 ratio of greater than 1 in lung allograft BAL fluid has been proposed as a biomarker to assess for underlying Th1 (and IFN-γ)-mediated lung allograft rejection after lung transplantation.

HUMORAL IMMUNODEFICIENCY AND THE LUNG

The respiratory tract is profoundly affected by systemic humoral immunodeficiency. Patients with defects in the B-lymphocyte (humoral) system have a tendency to develop sinopulmonary infections such as otitis media, sinusitis, bronchitis, and pneumonia as well as complications of recurrent bacteremia such as sepsis or meningitis. Encapsulated bacteria such as *S. pneumoniae, H. influenzae,* and *N. meningitidis* or, less commonly, gram-negative bacteria are often

the etiologic organisms. Recurrent infection often leads to chronic disease such as bronchiectasis as well as respiratory dysfunction.

Humoral immune deficiencies can vary from a complete failure of B-cell development, such as Bruton's agammaglobulinemia, to relatively mild conditions, such as selective IgG subclass deficiency. A number of molecular defects associated with B-cell deficiency have been described. These B-cell deficiencies are characterized by either a decreased ability to produce all or some immunoglobulin classes or a diminished ability to make an antigen-specific antibody response. Failure of antibody function results in recurrent infection and is the primary indication for antibody replacement with intravenous immunoglobulin. Almost all of the original descriptions of primary B-cell deficiencies were in children. However, over the last decade, people 18 years of age and older constituted an increasing percentage of those identified with primary immunodeficiency diseases.

Bruton's Agammaglobulinemia

Bruton's agammaglobulinemia or X-linked hypogammaglobulinemia was the first immunodeficiency disease described. It is an X-linked disorder caused by a wide variety of mutations in the gene of the B-cell–specific tyrosine kinase *Btk*. In this disorder, affected infants are relatively infection free for the first 6 to 9 months of life as a result of transplacental IgG. They then develop recurrent chronic middle ear, sinus, and pulmonary infections. Sepsis, meningitis, septic arthritis, osteomyelitis, pyoderma, and encephalitis may occur also. Gastrointestinal infections and malabsorption may develop. Occasionally, viruses such as echoviruses have caused a progressive, fatal neurological infection in these patients. Prior to antibiotics and immunoglobulin replacement, few patients survived past infancy.

IgG levels are usually below 200 mg/dl, and IgM, IgA, IgD, and IgE levels are extremely low or absent. There is a complete inability to make antigen-specific antibody to protein and polysaccharide antigens after stimulation. Pre-B cells are present in the bone marrow, but B lymphocytes bearing surface immunoglobulin are almost completely absent from the circulation. Lymph nodes without germinal centers and hypoplastic adenoids and tonsils are found due to the lack of B cells. Immunity involving T lymphocytes is completely intact.

Prior to diagnosis, multiple or recurrent pulmonary infections may occur because of *S. pneumoniae, H. influenzae, N. meningitidis,* and *Staphylococcus aureus.* This leads to the development of bronchiectasis. Even after diagnosis and the institution of antibody replacement with intravenous immunoglobulin (IVIG), chronic sinopulmonary disease may continue and worsen due to the inability to replace mucosal IgA. Delay in diagnosis and treatment with IVIG results in severe chronic pulmonary disease. In one study, approximately 75 percent of patients over 20 years of age had chronic lung disease, either obstructive disease or mixed obstructive and restrictive disease. Most of these older patients had received intramuscular immunoglobulin, which results in lower serum IgG levels. High doses of IVIG in the range of 400 mg/kg given every 3 weeks, leading to serum trough IgG levels of around 500 mg/dl, are associated with decreased infections, especially pneumonias. With early diagnosis and appropriate treatment, many of these patients now reach adulthood.

Common Variable Immunodeficiency

Common variable immunodeficiency (CVID) presents with hypogammaglobulinemia, decreased antigen-specific antibody function and increased recurrent infections. Patients with CVID are heterogeneous. Although most cases are sporadic and of unknown etiology, several different genetic defects have been reported as capable of causing this disorder. Unlike X-linked agammaglobulinemia, some ability to develop a functional antibody response is present. In addition, tonsils, adenoids, and lymph nodes are usually enlarged and splenomegaly is generally present. Cellular immune defects, such as a decreased CD4/CD8 ratio may be present. CVID generally has a later onset than Bruton's agammaglobulinemia and occurs in either sex. There is a marked predisposition to autoimmune disease, malignancy, and gastrointestinal malabsorption. The gastrointestinal manifestations of CVID are variable and tend to mimic known diseases, such as celiac sprue, pernicious anemia, and inflammatory bowel disease. There is a high prevalence of inflammatory, malignant, and infectious gastrointestinal disorders in patients with CVID.

Patients with CVID tend to develop chronic and recurrent otitis media, sinusitis, and pneumonia due to *S. pneumoniae, H. influenzae,* and *S. aureus.* Recurrent pulmonary infections with *Mycoplasma pneumoniae* are frequently seen. Due to the cellular immunologic abnormalities observed in these patients, infections with fungi, mycobacteria, and *Pneumocystis carinii* are possible. Bronchiectasis and pulmonary compromise are common sequelae in these patients. Of 47 patients with CVID, 42 patients had respiratory complications, 32 had bronchiectasis, seven had asthma, nine had recurrent chest infections without concomitant evidence of structural lung damage, and two granulomatous lung disease. There was a median 4-year delay between the first symptoms of the disease and diagnosis. Many of the patients were followed for chronic lung disease for a period of years before their underlying immune abnormalities were discovered.

Patients with common variable immune deficiency exhibit a variety of immune abnormalities; IgG levels are generally below 300 mg/dl. IgA and IgM levels are usually low. Antibody responses to specific antigens such as tetanus toxoid, pneumococcal vaccine, or the neoantigen bacteriophage øX 174 are diminished or absent. Peripheral B-cell numbers are usually normal but may be decreased. Lymphocytes do not differentiate into immunoglobulin-producing plasma cells in vivo and in vitro. B-cell activators such as pokeweed mitogen are also incapable of stimulating immunoglobulin production. Standard in vitro proliferation assays for mitogens and

antigens are abnormal in about 50 percent of patients with CVID. Thus, CVID is felt to result from an arrest in the terminal differentiation of B cells that prevents them from evolving into normal Ig-producing cells. This can either be secondary to defects in T-cell help or due to intrinsic defects in the B cell itself.

The most important aspect of therapy for patients with CVID is antibody replacement with intravenous immunoglobulin. Most patients are started on a dose of 400 mg/kg given once per month and show considerable improvement on these doses. Those patients with increased frequency of infection usually have the dose increased or the interval between doses decreased. There is evidence that patients with CVID and chronic lung disease respond to considerably higher doses of IVIG, in the range of 600 to 800 mg/kg. Chronic pulmonary infections may require long-term treatment with oral broad-spectrum antibiotics in addition to IVIG. Those patients with evidence of T-cell dysfunction are at risk of developing a wider variety of pulmonary infections, and appropriate investigations for *P. carinii,* mycobacteria, viruses, and fungi should be instituted in those patients when appropriate.

IgA Deficiency

IgA deficiency is a relatively common disorder, with the prevalence estimated to be between 1/300 to 1/2000. It is usually defined as an IgA level of less than 5 mg/dl, which is 1 to 3 percent of the normal age-adjusted levels. There is an increased incidence of IgA deficiency in first-degree relatives as well as evidence that it occurs more commonly in relatives of patients with common variable immunodeficiency.

The ability to produce Ig isotypes other than IgA is usually intact, as is the ability to produce antigen-specific antibody. Occasionally, IgA deficiency is associated with a deficiency of one or more IgG subclasses. When this happens, inability to make antigen-specific antibody may occur.

Infections of the sinopulmonary tract and gastrointestinal tract are usually due to encapsulated bacterial organisms rather than opportunistic infections. These infections are similar to CVID but with a greatly decreased frequency and severity. Patients with extremely low IgA levels combined with IgG subclass deficiencies tend to have more severe infections. Although recurrent pneumonias, bronchiectasis, chronic obstructive lung disease, and chronic bronchitis all have been described in patients with IgA deficiency, these clearly do not occur as often as in disorders associated with antigen-specific antibody deficiencies. IgE-mediated allergy is strongly associated with IgA deficiency, and allergic asthma occurs frequently in these patients. The asthma in these patients can be quite severe and difficult to manage. Gastrointestinal problems are also similar to CVID, with an increased risk of giardiasis, nodular lymphoid hyperplasia, and celiac disease. Malignancies, especially B-cell lymphoma, occur at a higher rate in IgA-deficient patients.

For patients with selective IgA deficiency, there is no specific therapy. Rapid identification of bacterial infections and prompt antibiotic therapy is usually all that is required. Prophylactic antibiotics may be of value in those patients with recurrent bronchitis or sinusitis. Asthma in these patients can be treated in the usual manner, although they are often resistant to therapy, and aggressive use of inhaled steroids and oral corticosteroids may be required. Those patients with both IgA deficiency and IgG subclass deficiency with a functional antibody defect can be cautiously treated with IVIG. Immunoglobulin replacement is complicated in these patients because of the possibility of IgA-deficient patients making anti-IgA antibodies capable of causing an anaphylactic reaction. Use of an IgA-depleted IVIG in these patients may be helpful in decreasing these reactions. For the same reasons, anaphylactic reactions to blood transfusions may occur, and anti-IgA antibody titers should be checked prior to the administration of any blood product. If anti-IgA antibody is detected, the red blood cells should be washed with saline to remove IgA.

IgG Subclass Deficiency

Clinical presentation of the IgG subclass deficiencies depends upon the subclass or subclasses involved. Measurement of serum concentrations of antibodies to specific bacterial antigens, such as *Haemophilus influenzae* type B, *pneumococcus*, *tetanus,* and *diphtheria* must be used in conjunction with IgG subclass levels to identify individuals at increased risk of infection and actual immune deficiency. Deficiency of IgG1 is associated with lifelong increased susceptibility to pyogenic infection and progressive deteriorating lung disease. It is commonly linked with deficiency of IgG2 and IgG3 and many consider it to be a form of CVID, particularly if the total IgG level is low. Most patients with IgG2 deficiency have normal total IgG levels and even elevated IgG1 and IgG3 levels. These patients tend to have difficulty making antibody to polysaccharide antigens. They tend to have infections with encapsulated organisms and will develop sinusitis, otitis media, and pneumonias leading to chronic lung disease or recurrent meningitis. IgG2 subclass deficiency may be associated with IgA deficiency, and these patients tend to have more severe lung disease than those with either deficiency alone. Patients with IgG3 deficiency tend to develop recurrent respiratory infections, and some have been reported with chronic lung disease. Defining IgG4 deficiency is problematic since 20 to 30 percent of the general population, have levels that are undetectable using standard techniques. Patients defined as absolutely IgG4-deficient using the most sensitive techniques (less than 0.005 mg/dl) have been reported with recurrent pulmonary infections and bronchiectasis.

It is important to realize that individuals exist who are completely healthy yet have one or more IgG subclasses missing. Before a diagnosis of IgG subclass deficiency is made, a thorough evaluation of the patient's ability to make a specific antibody response to tetanus toxoid and the pneumococcal vaccine must be pursued. Response to IVIG is good in those patients with a defect in specific antibody production.

CHAPTER 23

Cytokines and Chemokines in Lung Inflammation and Injury

Robert M. Strieter • John A. Belperio • Michael P. Keane

The cascade of events that dictate the initiation, maintenance, and resolution of pulmonary inflammation are usually the consequence of the host responding to direct and indirect insults. Infection, trauma, ischemia/reperfusion injury, and autoimmune disease are examples of clinically important insults that produce lung injury associated with inflammatory cell infiltration. These inflammatory responses involve coordinated interactions of specific signals that dictate the evolution of the inflammatory process. The signals, which are generated as the inflammatory response evolves, serve as important communication networks between the different cellular components of the local response. A variety of mediators are involved in the coordination of these networks. These include nucleotides, reactive oxygen and nitrogen intermediates, lipids, peptides, and polypeptides. This latter group of inflammatory agents comprises a large number of mediators collectively identified as *cytokines*. These polypeptide mediators are known to play key roles in a spectrum of pulmonary diseases.

Cytokines are soluble, hormonelike proteins produced by a variety of cells. It is now clear that the cellular source and biologic targets of these polypeptides are not restricted to cells of the immune system, since endothelial cells, stromal cells, and epithelial cells are all capable of both producing and responding to a number of different cytokines. An area of increasing importance in cytokine biology is the ability of nonimmune cells to participate as effector cells in the perpetuation of an inflammatory response by producing cytokines. This is particularly true in the lung, as pulmonary epithelial cells and stromal cells produce both proinflammatory and immunoregulatory cytokines under specific conditions.

Cytokines have a wide range of concentration-dependent physiological activities, but they are most distinguished for their activities associated with inflammation, immune reactivity, tissue injury, and potential loss of organ function. The broad scope of biologic activities of cytokines is fundamental to their ability to participate in various aspects of inflammation. For example, specific cytokines are known to initiate inflammation via the activities of early response cytokines, such as interleukin-1 (IL-1) and tumor necrosis factor (TNF), regulate inflammation through the effects of interleukin-10, and repair tissue injury through the activities of transforming growth factor-beta. These mediators are only representative of the many cytokines that participate in different facets of the evolving pulmonary response.

EARLY-RESPONSE CYTOKINES AND THE INITIATION OF PULMONARY INFLAMMATION

Cytokines are important communication links to initiate, maintain, and resolve the inflammatory response. The cytokines that are involved in the innate immune response of the lung are not constitutively expressed, and must be called into play by specific signals that alert the host to invading microorganisms or early triggering events. Evolution has provided the mammalian host with two major forms of host defense: the innate and the adaptive immune responses. The innate defense is the gatekeeper for immediate host defense against invading microorganisms and has been predetermined to recognize microorganism-associated molecular patterns. The adaptive immune response is naïve, delayed in development, and depends on two classes of specialized lymphocytes, T and B cells, which respond to antigen presentation by professional antigen-presenting cells (i.e., dendritic cells).

Microorganisms express highly conserved molecular patterns that are unique and distinguish themselves from the host. The host has evolved specific pattern recognition receptors to detect these pathogen-associated molecules. The mammalian Toll-like receptors (TLR) are important signaling receptors in innate host defense, and have evolved from the *Drosophila* Toll gene. Both toll and mammalian TLRs share similar signal-transduction pathways that ultimately involve the nuclear factor-κB (NF-κB) family of transcriptional factors. NF-κB plays an important role in the transactivation of a number of cytokines that are involved in the innate immune response and development of pulmonary inflammation.

While TLRs and the innate immune response are necessary to sense and initiate the host response to microorganism molecular patterns, cytokines are necessary for the full development of the innate host defense and the promotion of acute pulmonary inflammation. Early response cytokines are cytokines that are activated initially after TLR signal coupling. Two of the most important early response cytokines in innate immunity and acute pulmonary inflammation are IL-1 and TNFα. Almost all cells in the body possess functional receptor for IL-1 and TNF, suggesting that these cytokines are important in local and systemic cell communication.

Interleukin-1 Family of Cytokines

The interleukin-1 family of cytokines consists of two agonists, IL-1α and IL-1β, and one antagonist, interleukin-1 receptor antagonist (IL-1Ra). These two forms of IL-1 are distinguished by whether they are found predominantly membrane associated (IL-1α) or secreted (IL-1β). IL-1Ra is the only known naturally occurring cytokine with specific antagonistic activity. IL-1Ra acts as a pure antagonist of either IL-1α or IL-1β and can attenuate a variety of IL-1 actions, which may play a role in the resolution of the pulmonary inflammatory cascade.

IL-1 and IL-1Ra have been implicated in the pathogenesis of a variety of lung diseases, including bronchial asthma, acute respiratory distress syndrome (ARDS), panbronchiolitis, and pulmonary fibrosis. In ARDS, low levels of the anti-inflammatory cytokines, IL-10 and IL-1Ra, in the BAL of patients with early disease correlated with a poor prognosis. Intratracheal injection of LPS, IL-1, or TNF has similar effects with an intra-alveolar inflammatory response composed predominantly of neutrophils, followed later by mononuclear cells. In addition, LPS is capable of inducing both TNF and IL-1 gene expression in the lung, which is important for its effect in amplifying the inflammatory response. In contrast, IL-1ra reduces the inflammatory response to LPS in the lungs.

Chronic imbalance between IL-1β and IL-1ra may result in the propagation of an overexuberant reparative and fibrotic phase. Inhibition of IL-1–dependent collagenases may manifest as a lack of reabsorption of excessive collagen, and the failure to repair the matrix. IL-1ra levels from lung tissue homogenates of patients with idiopathic pulmonary fibrosis (IPF) may directly correlate with mortality. Similarly, IL-1ra is elevated in lung transplant patients with obliterative bronchiolitis and correlates with the development of obliterative bronchiolitis. Further support for the role of IL-1ra in the development of fibrosis is seen in the report of a polymorphism in the IL-1Ra gene that is associated with increased risk of development of IPF.

Tumor Necrosis Factor-alpha

Tumor necrosis factor (TNF) is produced primarily by monocytes/macrophages, and has many overlapping biologic activities with IL-1. Elevated levels of TNF have been implicated in the pathogenesis of a number of disease states, including septic shock/sepsis syndrome, ARDS, hepatic ischemia/reperfusion injury, graft vs. host disease, and heart, kidney, liver, and lung allograft rejection. TNF exhibits a variety of inflammatory effects, including induction of neutrophil- and mononuclear cell–endothelial cell adhesion and transendothelial migration; enhancement of a procoagulant environment; and acting as an early response cytokine in the promotion of a cytokine cascade.

Although the pathogenesis of septic shock and the development of acute lung injury are multifactorial, the role of TNF and IL-1 in mediating septic shock and ARDS has been clearly demonstrated. Serum levels of both TNF and IL-1 correlate with mortality in meningococcal septicemia. The ratio of TNF to IL-10 in BAL fluid is significantly higher in ARDS patients than at-risk patients. Administration of TNF to animals induces similar pathophysiological effects to either endotoxin or infusion of live gram-negative bacteria. Based on these studies, there was considerable enthusiasm for the inhibition of TNF in sepsis. However, inhibition of TNF in humans with sepsis has been disappointing, although there may be subgroups of patients that derive benefit.

TNF has an important role in the development of pulmonary fibrosis. (For further discussion of pulmonary fibrosis, see Chapter 26.) TNF levels are paralleled by the increase in the gene expression of TGF-β and precede the gene expression of both types I and III procollagen in the murine bleomycin model. Inhibition of the biologic effect of TNF attenuates fibrosis in animal models. In mice, transgenic expression of TNF in the lungs leads to a predominant lymphocytic alveolitis and the pathology of the lung demonstrates a continuum of inflammation to fibrosis demonstrating many features of UIP (usual interstitial pneumonia). These studies support the notion that TNF may be an important cytokine in the pathogenesis of pulmonary fibrosis; however, its role may be variable in different situations.

TYPE I AND TYPE II CYTOKINES

Type I (Th_1) cytokines, which include IFN-γ, IL-2, and IL-12, appear to be involved in cell-mediated immunity associated with autoimmune disorders and allograft rejection. Type II (Th_2) cytokines, which include IL-4, IL-5, IL-10, and IL-13, are predominantly involved in mediating allergic inflammation and chronic fibroproliferative disorders, such as asthma, atopic dermatitis, IPF, and systemic sclerosis. Therefore, it is reasonable to define certain diseases in terms of the predominant cytokine profile that is present (i.e., type I or II cytokine type) (Fig 23-1).

IFN-γ is a pivotal type I cytokine in regulating both the innate and adaptive immune responses. IFN-γ induces the expression of interferon-inducible CXC chemokines and CC chemokines from a variety of cells, and indirectly amplifies the recruitment of additional leukocytes to a site of innate host response. The recruitment of mononuclear cells expressing the CXC chemokine receptor, CXCR3, especially Th1 cells, leads to further amplification of the local expression of IFN-γ. In contrast, IFN-γ suppresses a number of ELR^+ CXC chemokines from a variety of cells. The suppression of ELR^+ CXC chemokines by IFN-γ and the induction of interferon-inducible CXC and CC chemokines may be an important mechanism for switching from a predominant neutrophil to mononuclear cell infiltration, allowing the transition from innate to adaptive immunity.

The cytokine profile of the inflammatory response determines the disease phenotype responsible for either resolution or progression to end-stage fibrosis (Fig 23-1). IFN-γ has profound suppressive effects on the production of extracellular matrix proteins, such as collagen and fibronectin, although it does not have a direct effect on collagen gene expression. IFN-γ is also a potent modulator of a major matrix-degrading metalloproteinase, stromelysin-1, inhibiting or activating expression differently in different cell types. It up-regulates gene expression of stromelysin-1 by human fibroblasts. Whether this in vitro observation applies in vivo is unclear, as IL-12 attenuates bleomycin induced pulmonary fibrosis via induction of IFN-γ.

Pulmonary expression of the type II cytokine, IL-4, in transgenic mice leads to little or no fibrosis, suggesting a disparity between the in vitro and in vivo effects. Similarly, IL-4 depletion studies and studies with IL-4 –/– mice fail to demonstrate an indispensable role for IL-4 in models of type II–mediated inflammation and fibrosis. Many of the fibroblast activation properties of IL-4 are shared by IL-13, which has similar biologic properties to IL-4, and has been implicated in the pathogenesis of fibroproliferative disorders. The phenotype of transgenic mice expressing IL-13 demonstrates airway epithelial cell hypertrophy, mucus cell metaplasia, and subepithelial airway fibrosis. Similarly, IL-13 has been shown to induce fibrosis by selectively stimulating production and activation of TGF-β. Furthermore, IL-13 can promote fibrosis through the elaboration of CCL5. In a model of *Schistosomiasis*-induced liver fibrosis, IL-13 can promote fibrosis by a mechanism that is independent of TGF-β.

Lung tissue in patients with IPF has been examined for type I and 2 cytokines, and the presence of type II cytokines predominated over the expression of IFN-γ. In further support of an imbalance of the presence of type II cytokines as compared with IFN-γ, is the finding that IFN-γ levels are inversely related to the levels of type III procollagen in the BALF of IPF patients. The levels of IFN-γ were especially correlated with patients that demonstrate progression of their pulmonary fibrosis by evidence of further deterioration of their pulmonary function. Further support for this notion comes from a recently completed phase 3 trial of IFN-γ in patients with IPF, which suggested an improvement in survival in patients treated with IFN-γ. These findings suggest that the persistent imbalance in the expression of type I and II cytokines in the lung may be a mechanism for the progression of pulmonary fibrosis.

IL-10 is a type II cytokine that inhibits a variety of innate and adaptive immune activities. IL-10 inhibits a number of proinflammatory cytokines that include IFN-γ, IL-1, TNF, IL-12, and CXC and CC chemokines. While the exogenous administration of IL-10 may protect the lung from injury in response to either LPS or immune-complex deposition, IL-10 can be detrimental to the host under conditions of microorganism invasion. The role of IL-10 in pulmonary fibrosis is controversial, with experimental data pointing to both anti-inflammatory and profibrotic activity.

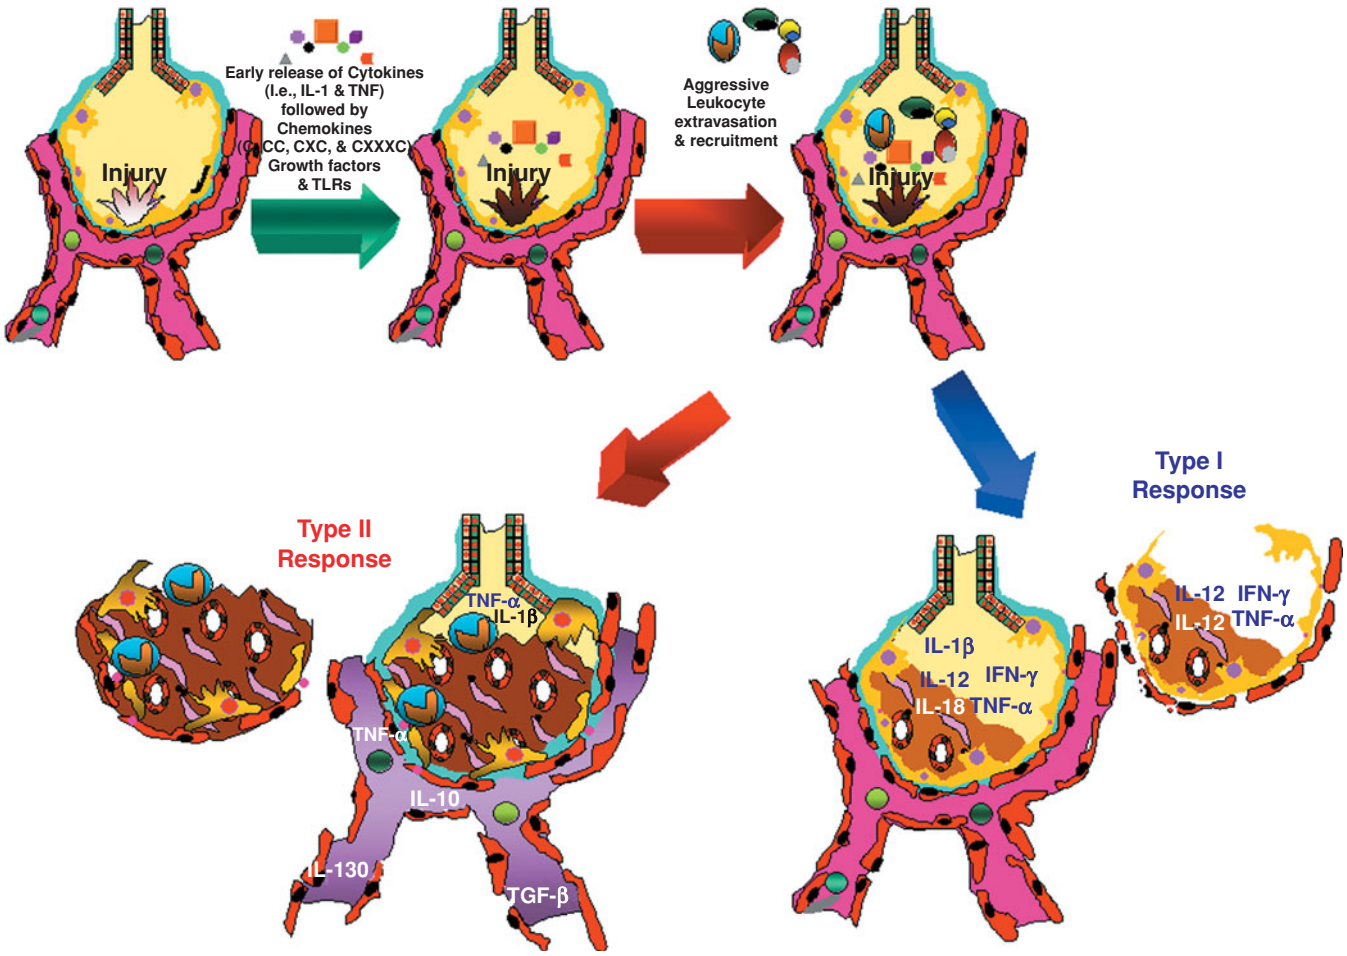

Figure 23-1 The inflammatory response to lung injury. The cytokine profile that is secreted by inflammatory cells during lung injury determines the ultimate outcome following injury. Polarization of the inflammatory response toward a type I response is associated with resolution of lung injury or infection. In contrast chronic infections (e.g., tuberculosis) and chronic inflammatory diseases (e.g., idiopathic pulmonary fibrosis) are associated with a type II profile.

FIBROTIC CYTOKINES

Transforming Growth Factor-beta

Mammalian transforming growth factor-beta (TGF-β) belongs to a superfamily of genes and exists as three closely homologous (72 to 80 percent) dimeric isoforms: TGF-β_1, TGF-β_2, and TGF-β_3. Although the three isoforms of TGF-β appear to have overlapping biologic activity, the predominant isoform of TGF-β is TGF-β_1. There are three TGF-β receptors and signal transduction to the nucleus is via the Smad group of proteins. Smad 1, 2, 3, 4, 5, 8, and 9 are activating signals, whereas Smad 6 and 7 are inhibitory signals of TGF-β_1 signaling.

TGF-β is produced by a variety of cells, including platelets, neutrophils, eosinophils, mononuclear leukocytes, fibroblasts, and endothelial cells. TGF-β is a pleiotropic cytokine that can modulate inflammatory and immune responses, and orchestrate fibrosis and tissue repair. TGF-β is a potent chemoattractant for monocytes and macrophages, and can activate these cells to express IL-1, TNF, PDGF, and itself (TGF-β_1). TGF-β is a potent immunosuppressive agent that inhibits IL-1–dependent lymphocyte proliferation.

TGF-β is chemotactic for fibroblasts and can indirectly induce their proliferation via the expression and autocrine and paracrine activity of PDGF-B. TGF-β is perhaps the most potent and efficacious promoter of extracellular matrix production–inducing gene expression and protein production of many of the constituents of extracellular matrix. Furthermore, it inhibits the generation of metalloproteinases and augments the expression of tissue inhibitors of metalloproteinases (TIMP).

Transient overexpression of active TGF-β_1 results in prolonged and severe interstitial and pleural fibrosis. Transfer of TNF-α or GM-CSF to rat lung induces pulmonary fibrosis, due in part to induction of TGF-β_x. Furthermore, transient expression of IL-1β using an adenoviral vector can lead to progressive fibrosis that is associated with a sustained increase in levels of TGF-β_1. Smad 3 –/– mice developed less fibrosis in response to bleomycin compared with wild-type controls. In contrast, IL-7 down-regulates TGF-β production and inhibits

bleomycin-induced pulmonary fibrosis, and this is mediated via Smad 7 signaling.

In IPF, increased expression of TGF-β has been found in bronchiolar epithelial cells, epithelial cells of honeycomb cysts, and hyperplastic type II pneumocytes. BALF from patients with IPF induces apoptosis in cultured bronchiolar epithelial cells, and this effect is attenuated using anti TGF-β_1 antibodies. In the bleomycin model, in vivo administration of TGF-β_1 enhanced Fas-mediated epithelial cell apoptosis and lung injury. While polymorphisms in the TGF-β gene do not predispose to the development of IPF, there is an increased rate of progression in patients with the presence of a proline residue at codon 10 of the TGF-β gene. These studies support the contention that TGF-β is an important mediator of human pulmonary fibrosis.

Connective Tissue Growth Factor

Connective tissue growth factor (CTGF) is a member of the structurally related CCN (ctgf/cyr61/nov) gene family, which contains six genes: CTGF, cyr61, nov, elm1, cop1, and WISP-3. CTGF I is produced by vascular smooth muscle cells, fibroblasts, endothelial cells, and epithelial cells, and is activated by a number of factors, particularly TGF-β. CTGF has in vitro activities that include fibroblast proliferation, fibroplasia, and extracellular matrix production. Furthermore, its presence has been documented in skin lesions of systemic sclerosis, keloids, scar tissue, and eosinophilic fasciitis and in BALF from patients with IPF and sarcoidosis. Transient overexpression of CTGF in a rat model leads to a moderate but reversible pulmonary fibrosis that is associated with increased levels of TIMP-1. Overexpression of TGF-β leads to a concomitant increase in CTGF and TIMP-1, suggesting that CTGF may be a co-factor for the development of fibrosis. CTGF may be responsible for some of the downstream actions of TGF-β and is a potential therapeutic target for the treatment of interstitial lung disease.

CHEMOTACTIC CYTOKINES AND THE INFLAMMATORY RESPONSE

The salient feature of inflammation is leukocyte infiltration. These recruited leukocytes contribute to the pathogenesis of chronic inflammation and promote fibrosis via the elaboration of a variety of cytokines. Maintenance of leukocyte recruitment during inflammation requires the expression of cell-surface adhesion molecules, and the production of chemotactic molecules, such as chemokines. The chemokines can be divided into four families—CXC, CC, C, and CXXXC—which behave as potent chemotactic factors for neutrophils, eosinophils, basophils, monocytes, mast cells, dendritic cells, NK cells, and T and B lymphocytes (Table 23-1). There is approximately 20 percent to 40 percent homology between the members of the four chemokine families. Chemokines are produced by an array of cells, including monocytes, alveolar macrophages, neutrophils, platelets, eosinophils, mast cells, T- and B-lymphocytes, NK cells, and various structural cells, including keratinocytes, mesangial cells, epithelial cells, hepatocytes, fibroblasts, smooth muscle cells, mesothelial cells, and endothelial cells. Production of chemokines by both immune and nonimmune cells supports the contention that these cytokines may play a pivotal role in orchestrating chronic inflammation.

CXC Chemokines

CXC chemokines can be further divided into two groups on the basis of a structure/function domain consisting of the presence or absence of three amino acid residues (Glu-Leu-Arg; ELR motif) that precede the first cysteine amino acid residue in the primary structure of these cytokines. ELR^+CXC chemokines are chemoattractants for neutrophils and act as potent angiogenic factors. In contrast, ELR^-CXC chemokines are highly induced by interferons, are chemoattractants for mononuclear cells, and are potent inhibitors of angiogenesis (Table 23-2).

CXC Chemokine Receptors

Chemokine activities are mediated through G-protein–coupled receptors. Seven CXC chemokine receptors have been identified (Table 23-3). The ELR+ chemokines bind to CXCR1 and CXCR2 receptors, which are found on neutrophils, T-lymphocytes, monocytes/macrophages, eosinophils, basophils, keratinocytes and mast cells, and endothelial cells. CXCR3 is the receptor for CXCL9, CXCL10, and CXCL11, and is expressed on activated T-lymphocytes. CXCR3 is also expressed on HUMVEC in a cell cycle–dependent fashion. CXCR4 is the specific receptor for CXCL12 and is the cofactor for lymphotropic HIV-1. In contrast to CXCR3, CXCR4 appears to be expressed on resting T-lymphocytes. Two other chemokine receptors have been identified that bind chemokines without a subsequent signal-coupling event. The DARC receptor is similar to other chemokine receptors and it binds both CXC and CC chemokines without apparent signal coupling. This receptor was originally found on human erythrocytes and was thought to represent a "sink" for chemokines. The second nonsignaling chemokine receptor is the D6 receptor, which binds several CC chemokines with high affinity, including CCL2, CCL4, CCL5, and $CCL7^-$.

CXC Chemokines in Pulmonary Inflammation

CXC chemokines play a significant role in mediating neutrophil infiltration in the lung parenchyma and pleural space in response to endotoxin and bacterial challenge. CXCL8 is in the bronchoalveolar lavage of patients with community-acquired pneumonia and nosocomial pneumonia and a variety of animal models of pneumonia. In a model of *Aspergillus fumigatus* pneumonia, neutralization of TNF resulted in marked attenuation of the expression of CXCL1 and CXCL2/3 that was paralleled by a reduction in the infiltration of neutrophils and associated with increased mortality. Administration of a TNF agonist peptide to animals

Table 23-1

The Human C, CC, CXC, and CXXXC Chemokine Families of Chemotactic Cytokines

C Chemokines	
XCL1	Lymphotactin
XCL2	SCM-1β
CC Chemokines	
CCL1	I-309
CCL2	Monocyte chemotactic protein-1 (MCP-1)
CCL3	Macrophage inflammatory protein-1 alpha (MIP-1α)
CCL4	Macrophage inflammatory protein-1 beta (MIP-1β)
CCL5	Regulated on activation normal T-cell expressed and secreted (RANTES)
CCL7	Monocyte chemotactic protein-3 (MCP-3)
CCL8	Monocyte chemotactic protein-2 (MCP-2)
CCL9	Macrophage inflammatory protein-1 delta (MIP-1δ)

that had been intratracheally inoculated with *Klebsiella pneumoniae* led to markedly elevated levels of CXCL2/3 associated with increased neutrophil infiltration. Interestingly, ELR-CXC chemokines have direct antimicrobial properties. These studies have established the critical importance of CXC chemokines in acute inflammation and the innate immune response to a variety of microorganisms.

CXCL8 significantly contributed to reperfusion lung injury in a rabbit model of lung ischemia-reperfusion injury, and ventilator-induced lung injury in a murine model is associated with increased expression of CXCL1 and CXCL2

that parallels lung injury and neutrophil recruitment. CXCR2 –/– mice were protected from ventilator-induced lung injury. These findings support the notion that ventilator-induced lung injury is secondary to stretch-induced chemokine release with a subsequent inflammatory response and neutrophil recruitment. CXCR2 –/– mice are also protected from hyperoxia-induced lung injury. In other studies, it has been demonstrated that hepatic ischemia-reperfusion injury and the generation of TNF can result in pulmonary-derived CXCL5, showing the importance of cytokine networks between the liver and lung. The production of CXCL5 in the lung was correlated with the presence of neutrophil-dependent lung injury, and passive immunization with neutralizing CXCL5 antibodies resulted in significant attenuation of lung injury.

Several studies have demonstrated that CXCL8 levels correlate with the development and mortality of ARDS. Early increases in CXCL8 in bronchoalveolar lavage fluid correlated with an increased risk of subsequent development of ARDS, and also demonstrated that alveolar macrophages were an important source of CXCL8 prior to neutrophil influx. Furthermore, there is an imbalance in the expression of ELR+ (CXCL1, CXCL5, CXCL8) as compared with ELR-CXC (CXCL10, CXCL11) chemokines from BALF of patients with ARDS as compared with controls. This imbalance correlated with angiogenic activity and both procollagen I and procollagen III levels in BALF. These findings suggest that CXC chemokines have an important role in the fibroproliferative phase of ARDS via the regulation of angiogenesis.

The Role of CXC Chemokines in Pulmonary Fibrosis

IPF is characterized by the progressive deposition of collagen within the interstitium and subsequent destruction of lung tissue. The mechanisms of cellular injury and the role of classic inflammatory cells remain unclear. While the number or proportion of neutrophils in BALF does not correlate with activity of alveolitis and has limited prognostic value, declines in BALF neutrophils typically occur among patients exhibiting favorable responses to therapy. CXCL8 is significantly elevated in IPF, as compared with either normal or sarcoidosis patients, and correlates with BALF presence of neutrophils. The alveolar macrophage is an important cellular source of CXCL8 in IPF. In addition, BALF levels of CXCL8 in IPF may correlate with a worse prognosis.

Vascular Remodeling in Pulmonary Fibrosis: The Role of CXC Chemokines

The existence of neovascularization in IPF was originally identified in 1963 by Turner-Warwick, who demonstrated that within areas of pulmonary fibrosis there was extensive neovascularization with anastomoses between the systemic and pulmonary microvasculature. Further evidence of neovascularization during the pathogenesis of pulmonary fibrosis has been demonstrated in a rat model of bleomycin-induced pulmonary fibrosis. Recently, an imbalance in the levels of angiogenic chemokines (CXCL5, CXCL8), as

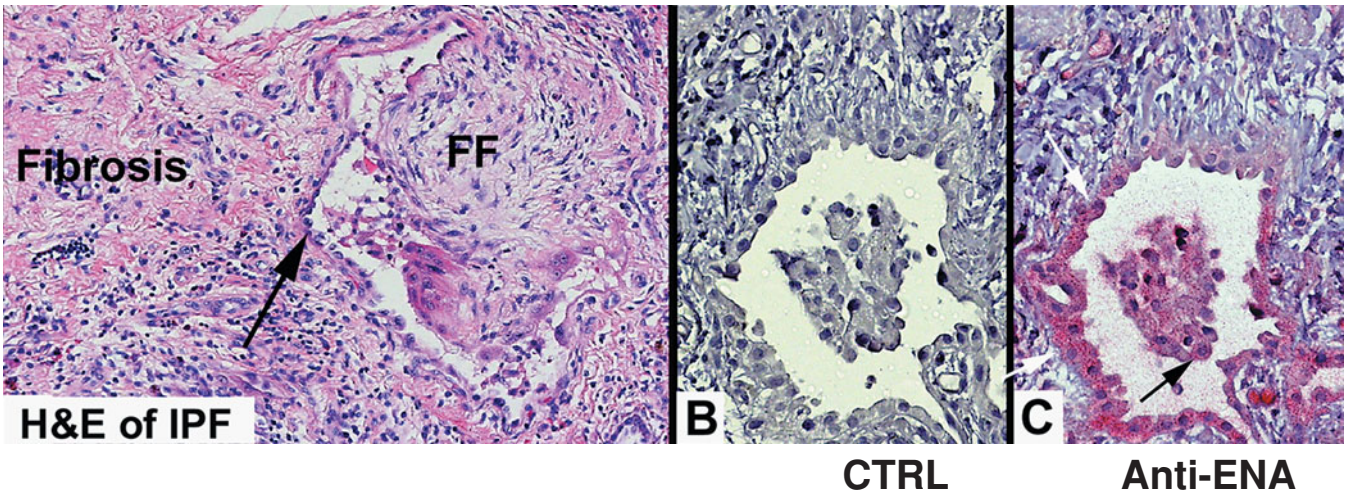

Figure 23-2 Photomicrograph showing immunolocalization of CXCL5 from idiopathic pulmonary fibrosis (IPF) lung tissue specimens. *A*. Hematoxylin and eosin stain of IPF lung tissue (×66) demonstrating a fibroblastic focus (FF) in close proximity to hyperplastic epithelium (arrow). *B*. IPF lung section (×66) stained with control antibodies demonstrating the lack of non specific staining. *C*. IPF lung section (×66) stained with anti-CXCL5 antibodies demonstrating immunolocalization to hyperplastic type II pneumocytes (white arrows) and macrophages (black arrow). *(From Keane MP, Belperio JA, Burdick MD, et al: ENA-78 is an important angiogenic factor in idiopathic pulmonary fibrosis. Am J Respir Crit Care Med 164:2239–2242, 2001.)*

compared with angiostaxic chemokines (CXCL9, CXCL10, CXCL11), favoring net angiogenesis has been demonstrated in both animal models and tissue specimens from patients with IPF (Fig. 23-2). Renzoni et al have demonstrated vascular remodeling in both IPF and fibrosing alveolitis associated with systemic sclerosis. Cosgrove et al provided further support for the concept of vascular remodeling in IPF when they demonstrated a relative absence of vessels in the fibroblastic foci of IPF. This appeared to correlate with increased expression of pigment epithelium–derived factor in the fibroblastic foci. Interestingly, they also noted significant vascularity in the areas of fibrosis around the fibroblastic foci, with numerous abnormal vessels in the regions of severe architectural distortion. These findings are similar to those of Renzoni and support the concept of regional heterogeneity of vascularity in IPF. This heterogeneity is not surprising, as usual interstitial pneumonia, which is the pathological description of IPF, is defined by its regional and temporal heterogeneity.

Furthermore, a phase II study of the administration of IFN-γ to patients with IPF demonstrated a significant upregulation of lung CXCL11 gene expression and BAL and plasma protein levels of CXCL11. These findings support the notion that vascular remodeling is a critical biologic event that supports fibroplasia and deposition of ECM in the lung during pulmonary fibrosis.

Chemokines and the Trafficking of Fibrocytes to the Lung

Fibrocytes present in the peripheral circulation were first identified in 1994, comprise a minor component of the circulating pool of leukocytes (less than 1 percent), and express a characteristic pattern of markers, including collagen (Col) I and CD45. Subsequent studies have revealed that circulating fibrocytes express chemokine receptors such as CXCR4 and CCR7 and extracellular matrix proteins, such as procollagen I and procollagen III. Fibrocytes migrate in response to CXCL12 and traffic to the lungs in a model of bleomycin-induced pulmonary fibrosis. Treatment of bleomycin-exposed animals with specific neutralizing anti-CXCL12 antibodies inhibits intrapulmonary recruitment of fibrocytes and attenuated lung fibrosis. These findings challenge the dogma that fibroblasts and myofibroblasts arise from an intrapulmonary pool of tissue fibroblasts.

The CC Chemokines

CC chemokines (Table 23-1) are chemoattractants for monocyte, T and B lymphocytes, NK cells, dendritic cells, basophils, mast cells, and eosinophils. The CC chemokines are produced by an array of cells, including monocytes, alveolar macrophages, neutrophils, platelets, eosinophils, mast cells, T cells, B cells, and NK cells, as well as structural cells such as keratinocytes, mesangial cells, epithelial cells, hepatocytes, fibroblasts, smooth muscle cells, mesothelial cells, and endothelial cells.

CC Chemokine Receptors

CC chemokine receptors are structurally homologous. Currently at least ten cellular CC chemokine receptors have been cloned, expressed, and identified to have specific ligand-binding profiles (Table 23-4). It has become increasingly recognized that chemokine receptors are differentially expressed on T cells depending on their antigenic experience and type of polarization. Chemokines and their receptors are essential components of type I– and II–mediated responses. Naïve

Table 23-4

The CC Chemokine Receptors

Receptor	Ligand
CCR1	CCL3, CCL5, CCL7, CCL14, CCL15, CCL16, CCL23
CCR2	CCL2, CCL7, CCL13
CCR3	CCL5, CCL7, CCL11, CCL11, CCL15, CCL26
CCR4	CCL17, CCL22
CCR5	CCL3, CCL4, CCL5
CCR6	CCL20
CCR7	CCL19
CCR8	CCL1
CCR9	CCL25
CCR10	CCL27

T cells express CXCR4 and CCR7 and migrate in response to CXCL12 and CCL19. CXCR3, CXCR6, and CCR5 are expressed at higher levels on type I cells than type II, whereas CCR3, CCR4, and CCR8 are more characteristic of type II cells.

CC Chemokines in Pulmonary Inflammation

The CC chemokines, CCL2, CCL3, CCL4, CCL5 have been implicated in mediating the innate host defense in animal models of *Influenza* A virus, *Paramyxovirus* pneumonia virus, *Aspergillus fumigatus*, and *Cryptococcus neoformans* pneumonias. *Cryptococcus neoformans* is acquired via the respiratory tract and is a significant cause of fatal mycosis in immunocompromised patients. CCL2 and CCL3 play important roles in the eradication of *Cryptococcus neoformans* from the lung and prevent cryptococcal meningitis. These studies support the notion that CC chemokine ligand/receptor biology plays a critical role in innate host defense and development of pulmonary inflammation that is important in eradication of microorganisms.

The host response to *Influenza* A virus is characterized by an influx of mononuclear cells into the lungs that is associated with the increased expression of CC chemokine ligands. CCR5 –/– mice displayed increased mortality related to severe pneumonitis, whereas CCR2 –/– mice were protected from the severe pneumonitis due to defective macrophage recruitment. However the delay in macrophage accumulation in CCR2 –/– mice was correlated with high pulmonary viral titers. In CCR1 –/– mice infected with *Paramyxovirus* pneumonia virus, the inflammatory response was found to be minimal, the clearance of virus from lung tissue was reduced, and mortality was markedly increased.

The effect of CC chemokines in mediating the recruitment of mononuclear cells during the innate host defense is not limited to viral infections. Mehrad and colleagues have shown that CCL3 and the recruitment of mononuclear cells play an important role in the eradication of invasive pulmonary aspergillosis. They demonstrated that in both immunocompetent and neutropenic mice CCL3 is induced in the lungs in response to intratracheal inoculation of *Aspergillus fumigatus*. Depletion of endogenous CCL3 resulted in increased mortality in neutropenic mice, which was associated with a reduced mononuclear cell infiltration and markedly decreased clearance of lung fungal burden. These findings have been confirmed by the demonstration that CCR1 –/– mice exposed to *Aspergillus fumigatus* had markedly increased mortality compared with wild-type mice. These studies indicate that CCL3 and elicitation of mononuclear cells are crucial in mediating host defense against *Aspergillus fumigatus* in the setting of neutropenia.

CC Chemokines in Pulmonary Fibrosis

Animal models, such as bleomycin-induced pulmonary fibrosis, have demonstrated the presence and contribution of CC chemokines to the pathogenesis of fibrosis. CCL2 is an important cofactor for the stimulation of fibroblast collagen production and induction of the expression of TGF-β_1. Inhibition of CCL2 or CCL3 resulted in a reduction of infiltrating cells into the lungs of bleomycin-treated animals.

Furthermore, it has been shown that CCL2 can stimulate interleukin-4 production, indicating that it might be involved in type II polarization. Neutralization of CCL2 leads to a reduction in IL-4 and an augmentation in IFN-γ production by CD4+ lymphocytes when co-cultured with fibroblasts. These findings suggest that endogenous CCL2 has an important role in the modulation of CD4+ T-cell activation during cell-cell interactions with lung fibroblasts and that these interactions may dictate the cytokine profile associated with an inflammatory response. IL-13 promotes bleomycin-induced fibrosis through the elaboration of CCL6. Both CCL17 and CCL22 and their receptor, CCR4, are significantly elevated in the bleomycin model and neutralization of CCL17 attenuates pulmonary fibrosis. Thus, chemokines may have an important role in the switch toward a profibrotic type II phenotype.

Both CCR1 and CCR2 have been shown to play an important role in the pathogenesis in the mouse model of bleomycin-induced pulmonary fibrosis. Treatment with antibodies to CCR1 leads to a reduction in both inflammatory cell infiltrates and the development of fibrosis. Similarly, CCR2 –/– mice are protected from pulmonary fibrosis in response to bleomycin. Furthermore, alveolar epithelial cells from CCR2 –/– mice suppress fibroblast proliferation more than AECs from wild-type mice. CCL2 and CCR2 have an important

role in suppression of PGE2, thereby promoting fibroproliferation. Similarly, an important role for CCR2 has been seen in murine model of obliterative bronchiolitis, in which the fibrotic response associated with this disorder was attenuated in CCR2 –/– mice. Accordingly, targeting chemokine receptors may be an efficient way to inhibit pulmonary fibrosis.

CCCL2 and CCL3 are elevated in BALF and lung tissue of ILD patients. Furthermore, pulmonary fibroblasts isolated from patients with IPF produced greater amounts of CCL3 after challenge with IL-1β, than did similarly treated normal pulmonary fibroblasts. In addition, CCL2 was produced to a greater extent in the presence of either TNF or IL-1β from isolated pulmonary fibroblasts of patients with IPF, as compared with normal controls. Moreover, pulmonary fibroblasts from IPF patients demonstrate a reduced ability to down-modulate their CCL2 expression in the presence of either PGE_2 or the glucocorticoid dexamethasone.

Choi et al described enhanced expression of the chemokines CCL7 and CCL22, in lung tissue of patients with IPF as compared with nonspecific interstitial pneumonia, and nonidiopathic interstitial pneumonia. Furthermore, they describe increased expression of CCL5 in nonspecific interstitial pneumonia as compared with usual interstitial pneumonia. Interestingly, CCL5 protein was identified in nonspecific interstitial pneumonia more prominently than usual interstitial pneumonia. This is all the more interesting as CCL5 is a major stimulus for the production of CCL7 through its interactions with CCR5. These findings raise the possibility that there is a continuum from nonspecific interstitial pneumonia to usual interstitial pneumonia with higher levels of CCL5 in nonspecific interstitial pneumonia leading to subsequent increased CCL7 expression as the disease progresses to usual interstitial pneumonia. There is considerable controversy as to whether nonspecific interstitial pneumonia is an earlier lesion of usual interstitial pneumonia. Several studies have demonstrated the presence of usual interstitial pneumonia and nonspecific interstitial pneumonia patterns in the same patients, which suggests that these are overlapping processes. The findings of Choi suggest a transition from a predominance of CCL5 to CCL7 and further support this notion. Of further interest is the previous description that CCL7 can act as a natural antagonist at the CCR5 receptor, which raises the possibility that CCL7 may play a role in regulating its own production. It is possible that fibroblasts from patients with usual interstitial pneumonia have an inherent defect that prevents CCL7 from shutting off its own production.

Recently the importance of receptor polymorphisms in various disease states has been demonstrated. CCR5 is the major receptor for CCL3, CCL4, and CCL5. Homozygosity for the CCR5Δ32 mutation has been shown to predict prolonged renal allograft survival (90 percent at 20 years), reduced risk of asthma and decreased severity of rheumatoid arthritis. In contrast, there was an increased frequency of the CCR5Δ32 allele in patients with sarcoidosis that was associated with more apparent disease and an increased need for corticosteroids. This suggests that CCR5Δ32 is associated with altered susceptibility to immunologically mediated diseases and that the balance between chemokines and their appropriately expressed receptor is necessary for the full manifestation of various diseases. Similarly, polymorphisms in the CXCR2 gene have been described in patients with systemic sclerosis both with and without evidence of interstitial lung disease, suggesting that CXCR2 may have a role in the fibrotic process.

CONCLUSIONS

Cytokine and chemokine expression often occur via an amplified cascade or network that involves cellular activation by an early-response cytokine that triggers the expression of more distal cytokines. The generation of cytokine networks is necessary for both the pathogenesis and resolution of a variety of acute and chronic lung diseases, as these mediators are fundamental to the initiation, maintenance, and final resolution of the inflammatory response. Studies that illuminate the mechanistic role of cytokines and chemokines in mediating lung inflammation are likely to lead to novel cytokine-based forms of therapies, which will significantly aid in treating enigmatic lung disease.

Leukocyte Accumulation in Pulmonary Disease

Nicholas W. Lukacs • Peter A. Ward

Mediators produced during inflammatory/immune responses dictate the severity and intensity of pulmonary disease. The profile of inflammatory and chemotactic factors produced during acute and chronic pulmonary disease is responsible for the cell-to-cell communication that orchestrates leukocyte adhesion to vascular endothelium, extravasation, and localization of leukocytes at the site of inflammation. Recruitment of leukocyte populations into inflamed tissues is initiated by cytokine-induced expression of adhesion molecules on vascular endothelium. Endothelial adhesion molecules, which can be up-regulated primarily by tumor necrosis factor (TNFα) and interleukin-1β (IL-1β), include intracellular adhesion molecule-1 (ICAM-1), vascular cell adhesion molecule-1 (VCAM-1), as well as E- and P-selectins. These adhesion molecules play an essential role in facilitating leukocyte adhesion to the endothelium, a necessary step for leukocyte transmigration. Subsequently, leukocyte adhering to the activated vascular endothelium is followed by leukocytic migration into the inflamed tissue, directed by chemotactic molecules at the site of the inflammatory/immune response. Up-regulation of the early response cytokines is crucial for the initiation of these early events to alleviate the inciting agent whether it is infectious or noxious in nature. However, the continuous overproduction of these activating and chemotactic mediators can lead to destructive, pathological consequences. In human lung, inflammation-induced damage can be observed in multiple human diseases, including both acute and chronic inflammatory settings. In this chapter we will examine the factors, molecules, and mediators required in initiation and maintenance of pulmonary inflammatory events in both acute and chronic inflammatory conditions.

LEUKOCYTE ADHERENCE AND MIGRATION REGULATED BY ADHESION MOLECULES

The release of early response mediators leads to the up-regulation of selectins (E and P) and other adhesion molecules (ICAM-1, VCAM-1, etc.) on the surface of vascular endothelial cells within and around the site of inflammation. Selectin molecules (L, P, and E) interacting with their "counter

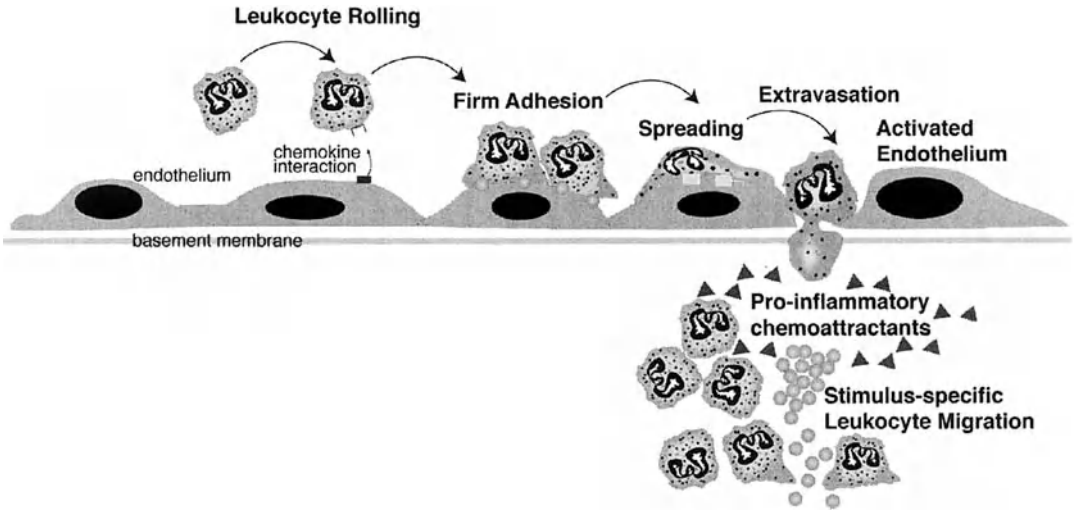

Figure 24-1 Leukocyte adhesion and extravasation into inflamed tissue.

receptors" have been shown to play a role in early adhesion events. E and P selectins are rapidly inducible and initiate rolling of leukocytes on activated endothelium through Ca^{2+}-dependent recognition of cell surface carbohydrates of the sialyl Lewis X family and related oligosaccharides that may be expressed on glycoproteins or glycolipids. L-selectin on lymphocytes, originally referred to as the "lymphocyte homing receptor", has been associated with adhesion of lymphocytes to high endothelial venules (HEV) of lymph nodes. Initial and rapid expression of selectin molecules function to slow the flow of leukocytes in the vascular compartment and allow transient adherence to "counter receptors" expressed on activated vascular endothelium. Normally, adhesion molecules or their "counter receptors" are tightly regulated, while inappropriate or excessive and prolonged expression contributes to inflammatory disorders. The currently held concept is that the rapid expression of selectin molecules facilitates the reversible binding resulting in "rolling" of leukocytes along the activated vascular endothelial surface. This rolling allows the leukocytes to be slowed from circulatory flow, permitting development of firm adhesion to endothelial cell expressed adhesion molecules (VCAM-1 and ICAM-1) at the site of inflammation. These interactions are outlined in Figure 24-1.

The expression of endothelial adhesion molecules leads to a sequence of adherence- promoting events whereby leukocytes ultimately bind firmly to the vascular endothelium via β-integrin receptors on leukocyte surfaces. Although the mechanism is not entirely clear it appears that, at least in the case of β_2 integrins, a change in affinity occurs (at least in CD11a/CD18, LFA-1) during cell activation events, which allows an increased avidity of adhesion-promoting molecules. The change of affinity can be mediated, at least in part, by the interaction of the rolling leukocytes with endothelial cell bound chemokines that can bind to glycosylaminoglycans (GAGs) or are expressed on the surface of the endothelial cell. The β1α4 integrins (VLA-4), expressed primarily on mononuclear cells and eosinophils, have been shown to bind to VCAM-1, while β2-integrins (CD11/CD18), expressed on all leukocytes, bind in varying degrees to intracellular adhesion molecules-1,2,3 (ICAM-1,2,3), the first of which is highly expressed on endothelial cells. These two families of adhesion molecules are able to facilitate leukocyte binding to the activated endothelium and can further dictate the type of leukocytes that bind and extravasate into the inflamed tissue. For example, while neutrophils rely on CD11/CD18 binding to ICAM-1, eosinophils depend upon VLA-4/VCAM-1 interactions to firmly adhere to the endothelial cell wall. Once firmly adherent, leukocytes may then enter the tissue following chemotactic gradients through a series of detachment/readherence events typified by the polar expression of integrins specific for the adhesion molecules on the surface of mesenchymal-derived cells.

Cell-to-cell communication during inflammatory events is mediated by cytokines that mediate, maintain, and regulate the inflammatory responses and dictate the intensity of the reaction. The early response cytokines IL-1 and TNFα appear to play a pivotal role in the induction of inflammatory responses through the initiation of cytokine cascades. The exuberant production of IL-1 and TNFα may lead to multisystem injury and systemic complications, as exemplified in septic shock syndromes. As previously indicated, IL-1 and TNFα initially up-regulate the selectin (E-selectin) and adhesion molecules (ICAM-1, VCAM-1) needed for the first step of leukocyte extravasation into tissue. In addition, IL-1 and TNFα up-regulate other inflammatory cytokines (e.g., IL-6) involved in the chemotactic responses of leukocytes into inflamed tissue. Interestingly, the type of cytokine can dictate the nature of the inflammatory response based upon the adhesion molecule that it induces. For example, while TNF and IL-1 are critical for up-regulation of ICAM-1, which allows neutrophil and monocyte adhesion, IL-4 produced during allergic responses preferentially up-regulates VCAM-1, which mediates eosinophil adhesion. Thus, the inflammatory/immune cytokine environment of the lung can help to tailor the initiation and adhesion of a particular leukocyte

recruitment profile. The production of one of a number of classes of chemotactic factors is required for the movement of leukocytes from the vascular compartment to the interstitium of the lung. We will next describe and characterize the function of chemotactic mediators that are expressed in the lung during specific disease conditions.

CHEMOATTRACTANT MOLECULES DURING LUNG RESPONSE

Complement---An Expande d Role in Acute and Chronic Immunity

The initiation of the complement cascade can be accomplished via multiple mechanisms, including antibody-antigen complexes, bacterial products, and toxins (Fig. 24-2). Of the complement activation products, fragments from C3 and C5 have the most profound effects on the inflammatory response. The split products of C3, C3a and C3b, generated by C3 convertase (as well as further products [iC3b, C3d, C3g]) have important activating roles in the inflammatory pathway. C3a is an anaphylatoxin that induces the activation of mast cells/basophils and appears to have direct and indirect effects on vascular permeability. C3b acts as a potent opsonizing component; it binds to bacteria and allows accelerated phagocytosis and clearance of pathogens via its receptor on neutrophils and macrophages, Mac-1 (CD11b/CD18). The split products of C5, C5a, and C5b can subsequently be induced through the sequential participation of C3b and C5 convertase. Similar to C3a, but much more potent, C5a is an anaphylatoxin, which activates mast cell and basophil degranulation as well as neutrophils and induces immediate changes in vascular permeability. In addition, C5a stimulates smooth muscle contraction and has neutrophil chemotactic and activating characteristics that promote directed migration of these leukocytes toward a concentration gradient. Furthermore, C5a stimulates neutrophil oxidative metabolism, granule discharge, and adhesiveness to vascular endothelium. C5a can directly stimulate endothelial cells in a G protein receptor-dependent fashion (C5aR), to cause signal transduction events resulting in increased intracellular Ca^{2+}, induction of superoxide (O_2^-), and expression of P-selectin. C3a lacks these latter activities. Accordingly, C5a has the ability to stimulate both leukocyte as well as endothelial cells. Altogether, these functions of C3 and C5 split products suggest that they are potent inflammatory mediators.

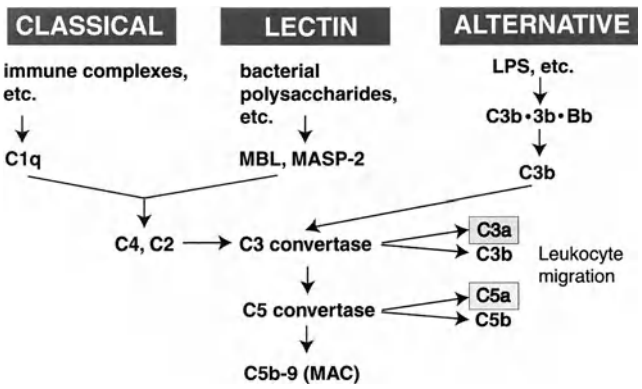

Figure 24-2 Activation pathways for complement cascade.

Elevated complement component levels have been described with several pulmonary diseases, including sarcoidosis, idiopathic pulmonary fibrosis (IPF), acute respiratory distress syndrome (ARDS), and chronic obstructive pulmonary disease (COPD). Bronchoalveolar lavage fluid (BALF) samples from sarcoid and patients with IPF demonstrate a significant increase in complement component C2/CH50 ratio when compared to BALF analysis from normal individuals, suggesting the presence of complement pathway activation within the lung. In trauma patients at risk for ARDS, an increased ratio of BALF C3a to plasma C3a has been associated with development of ARDS, suggesting substantial complement activation locally within the lung. Using animal models of acute pulmonary disease related to sepsis, blocking C5a or C5aR has been demonstrated to prevent severe pulmonary consequences and long-term disease, suggesting a potential therapeutic strategy to blocking C5a activation. Interestingly, a major source of complement component C3 within the lung has been identified as type II epithelial cells with synthesis being induced by several mechanisms, including IL-4 activation. In addition to being activated by IL-4, recent data have begun to outline the differential role that C3a and C5a have on induction of immune responses. These complement components are able to direct the development of immune responses during the initiation of immune responses by regulating IL-12 production. Specifically, C3a appears to drive IL-12 production that then favors type 1 immune responses, while C5a down-regulates IL-12 and allows IL-4–mediated type 2 immune responses to be induced. This scenario may be especially important during sensitization to various antigens in determining the extent and severity of the pulmonary immune response. However, these two complement activation products maintain their ability to be potent recruitment factors when generated during an established allergic/immune response and will promote additional leukocyte recruitment and activation. Although increased levels of complement components, which likely amplify the inflammation and injury within the lung, can accompany pulmonary diseases, it is not clear whether these components have causative or potentiating effects in end-stage lung disease. Thus, conclusions of the role of C3a and C5a should be viewed cautiously in relationship to chronic inflammatory diseases of the lung, while targeting these molecules during pulmonary inflammatory disease continues to be a controversial topic.

The receptors for C3a and C5a have been a source of intense research over the past several years and have led to the resurgence of interest in potentially blocking specific responses during pulmonary disease. The distribution of these receptors depicts their broad role in innate and acquired immune responses as both C3aR and C5aR can be found on

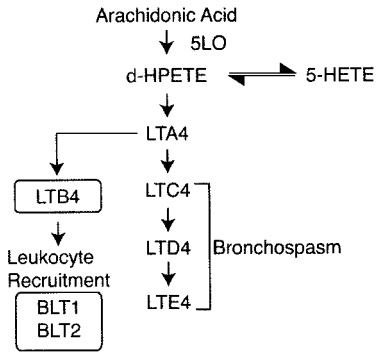

Figure 24-3 Arachidonic acid metabolism for leukotriene biosynthesis.

alveolar macrophages, dendritic cells (DCs) and mast cells, and in sentinel cell populations in the lung that provide important cues for the immediate and prolonged determination of effective immune responses. In particular, activation of these cell populations has been assessed for the differential activation consequences of C3a and C5a. At the same time the expression of C5aR on neutrophils allows an immediate and efficient migration into the lung and activation at the site of inflammation. C5aR is also displayed on cells involved in chronic immune responses, such eosinophils recruited during allergic responses. Thus, the activation of the complement system likely has potent effects on both acute inflammatory responses as well as chronic inflammation that can lead to long-term pulmonary dysfunction. Interestingly, recent findings have described an additional C5a receptor, C5L2, which binds C5a extremely efficiently, but has no linkage to G protein and therefore conveys no activation pathways for inflammation. Research examining the possible implications of this second receptor for modulating C5a-mediated responses by competitively binding up C5a during inflammatory responses is the subject of focus from several laboratories.

Arachidonic Acid and Lung Responses

The enzymatic processing of arachidonic acid (AA) produces a number of lipid mediators that have long been known to be associated with acute and chronic inflammatory responses in the lung. Phospholipase A2 degradation of AA-containing phospholipids lead to the breakdown into PAF-derivative and free AA that can be immediately processed by 5-LO into 5-HPETE and further processed by 5-LO into leukotriene A4 (Fig. 24-3). 5-HPETE can alternatively be processed into 5-HETE by peroxidase. Leukotriene A4 can be further processed into LTB4 by LTA4 hydrolase or LTC4 by LTC4 hydrolase, followed by continued processing of LTC4 into LTD4 and finally LTE4. These latter metabolites, C4, D4, and E4, are known as the cysteinyl leukotrienes and provide an important stimulus for airway reactivity and decreased lung function during large airways disease, such as asthma. In fact, targeting the cysteinyl leukotrienes has provided significant relief to particular subsets of asthmatics.

Of these AA metabolites, PAF and LTB4 have been best characterized for their chemotactic activity promoting migration of leukocytes into sites of inflammation. These mediators were originally identified as potent neutrophil chemoattractants and associated with acute inflammation-induced airway damage. PAF has a broad range of specificity in its ability to induce leukocyte chemotaxis, since it induces the recruitment of not only neutrophils, but also of monocytes, lymphocytes, and eosinophils. During allergic diseases, PAF may have a particular role in augmentation of eosinophil responses. Although PAF is a relatively weak eosinophil chemotactic factor compared to LTB4 or RANTES, PAF does have activating effects on eosinophils, inducing superoxide production, and release of ECP as well as eosinophil peroxidase release. As with all of the eosinophil chemotactic factors, IL-5 enhances the ability of PAF to induce eosinophil chemotaxis. In addition, PAF also appears to have a significant application for augmenting and directly stimulating cytokine production from leukocyte populations. PAF dose dependently stimulates the production of IL-1, but not TNFα, in monocyte and macrophage cultures. PAF-primed neutrophils and monocytes have demonstrated increased superoxide production, elastase release, and endothelial cell lysis in response to phorbol ester or bacterial-derived f-met-leu-phe (fMLP). Not only does PAF have an effect on phagocytic cells, it also can augment T-lymphocyte–derived cytokine production. The actions of PAF on endothelial cells indicate that PAF has a direct role in up-regulation of selectin and adhesion molecules and can induce the release of superoxide anion. Instillation of PAF into human, monkey, or guinea pig airways induces an immediate LTC4-independent bronchoconstrictor response, suggesting a possible role in development of pathophysiology in asthmatic responses. In addition, even the earliest publications identified that PAF airway instillation resulted in an accumulation of leukocytes, including macrophages, neutrophils and eosinophils, accompanied by significant epithelial cell degeneration. Overall, these studies indicate that the signals provided by PAF are not only chemotactic but can also participate in the augmentation of the immune/inflammatory pathway. However, over the years a number of PAF- specific inhibitors have been developed that have not been effective for blocking or attenuating inflammatory responses in the lung.

While leukotrienes in general have broad effects on inflammatory responses, LTB4 is one of the most potent neutrophil chemotactic molecules known and induces superoxide production. However, LTB4 can also act to recruit other leukocyte populations, such as monocytes and eosinophils. In eosinophil chemotactic assays, LTB4 is more potent than PAF in the activation and degranulation of eosinophils. LTB4 has been found in many disease states, including psoriasis, bacterial peritonitis, inflammatory bowel disease, and asthma. LTB4 is rapidly synthesized by phagocytic cells (polymorphonuclear cells [PMNs] and macrophages) after stimulation with bacterial LPS or fMLP. More recently, the LTB4 receptor, BLT1, has been implicated in preferential recruitment of Th2 type T lymphocytes during allergic pulmonary

responses. This receptor has also been implicated in recruitment of T lymphocytes that mediate lung rejection and obliterative bronchiolitis using rodent models. Thus, LTB4 and BLT1 are now being considered targets for therapy in chronic immune responses in the lung compared to their traditional role as a potent neutrophil chemoattractant in acute lung injury.

Chemokines and Immune Cell Migration

Chemokines and their receptors have been primarily divided into two main families based upon their sequence homology and the position of the first two cysteine residues, C-x-C (α) and C-C (β) (Table 24-1). There are two minor families—the C and Cx3C families—each with a single member. Much of our understanding of chemokines has centered upon their role in mediating leukocyte recruitment to the site of inflammation or specifically directing recirculation of leukocytes during homeostasis. Interestingly, results have indicated that many of these family members also have diverse roles in the activation and differentiation of various immune and nonimmune cell populations. While the fact that the chemokine family contains so many members creates confusion of function, the promiscuous binding relationship between multiple members with a single receptor as well as a specific receptor able to bind multiple chemokines contributes considerably to our relative lack of understanding of the biology of the family. In particular, it is often difficult to understand how such a vast number of chemotactic molecules, several being produced at any one time, could coordinate inflammatory responses. Accordingly, studies demonstrate that it may be the overall profile of chemokines that are produced that dictates the inflammatory cell response that accumulates at a site of injury or infection. This latter aspect can be best displayed during acute inflammatory responses, such as in bacterial infections, when the cellular infiltrate is primarily neutrophilic and it is the production of CxCR binding chemokines that mediate this process. Likewise, when more insidious pathogens are present and acute inflammatory mechanisms cannot control the infectious process, immune cytokines, such as interferon (IFN) and IL-4, tend to drive the production of chemokines that allow the mononuclear cells, macrophage, and lymphocytes to be elicited to the site of infection and allow a more sophisticated immune response to develop for clearance of the pathogen. Thus, although there are numerous chemokines being produced during any single response, the overall profile of the response may be directed to recruitment of cells that are most appropriate to deal with the particular stimuli.

In addition to coordinating a response based upon the profile of chemokines being produced, the differential expression of chemokine receptors can also predict what cell populations may migrate into an inflamed lung. The C-x-C family of chemokines has six receptors described to date, C-x-CR1 to C-x-CR6. In general, the C-x-CR1 and R2 appear to be primarily displayed on neutrophils, whereas C-x-CR3 and R4 are displayed on mononuclear cells. This pattern follows the specificity and chemoattractant function of the specific ligands for these receptors as the ELR-containing C-x-C chemokines bind to C-x-CR1 and 2, whereas the non–ELR-containing chemokines bind to C-x-CR3 and SDF binds to C-x-CR4. A fifth C-x-C receptor has been recently identified with specificity for B lymphocytes (BLR1) and appears to have specificity for primarily those cells, while a sixth receptor has been identified that binds a single ligand. This latter receptor has not been well characterized in pulmonary diseases, but has recently been associated with T-cell alveolitis in sarcoidosis.

The CC chemokine receptors have also expanded over the past several years. There are now at least 10 different receptors and their ligand specificity has not completely been identified. The newer receptors of this family (CCR6 through CCR10) have been less well characterized compared to the first five receptors. The first receptor, CCR1, was shown to bind CCL3, CCL4, CCL5, and appears to be expressed on most leukocytes. CCR2 was originally shown to bind CCL2 (MCP-1), and subsequently appears to bind all of the CCL2 family members (CCL2, 7, 8, 12, and 13). CCR3 is highly expressed on eosinophils, is associated with allergic responses, and binds CCL5, CCL7, CCL11, CCL4, CCL24, and CCL26. All of these latter chemokines that bind to CCR3 have been implicated in eosinophil accumulation during allergic responses, such as asthma. CCR4 appears to bind two chemokines, CCL17 and CCL22, and has been linked to both acute and disease conditions. Perhaps the best-characterized receptor is CCR5 due to its use as a coreceptor for human immunodeficiency virus (HIV) infectivity. This receptor binds CCL3, CCL4, and CCL5, and when ligated with these chemokines, can inhibit HIV infectivity in vitro. The CCR6 and CCR7 were initially identified as having a predominant function as homeostatic chemokines providing a function for recirculation of inactivated leukocytes, especially naïve lymphocytes and DCs. However, more recent evidence suggest that these receptors are found on a whole host of leukocyte populations, including memory T cells, suggesting that their function is more extensively involved in the development of chronic disease and long-term immune function. Although the research community has made great strides in our understanding of the role of chemokines and their receptors, we still do not fully understand their diverse functional properties during homeostatic and inflammatory responses.

Chemokines regulate migration of leukocytes in three distinct phases of the response. Initially, chemokine binding to its receptor at the endothelial border allows leukocytes rolling along selectin molecules to activate their β-integrins for firm adhesion to the activated endothelial cells. This initial conformational change is usually mediated by chemokines either bound to the GAGs on the endothelial wall or by membrane-anchored Cx3CL1 (fractalkine) or CxCL16. Both of the latter chemokines are displayed on the surface of cells anchored by an adhesion molecule-like stalk with a transmembrane domain and a cytoplasmic tail. The chemotactic region of this molecule can be cleaved off and still

Table 24-1

Chemokines and Their Receptors

Chemokine	Former Designation	Known Receptor(s)
CC Chemokine Ligands		
CCL1	TCA3/I-309	CCR8

remains active in its soluble form. Once activated by whatever form of chemokine on the endothelium the β-integrins permit the leukocyte to stop, firmly adhere, and allow cytoplasmic spreading. The second phase of migration, movement from the vascular wall into the tissue can be mediated by chemokine gradients maximized at the source of inflammatory stimuli. Once at the site of highest concentration, the cells can then be further activated by the chemokines for effector functions, such as CxCL8-mediated neutrophil degranulation. Thus, it is likely that multiple chemokines could be involved in the process of migrating leukocytes along with other chemotactic molecules, such as C5a or LTB4.

G PROTEIN--COUPLED RECEPTOR-MEDIATED REQUIREMENT FOR MIGRATION

Binding of chemoattractants to specific cell surface receptors on leukocyte populations can initiate directed leukocyte chemotaxis toward the site of inflammation, as well as a number of other biologic events. The chemoattractant receptors appear to all be coupled to protein G_i-mediated pathways (Fig. 24-4). Traditionally, monitoring the hydrolysis of polyphosphoinositides to initiate Ca^{2+} mobilization and cellular activation has been a key end point. However, more information suggests that different subunits of the G protein signaling pathway are involved in Ca^{2+} mobilization and cellular migration, with the alpha subunit inducing Ca^{2+} flux and beta/gamma subunits together responsible for chemotaxis. There appear to be critical signal pathways that are activated and determine chemotactic movement of cells through the beta/gamma subunits (Fig. 24-4). The subunits of heterotrimeric G proteins are known to activate PI3K, MAPKp38, and FAK signaling pathways. While a number of other pathways such as ERK can often be initiated, the essential activation of the ERK1, two pathways required for migration of leukocytes in response to chemoattractants, is not clear. Of these different pathways, PI3K activation has been the most thoroughly studied after a chemotactic signal and acts at the apex of the activation scheme. PI3K activation generates phosphatidylinositols (Ptdlns) species, especially Ptdlns (3,4,5)P_3 (PIP3), which are enzymatically modified by a series of kinases and phosphatases to regulate chemotaxis. The characteristic of a PI3K-mediated chemotactic response via the P110 subunits α, β, γ, which complex with one of seven known adapter molecules, is its sensitivity to pertussis toxin which inhibits the G_i protein–mediated activation of PI3K and blocks cellular migration. Although all three P110 subunits of PI3K may be involved in chemotaxis, the P110γ subunit has been the focus of much of the research in this area and several in-depth reviews have been written. Evidence of the importance of PI3K for chemotaxis can be found in studies using cells deficient in PI3K P110γ as well as in localization studies that have identified activated P110γ

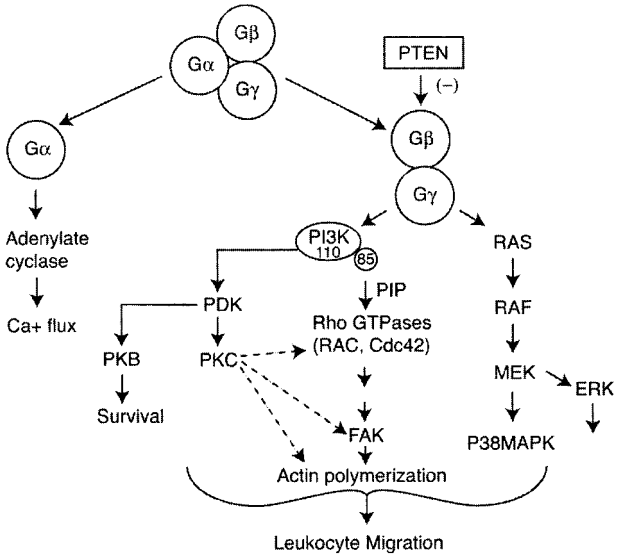

Figure 24-4 G protein–coupled chemoattractant receptor signal transduction pathways.

at the leading edge of migrating cells. Once activated, PI3K appears to couple with the p85 adaptor protein to mediate activation of other important pathways, including activation of rac, rho, and Cdc42 GTPases that subsequently activate actin polymerization pathways. The PI3K-induced responses can be actively regulated by PTEN (phosphatase and tensin homology deleted on chromosome 10 protein) processes. Interestingly, while PI3K appears to be localized to the leading edge during migration, PTEN is found in the trailing edge and is excluded from the leading edge via mechanisms related to GTPase-associated amplification of PIP3 activation. Thus, polarization of PI3K and PTEN in migrating cells is actively achieved by chemoattractant-induced G_i protein–coupled signaling.

Several groups have documented that the tyrosine phosphatase SHP-2 positively regulates cell adhesion and migration by modulating the tyrosine phosphorylation of FAK. It has been proposed that FAK may participate in the regulation of chemotaxis by modulating the turnover of focal adhesions. FAK has been shown to associate with SHP-2 in immune complexes and this association has been shown to increase the tyrosine phosphorylation of FAK, suggesting that SHP-2 may play a role in the activation FAK. Additionally, the protein tyrosine phosphatase PTEN has also been shown to negatively modulate FAK and FAK functions. Together, these studies suggest a mechanism in which chemokine receptors could stimulate the activation of SHP-2 and FAK in order to induce cell migration. Overall, the requirement of multiple parallel signaling pathways to be activated for cellular movement allows better fidelity and control of the migration of leukocytes via G protein–coupled receptors. While these signaling cascades continue to be better defined, there is a paucity of information regarding the differential regulation of migratory signals to control leukocyte recruitment.

PROGRESSION OF LEUKOCYTE MIGRATION DURING PULMONARY INFLAMMATION

The primary function of the immune system is for protection of the host from invading pathogens. Instigating the proper leukocyte populations to migrate into the lung for clearance of a specific pathogen is paramount for efficient clearance of pathogen and preservation of lung function. This process can be regulated based upon the level and type of chemoattractant that is produced. Each type of chemoattractant has a specific and important role for immediate and rapid induction of leukocyte migration or prolonged and more stable recruitment of leukocyte subsets. Unfortunately, the most insidious disease phenotypes in the lung are a result of inappropriate and chronic recruitment of leukocytes that damage the airways and can lead to organ dysfunction. By examining specific types of pulmonary insults, infectious and noninfectious, patterns of mediator involvement emerge that dictate the profile of leukocytes recruited for specialized function. It is this inflammatory response that needs to be controlled for regulation of the long-term effects of lung damage. Our understanding of pulmonary disease has been better defined by examining the differential aspects of infectious and noninfectious lung inflammation.

Bacterial Infection and Sepsis

The early response to infectious organisms is most important when dealing with bacterial infections that can be battled by preventing colonization and by quickly eliminating the inciting agents. This is especially important since bacteria, once established, can proliferate at an expedited rate that outpaces our ability to clear the bacteria. Subsequently, large numbers of bacterial expansion can provide a systemic response leading to sepsis, which is ultimately characterized by multi-organ involvement and often leads to severe pulmonary disease, such as ARDS. The first process that is initiated in this case is the activation of the complement system which quickly responds by the generation of C3a and C5a and provides a quick and effective chemoattractive mechanism for the recruitment of PMNs and monocytes. This early wave of leukocytes is often sufficient for the removal of the invading pathogens. In a parallel process of de novo synthesis, continued persistence of the bacteria quickly leads to LTB4 to be sequentially released from granulocyte stores, such as C3a/C5a-induced mast cell degranulation, or an induced production from macrophages. LTB4 release effectively maintains the inflammatory influx of PMNs for the disposal of the infectious bacteria. As these initial chemoattractant factors are being produced resident and migrating macrophage populations begin producing early response cytokines, IL-1 and TNF, which activate both adhesion molecule expression and chemokines, such as IL-8, that promote continued influx of PMNs. Thus, a well-coordinated and multifaceted series of chemoattractants are produced to promote the most effective acute inflammatory response to control the bacterial infection. In addition to recruiting the leukocyte migration, these chemoattractants activate PMNs and macrophages to promote enhanced phagocytosis and killing.

Although during most bacterial infections the inflammatory response can be controlled and localized, during certain situations of catastrophic injury or severe bacterial contamination/colonization the response can spiral out of control. This is clearly the situation in septic shock where overproduction of activating and chemotactic molecules leads to an intense influx and activation of PMNs and monocyte/macrophages. This often-devastating response has an especially harsh impact on the lung where the edematous and inflammatory response can quickly overwhelm the pulmonary airspace. ARDS is one of the most common disorders encountered in the intensive care unit in septic patients. ARDS can be described as an overwhelming inflammatory response characterized by a mediator "storm" produced that can only be clinically managed and not controlled. Since the failure of anti-TNFα therapy, researchers have turned to downstream chemotactic mediators, which have been successfully targeted in animal models. In particular, the primary strategy has been to target the neutrophil influx and activation. Inhibition of the complement system (either by complement depletion or infusion of sCR1, the soluble complement receptor) has significantly reduced neutrophil recruitment, adherence, and degranulation, thus blocking release of destructive proteases and oxygen radicals in animal models. More recently, use of antibodies to target C5a or C5aR have proved extremely efficacious in several models of sepsis and indicate striking effects on recovery of lung function. These latter studies have re-ignited the idea that by blocking this early and persistent mediator throughout the septic and ARDS responses an attenuated disease process could be attained.

The blockade of other important systems has also led to some successes in animal models. In studies utilizing blocking antibodies to selectin and adhesion molecules an attenuation of neutrophil accumulation can be attained, however, severe pulmonary effects cannot be modulated suggesting a more complex disease pattern. This likely stems from the unique pulmonary vasculature that does not require adhesion molecule-mediated events for neutrophils to transmigrate into the alveolar space. Although early attempts to target LTB4 and other lipid mediators were seen as a feasible option, blocking these mediators in animal models of sepsis has made little progress.

The continuous production of CxC chemokines during sepsis has been identified as a direct correlative factor for the severity of disease and a predictor of whether a septic patient will progress to developing ARDS. The high levels of CxC chemokines related to severe bacterial infections, such as with COPD and cystic fibrosis patients, have also provided convincing data for understanding their function in disease progression. Thus, targeting these molecules during severe bacterial infections and septic responses may have a beneficial effect on survival. In fact, blocking IL-8 homologues or their receptor in mouse studies of pulmonary bacterial

infections appear to have one of the most impressive effects on pulmonary disease through the reduction of neutrophil accumulation and activation. The activation of CxCL8 (IL-8) and other neutrophil-associated chemokines are quickly induced by TLR4 activation through LPS that up-regulates NF-κB activation and initiates high levels of CxCL8 to be produced from resident and infiltrating macrophages. In addition, the production of TNF and IL-1 from macrophages subsequently causes high levels of CxCL8 and other neutrophil-active chemokines to be produced from the structural cells of the lung. Thus, infecting bacteria provide both direct and indirect stimulation of chemokines that greatly exacerbate the disease process. Although clinical trials to block these chemokines have not been initiated in bacterial pulmonary diseases or in septic patients, there continues to be a great deal of interest for targeting these molecules in the lung.

Viral Clearance

While bacterial infections continue to provide clinical challenges, recent data suggest that many long-term pulmonary problems in otherwise healthy individuals are likely initiated by viral infections. This may be especially the case in developed countries where antibiotic therapy is pervasive and bacterial infections controllable. The clinical data appear clear that one of the common features of most pulmonary viral infections is the early and intense production of chemokines. The viruses that have been ascribed to producing chemokines upon infection of target cells include rhinovirus (RV), adenovirus, influenza virus, respiratory syncytial virus (RSV), as well as parainfluenza and severe acute respiratory syndrome (SARS). The one characteristic that these viruses have is an often intense inflammatory response that initiates damage in the lungs of susceptible patients. Those most at risk usually have underlying pulmonary diseases, such as asthma, COPD, or are transplant recipients, premature infants, and so forth, and suffer the most severe disease from the initiation of the antiviral inflammatory responses. Unlike bacterial infections the recruitment of neutrophils has little effect on the virus itself and only serves to promote pulmonary damage in the lung. Thus, in many patients with underlying pulmonary disease the side effects of virus-induced inflammation can be devastating.

The initiation of the earliest events in viral responses is the recognition of one of many types of viral nucleic acids, double- and single-stranded RNA or DNA, by immune cell-associated proteins that recognize pattern-associated molecular patterns (PAMPs). The best characterized of the innate receptors are toll-like receptors that can quickly initiate an effective innate immune response by activation of several mediator pathways and initiate the production of chemotactic factors for recruitment of the proper immune cell types. One of the clearest activation events is via MyD88 adapter protein pathways that are initiated with all TLRs but TLR3, which recognizes dsRNA. Importantly, antiviral TLR7 and TLR8 that recognize ssRNA and TLR9 that recognizes unmethylated CpG motifs found in bacteria and DNA viruses potentially promote a common set of mediators (Fig. 24-5). These TLRs, through MyD88-mediated pathways, activate NF-κB and allow a number of chemokines to be produced, such as CxCL8 and CCL2. In addition to the NF-κB–mediated chemokine production, an alternative activation pathway via IRF7 can also be initiated for the production of a number of other chemokines including CCL3, CCL5, and CxCL10 via a type I IFN-mediated pathway. These important chemokines together allow the accumulation of specific leukocyte populations associated with effective viral clearance, including natural killer (NK) cells and CD4 T cells as well as CD8 cytotoxic T-cell populations. MyD88-mediated pathways are also initiated by most IL-1R family responses, including IL-1β and IL-18. In addition to the MyD88-mediated pathway of activation another adapter, TICAM-1 (TRIF), which is the only adapter known to be used by TLR3, also initiates a specific subset of chemokines due to the activation of IRF-3. In particular, those same chemokines induced by IRF7, CCL5, and CxCL10 are also induced by this pathway along with type I IFN production. Thus, these pathways likely synergize to create multiple activation sources for a whole array of chemokines. For example, a negative strand RNA virus such as influenza will go through both an ssRNA and dsRNA

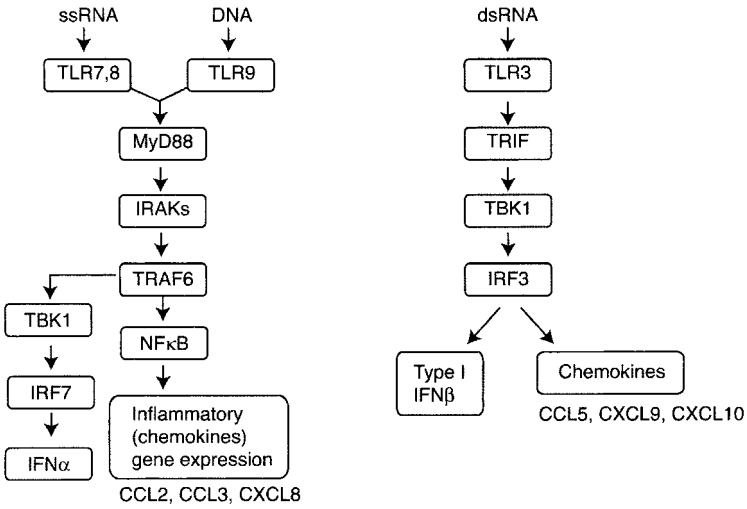

Figure 24-5 TLR activation by viral pattern-associated molecular patterns (PAMPs) lead to inflammatory chemokine production.

stage and would therefore induce both a TLR3 → TICAM-1 → IRF3 pathway and TLR7,8 → MyD88 → NF-κB or IRF7 pathway. Thus, a broad profile of chemokines to recruit multiple cell types would be produced both for the benefit and to the detriment of the lung, depending upon the success of the clearance mechanisms. Although these TLRs have been primarily subscribed to promote immune cell function, many of the studies outlining these processes have been performed on structural cells. Several studies have now outlined that viral responses themselves can up-regulate TLR expression on airway epithelial cells and other structural cells of the lung. Thus, one must consider that epithelial cells, which are usually the primary target for infection, would be the initial source of chemokines due to their expression of TLRs and may provide a significant source of chemokines initially needed for clearance of virus, but can also lead to tissue damage if overactivated. Future studies designed to focus on the differential role of TLR activation in acute and chronic pulmonary disease should highlight these differences.

Asthma

Asthmatic inflammation is one area that has attracted a great deal of attention and funding from both private and public organizations. The early immune responses in allergic asthma stem from immunoglobulin E (IgE)-mediated mast cell degranulation and release of chemotactic mediators, such as LTB4 and chemokines. The release of these factors quickly causes the recruitment of granulocytes and mononuclear cells that continue to respond to the allergen by production of type 2 cytokines, IL-4, IL-5, and IL-13. The initiation of this Th2-type environment promotes the production of a characteristic set of chemokines that has been associated with severe asthmatic responses, including CCL11, CCL2, CCL7, CCL17, CCL22, as well as several others. The receptors for these chemokines, CCR3 and CCR4, have been long implicated in the disease process due to their expression on eosinophils and Th2 cells, respectively. Thus, the immune environment created by the immune response dictates the chemotactic molecules that are produced. Although our understanding of how severe asthma develops and progresses has become more focused on inflammation, a number of issues still remain. It appears, for example, that viral exacerbation of asthma promotes the most severe disease phenotypes and initiates crisis events leading to emergency room visits. As indicated previously, this may be due to the activation of a distinctly different set of chemotactic mediators that, together with those induced by the allergen response itself, promote a very intense and diverse set of responses that appear to persist for long periods of time. The lack of resolution of these infectious stimuli in the asthmatic lung, perhaps due to the Th2 environment, likely leads to the chronic phenotype and remodeling of the airway that is associated with the most severe conditions. In addition to enhancing recruitment of cell populations associated with asthma, eosinophils, and CD4+ T cells, additional cell populations are also recruited in an attempt to take care of the viral responses, including CD8+ T cells. It has now been recognized that the CD8+ T cell is associated with the most intense and severe asthmatic disease phenotypes. Thus, the severity of asthmatic disease may not be due to a single set or class of chemoattractants, but rather to the overproduction of several different mediators leading to the recruitment and activation of a number of leukocyte subsets that are not characteristic to allergen or virus responses alone.

CONCLUSIONS

The chemotactic migration of leukocytes during inflammatory/immune reactions in lung requires multiple steps and participation by many chemotactic factors. The use of specific chemoattractants during various phases of disease progression can dictate not only the type of cell to be recruited, but also the outcome on the tissue cells in the area of disease. In the lung, the overproduction or incorrect profile of chemoattractants can cause damaging processes that lead to severe and chronic disease and dysfunction. The specific inhibition of particular chemoattractant molecules during inflammatory events may provide beneficial therapeutic outcomes although it is likely that during any inflammatory response multiple mediators are involved and the inhibition of a single chemoattractant molecule may not offer complete control of the response.

Oxidative and Nitrosative Lung Injury

John D. Lang, Jr. • Ian C. Davis • Rakesh P. Patel • Sadis Matalon

Lung injury can present with differing signs and symptom complexes that emanate from a variety of etiologies. However, whether it is the adult respiratory distress syndrome (ARDS) or other forms of lung injury, inflammatory stimuli giving rise to the generation of reactive oxygen species (ROS) and reactive oxygen-nitrogen species (RONS) contribute to lung pathophysiology. Generation of RONS not only initiates injury, but amplifies inflammatory pathways ultimately culminating in enhanced tissue damage, in this case, in the lung. Thus, precursor cell activation leads to the formation of RONS, which perpetuate a vicious cycle of inflammatory cell recruitment and production of cytotoxic mediators that culminates in injury to the alveolar capillary endothelium, epithelium, and connective tissue—all of which are important in maintaining lung integrity. Clinically, the net result will generally be dyspnea, tachypnea, and arterial hypoxemia due to respiratory failure, and may require intubation and mechanical ventilation. While many patients manifest predominantly respiratory signs and symptoms, systemic inflammation fueled in part by RONS can involve extrapulmonary vital organ systems, many times leading to the development of the multiple organ dysfunction syndrome (MODS) and death.

FORMATION OF OXIDATIVE AND NITROSATIVE SPECIES

Reactive Oxygen Species

Most forms of lung injury involve oxidative injury via the liberation of ROS from the reduction of molecular oxygen. ROS implicated in pulmonary pathophysiology include superoxide radicals ($\cdot O_2^-$), hydrogen peroxide (H_2O_2), hydroxyl radical (OH^-), and hypochlorous acid (HOCl) (Fig. 25-1). Superoxide anion generation has been demonstrated from a variety of biologic sources. An important enzymatic source of superoxide is nicotinamide adenine dinucleotide phosphate (NADPH) oxidase which catalyzes a one-electron reduction of molecular oxygen to form $\cdot O_2^-$. NADPH oxidase is an

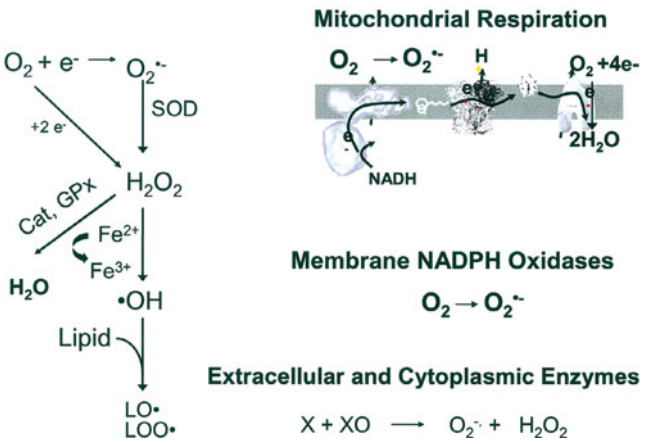

Figure 25-1 Generation of reactive oxygen intermediates by the incomplete reduction of oxygen in the mitochondria, cytoplasm, and cell membrane and extracellular space. O_2 = oxygen; $\cdot O_2^-$ = superoxide radical; H_2O_2 = hydrogen peroxide; $\cdot OH$ = hydroxyl radical; SOD = superoxide dismutase; Cat, GPx = catalase and glutathione peroxidase; LO·, ·LOO = lipid peroxides; X, XO = xanthine and xanthine oxidase, respectively; NADH = nicotinamide adenine dinucleotide; NADPH = nicotinamide adenine dinucleotide phosphate.

enzyme complex derived after the activation of phagocytes by microorganisms or their products that includes lipopolysaccharide (LPS), tumor necrosis factor (TNF), and interleukin (IL)-8. NADPH oxidase is vital for yielding ROS in phagocytic cells that inhabit the lung (e.g., macrophages and polymorphonuclear cells) where these species play a role in host defense mechanisms, targeting killing and removal of invading microorganisms. However, RONS (see later) are also implicated in the pathogenesis of both pulmonary- and nonpulmonary-based diseases which typically are also associated with inflammation. It is not surprising then that a variety of systems are present to prevent or limit oxidative tissue injury. In this context, and specific for superoxide, are superoxide dismutases (SOD) that catalyze the conversion (dismutation) of two moles of $\cdot O_2^-$ to H_2O_2, which is subsequently converted to water by catalase and glutathione peroxidase (Fig. 25-1). Copper (Cu)/zinc (Zn) SODs (CuZn) are present in the cytosol, while manganese (Mn) SOD is found in the mitochondria. An extracellular form of SOD (ECSOD) has also been identified and may play an important role not only in converting extracellular $\cdot O_2^-$ to hydrogen peroxide but also in controlling blood pressure by modulating the reaction of $\cdot O_2^-$ with nitric oxide (NO). In newborns ECSOD exists both intracellularly and extracellularly and plays an important role in intracellular antioxidant defenses. These enzymes possess a very high reaction constant that allows for the rapid dismutation of $\cdot O_2^-$ to H_2O_2.

Additional sources of superoxide include xanthine oxidase, nitric oxide synthase (under conditions that lead to uncoupling of electron transfer; discussed later), and components of the mitochondrial electron transport chain (Fig. 25-1). Xanthine oxidase (XO) catalyzes the oxidation of xanthine (or hypoxanthine) by molecular oxygen to form uric acid and $\cdot O_2^-$. Xanthine dehydrogenase (present in the liver) converts xanthine (or hypoxanthine) to uric acid without forming partially reduced forms of molecular oxygen. During ischemia and the subsequent reperfusion phases, xanthine dehydrogenase is reduced to XO, which may be released into the circulation, and is known to bind to pulmonary endothelial cells, thus acting as an intense focus for the production of ROS. Similarly, mitochondrial generation of superoxide also has been documented, and although precise function for this process remains unclear, roles in cell signaling and regulation of cell death have been proposed.

PRODUCTION OF NITRIC OXIDE AND REACTIVE NITROGEN SPECIES

Nitric oxide synthases (NOS) catalyze the formation of ·NO and L-citrulline from L-arginine, and oxygen via a 5-electron redox reaction that also involves cofactors including NADPH, flavin adenine dinucleotide (FAD), and tetrahydrobiopterin. Various forms of NOS have been identified: NOS-1 or neuronal NOS (nNOS), NOS-2 or inducible NOS (iNOS), and NOS-3 or endothelial NOS (eNOS). nNOS and eNOS are expressed constitutively, and their activity is regulated largely by changes in intracellular Ca^{2+} concentration. Although previous studies claimed that iNOS was not expressed constitutively, more recent findings show expression of iNOS in both inflammatory and lung cells of humans and mice under baseline conditions with significant up-regulation of mRNA, protein, and activity following exposure to cytokines and LPS. A form of NOS also has been identified in the mitochondria and may play an important role in regulating mitochondria function.

RONS refer to a variety of nitrogen-containing molecules that are typically derived via nitric oxide (·NO) reactions. RONS implicated in pulmonary pathology include peroxynitrite ($ONOO^-$), nitrogen dioxide (NO_2), and nitroxyl (HNO) which can be formed via NO reactions, as discussed later in the chapter, but also through environmental exposure and inhalation (Fig. 25-2). Peroxynitrite is formed by the rapid reaction of NO with superoxide and when protonated (addition of H^+), will decompose into nitrogen dioxide (NO_2) and hydroxyl radicals (·OH) as well as nitrate (NO_3^-). These species may then interact with each other as well as with oxygen, forming higher oxides of nitrogen which may oxidize thiols, nitrate aromatic amino acids (most notably tyrosines), nitrosate, and glutathionylate cysteines and oxidize a variety of amino acids including methionine and cysteines (Table 25-1). Myeloperoxidase (MPO), present in pulmonary neutrophils and secreted during their activation, catalyzes the production of nitrating, oxidizing, and chlorinating species from H_2O_2, chloride and nitrite (Fig. 25-2). Currently, there is considerable controversy as to the source and origin of nitrating intermediates in vivo, with some studies showing that MPO knockout mice (but not iNOS knockout mice, or mice-depleted of inflammatory cells) exhibit significantly less nitration following exposure to pathogens as well oxidant gases.

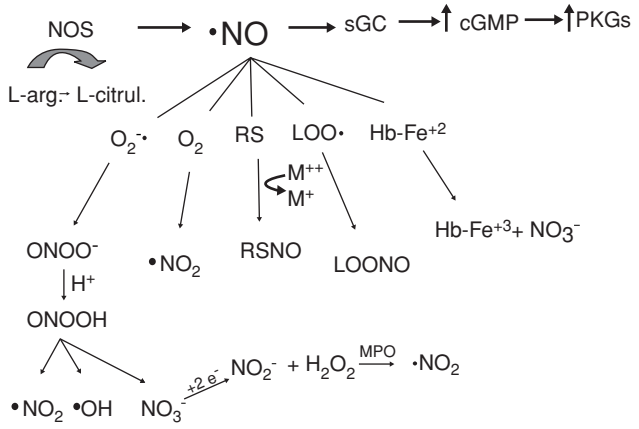

Figure 25-2 Generation of reactive nitrogen species. Nitric oxide synthases (NOS) catalyze the formation of nitric oxide (·NO) and L-citrulline from L-arginine. NO either binds to the heme center of soluble guanylate cyclase (sGC) leading to increased production of cyclic guanosine monophosphate (cGMP) and activation of cGMP-dependent protein kinases (PKGs), binds to oxygenated hemoglobin (Hb-Fe^{+2}) to form nitrate (NO_3^-), or interacts with superoxide ($\cdot O_2^-$), molecular oxygen (O_2), thiols (RS), or lipid peroxides (LOO·) to form various intermediates. $ONOO^-$, ONOOH = peroxynitrite and peroxynitrous acid, respectively, $\cdot NO_2$ = nitrogen dioxide, RSNO = nitrosothiols; LOONO = nitrated unsaturated fatty acids; ·OH = hydroxyl radicals, NO_2^- = nitrite; MPO = myeloperoxidase; M = metal.

As shown in Fig. 25-2, nitrite (NO_2^-) may serve as a substrate for nitrotyrosine formation via reactions with peroxidases. More recently, nitrite has emerged as playing a key role in supporting NO formation during hypoxemia and tissue ischemia and in this context is shown to protect against reperfusion injury. Moreover, nitrite reactions in vivo also lead to diverse NO-dependent protein adducts including S-nitrosothiols and C-/N-nitrosamines, underscoring the rich biochemical interplay between distinct RNS and ROS. The therapeutic potential for this inorganic anion in replenishing NO during low oxygen states has also been demonstrated in the lung, with inhalation of nitrite-reversing pulmonary hypertension analogous to inhaled NO. A key difference between nitrite and NO however is the lack of rebound hypertension upon withdrawing inhaled nitrite.

Reactive Oxygen-Nitrogen Species as Signaling Molecules

Formation of RONS is related to the inflammatory environment within the lung at a particular point in time, which has the potential to generate noxious concentrations of products detrimental to lung function. Production of ·NO in the lung serves as an important regulator of local functions, including airway tone, pulmonary vascular tone, mucin secretion, ciliary function, and ion channel activity. The role of ·NO is extremely complex, and probably depends ultimately on its concentration, timing of production during injury, and association with other biomolecules and proteins and formation of specific redox congeners. In the latter context, in addition to the RNS discussed previously, relatively stable NO adducts including S-nitrosothiols are important and discussed later.

Activation of Cyclic Guanosine Monophosphate (cGMP)-dependent Protein Kinase

NO binds to the heme group of soluble guanylate cyclase (sGC) leading to an increase in cGMP levels. Many effects of cyclic guanosine monophosphate (cGMP) are mediated by various isoforms of cGMP-dependent protein kinase (PKG) which phosphorylate various substrate proteins, thereby reducing intracellular Ca^{+2} and causing smooth muscle relaxation. ·NO-mediated increases in cGMP levels also decrease platelet aggregation and adhesion of neutrophils to endothelial cells, thus reducing oxidant load. At lower concentrations, RONS function as signaling molecules (Table 25-1) regulating fundamental cellular activities such as cell growth and adaptation responses, while at higher concentrations they can induce significant cellular injury, apoptosis, and death.

Activation of Nuclear Factor-κB

Nuclear factor-κB (NF-κB), a transcriptional regulating protein, is among the most important transcription factors responsive to ROS during inflammation and oxidant stress. NF-κB is one member of a ubiquitously expressed family of *Rel*-related transcription factors. These are a family of structurally related eukaryotic transcription factors that are involved in the control of a vast array of processes, including immune and inflammatory responses, growth, development, and apoptosis. The production of ROS, cytokines, or other inflammatory stimuli can activate NF-κB and induce gene expression, eliciting a response generally observed to be proinflammatory in nature. Specifically, various signals such as ROS/RNS, cytokines, or inflammatory stimuli converge to activate the inhibitory-κB kinase (ILK) complex via the upstream NF-κB–inducing kinase (NICK). The ILK-α/ILK-β complex then phosphorylates inhibitory-κB (I-κB) at two N-terminal serines that signal its ubiquitination and destruction by the ^{26}S proteasome system. NF-κB can then enter the nucleus and bind specific κB-promoter sequences to activate gene expression. Various studies have reported activation of NF-κB in alveolar macrophages from patients suffering from ARDS.

Intracellular Ca^{+2}, Protein Kinase C, and Mitogen-activated Protein Kinase

Evidence also indicates that ROS lead to increases in intracellular calcium concentrations which correlate with endothelial permeability. Some observations suggest that Ca^{2+} influx occurs through membrane Ca^{2+} channels that are regulated by ·OH generation; however, this remains controversial due to differing effects depending on cell lines. Myosin light chain kinase phosphorylation also increases when endothelial cells are treated with H_2O_2, suggesting that endothelial contraction

Table 25-1

Actions of Reactive Nitrogen Species

Immunoglobulins (Fe Receptors)	**Complement Receptors for**
Signal Transduction	
	Vessel relaxation
Activation of cGMP/PKG	Bronchodilation
	Modification of ion channel function
	Inhibition of platelet aggregation
cGMP-independent	Activation of NF-κB; MAPK

Abbreviations: NF-κB, nuclear factor = κB; MAPK, mitogen-activated protein kinase; NMDA; PKC, protein kinase C; GPx, glutathione peroxidase; CFTR, cystic fibrosis transmembrane conductance regulator; ATP, adenosine triphosphate; NOS, nitric oxide synthases; SP-A, Surfactant protein-A; Mn SOD, manganese superoxide dismutases.

may play an essential role in oxidant-induced endothelial barrier dysfunction. It appears that an important fundamental requirement for vascular endothelial permeability is the activation of endothelial contraction.

Additional signaling molecules such as protein kinase C (PKC), mitogen-activated protein kinase (MAPK), tyrosine kinases, and Rho GTPases appear vital in mediating endothelial barrier dysfunction. PKC (a family of serine/threonine protein kinases consisting of at least 12 isoforms) is activated in response to oxidants and increases endothelial permeability. In guinea pig lungs pretreated with H-7 (a nonspecific PKC inhibitor acting on the catalytic site of the enzyme), there was no increase of the pulmonary capillary filtration coefficient in response to perfusion of H_2O_2. Increases in pulmonary microvascular permeability were accompanied by reorganization of actin cytoskeleton, a process inhibited by PKC inhibitors. The exact mechanism(s) of the role PKC plays in endothelial barrier function is complex but appears due to activation of ROS and probably involves only a few select PKC isoforms. The MAPK pathway is activated by ROS and is an important mediator of cellular responses to oxidant stress. The ERK (extracellular signal-regulated kinases), JNK (c-JUN NH_2-terminal kinase), and p38 cascades all contain the same series of three kinases. A (MEK) MAPK/ERK kinase phosphorylates and activates an MAPK, and then MEK phosphorylates and activates an MAPK. Various ROS, most notably H_2O_2, have been demonstrated to mediate endothelial injury via stimulation of ERK pathways. This H_2O_2-mediated action was inhibited by PD-98059, an ERK (MEK) inhibitor. Furthermore, both ROS and RNS induce a variety of actions that are potentially detrimental and include abnormal cell differentiation/proliferation, apoptosis, and DNA damage, with the ERK pathway implicated as playing the predominant role.

There also appears to be an emerging role for tyrosine-mediated phosphorylation of functional proteins resulting in increased endothelial cell permeability. Focal adhesion kinase (FAK) is a nonreceptor kinase involved in regulating structure and function of focal adhesions, which are critical for maintaining endothelial integrity via cell-cell and cell-matrix interactions. Tyrosine phosphorylation of FAK has been associated with alterations in the actin cytoskeleton network and relocation of focal adhesion-associated proteins, actions potentially precipitating pulmonary edema formation.

Adhesion Molecules

In addition to inducing changes in endothelial cell conformation and integrity, ROS have been shown to promote cellular and molecular events that result in enhanced aggregation and adhesion of leukocytes to endothelium. Prominent inflammatory participants emanating from these investigations include intercellular adhesion molecule-1 (ICAM-1) and selectins (a family of transmembrane molecules, expressed on the surface of leukocytes and activated endothelial cells involved at enhancing leukocyte-endothelial interactions). Investigations in diverse models implementing a variety of oxidant-generating systems (hypoxanthine/xanthine oxidase, H_2O_2, prolonged hyperoxia) have demonstrated consistent increases in ICAM-1 and P-selectin expression in the vascular endothelium, which promote leukocyte adhesion. Interestingly, expression of these biomolecules is not uniform throughout the vasculature. For example, following exposure of isolated lungs to normobaric hyperoxia, P-selectin expression was augmented in the arterioles, while ICAM-1 expression was induced in the pulmonary venules and capillaries.

Post-translational Modifications

The generation of oxidants has been documented under a variety of clinical conditions in a number of studies. Unfortunately, direct evidence implicating oxidants as pathological contributors in diseases such as acute lung injury (ALI) and ARDS is very difficult to find. Unequivocal measurements of ROS in biologic tissues and fluids are nearly always unsuccessful, both because the biologic half-life of these molecules is in the range of nanoseconds to milliseconds, and because concentrations may vary dramatically within the time course of a particular disease state. On the other hand, relatively stable byproducts of these species, such as hydrogen peroxide, nitrite and nitrate as well as long-lived products of reactions of RNS/ROS with tissues and specific proteins are routinely detected in exhaled breath, alveolar lavage, plasma, urine, and autopsy or biopsy specimens.

Higher oxides of NO (such as NO_2, N_2O_3, etc.) induce the formation of *S*-nitrosothiols from cysteine residues in the reaction called *S*-nitrosylation. This reaction has been determined to modify the activity of a large number of proteins involved in cellular regulatory mechanisms in a reversible fashion and has been the subject of numerous reviews.

$ONOO^-$ can oxidize thiols and lipoproteins, and damages both DNA and the mitochondrial electron transport chain. Equally important, $ONOO^-$ nitrates phenolics, including tyrosine residues in proteins. 3-Nitrotyrosine residues, which are the products of the addition of a nitrogroup (NO_2) to the other position of the OH group of tyrosine, are stable end products of RONS-mediated reactions. Thus, they represent "footprints" of RNS activity that can be detected by immunohistochemistry, enzyme-linked immunoabsorbent assay, high-pressure liquid chromatography, or mass spectrometry. In vitro, proteins can be nitrated by either $ONOO^-$ per se or by reactive intermediates formed by peroxidase (e.g., MPO) catalyzed reactions of reactive species (H_2O_2, Cl^-, and $\cdot NO_2^-$) liberated from activated neutrophils. A number of studies have provided evidence that nitration reactions occur in vivo during inflammatory processes.

FUNCTIONAL CONSEQUENCES OF PROTEIN NITRATION IN VITRO

Surfactant Protein-A

Protein nitration and oxidation by ROS and RNS in vitro have been associated with the diminished function of a variety of crucial proteins. Considerable levels of protein-associated nitrotyrosine (~400–500 pmol/mg protein), as well as nitrated surfactant protein-A (SP-A) were present in pulmonary edema fluid from patients with either ALI/ARDS or hydrostatic pulmonary edema, and in bronchoalveolar lavage fluid (BALF) of patients with ARDS (Fig. 25-3). In vitro studies have indicated that nitrated SP-A loses its ability to enhance the adherence of *Pneumocystis carinii* to rat alveolar macrophages. Thus, nitration of SP-A may be one factor responsible for the increased susceptibility of patients with ARDS to nosocomial infections. The use of inhaled NO in patients with ARDS was shown to increase both 3-nitrotyrosine and 3-chlorotyrosine (an index of neutrophil activation) concentrations compared to similar patients that did not receive inhaled NO.

Histone Deacetylases

A study by Ito et al demonstrates the complex interplay that exists between ROS and RNS, and their potential contributions to the pathogenesis of disease. Histone deacetylases (HDAC) are important enzyme systems that protect DNA after cell activation in order to minimize DNA vulnerability. Reduction in HDAC activity is thought to be one factor that may aggravate inflammation. In this study, IL-1β stimulated BEAS-2B cells were exposed to H_2O_2 and peroxynitrite for 2 h. Interestingly, HDAC-2 was significantly nitrated at 0.5 h after stimulation, and nitration was maximum at 4 h (Fig. 25-4). Additionally, HDAC-2 activity was observed to be directly regulated by $ONOO^-$ as demonstrated by enhanced nitrotyrosine formation in the presence of SIN-1 (an $ONOO^-$ generator). Lastly, SIN-1 significantly decreased IL-1β–induced HDAC-2 activity. These findings support the notion, at least in vitro, that ROS/RNS-enhanced IL-1β–induced inflammatory cytokine release is a consequence of reduced HDAC activity due to tyrosine nitration.

Current In Vivo Evidence Implicating Reactive Nitrogen Species and Reactive Oxygen Species as Contributors to Lung Injury

Toxicity from oxygen-nitrogen metabolites released by stimulated neutrophils, macrophages, and other cells has been proposed as one of the significant mechanisms of lung injury.

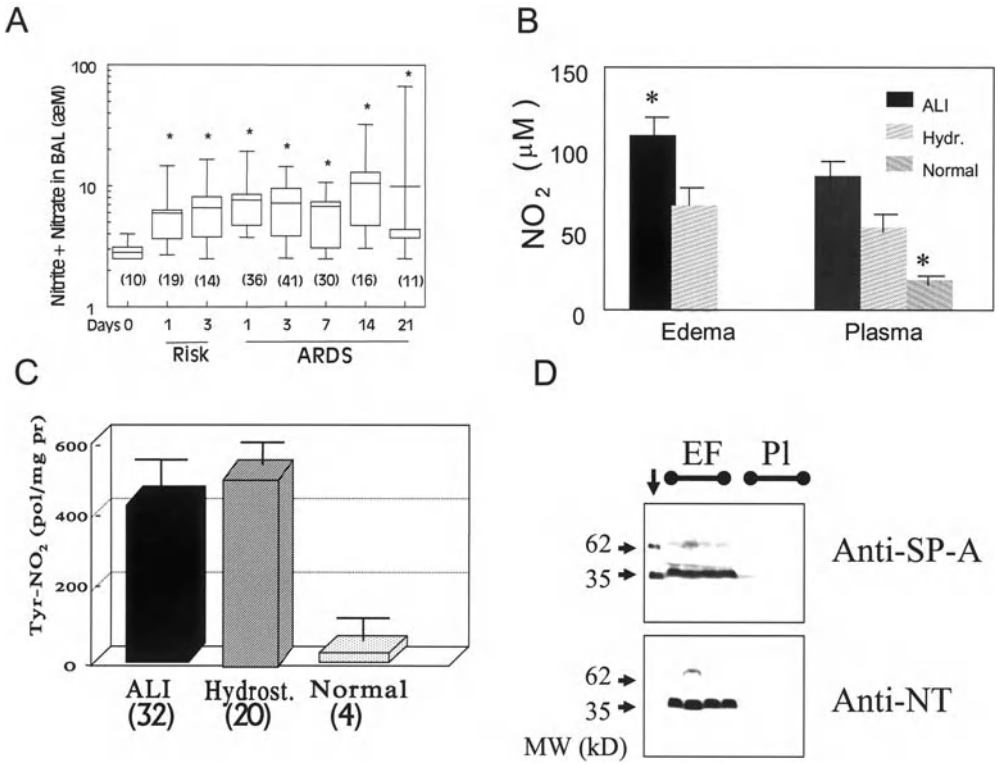

Figure 25-3 Evidence for increased levels of reactive oxygen-nitrogen intermediates and nitrated proteins in the bronchoalveolar lavage fluid (BALF), edema fluid (EF), and plasma (Pl) of patients with acute respiratory distress syndrome (ARDS) and hydrostatic pulmonary edema. *A*. Nitrate and nitrite concentration in BALF from normal volunteers (NL), patients at-risk for ARDS (RISK), and patients with established ARDS (ARDS) studied at sequential times. The horizontal axis shows the patient group and the day on which the BAL was performed. (n) = number of subjects in each group. The data are presented as box plots showing the 10th, 25th, 75th, and 90th percentiles and the median. (*) $p \leq 0.005$ vs. normal subjects. (*From Sittipunt C, Steinberg KP, Ruzinski JT, et al: Nitric oxide and nitrotyrosine in the lungs of patients with acute respiratory distress syndrome. Am J Respir Crit Care Med 163:503–510, 2001.*) *B*. Nitrate and nitrite in pulmonary edema fluid and plasma samples from acute lung injury (ALI), hydrostatic edema patients (Hydr.), and normal volunteers. Numbers in parenthesis are sample numbers. Values are means ± SEM. (*From Zhu S, Ware LB, Geiser T, et al: Increased levels of nitrate and surfactant protein A nitration in the pulmonary edema fluid of patients with acute lung injury. Am J Respir Crit Care Med 163:166–172, 2001.*) *C*. Levels of nitrated proteins (measured by enzyme-linked immunosorbent assay) in the plasma of patients with acute lung injury (ALI), hydrostatic edema (Hydrost.), and normal volunteers (Normal). Values are means ± SEM (n = number of patients or volunteers). (*Data adapted from Zhu S, Ware LB, Geiser T, et al: Increased levels of nitrate and surfactant protein A nitration in the pulmonary edema fluid of patients with acute lung injury. Am J Respir Crit Care Med 163:166–172, 2001.*) *D*. Nitration of surfactant protein A (SP-A) in pulmonary edema fluid samples from ALI/ARDS patients. SP-A was immunoprecipitated from edema fluid (EF) or plasma (Pl) from four patients with ALI/ARDS. Immunoprecipitated SP-A was probed with polyclonal antibodies to SP-A (anti-SP-A) or nitrotyrosine (anti-NT). Nitrated SP-A was detected in the pulmonary edema fluid but not in the plasma of all patients. Vertical arrow shows purified human SP-A from a patient with alveolar proteinosis. Notice the lack of nitration in the control sample. (*From Zhu S, Ware LB, Geiser T, et al: Increased levels of nitrate and surfactant protein A nitration in the pulmonary edema fluid of patients with acute lung injury. Am J Respir Crit Care Med 163:166–172, 2001.*)

One of the initial studies published described the effects of inflammation on α-1-proteinase inhibitor (α-1-PI), which was found to be inactivated in BALF samples from patients with ARDS. This contrasted to plasma samples from the same patients that retained more than 90 percent α-1-PI activity. The activity of α1-PI could be restored by the reducing agent, dithiothreitol, implicating oxidants generated in bronchoalveolar lavage as responsible for its loss of function. Shortly thereafter a different group measured expired fractions of hydrogen peroxide (H_2O_2), a more stable membrane-permeable and volatile oxidant. These samples were collected in patients with normal lungs undergoing elective surgery and critically ill patients suffering from acute hypoxemic respiratory failure (AHRF). Expired breath condensates of H_2O_2 were observed to be significantly greater in patients suffering from AHRF and focal pulmonary infiltrates than those without pulmonary infiltrates, indirectly implicating increased oxidation. Interestingly, H_2O_2 concentrations were greatest in patients with head injury and sepsis, whether pulmonary infiltrates were present or not. This unexpected finding suggested the participation of oxidants in sepsis and other forms of vital organ injury, such as in the brain.

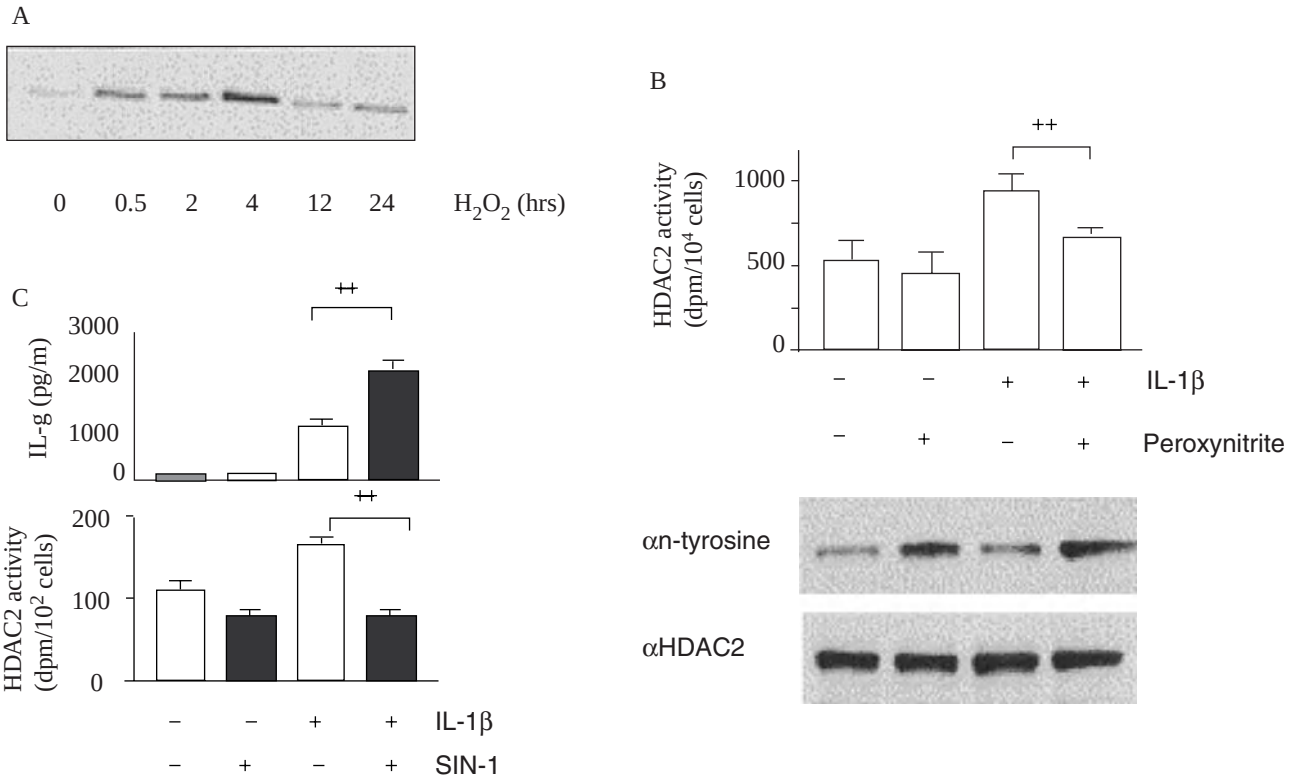

Figure 25-4 H_2O_2 and peroxynitrite induce histone deacetylase-2 (HDAC-2) tyrosine nitration and suppression of HDAC activity. *A*. Western blotting analysis of H_2O_2-induced tyrosine nitration of HDAC-2 in BEAS-2B cells. Cells were collected after the indicated time, HDAC-2 immunoprecipitated, and nitrotyrosine levels were determined. *B*. Peroxynitrite directly regulates HDAC-2 activity and nitration. Cells were stimulated with interleukin (IL)-1β (1 ng/ml) or control medium and after 1 h were collected, lysed with immunoprecipitation buffer, and immunoprecipitated with anti-HDAC-2 antibody. Peroxynitrite (500 nM) was incubated with the immunoprecipitates from IL-1β-treated or nontreated cells for 10 min at 30°C. HDAC activity assay and Western blotting for nitrotyrosine and HDAC-2 protein were performed. Results are expressed as means ± SEM (n = 3). $^{**}p < 0.01$ compared to IL-1β-stimulation. *C*. SIN-1 (500 μM) attenuates HDAC-2 immunoprecipitated HDAC-2 activity and enhanced IL-8 production. Results are expressed as means ± SEM (n = 3). $^{**}p < 0.01$ compared to IL-1β-stimulation. (*From Ito K, Hanazawa T, Tomita K, et al: Oxidative stress reduces histone deacetylase 2 activity and enhances IL-8 gene expression: Role of tyrosine nitration. Biochem Biophys Res Commun 315:240–245, 2004.*)

Further studies have continued to create a solid foundation that implicates oxidant generation as a significant contributor to inflammatory-mediated lung injury. In fact, in one of the most recent studies, levels of plasma hypoxanthine, a key cofactor that accumulates during intervals of hypoxia leading to the production of O_2^- and H_2O_2, were found to be significantly elevated in patients with ARDS. Moreover, the highest concentrations occurred in patients that did not survive, implicating oxidative damage as an influential contributor to mortality. Higher levels of nitrate and nitrite were also noted in the bronchoalveolar lavage of patients with ARDS as compared to those of healthy volunteers, as well as in the edema fluid of patients with either ARDS or cardiogenic pulmonary edema (Fig. 25-3).

Substantial evidence supports the notion that ROS and RNS are injurious to the pulmonary epithelium in a number of pathological conditions. Induction of immune complex alveolitis in rat lungs results in increased alveolar epithelial permeability, which is associated with the presence of ·NO decomposition products in the BALF. Moreover, alveolar instillation of the NOS inhibitor N(G)-monomethyl-L-arginine ameliorates ·NO production and alveolar epithelial injury. Infection with pathogens such as *Bordetella pertussis* and influenza is associated with significant increases in ·NO production. While animals infected with *B. pertussis* demonstrated a significant reduction in ·NO production with NOS inhibition, the administration of NOS inhibitors to animals exposed to influenza increased survival.

Further evidence suggesting that RONS plays a role in pulmonary inflammation is derived from studies using transgenic *Nos2*$^{-/-}$ mice. Lung injury provoked by influenza exposure or hemorrhage and resuscitation is significantly reduced in these mutant mice. Contradictory results have been reported concerning the responses of *Nos2*$^{-/-}$ mice to hyperoxia, with some investigators reporting shorter survival periods while others found that these mice survived considerably longer, indicative of a protective effect of NO in oxidant injury.

The ''Good Side of NO"

Although formation of $ONOO^-$ can result in tissue damage, NO can ameliorate tissue injury by several mechanisms. As mentioned previously NO increases steady-state levels of cGMP resulting in vasodilation, and decreased platelet and neutrophil adhesion to endothelium, thereby reducing cell-mediated inflammatory damage. Additional anti-inflammatory mechanisms include down-regulation of the NF-κB pathway. The reaction of $\cdot NO$ with $\cdot O_2^-$ reduces steady-state levels of O_2^- and limits H_2O_2 buildup, which may be especially important under conditions favoring O_2^--dependent hydroxyl radical formation. Finally, by scavenging lipid radical species, such as alkoxyl ($LO\cdot$) and peroxyl ($LOO\cdot$) radicals, NO can inhibit oxidant-induced membrane and lipoprotein oxidation and terminate chain radical propagation reactions. These reactions may be of particular importance, since NO significantly concentrates in lipophilic cellular compartments. However, species resulting from the reaction of NO with lipid peroxides may themselves have biologic activity which could be either pro- or anti-inflammatory.

Inhaled Nitric Oxide and Acute Respiratory Distress Syndrome: An Ongoing Debate

Clinically, inhaled NO initially appeared to possess ideal properties for a selective pulmonary artery vasodilator in patients suffering from ALI/ARDS. In theory, selective pulmonary vasodilation would act on the endothelial surface of the lung to produce regional vasodilation in ventilated lung units, with the net effect being improved Pa_{O2}/F_{IO2} ratios and reduced pulmonary artery pressures. Unfortunately, this ideal agent has not withstood clinical scrutiny of its efficacy when administered to patients with lung injury. In fact, a recent review of inhaled NO compared to placebo or no therapy administered to patients with AHRF concluded that inhaled NO produced only moderate improvements in oxygenation and demonstrated no reduction in patient ventilator days or mortality. However, there is agreement that oxygenation generally improves for 24 to 36 hours, which under certain clinical circumstances and combined with alternative treatment strategies, may lend itself to a multimodal approach to treatment in a particular patient with ALI/ARDS. Potential pitfalls of the recent clinical evidence using inhaled NO in the treatment of patients suffering from inflammatory-mediated lung injury include: (1) oxygenation may have very little to do with survival in patients suffering from inflammatory-mediated lung injury (only ~20 percent of patients die of refractory hypoxemia); (2) benefits may have been masked by the negative effects of ventilator-induced lung injury; (3) long-term inhalation of NO may damage the lung by increasing steady state concentrations of RNS/ROS and thus overshadow their acute physiological benefit; (4) as many intensivists expect, inhaled NO may have been applied too late after the onset of injury since most enrollment occurred up to 72 h after patients presented. Thus, at the present time, the only recognized and Food and Drug Administration (FDA)-approved application for inhaled NO is for the treatment of hypoxic respiratory failure of term and near-term newborns.

HYPERCAPNIA: AN EXAMPLE OF A RADICAL QUANDARY?

The effect of CO_2 in excess (hypercapnia) and its impact on the generation of ROS/RNS is generating increasing clinical interest. Due to the relatively higher concentration of CO_2 in plasma (1.2 mM), the majority of $ONOO^-$ generated in biologic fluids will react with CO_2 to form the nitrosoperoxycarbonate anion ($O=N-OOCO_2^-$). These species are more likely to nitrate and less likely to oxidize proteins (Fig. 25-5). CO_2 also up-regulates iNOS by an as-yet uncharacterized mechanism. Thus, hypercapnia may either protect or enhance oxidant injury. For example, hypercapnia augmented the LPS-induced injury across fetal alveolar epithelial cells in vitro and rabbit lungs in vivo. On the other hand, hypercapnia and acidosis decreased the inactivation of pulmonary surfactant by plasma proteins. Thus, the precise mechanism and consequences of hypercapnia are still unknown.

Therapies to Attenuate Reactive Nitrogen Species/Reactive Oxygen Species-Mediated Lung Injury

While the direct measurements of oxidants pose problems, monitoring of antioxidant concentrations and oxidant-antioxidant balance can also be assessed. For instance, levels of selected antioxidants, including plasma ascorbate, a major plasma antioxidant, were significantly decreased in patients with ongoing ARDS when compared to healthy controls. In addition, ubiquinol, a key lipid-soluble antioxidant residing in the membranes of the mitochondria, was significantly decreased in patients suffering from ARDS. Interestingly, α-tocopherol, another plasma antioxidant, was unchanged. In a series of separate experiments, after plasma from a healthy donor was incubated with activated polymorphonuclear cells, rapid oxidation of ascorbate was observed. The ubiquinol concentration slowly and steadily decreased over time, whereas α-tocopherol levels remained virtually unchanged. Glutathione (GSH), which is the most abundant non-protein thiol, is also an important antioxidant, especially for reducing H_2O_2 and HClO, which are produced by activated neutrophils. Recently, samples of BALF and epithelial lining fluid were analyzed for GSH in 10 patients with ARDS and found to be decreased when compared to healthy controls. In a subsequent study, N-acetylcysteine was administered to patients with ARDS and significantly improved oxygenation, pulmonary mechanics, and increased total plasma GSH concentrations. Catalase, a scavenger of H_2O_2, was found to increase in patients with sepsis with and without the eventual progression to ARDS. Interestingly, GSH peroxidase activity was unchanged when compared between control subjects, septic patients without ARDS, and septic

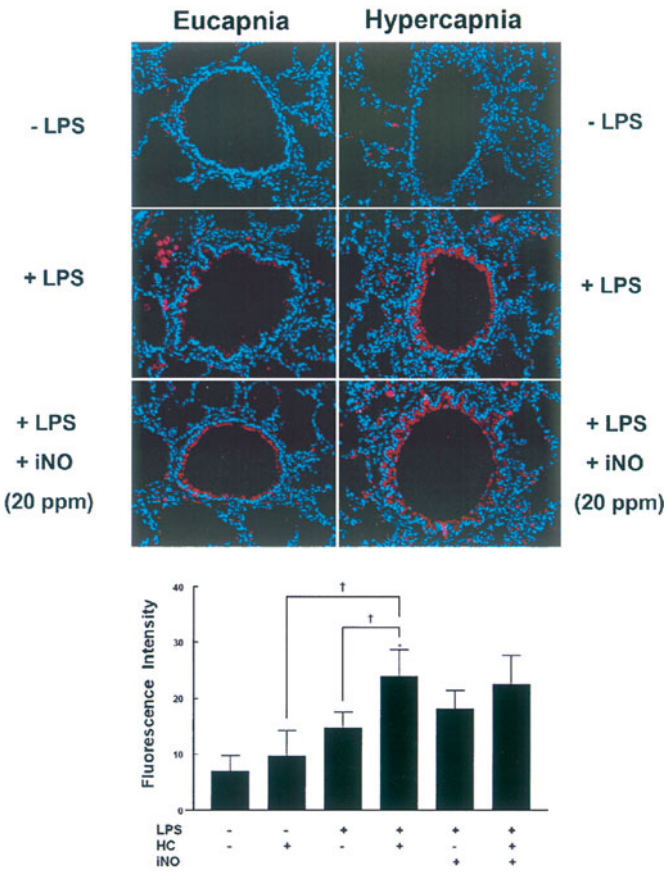

Figure 25-5 Effects of hypercapnia and inhaled nitric oxide (iNO) in distribution of bronchoalveolar lavage protein 3-nitrotyrosine (3-NT) rabbits' lungs. New Zealand white rabbits were treated with intravenous lipopolysaccharide (LPS) and ventilated under eucapnic ($Pa_{CO2} = 40$ torr) or hypercapnic ($Pa_{CO2} = 59$ torr) conditions. Formalin-fixed lung tissues were immunostained with a monoclonal antibody to nitrotyrosine. Lungs of rabbits treated with LPS and ventilated under hypercapnic conditions exhibited significantly higher nitrotyrosine levels compared to eucapnic ventilation. The formation of 3-NT significantly also increased in groups receiving inhaled nitric oxide (iNO compared with the eucapnia-alone group. *Significant difference compared with eucapnia alone, $p < 0.05$; †significant difference from the eucapnia group in the same treatment group, $p < 0.05$. (*From Lang JD, Figueroa M, Sanders KD, et al: Hypercapnia via reduced rate and tidal volume contributes to lipopolysaccharide-induced lung injury. Am J Respir Crit Care Med 171:147–157, 2005.*)

patients with ARDS. Endothelial injury as measured by ^{51}Cr release was greatest in the control group and least in patients with sepsis and ARDS. Additional studies have confirmed that in sepsis and lung injury, antioxidant responses are significantly elevated when compared to control patients.

Describing the influences of inflammation on host oxidant production and antioxidant defense mechanisms has been extremely important in our understanding of ALI/ARDS. However, treatment strategies employing antioxidants have failed to show a benefit in ARDS. Recently, 8 patients with ARDS receiving "standardized" total parenteral nutrition were compared to 17 healthy individuals on standard diets without vitamin or trace element supplementation in an attempt to assess the influence of micronutrients on the oxidative system. Plasma antioxidants and antioxidant enzyme systems were measured at baseline and days 3 and 6. In addition, the lipid peroxidation product, malondialdehyde (MDA), superoxide anion, and H_2O_2 were measured over the same time points. Plasma levels of α-tocopherol, ascorbate, β-carotene, and selenium were reduced when compared to controls. MDA was significantly increased and was observed to increase significantly over the 6-day interval. The authors concluded that in patients with ARDS, the antioxidant systems are severely compromised and there is evidence of progressive oxidant stress, as per the steady increase in MDA. Thus, administration of "standardized" total parenteral nutrition seems inadequate to compensate for the increased requirement for antioxidants in ARDS.

In a contrasting study, when patients with ARDS were entered into a prospective, multi-centered, double-blind randomized control trial comparing a specialized enteral formulation containing fish oil (eicosapentaenoic acid), borage seed oil (γ-linoleic acid), and elevated antioxidants (vitamin A, α-tocopherol, ascorbate, and β-carotene) vs. an isonitrogenous, isocaloric standard diet, beneficial anti-inflammatory effects were observed, which translated into a reduction in mechanical ventilator days, a decreased length of stay in the ICU and reduction in new organ failure. When administered over a 4- to 7-day interval, the formulation significantly increased Pa_{O2}/FI_{O2} ratio, decreased the production of neutrophils in BALF, and decreased the total cell count in the BALF. Oxidants and antioxidants per se were not directly measured, but a decrease in pulmonary inflammation with reduced neutrophil adhesion and oxidant production was observed. In a subsequent study conducted retrospectively by the same group, enteral feeding with the same formulation resulted in decreased BALF IL-8 and leukotriene B_4 levels, together with a trend toward decreased BALF total protein and neutrophils.

Albumin also has potential antioxidant ability, as a consequence of an exposed thiol group (Cys 34). Quinlan and colleagues administered 25 g of albumin solution every 8 h for a total of 9 doses to patients meeting criteria for ARDS and compared them to a placebo group. In this cohort of patients, supplementation with albumin increased total plasma albumin concentrations and decreased plasma protein carbonyls (a marker of protein oxidation). Positive correlations

were found between albumin and plasma thiol concentrations, and thiols and antioxidant capacity. This result was not observed in the placebo group. These studies are first steps in this complex area of investigation—clearly additional studies are warranted.

CONCLUSIONS

RONS, produced by the interaction of NO with partially reduced oxygen species, affect lung function and homeostasis in a variety of different ways. They act as signaling agents and play an essential role in the killing of pathogens. On the other hand, they may contribute to tissue injury by upregulating genes responsible for production of inflammatory mediators and by directly nitrating and oxidizing proteins, events known to adversely affect critical functions. A significant challenge to defining their role in lung injury results from their short biologic half-lives, lack of sensitive detection techniques, and the difficulty in deciphering the relevance of the various substrate concentrations to a particular measured response. Thus, many questions relating to the chemical, physiological, pathobiological, and clinical consequences of RONS generation remain unanswered. Therapeutic strategies, such as enhanced anti-inflammatory and antioxidant therapies are in their infancy in the clinical arena. Hence, this discussion of what is known or most likely known leads one to realize how much is not known with regard to the role of RNS/ROS in lung injury.

The Pathogenesis of Pulmonary Fibrosis

Moisés Selman • Annie Pardo

Pulmonary fibrosis is the end result of a diverse group of lung disorders known as interstitial lung diseases (ILDs). In these disorders, fibrosis results from chronic damage to the lung parenchyma and it is characterized by the excessive accumulation of extracellular matrix (ECM) proteins, primarily fibrillar collagens.

Usually after lung injury, parenchymal cells regenerate and replace the necrotic or apoptotic cells. This process is associated with a controlled inflammatory response and probably a limited remodeling of the ECM. However, if the magnitude of the lung damage overwhelms the mechanisms of defense and/or if lung injury persists (i.e., drug intake, environmental exposure), or if some unknown and uncontrolled event takes place [idiopathic pulmonary fibrosis (IPF)], lung regeneration fails and parenchymal cells are substituted with abundant ECM, with the subsequent destruction of the lung architecture. Under all circumstances, development of fibrosis provokes dramatic changes in the lungs resulting in progressive and irreversible respiratory insufficiency and a terminal outcome in a relatively short period of time.

It is important to appreciate that the fibrotic remodeling in ILDs is not restricted to the interstitium—the anatomic space interposed between the alveolar epithelial and endothelial basement membranes—but also occurs in the alveolar spaces. Therefore, it would be more appropriate to refer to ILDs as diffuse parenchymal lung diseases.

PATHWAYS TO PULMONARY FIBROSIS

In most ILDs inflammation is a crucial profibrotic event that precedes the development of pulmonary fibrosis. The mechanisms of alveolitis differ from one to another ILD, but all inflammatory cell types, macrophages, lymphocytes, and polymorphonuclear cells have the potential to provoke a fibrotic reaction and several essential common cytokine networks are involved.

By contrast, it has been hypothesized recently that IPF, a devastating condition of unknown etiology, represents an inflammatory-independent, epithelial-dependent fibrotic process mirroring abnormal wound healing (Fig. 26-1). Therefore, at least two different cellular routes, *the inflammatory pathway* and *the epithelial pathway*, may lead to the development of lung fibrosis.

It is important to indicate that experimental models of lung fibrosis, typically provoked with bleomycin, and less frequently with radiation, silica, or other agents, have been useful to dissect some of the pathogenic mechanisms of the

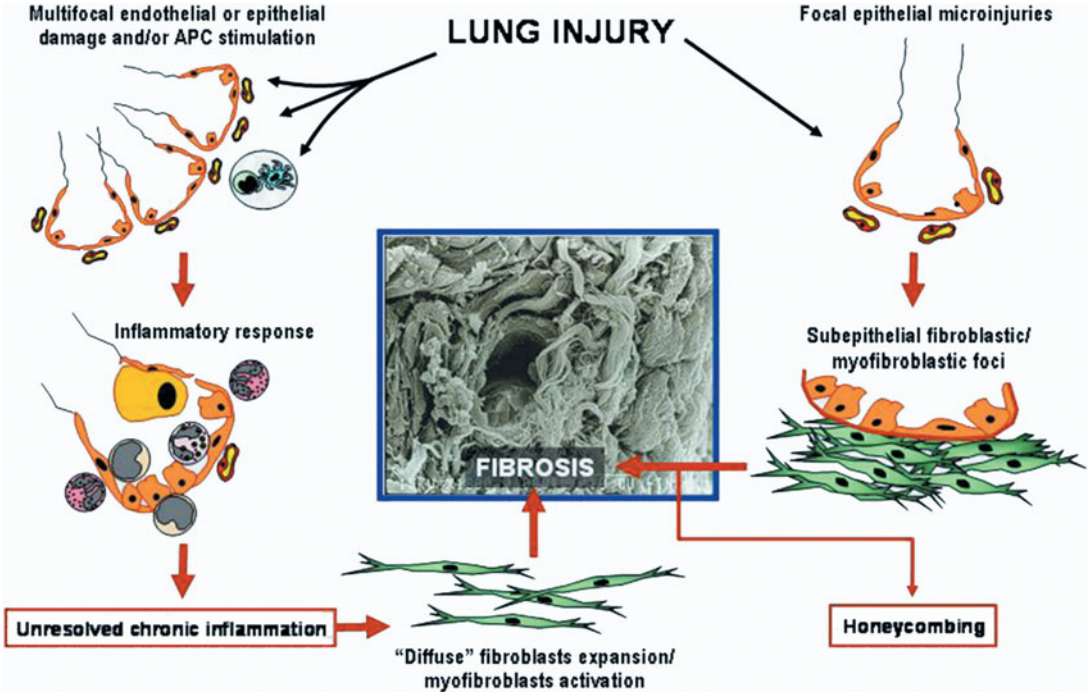

Figure 26-1 Hypothetical scheme of the two proposed pathways leading to pulmonary fibrosis. In the inflammatory pathway, a multifocal and essentially concurrent injury of known or unknown etiology provokes the up-regulation of diverse cytokines, chemokines/chemokine receptors, and adhesion molecules leading to alveolitis. Perpetuation of inflammation results in the release of cytokines/growth factors causing fibroblast migration/proliferation and differentiation to myofibroblasts. In the epithelial pathway, alveolar micro-injuries occurring over a long period of time result in dynamic alterations in the alveolar microenvironment that also promote accumulation of activated fibroblasts/myofibroblasts but mostly forming characteristic subepithelial foci. In both pathways, fibroblasts/myofibroblasts induce irreversible changes in extracellular matrix architecture resulting in an erratic remodeling of the lung parenchyma. Although honeycomb-like changes may be seen in advanced/terminal lesions of many interstitial lung diseases, it is a distinguishing feature of idiopathic pulmonary fibrosis.

inflammatory-driven pathway to fibrosis but none of them replicates human IPF.

The Inflammatory Pathway

Almost immediately after lung injury and loss of lung homeostasis, cytokines and chemokines are released from the tissue. These mediators stimulate leukocyte migration from the blood into the lung and vascular endothelial cells to express adhesion molecules on the luminal surface. The adhesive interactions of endothelial cells with their counter-receptors on leukocytes, selectins and integrins, initiate the process of leukocyte entry into injured tissues (Fig. 26-2).

Chemokines/Chemokine Receptors

Chemotactic cytokines, termed "chemokines", are involved in leukocyte chemotaxis and migration through the endothelial barrier into the injured lungs. Chemokines are a group of small molecules characterized by a distinctive pattern of conserved cysteine residues. They are classified into two major (CXC and CC) and two minor groups depending on the number and spacing of the first two conserved cysteine residues. Chemokines mediate their effects by binding G protein–coupled receptors. There is redundancy and binding promiscuity between chemokines and receptors; a single chemokine may bind to several receptors, and a single chemokine receptor may transduce signals for several chemokines. Chemokines can also influence cell survival and proliferation, and have emerged as a prominent superfamily whose importance extends far beyond their function as inflammatory mediators. Thus, the release of chemokines may exert effects not only on inflammation but also on remodeling events.

Chemokines in Inflammatory/Fibrotic Lung Disorders

A number of chemokines are up-regulated and seem to play a role in the inflammatory and/or the fibrotic response in experimental models and in human ILDs. Macrophage inflammatory protein-1α (MIP-1α/CCL3) and monocyte chemoattractant protein-1 (MCP-1/CCL2), which are chemotactic for macrophages, basophils, eosinophils, and subsets of T lymphocytes, are up-regulated in systemic sclerosis where they correlate with the presence of pulmonary fibrosis. MIP1α/CCL3, interleukin (IL)-8/CXCL8 (a chemoattractant for neutrophils), and RANTES/CCL5 (*regulated on activation, normal T cell expressed and secreted*), a potent eosinophil and lymphocyte chemoattractant, are increased in patients with sarcoidosis while CCL18/DC-CK-1, a

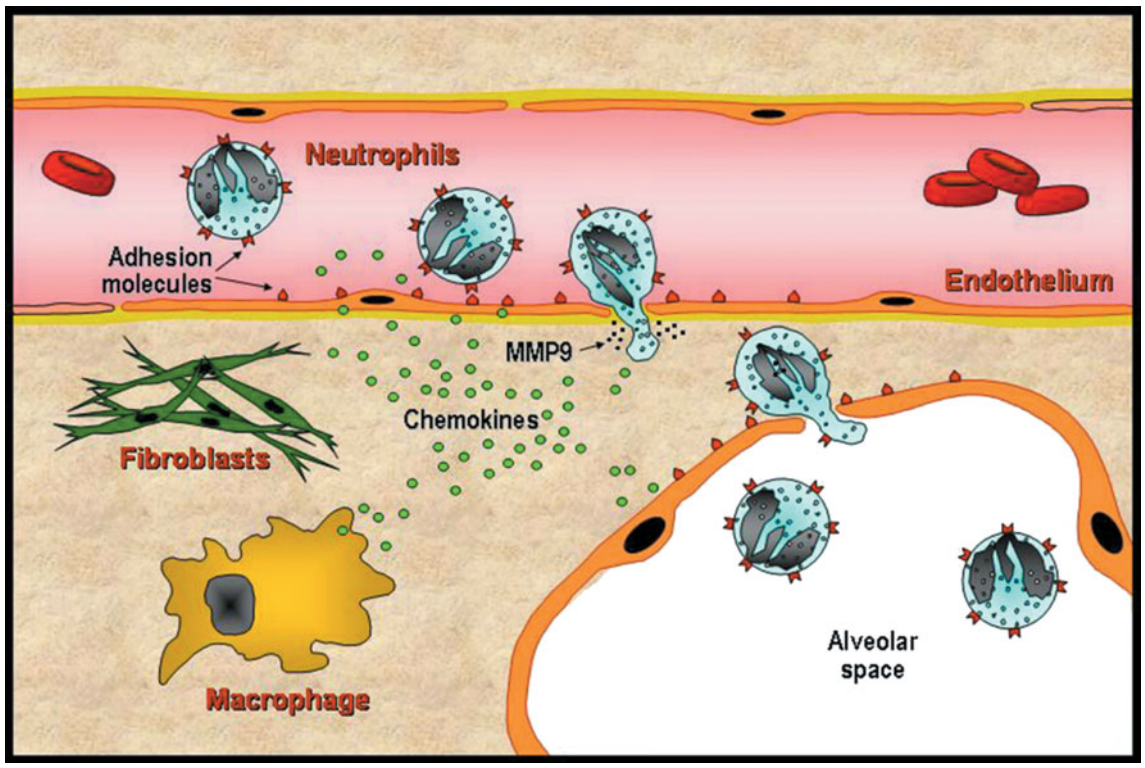

Figure 26-2 Mechanisms of leukocyte recruiting/homing into the injured lung. A multistep and coordinated process regulates leukocyte migration to the extravascular tissue. Chemokines (green dots) diffuse into the bloodstream through the junctions between endothelial cells or are internalized and transcytosed by the endothelial cells from venular walls to their luminal side where they are presented to the chemokine receptors on rolling leukocytes. The cascade of cellular responses involved in this process includes rolling of leukocytes within the vascular lumen, firm adhesion to, and migration of, leukocytes on the surface of the endothelium and subsequent transendothelial movement. This stepwise process involves interactions between specific adhesion molecules (e.g., selectins, integrins, and immune globulin superfamily molecules) and their counter-receptors. The up-regulation of some integrins and proteases (e.g., MMP-9) enhance the interaction of leukocytes with basement membrane constituents. Following transendothelial migration, leukocytes may express increased levels of integrins and proteases which might facilitate their migration through the interstitial and alveolar spaces. Transmigration induces changes in leukocyte phenotype mainly characterized by a different repertoire and distribution of the cell surface and intracellular molecules.

chemokine involved in naïve T-cell recruitment, and CXCL9 and CXCL10 which participate in polarized T-helper (Th) 1 response, are strongly up-regulated in the lung in hypersensitivity pneumonitis (HP). In systemic sclerosis the up-regulation of fractalkine/CX3CL1 and its receptor CX3CR1 cooperatively augments the recruitment of mononuclear cells into the affected tissues including lung.

In IPF, three CC chemokines, CCL2, CCL3 and CCL4, are increased in the bronchoalveolar fluid (BALF) associated with a decreased expression of cellular receptor CCR5 in lymphocytes. Furthermore, CCL2 shows a significant correlation with the severity of the disease. Since activation of CCR5 induces increased production of interferon-γ (IFN-γ), down-regulation of this receptor could result in a decrease in the levels of this strong antifibrogenic cytokine. CCL7 is also significantly increased in IPF lungs and fibroblasts compared with those in nonspecific interstitial pneumonia and respiratory bronchiolitis-ILD, suggesting that this CC chemokine may have a role in the progression of fibrosis.

Chemokines may participate in the expansion of the fibroblast population during lung fibrosis. In some experimental models, CCR2/CCL2 pathway is involved in the recruitment and activation of lung fibrocytes, a source of fibroblasts during lung injury.

Chemokines also play a role in neovascularization, a fundamental process in tissue repair after injury. Some are angiogenic (i.e., IL-8/CXCL8 and the growth-related genes alpha, beta, and gamma [GROα, GROβ, and GROγ]), while others are angiostatic (CXCL9, CXCL10, and CXCL4). It is unclear whether angiogenesis is involved in the resolution of the inflammatory process or in the progression to fibrosis. In some experimental models of lung injury, angiogenesis seems to be associated with an increased fibrotic response.

By contrast in IPF, where there is aberrant vascular remodeling, capillaries are virtually absent within the fibroblastic foci, which are thought to represent areas of active ECM synthesis and are considered to be the "leading edge" of the fibrotic response. A similar situation has been noticed

in fibrotic skin lesions where a significant reduction in the vascular density has been found in keloids when compared with surgical and hypertrophic scars. Thus, it appears that under certain pathological settings increased angiogenesis plays a profibrotic role while in others decreased angiogenesis enhances fibrosis.

In summary, chemokines play a pivotal role in the regulation of inflammation/fibrosis processes. Up-regulation/down-regulation of certain chemokines and receptors may participate in the control of the responses at least at four levels (i.e., inducing and perpetuating inflammation, altering angiogenesis, polarizing the immune response to a type 2 profibrotic reaction [see below], and recruiting bone marrow/circulating fibroblast precursors).

Leukocyte Emigration

Endothelial cells play a central role in the organization and composition of the inflammatory microenvironment. They communicate with underlying cells coordinating the traffic of leukocytes through direct communication as well as via soluble mediators released at sites of inflammation (Fig. 26-2). During leukocyte migration through the endothelial cell barrier, both leukocytes and the endothelium actively participate in the regulation of this process through bidirectional signaling. Molecular specificity in the targeting of leukocytes at sites of inflammation is tightly regulated by at least three families of cell adhesion molecules (CAMs): integrins, selectins, and the immunoglobulin gene superfamily, each structurally distinct and whose function is controlled by a diverse set of signaling pathways.

Integrins are a family of heterodimeric transmembrane glycoproteins that attach cells to ECM proteins of the basement membrane or to ligands on other cells. Integrins contain large (α) and small (ß) subunits of sizes 120 to 170 kDa and 90 to 100 kDa, respectively. Selectins are a family of transmembrane molecules, expressed on the surface of leukocytes and activated endothelial cells. Members of the immunoglobulin superfamily are expressed by the vascular endothelium acting as counter-receptors for leukocyte integrins.

Studies of CAMs in human inflammatory/fibrotic lung diseases are scanty. Intracellular adhesion molecule-1 (ICAM-1) and vascular cell adhesion molecule-1 (VCAM-1) have been found broadly distributed on the endothelium both in sarcoidosis and IPF, while ELAM-1 is mostly found in progressive sarcoidosis. Macrophages bearing the ICAM-1 antigen are present in sarcoid tissue but not in the interstitial or alveolar spaces of IPF lungs. Lymphocyte function-associated antigen-1 (LFA-1, CD11a/CD18) and very late antigen-4 (VLA-4; CD49d/CD29) are usually present on leucocytes but seem to be more highly expressed on lymphocytes in sarcoidosis. These findings suggest that the LFA-1/ICAM-1 and VLA-4/VCAM-1 pathways are involved in leukocyte migration in sarcoidosis and perhaps in IPF while in the active phases of sarcoidosis ELAM-1 is also involved.

Inflammatory Cells and Pulmonary Fibrosis

Lymphocytes

In many chronic inflammatory lung diseases evolving to fibrosis, inflammation is characterized by the influx into the lungs of immune cells. For example, a vast infiltration of T lymphocytes and macrophages, with the subsequent formation of noncaseating granulomas, characterizes sarcoidosis. Patients with this disorder typically show a lymphocytosis predominantly with activated CD4+ T cells oriented to a Th1 cell pathway (see below). The majority of these cells expresses CXCR3 and produces IFN-γ. The CXCR3 ligand IP-10 is also increased in the BALF and localizes to macrophages and epithelioid cells in the lung granulomas.

T Lymphocytes and Type 1 and Type 2 Cytokine Network in the Fibrotic Response

Key regulators in the orchestration of the immune response are the Th-cell subsets. When naïve Th cells first encounter antigen, they are induced to differentiate into one of two lineages, termed *Th1* and *Th2*.

A number of studies have shown that fibrogenesis is strongly linked with a polarized Th-cell response. In general, Th1 cytokines are mostly involved in cell-mediated immunity associated with autoimmune disorders and allograft rejection, whereas Th2 cytokines are primarily implicated in mediating allergic inflammation and importantly, chronic fibroproliferative disorders.

When an inflammatory reaction develops with a Th1 response, which is characterized by the local production of IFN-γ, the development of tissue fibrosis is attenuated. This cytokine substantially decreases fibroblast proliferation, differentiation to myofibroblasts, and ECM synthesis in vitro and reduces the lung fibrotic response in vivo. By contrast, the development of a Th2-cell response involves the secretion of at least two putative fibrogenic cytokines, IL-4 and IL-13. These interleukins activate fibroblasts, and induce the production of ECM components. Both IL-4 and IL-13 are capable of modulating the phenotype of human lung fibroblasts to myofibroblasts through a c-Jun NH2-terminal kinase-dependent pathway. In vivo experimental models have strongly supported the assumption that a Th2 reaction is related to fibrosis. Interestingly, IL-13 selectively stimulates the production of latent TGF-β1 in both transgenic mice and isolated macrophages, and it also can indirectly activate this factor by up-regulating the expression of matrix metalloproteinase-9 (MMP9) that cleaves the LAP-TGF-β1 complex. Therefore, the fibrotic reaction associated with polarized Th2 responses might involve a pathway in which IL-13–producing CD4+ Th2 cells stimulate TGF-β1 expression.

Human lung tissues of different idiopathic interstitial pneumonias (IIP) show an abnormal, heightened expression of the receptor subunits that bind IL-4 and IL-13. Specifically, IL-4Rα and IL-13Rα-2 are present in greater abundance in tissues and fibroblasts from the lungs of patients with IIP compared with normal lungs. When exposed to increasing

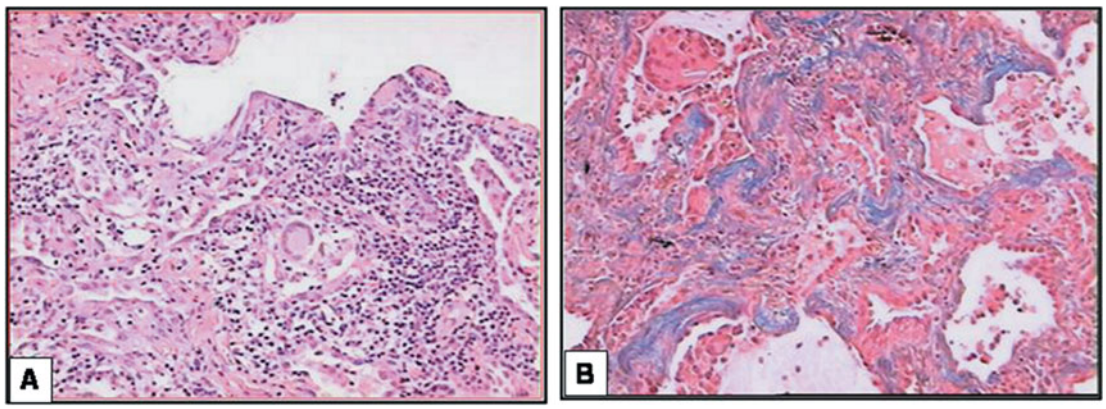

Figure 26-3 Hypersensitivity pneumonitis is an inflammatory disorder provoked by exposure to organic particles *(A)* that may progress to fibrosis *(B)*. The reasons are unknown, but may be partially related to a Th1/Th2 switch.

concentrations of a chimeric protein comprised of human IL-13 and a truncated version of *Pseudomonas exotoxin*, the proliferation of primary IPF fibroblasts was inhibited to a much greater extent compared with fibroblast lines from other lung disorders. In experimental models the intranasal administration of this chimera significantly attenuated the fibrotic response.

CD8+ T cells obtained through BAL from the majority of patients with systemic sclerosis—an autoimmune disease highly associated with pulmonary fibrosis—express IL-4 and/or IL-5 mRNA, and this type 2 dominant response is associated with a greater decline in pulmonary function. Likewise, reduced Th1 responses with decreased INF-γ production have been found in patients with ILD who subsequently showed spontaneous lung functional deterioration.

A hypothetical scenario exemplifying the Th1/Th2 role in lung inflammation/fibrosis could be drawn from HP. HP is a diffuse granulomatous lymphocytic alveolitis provoked by the exposure to a variety of organic particles, which is believed to be a predominantly Th type 1 lung disorder. While a number of patients improve or heal after therapy, around 30% progressively evolve to fibrosis even if they avoid further exposure (Fig. 26-3). The fibrotic response is accompanied by a change in the inflammatory infiltrate with an increase of Th2 lymphocytes and neutrophils loaded with MMP8 and MMP9. Therefore, it can be speculated that in this ILD, the host reaction to the organic particle or the chronicity of the disorder or some unknown event may induce a response dominated by the type 2 cytokine phenotype, whose consequence is the development of progressive fibrosis.

A non-Th1, non-Th2 effector T cell termed *follicular B-helper T* (T_{FH}) is capable of providing help for B cells in lymphoid tissues through expression of the chemokine receptor CXCR5. T_{FH} cells are a cellular subset displaying a distinct pattern of gene expression of cytokines (predominantly IL-21), chemokine receptors, and transcription factors, and recent evidence suggests that they may participate in autoimmune diseases. In a recent study of patients with HP, several genes associated with this cell subset were found to be up-regulated.

Macrophages

Alveolar macrophages are key sentinels of the lung parenchyma and play an essential role in mediating the inflammatory response. After injury, monocytes, the precursors of alveolar macrophages, are recruited readily to the lungs through a number of specific chemokines such as MCP-1/CCL2, MIP-1α/CCL3, and MIP-1β/CCL4 with the expression of the chemokine receptors (CCR1 and CCR2).

Lung macrophages are implicated in the pathogenesis of several ILDs where an increase of interstitial/alveolar macrophages is usually noticed. Surface phenotypic analysis reveals that alveolar macrophages are quite heterogeneous in ILD. In general, macrophages from patients with ILD bear adhesion receptors (CD11c, CD29, CD36, CD44, CD49e, and CD54), molecules involved in signal transduction and/or inflammation (CD13, CD45, and CD53), and other markers (CD9, CD52, CD71, and CD98). In addition, a massive monocyte influx takes place during the development of the alveolitis, as shown by the increased expression of CD14.

Acting as accessory cells, macrophages release various biologic mediators of the immune response, such as IL-1, IL-6, IL-15, and granulocyte-macrophage colony-stimulating factor (GM-CSF) that may enhance local effector cell functions. They also release proteases and oxygen radicals that contribute to amplify inflammation.

Some typical examples of ILDs where macrophages are thought to have a relevant role include diseases provoked by inhaled inorganic or organic particles and some idiopathic interstitial pneumonias, such as desquamative interstitial pneumonia and respiratory bronchiolitis associated with ILD.

Ingestion of silica provokes alveolar macrophage damage and activation with the subsequent release of reactive oxygen species, proteases, inflammatory cytokines/chemokines, and arachidonic acid metabolites. These mediators in turn recruit inflammatory cells into the alveolar wall and alveolar epithelial surface, initiating alveolitis. In sarcoidosis, activated macrophages spontaneously secrete exaggerated levels of a number of cytokines and chemokines including IL-1, TNFα, MIP-1, MCP-1, RANTES, IL-8, IL-12, and IL-18.

Macrophages also synthesize several profibrotic mediators including platelet-derived growth factor (PDGF), insulin-like growth factor-1 (IGF-1) and TGF-β a dual mediator that on one hand is a potent immunosuppressive molecule and on the other is a strong profibrotic factor. Through the secretion of these molecules to the local milieu it is thought that macrophages contribute to the development of lung fibrosis in a variety of ILDs.

Eosinophils

Eosinophils have been associated with fibrotic processes. In bleomycin-induced lung fibrosis in rats, a causal correlation between an early eosinophilic reaction and subsequent development and severity of pulmonary fibrosis has been reported. Overexpression of IL-5 in transgenic mice or by adenoviral gene transfer induced eosinophilia and increased bleomycin-induced lung fibrosis. In some types of human pulmonary fibrosis, the number of eosinophils is increased and seems to correlate with the severity of clinical symptoms and functional abnormalities.

Eosinophils stimulate a number of fibroblast activities, and hence modulate tissue remodeling through the release of their distinct granule basic proteins and an array of cytokines. Eosinophil cationic protein inhibits proteoglycan degradation while eosinophil-derived neurotoxin stimulates fibroblast proliferation. In addition, eosinophils store and release one of the most potent fibrogenic factors, TGF-β, which enhances the differentiation of fibroblasts to myofibroblasts and increases ECM accumulation through several mechanisms. Furthermore, eosinophils modulate fibroblast properties by other cytokines such as IL-4 and IL-13, which promote fibroblast functions by up-regulating matrix protein expression. Eosinophils also contain preformed matrix metalloproteinases (MMPs) such as MMP9 that is released by TNF-α stimulation and some tissue inhibitors of MMPs (i.e., tissue inhibitor of metalloproteinase-1, or TIMP1), suggesting that they can also modulate ECM formation in the lung.

Neutrophils

Persistence of neutrophils may enhance lung fibrosis to a number of injuries. In experimental lung fibrosis induced by silica or bleomycin, the increase of neutrophils and duration of tissue neutrophil activation has been correlated with chronic alveolitis progressing to fibrosis. Likewise, increased BAL neutrophils and increased levels of granulocyte colony-stimulating factor (G-CSF) and IL-8, two potent neutrophil chemotactic glycoproteins, have been found in a number of ILDs that result in fibrosis. Furthermore, neutrophil migration and activation are usually higher in patients with more aggressive and worse prognosis fibrotic lung disorders, and increased tissue neutrophils containing MMP9 (gelatinase B) and MMP8 (collagenase-2) seem to be implicated in the fibrotic reaction of patients with chronic HP. In this disorder a significant correlation between lung neutrophils and the percentage of pulmonary fibrosis has been described. Therefore, the persistence of activated tissue neutrophils may be one of the processes underlying the inflammatory-driven fibrotic response. However, neutrophils are a source of hepatocyte growth factor (HGF) in IPF lungs that could be beneficial for regeneration since HGF induces epithelial cell proliferation and inhibits apoptosis, and gene transfer of human HGF to alveolar septa suppresses bleomycin-induced lung fibrosis.

Mast Cells

Several lines of evidence suggest that mast cells may be involved in fibrotic processes. In several ILDs mast cell populations increase, expanding from small numbers in normal alveolar septa to an abundance of activated and degranulating cells that infiltrate the remodeling interstitium where they are in close apposition with fibroblasts. Mast cells can participate in polarizing T cells toward the Th2 "profibrotic" phenotype through the effects of IL-4 and IL-13. In culture, mast cells induce fibroblasts to lose contact inhibition, proliferate, and synthesize increased amounts of type I collagen. However, it is unclear whether they actively contribute to lung fibrogenesis in vivo or are merely attracted to areas of injury in a nonspecific way.

Ultimately, the temporal and spatial sequence of the inflammatory-driven fibrotic response seems to be mediated by an as yet unclear repertoire of chemokines, cytokines, and growth factors released by immune and inflammatory cells. However, the large number of mediators whose expression is increased in experimental and human fibrosis as well as their redundancy and pleiotropic effects makes it difficult to distinguish the factor(s) that play a pivotal role in fibrogenesis. The key and unsolved question is whether an up-regulated mediator is a cause or an epiphenomenon.

The Epithelial Pathway

Normally following alveolar injury, the alveolar epithelium is repaired by the proliferation of alveolar epithelial type II cells with the subsequent differentiation into new alveolar epithelial type I cells. Also, injured alveolar epithelial cells may be replaced by bone marrow and airway progenitor cells.

It has been proposed that IPF, which is by far the most aggressive fibrotic lung disorder, develops as a result of an aberrant reaction of epithelial cells to multiple cycles of alveolar injury resulting in disturbed epithelial cell function and inappropriate re-epithelialization after damage. Ordered re-epithelialization is fundamental for lung regeneration, as demonstrated, for example, in cryptogenic organizing pneumonia, usually a reversible disorder, where alveolar re-epithelialization is significantly more widespread and structured compared with IPF. The cause of epithelial cell injury is unknown. It is probable that no single mechanism initiates the disease response in the lung; rather, a combination of injuries may potentially contribute to the development of IPF. Virus, tobacco smoke, metal dust exposure, and other agents may be important sources of injury, and may trigger the disease in genetically predisposed individuals.

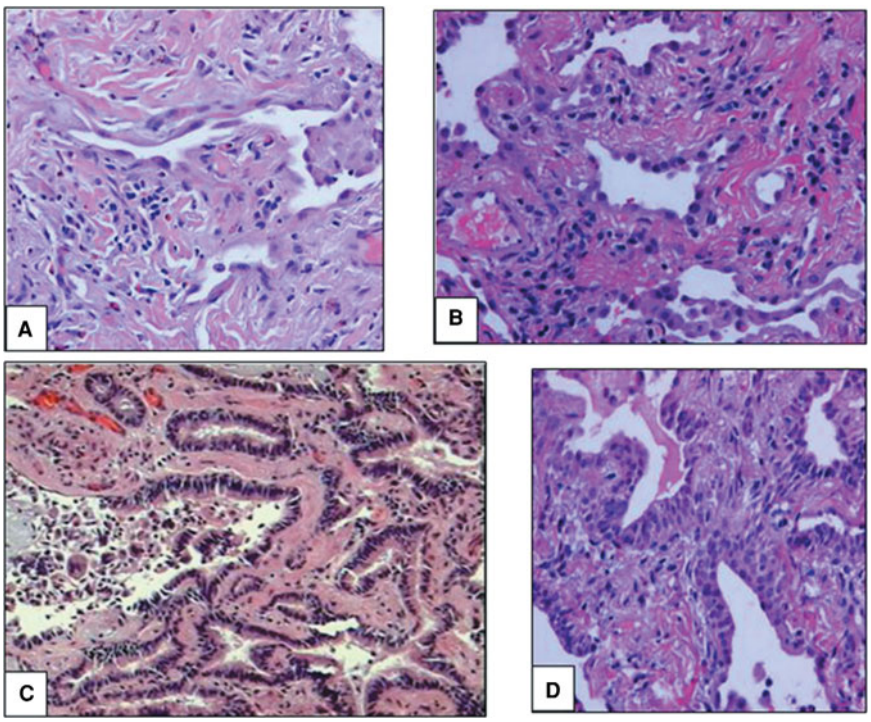

Figure 26-4 Lungs with idiopathic pulmonary fibrosis show several phenotypic changes in epithelial cells. *A.* Attenuated and flat cells may be noticed overlying fibroblastic focus. *B.* Hyperplastic cuboidal epithelial cells or a bronchiolar type of epithelium tend to line the fibrotic thickened alveolar septa. *C.* Extensive proliferation of bronchiolar epithelium (*bronchiolization*). *D.* Epithelial squamous metaplasia.

A striking disturbance in the integrity of the alveolar epithelium with presence of several altered phenotypes is a distinctive characteristic in IPF lungs (Fig. 26-4). The most conspicuous feature is represented by the presence of numerous hyperplastic and hypertrophic (cuboidal) type 2 pneumocytes. Levels of circulating KL-6, a marker of regenerating type 2 pneumocytes and indirectly a marker of the magnitude of the death of type 1 pneumocytes, are increased, and high levels seem to predict rapidly progressive IPF. Other frequent morphologic phenotypes include flattened and attenuated epithelial cells usually overlying the fibroblastic foci, bronchiolar-type epithelium lining the enlarged airspaces of honeycomb lesions (bronchiolization), and squamous metaplasia.

The reasons for, and the significance of, the epithelial changes described above are unknown, but some of them seem to be related to the putative initial insult while others are a consequence of accelerated epithelial cell proliferation/migration indicating regenerative epithelia after injury. Up-regulation of HGF and its high-affinity receptor c-Met, as well as of the recently described mediator, hepatoma-derived growth factor, may explain some of the epithelial changes. Also, alveolar epithelial cells from some patients with IPF exhibit microsatellite instability of the type 2 receptor for TGF-β that may be relevant to the epithelial proliferative responsiveness to this growth factor.

Epithelial Cell Apoptosis

In IPF, epithelial cell apoptosis is a common event and probably an essential feature. Several mechanisms appear to be implicated in this process including a fas-signaling pathway which has been found up-regulated in alveolar epithelial cells from IPF lungs, and the release by fibroblasts/myofibroblasts of angiotensin peptides which induce epithelial apoptosis. Mitochondrial-mediated apoptotic pathways are also implicated in the increased apoptotic rates of epithelial cells in IPF. Oxidant stress may also contribute to epithelial cell damage and death. H_2O_2 secreted from myofibroblasts functions as a diffusible death signal for lung epithelial cells, and oxidative modifications of DNA caused by reactive oxygen species are present in the nuclei of alveolar epithelial cells in IPF.

Epithelial Cell Expression of Profibrotic Cytokines/Growth Factors

In IPF, alveolar/bronchiolar epithelial cells are the main source of a variety of profibrotic mediators. These include PDGF, TGF-β, tumor necrosis factor α (TNFα), endothelin-1, connective tissue growth factor (CTGF), and osteopontin.

Recently, a new product of alveolar epithelial cells has been identified that may explain why fibroblastic/myofibroblastic foci in IPF lungs lack capillaries. Pigment epithelium-derived factor (PEDF), a 50-kD protein with strong angiostatic properties is highly up-regulated in IPF. PEDF, a TGF-β target gene, has been co-localized with this mediator, particularly within the fibrotic interstitium, and within the alveolar epithelium directly overlying the noncapillarized fibroblastic foci.

Alveolar epithelial cells may enhance a fibrotic response by inducing a procoagulant milieu. Alveolar damage results in transudation of plasma proteins and activation of the coagulation cascade leading to the formation of a fibrin-rich provisional matrix that needs to be degraded for appropriate repair. However, the coagulation cascade and the subsequent fibrinolytic pathway, responsible for clearing the fibrin clot, are dysregulated in lung fibrosis, including IPF. Importantly, alveolar epithelial cells seem to play a pivotal role in this pathological process. Tissue factor, the primary cellular initiator of

the coagulation protease cascade, and plasminogen activator inhibitor (PAI)-1 are strongly expressed by these cells. Moreover, tissue factor is synthesized by alveolar epithelial cells covering the affected alveolar septa and the fibroblastic foci, near where fibrin is being deposited.

Increased procoagulant activity in the lung microenvironment may enhance fibrosis in several ways, including fibrin accumulation, lack of activation of some MMPs responsible for ECM degradation, impairment of epithelial cell migration, and a thrombin-mediated increase of fibroblast activation and transition to myofibroblasts.

Injury of type II epithelial cells and fibrin deposition may also have a profound effect on the pulmonary surfactant. IPF lungs exhibit markedly impaired surfactant function and altered biochemical composition, alterations including changes in phospholipid species distribution, and pronounced modifications in the fatty acid profiles of phosphatidylcholine, phosphatidylglycerol, and phosphatidylinositol. Surfactant-associated proteins A and D also show quantitative changes. These alterations in surfactant may contribute to alveolar collapse and impairment of gas exchange.

The alveolar epithelium may also generate a Th2-like pattern in IPF lungs. For instance, while in HP and sarcoidosis—two reversible ILDs—type II alveolar epithelial cells express both IL-4 and INF-γ in IPF, yet only IL-4 is detectable. These results are consistent with a predominantly type 2 pattern of cytokine network in IPF and support a role for epithelial cells in the characteristic imbalance of profibrogenic cytokines in the distal lung of patients with this disease.

Epithelial Cells and the Loss of Antifibrotic Functions

Epithelial cells on the alveolar surface of the fibrotic microenvironment in IPF may contribute to fibrogenesis not only because they overexpress profibrotic cytokines, but also because they might not secrete mediators with inhibitory effects on fibroblasts. Under physiological conditions alveolar epithelial cells suppress fibroblast migration, proliferation, and activation, including collagen synthesis, through the action of prostaglandin E_2 (PGE_2). In IPF lungs, epithelial cell expression of both cyclooxygenase-1 (COX-1) and COX-2, responsible for PGE_2 synthesis, is significantly reduced compared with controls.

FIBROBLASTS/MYOFIBROBLASTS: THE BRIDGE BETWEEN INFLAMMATION OR EPITHELIAL ACTIVATION AND RELENTLESS FIBROSIS

Expansion of the fibroblast/myofibroblast population is a critical event in IPF that precedes the fibrotic remodeling. Fibroblasts migrate and proliferate under a number of stimuli, and myofibroblasts develop from fibroblasts in response to stimulation by TGF-β and other growth factors and cytokines (Table 26-1). It has been proposed that myofibroblast differentiation occurs in two steps. First, fibroblasts differentiate into proto-myofibroblasts, which form cytoplasmic actin-containing stress fibers that terminate in fibronexus adhesion complexes. Functionally, these cells can generate contractile force. After that, TGF-β1 and ED-A fibronectin, in the presence of mechanical stress, promotes the modulation of proto-myofibroblasts into differentiated myofibroblasts that are characterized by the de novo expression of α smooth muscle actin (αSMA) in more extensively developed stress fibers and by large fibronexus adhesion complexes. Functionally, differentiated myofibroblasts generate greater contractile force than proto-myofibroblasts, which is reflected by a higher organization of extracellular fibronectin into fibrils.

In chronic, unresolved lung inflammation or sustained epithelial activation, increased numbers of fibroblasts and myofibroblasts with excessive ECM deposition are a hallmark of the lung fibrotic response. Interestingly, while fibroblasts proliferate ubiquitously in the chronic inflammatory areas in the fibrotic reaction associated with an inflammatory-driven disease, in IPF fibroblasts usually form widely scattered subepithelial fibroblastic foci. These

Table 26-1

Cytokine/Growth Factors Involved in Fibroblast/Myofibroblast Expansion

Intrapulmonary fibroblast migration	PDGF PDGF/IL-1β,TNFα KL-6 Fibronectin NGF Tenascin-C
Fibrocyte migration	CXCL12 CCL2
Fibroblast proliferation	IGF-1 PDGF FGF-2
Differentiation to myofibroblasts	TGFβ1 ED—a splice variant of cellular fibronectin Tenascin-C N-terminal domain of CTGF PTEN (suppresses)

Abbreviations: PDGF, platelet-derived growth factor; IL-1β, interleukin-1 beta; TNFα, tumor necrosis factor alpha; KL-6, mucin-like glycoprotein; NGF, nerve growth factor; CXCL12, stromal-derived factor 1; CCL2, monocyte chemotactic protein 1; IGF-1, insulin growth factor 1; FGF-2, basic fibroblast growth factor; TGFβ1 transforming growth factor beta 1; CTGF, connective tissue growth factor; PTEN, phosphatase and tensin homologue deleted on chromosome 10.

Figure 26-5 Typical subepithelial fibroblastic/myofibroblastic focus in idiopathic pulmonary fibrosis. Numerous spindle-shaped cells are arranged with their long axis parallel to the long axis of the alveolar septum.

aggregates are characterized by spindle-shaped cells within lightly staining, myxoid-appearing matrix, usually arranged with their long axis parallel to the long axis of the alveolar septa (Fig. 26-5).

The Origin of Fibroblasts: Emerging Evidence for an Extrapulmonary Source

For decades the prevailing view has been that in response to lung injury resident mesenchymal cells migrate, proliferate, and synthesize ECM. However, recent findings challenge this concept suggesting that at least part of the expanded fibroblast population has an extrapulmonary origin (Fig. 26-6). It is well known that lung fibroblasts in IPF are phenotypically and functionally heterogeneous. This heterogeneity may reflect not only activation and differentiation processes that take place in the cells but that the cells have different sites of origin.

Bone Marrow-derived Fibroblasts

Bone marrow-derived stem cells possess the unique ability to self-renew and differentiate into multiple lineages, and recent evidence suggests that these cells may participate in tissue repair/fibrosis. Thus, in one study bone marrow-chimeric mice exposed to total lung irradiation exhibited homing and proliferation of bone marrow-derived stromal cells to sites of developing organizing alveolitis/fibrosis. In this study, bone marrow cells comprised almost half of detectable cells, primarily macrophages and fibroblasts, in areas of fibrosis at the time of death. Similar results were reported in bleomycin-induced

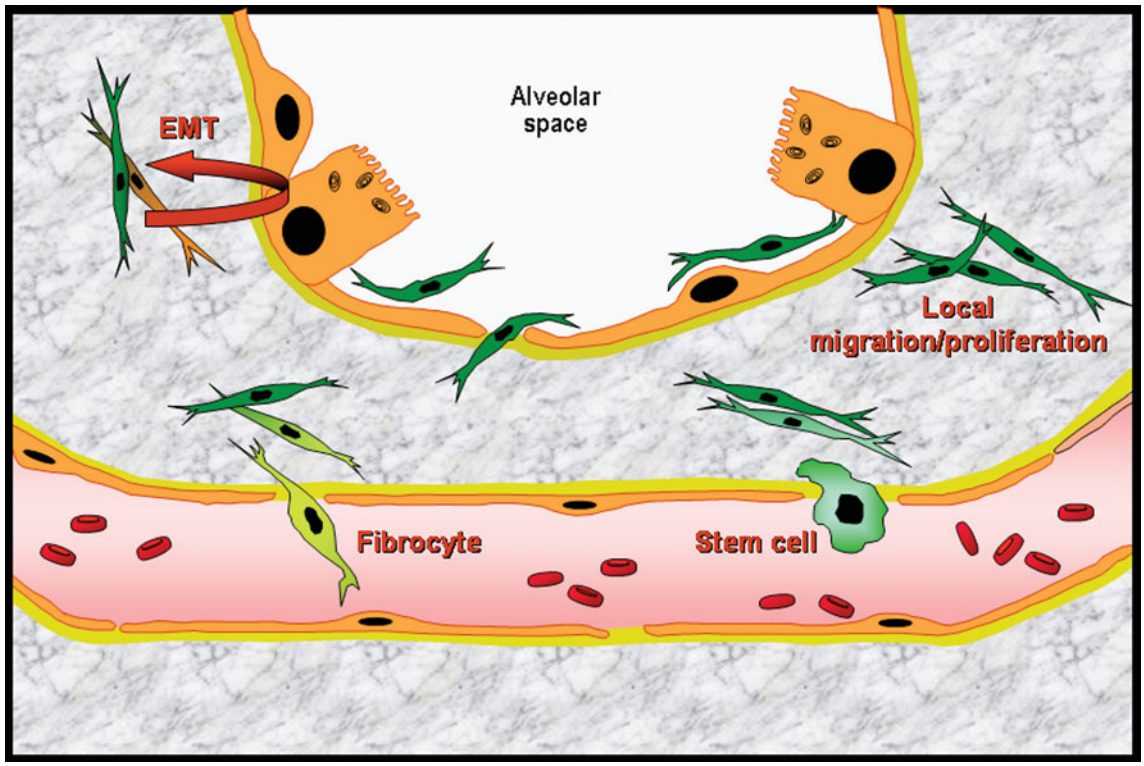

Figure 26-6 Where do fibroblasts come from in pulmonary fibrosis? Theoretically, at least four mechanisms/sources may account for the expanded fibroblast/myofibroblast population in pulmonary fibrosis. (1) Release of growth factors (e.g., PDGF, IGF-1) may induce migration/proliferation of resident mesenchymal cells. (2, 3) Signal(s) from the injured lung may reach the circulation and bone marrow to stimulate recruitment of circulating fibrocytes (e.g., CCL2, CXCL12) or bone marrow-derived stem cells. (4) Alveolar epithelial cells may transition into fibroblasts and myofibroblasts in response to TGF-β and other growth factors/cytokines. However, there is limited definitive in vivo evidence to support the contribution of these potential mechanisms/sources.

lung fibrosis in mice. Mice durably engrafted with bone marrow cells isolated from transgenic mice expressing green fluorescent protein (GFP+) and then injured with bleomycin showed a large number of GFP+ cells expressing type I collagen in fibrotic lungs.

Fibrocytes: A Distinct Mesenchymal Cell Type from Peripheral Blood May Mediate Fibrosis

Another potential extrapulmonary source of fibroblasts/myofibroblast is the circulating progenitor fibrocyte. Fibrocytes are a distinct population of blood-borne cells that display a unique cell surface phenotype and exhibit potent immunostimulatory activities. These cells comprise 0.1 to 0.5 percent of nonerythrocytic cells in peripheral blood and display an adherent, spindle-shaped morphology when cultured in vitro. Circulating fibrocytes rapidly enter sites of tissue injury, and may contribute to connective scar formation.

Indeed, there is evidence that fibrocytes may participate in tissue fibrosis. For example, allergen exposure in patients with allergic asthma induces the accumulation of fibrocyte-like cells in the bronchial mucosa that localize to areas of collagen deposition below the epithelium. Likewise, in a mouse model of allergic asthma, circulating fibrocytes were recruited into the bronchial tissue following allergen exposure and differentiated into myofibroblasts. In pulmonary fibrosis this mechanism may participate in the accumulation of fibroblasts since infiltrating fibrocytes have been demonstrated in lung tissue of mice injured by bleomycin. However, evidence in human lung fibrotic disorders is lacking.

Epithelial-Mesenchymal Transition

Epithelial-mesenchymal transition (EMT) is a central mechanism for diversifying cells during embryonic development and it may play a role in the genesis of fibroblasts during organ fibrosis in adult tissues. Epithelium in transition displays loss of cell-cell and cell-matrix attachments, new actin rearrangements, and gain of mobility. This phenotypic conversion requires the molecular reprogramming of epithelium. To date, the participation of EMT in the fibrotic response has been demonstrated mainly in progressive kidney diseases. The intracellular signaling pathways leading to initiation of EMT remain largely unknown, though recent studies have identified β-catenin and Smad3 activation of lymphoid-enhancer factor, integrin-linked kinase, small GTPases, and mitogen-activated protein kinases as key components.

EMT appears to occur in IPF and may also occur in other forms of lung fibrosis. Lung tissue from patients with IPF has revealed transitional cells lining cystic airspaces that co-express alveolar epithelial and mesenchymal markers, suggesting that alveolar epithelial cells may serve as a source of myofibroblasts in pulmonary fibrosis.

Translocation of β-catenin to the nucleus may play a role in this process since induces the expression of genes that are involved in proliferation as well as in EMT. Interestingly, accumulation of nuclear β-catenin in both epithelial cells and myofibroblasts has been reported in IPF lungs. Likewise, several genes that are implicated in the Wnt signaling pathways (Wnt1, secreted frizzled-related protein 2, and collagen type XVIII), as well as N-cadherin, a mesenchymal cadherin preferentially expressed in migratory cells, are strongly upregulated.

In summary, the origin of fibroblasts/myofibroblasts in the fibrotic lung disorders has not been fully clarified, but it appears that both intra- and extrapulmonary cells may participate.

Myofibroblast Persistence in the Active Fibrotic Site

During the resolution of normal wound healing, there is a striking decrease in cellularity, including the disappearance of myofibroblasts through apoptosis. Indeed, the finding of markers of apoptosis within myofibroblast populations in vivo has led to the speculation that fibroblast differentiation to the myofibroblast phenotype might represent a terminal pathway leading to apoptosis.

The question that arises is why this process does not seem to occur during the development of IPF. In IPF, apoptotic activity is remarkably lower in fibroblastic/myofibroblastic foci compared to the fibromyxoid lesions of cryptogenic organizing pneumonia, a reversible disease, suggesting that in IPF fibroblasts/myofibroblasts have longer survival. The reasons for this behavior have not been elucidated, but inhibition of inducible nitric oxide synthase expression and the prevention of a decline in bcl-2 expression seem to be involved. Also IGF-1 may play a role.

Extracellular Matrix Remodeling: The Role of Matrix Metalloproteinases (MMPS) and Tissue Inhibitors of Metalloproteinases (TIMPS)

The ECM plays a key role in lung architecture and homeostasis, providing much of the supporting framework necessary for the organization and communication between cells. ECM in the lung parenchyma is comprised of numerous molecules including collagens (mainly type I and III), elastin, proteoglycans, and fibronectin. Other proteins contribute to specialized components of the ECM structure, such as the epithelial and endothelial basement membranes, including laminin, entactin, and collagen IV.

Independent of etiology, lung fibrosis is associated with major alterations in both the quantity and composition of ECM. In advanced stages, the fibrotic lung contains approximately two to three times more ECM than normal, including collagens (I, III, V, VI, and VII), fibronectin, elastin, and proteoglycans. Likewise, disruption of basement membranes is often found.

ECM turnover depends on a balance between MMPs and their tissue inhibitors (TIMPs). Disturbances in the complex process of matrix metabolism (synthesis and degradation) have been linked to the aberrant remodeling characteristic of lung fibrosis.

In this context, recent work has explored the possible role of MMPs during ECM remodeling. MMPs represent a family of 24 distinct genes that are collectively capable of cleaving all components of the ECM and basement membranes, as well as many other nonmatrix substrates

including chemokines, cytokines, growth-factor receptors, CAMs, apoptotic ligands, and angiogenic factors. This plethora of MMP substrates has significantly broadened our understanding of these enzymes as proteolytic executors and regulators in various physiological and pathological states. Therefore, they participate in the regulation of multiple cellular functions including cell growth, apoptosis, angiogenesis, and inflammatory and immune responses. MMPs can be classified according to their structural domains into several subfamilies including: collagenases, gelatinases, stromelysins, matrilysins, furin-activated MMPs which include secreted and membrane bound, and other MMPs that do not appear to fall into any of these subgroups.

The regulation of MMPs is controlled at several levels including gene transcription, activation of latent enzyme, and inhibition through binding to a specific family of four proteins referred to as TIMPs 1 through 4. TIMPs differ in expression patterns, and other properties such as pro-MMP activation, cell growth-promoting activity, matrix binding, inhibition of angiogenesis, cell survival promoting activity, and induction of apoptosis.

The possible role of MMPs and TIMPs in the development of lung fibrosis has been analyzed in humans and in experimental models with some similar and some contradictory findings. In general, increases of MMP2 and/or MMP9, also known as gelatinases A and B, are usually found. MMP2 is mostly constitutively expressed with only moderate up- or down-regulation under various conditions. MMP9, however, is highly inducible and under the control of a variety of cytokines and growth factors. Gelatinase substrates include a broad assortment of molecules including ECM proteins, proteinases, proteinase inhibitors, blood clotting factors, chemokines, latent growth factors, cell surface receptors, and adhesion molecules. However, the relevance of these events in vivo is presently unclear. In IPF, MMP2 is found in alveolar and bronchiolar epithelial cells and in fibroblastic foci; MMP9 is also expressed by epithelial cells, and fibroblast type cells. Increases of MMP2 and MMP9 in lung fibrosis have been suspected to have a role in the disruption of the basement membranes, which may enhance the fibroblast invasion into the alveolar spaces, and epithelial cell apoptosis.

Another MMP that seems to play a role in lung fibrosis is MMP7, also known as matrilysin. MMP7 cleaves many substrates, including fibronectin, collagen type IV, laminin, elastin, and fibrin/fibrinogen cleavage, suggesting it has a role in cell migration and tissue remodeling. MMP7 also cleaves pro-forms of the proteases MMP2 and MMP9 leading to their activation, and ADAM28 (a disintegrin and metalloproteinase), which is highly expressed by lymphocytes. MMP7 is highly up-regulated in IPF lungs where it is expressed primarily by the abnormal epithelium. Of note, MMP7-deficient mice do not develop lung fibrosis in response to bleomycin.

Probably the main disparity between the different experimental models of pulmonary fibrosis explored so far and human IPF is related to the subfamily of collagenases (MMP1, MMP8, and MMP13) and TIMPs. In general, animal models show either no changes or a decrease in expression of collagenases (MMP13 and MMP8) with an increase of TIMP1, whereas IPF is characterized by a huge increase of MMP1 (the main interstitial collagenase) with a modest increase of TIMP1 and TIMP3.

The finding of high levels of collagenase in IPF, a fibrotic disorder where the main characteristic is the exaggerated deposition of ECM, is of course a paradox, since MMPs are mainly viewed as enzymes contributing to pathological ECM destruction. However, the location of MMPs and TIMPs in the microenvironment is critical for ECM degradation. In IPF, collagenase (MMP1) is primarily localized to reactive alveolar epithelial cells and bronchiolar epithelial cells lining honeycomb cystic spaces. It is virtually absent in the interstitial compartment where collagen is being accumulated. Lack of this enzyme in interstitial fibroblasts might explain in a simplistic way the persistence of fibrosis in IPF. Additionally, TIMP2 and TIMP3 are expressed in the fibroblastic foci in IPF.

GENETIC SUSCEPTIBILITY AND PULMONARY FIBROSIS

Numerous observations support the notion that genetic factors determine susceptibility or resistance to the development of lung fibrosis. Thus, for example, substantial variability exists in the development of lung inflammation/fibrosis among individuals similarly exposed to organic particles (i.e., HP), inorganic particles (i.e., asbestosis), or drugs (i.e., amiodarone). Similar observations have been made in experimental models of pulmonary fibrosis in mice of different strains.

Familial forms of IPF-like pulmonary fibrosis have been described, and the disorder has also been found in monozygotic twins who were separated at early age. Familial IPF may be inherited as an autosomal recessive trait or as an autosomal dominant pattern of inheritance perhaps with reduced penetrance. Genetic studies in familial lung fibrosis (that often include IPF and other forms of idiopathic interstitial pneumonias) have demonstrated an association with surfactant protein-C (SP-C) genes where two mutations resulting in protein misfolding cause type II epithelial cell damage. In other cases of familial IPF a deficiency of SP-C seems to exist which may cause abnormal shear forces in the alveoli, thereby causing mechanical injury of the respiratory epithelium. Recently, mutations in the genes encoding telomerase components were reported in familial IPF.

Also, lung fibrosis often occurs in a number of pleiotropic inherited syndromes such as Niemann-Pick disease, infantile Gaucher's disease, neurofibromatosis, tuberous sclerosis, and Hermansky-Pudlak syndrome.

Genetic Polymorphisms and Pulmonary Fibrosis

Association studies designed to explore the co-occurrence of a genetic marker and a specific disease at the population level are widely used for discovering susceptibility loci. Several gene

polymorphisms have been studied in different cohorts of IPF patients but results have shown weak associations or no associations at all. Genes analyzed so far include TNFα (–308 adenine), IL-1 receptor antagonist (+2018 thymidine), complement receptor-1 gene (GG genotype for the C5507G, exon 33), plasminogen activator inhibitor-1 (4G/5G in the promoter region), IL-12 p40 (1188 (A/C) 3′ untranslated region), IFN-γ (5644 (G/A) 3′ untranslated region), and IL-10 (G to A substitution of +43). Interestingly, severity and progression of IPF have been associated with IL-6/TNF receptor II (IL-6 intron 4G; TNF-RII 1690C) and TGF-β1 (+869 cytosine).

In some inflammatory-driven fibrosis where an autoimmune or exaggerated T-cell response is involved, associations with the major histocompatibility complex have been found. In systemic sclerosis, antitopoisomerase antibodies are associated with the carriage of human leukocyte antigen (HLA) DRB1*11 and DPB1*1301 alleles, suggesting the recognition of a specific amino-acid motif. In a different cohort, pulmonary fibrosis was associated with HLA-B*62 and HLA-Cw*0602.

In general, however, there are several problems with all of these studies. First, a significant association between an allele and a disease does not mean that the candidate gene is a causal one. Thus, a positive finding always needs confirmation in another group of subjects with different ethnic background. It is now evident that only a combined approach studying large numbers of familial and sporadic cases, all clinically well phenotyped, using multiple distinct cohorts, and genotyped according to relevant gene ontologies will be successful.

Gene-Gene Interactions

Different gene alterations involving key pathways may provoke the development of a complex disease. If IPF is primarily an epithelial/fibroblastic disorder, perhaps changes in genes involving both cells are important in the pathogenesis of the disease. In this context, it has been observed that alveolar epithelial cells from some patients with IPF exhibit microsatellite instability in the TGF-β1 type 2 receptor gene (deletion in the polyadenine tract in exon 3), and coincidentally exhibit low expression of the receptor. The putative pathogenic effect, if any, of this deletion mutation is still unclear, although hyporesponsiveness to TGF-β may induce increased expression of the cytokine and consequently promote fibrosis.

Also, lung fibroblasts isolated from IPF patients have shown a defect in the expression of COX-2, and a failure in their capacity to synthesize PGE_2 that has, among other functions, a strong antifibrogenic effect. Furthermore, mice deficient in COX-2 exhibited an enhanced fibrotic response to bleomycin. Therefore, it seems that a reduced capacity to upregulate COX-2 expression and COX-2–derived PGE_2 synthesis may lead to unopposed fibroblast proliferation and collagen synthesis and contribute to the pathogenesis of pulmonary fibrosis. A defect in PGE_2 may also contribute to a decrease in the production of HGF, another important antifibrotic mediator. Likewise, a substantial difference in the response to some cytokines between normal-derived and fibrosis-derived fibroblasts has been observed. For example, while IL-6 inhibits proliferation of normal fibroblasts it was a potent mitogen for IPF-derived fibroblasts. The switch in responsiveness seems to correspond with a shift from STAT-3–dependent signaling in normal cells to extracellular signal-regulated kinase-dependent signaling in IPF cells.

Gene-Environment Interactions

Genetic dissection of complex disorders should take into account that the risk to develop the pathological condition might be conferred jointly by the interaction of multiple genes and environmental factors. For example, IPF is more frequent in smokers, and some studies suggest associations of polymorphisms of surfactant-associated proteins with or without smoking and the occurrence of IPF. Gene-environment interactions are clearly exemplified in some ILDs of known etiology such as HP, where an increased frequency of the HLA haplotype DRB1*1305-DQB1*0301, and of TNF-2 (–308) allele significantly increase the risk of developing the disease in some cohorts exposed to organic particles, while in others it has been associated with HLA-DQw3.

CONCLUSIONS

Pulmonary fibrosis is the final common result of multiple forms of chronic lung disease, and it is characterized by a marked disruption of the lung architecture with accumulation of excess abnormal ECM resulting from both increased synthesis and decreased degradation of matrix components. A complex interplay among different lung cell types takes place during tissue fibrogenesis. In most ILDs the fibrotic response is triggered by unresolved chronic inflammation leading to the end-stage fibrotic scar. In others, primarily IPF, fibrosis is provoked by aberrant and not yet completely understood epithelial cell activation. In both pathways, a number of imbalances take place causing an excessive release of chemokines, cytokines, growth factors, eicosanoids, oxidants, and procoagulant factors in the alveolar microenvironment leading to dysregulated repair and aberrant tissue remodeling. However, there are substantial differences between the inflammatory-driven and the epithelial-driven lung fibrosis. The latter is temporally and topographically heterogeneous, and the fibroblasts/myofibroblasts usually gather together in peculiar subepithelial foci which seem to represent the sites of ongoing injury and repair. Delayed or ineffective re-epithelialization is a crucial trigger for recruiting, activating, and sustaining mesenchymal cells in these foci. Inflammatory-driven fibrotic lung disorders vary in the inflammatory composition and phenotypes and the intra-alveolar and interstitial milieu of mediators can be diverse according to the specific ILD.

Certainly, epithelial injury and activation may be observed in several ILDs, and some inflammation is usually

noticed in IPF, but their respective pathogenic roles are most likely negligible.

The cells primarily responsible for ECM production in the fibrotic lung are myofibroblasts. The origin of the expanded lung fibroblasts/myofibroblast population has not been determined but probably includes intra- and extrapulmonary sources. The putative roles of resident cells, bone-marrow stem cells, circulating fibrocytes, and EMT need to be elucidated.

Symptoms and Signs of Respiratory Disease

This page intentionally left blank

27
CHAPTER

Approach to the Patient with Respiratory Symptoms

Darren B. Taichman • Alfred P. Fishman

The most common respiratory complaint for which a person seeks medical help is either shortness of breath or cough. Less frequent are hemoptysis, thoracic pain, cyanosis, and an abnormal breathing pattern. As in the case of any medical evaluation, the paramount diagnostic mainstays are the history and physical examination. The use of plain chest radiography for routine screening, once popular in the hope of uncovering silent disease amenable to therapy, has fallen into disuse and remains controversial because it has not been proven to decrease mortality, to be cost-effective, or to be worth either the inconvenience to the patient or the exposure to radiation. The use of computed tomography of the chest as a screening tool is also being debated and of unproven benefit. Chest radiography is now usually reserved for patients who have clinical manifestations of chest disease or are from families or populations known to be particularly vulnerable to chest disease. Serial chest radiographs often provide invaluable clues into the nature of chest lesions. More sophisticated diagnostic measures and interventions help to complete and supplement the clinical picture. Regardless of whether the analysis and diagnostic synthesis are accomplished in the clinician's mind or by computer-assisted mathematical modeling, the history, physical examination, and chest radiograph still remain the three-legged underpinning for diagnosis in chest medicine.

HISTORY

Even though seasoned clinicians may be adept at spotting telltale diagnostic clues, there still is no substitute for a comprehensive, penetrating medical history. This should include a detailed inventory of substances in the air that can harm the lungs. One of the most common offenders is cigarette smoking. An attempt should be made to quantify the exposure. When did it begin? When did it stop? How many cigarettes per day (expressed in number of pack-years)? Often, the workplace is the site where toxic air is inhaled. An almost forgotten exposure to a toxic inhalant 20 years ago can explain certain types of pulmonary or pleural diseases. Symptoms that appear to improve during weekends or other periods away from work may be a clue to an occupational exposure that causes a respiratory ailment. A newly installed home humidifier or an air-conditioning system that incorporates stagnant pools of water can point the way to resolving a mysterious illness. A brief residence in an area where either cryptococcosis (southwestern United States) or histoplasmosis (southern and midwestern United States) is endemic may help to clarify the nature of an illness that mimics tuberculosis. A recent visit to a South or Central American country may bring into focus a more remote possibility (e.g., South American blastomycosis) (Fig. 27-1).

The history should include a thorough evaluation of prior and current medical problems. Rheumatologic disorders such as systemic sclerosis (scleroderma) may be associated with interstitial lung disease, aspiration pneumonia due to the involvement of the esophagus, or pulmonary vascular disease. Certain malignancies often metastasize to the lung (e.g., breast or colon carcinoma), or predispose to the development of venous thromboembolism (e.g., pancreatic carcinoma). Infection with the human immunodeficiency virus (HIV) should not be overlooked since pulmonary complications are often the initial presentation of acquired immunodeficiency syndrome (AIDS). Other causes of immunodeficiency, such as a hematologic malignancy or chemotherapeutic treatment of cancer, should

heighten suspicion of infection as the cause of respiratory symptoms.

Personal habits of the patient, such as intravenous drug abuse or sexual practices, may also help to uncover the cause of an unusual pulmonary disorder. Recent treatment of a disorder with immunosuppressive agents can arouse suspicion of toxicity caused by the therapeutic agent or of pulmonary infection by organisms that are usually noninvasive.

Certain pharmacologic agents have a propensity for inflicting lung damage. Among these are bleomycin, nitrofurantoin, and methotrexate (Fig. 27-2). Beta blockers, administered as part of a cardiac regimen, can evoke bronchoconstriction. Even a common medication, such as aspirin may, on rare occasion, cause a severe pulmonary disorder (e.g., pulmonary edema).

The family history is an essential ingredient of the medical inventory. This history can be particularly helpful in uncovering heritable diseases of the lungs (e.g., cystic fibrosis, α_1-antitrypsin deficiency, alveolar microlithiasis, and hereditary telangiectasia). The unraveling of a familial history of asthma, a common disease, or of familial pulmonary arterial hypertension, a rare disease, can be much more difficult.

PHYSICAL EXAMINATION

Before the widespread use of chest radiography, the physical examination, along with the history, played the pivotal role in the diagnosis of pulmonary disease. The advent of chest radiography and of more sophisticated methods of imaging has tended to de-emphasize the value of the physical examination. Nonetheless, the physical examination remains a key diagnostic measure in the proper appraisal of chest disease.

General Aspects

Important clues are often available before examination of the chest. Neglected pyorrheal teeth raise the prospect of a necrotizing aspiration pneumonia. A lacerated tongue suggests that a convulsive episode may have led to aspiration (Fig. 27-3).

Pursing of the lips during expiration ("pursed lip breathing") is frequent in patients with chronic obstructive pulmonary disease (COPD). Subtle changes in consciousness or coordination may signal that metastasis has occurred to the brain from a primary carcinoma of the lung. In the patient with COPD, a clouded sensorium or a disturbed personality can signify acute CO_2 retention.

Inspection of the skin can often provide clues to diseases of the chest. Evidence to support the diagnosis of pulmonary sarcoidosis may be found in the eyes and skin. Petechiae in the skin may reflect a systemic vasculitis that also affects the vessels of the lungs. The skin lesions of neurofibromatosis type 1 (von Recklinghausen's disease) may signify that a solitary pulmonary nodule in the paraspinal region may be a neurofibroma. A minute skin abscess can turn out to be the source of multiple lung abscesses. Distinctive scars over the antecubital veins of a drug addict can help to clarify the etiology of old lesions in the lungs as well as of fresh abscesses. Erythema nodosum and erythema multiforme occasionally complicate sarcoidosis, tuberculosis, histoplasmosis, and coccidioidomycosis; on occasion, these skin lesions may be part of a drug reaction.

A variety of endocrine syndromes can accompany a carcinoma of the lung. An altered mental status may be due to hyponatremia caused by the syndrome of inappropriate antidiuretic hormone (SIADH) in a patient with a lung cancer. Clubbing of the digits may accompany various clinical disorders, including idiopathic pulmonary fibrosis, bronchiectasis, and certain carcinomas of the lung (Table 27-1). A puffy face, neck, and eyelids, coupled with dilated veins of the neck, shoulder, thorax, and upper arm (i.e., superior vena cava syndrome) may constitute the first clinical evidence of obstruction of the superior vena cava by a neoplasm of the lung. Although the causes of superior vena cava syndrome are many and diverse, at least 80 percent are attributable to a primary carcinoma of the lung (Fig. 27-4). In the patient in whom a neoplasm has evoked acute signs and symptoms of increased systemic venous pressure that progresses rapidly (e.g., to laryngeal edema), early diagnosis and prompt treatment of the neoplasm can be lifesaving. The presence of Horner's syndrome—unilateral ptosis, miosis, and anhidrosis—in a patient with a carcinoma of the lung suggests a pulmonary sulcus tumor with involvement of the ipsilateral sympathetic pathway within the thorax (Fig. 27-5).

Table 27-1

Clinical Disorders Commonly Associated with Clubbing of Digits

Pulmonary and thoracic
Primary lung cancer
Metastatic lung cancer
Bronchiectasis
Cystic fibrosis
Lung abscess
Pulmonary fibrosis
Pulmonary arteriovenous malformations
Empyema
Mesothelioma
Neurogenic diaphragmatic tumors
Cardiac
Congenital
Subacute bacterial endocarditis
Gastrointestinal and hepatic
Hepatic cirrhosis
Chronic ulcerative colitis
Regional enteritis (Crohn's disease)
Miscellaneous
Hemiplegia

Inspection of the Chest

Observation of the chest from the foot of the bed can be informative: a visible lag of one side of the thorax localizes a pleural effusion, pulmonary infection, or a paralyzed diaphragm. The position of the trachea with respect to the midline can be a useful clue to atelectasis of one lobe or to obstruction of a major bronchus. The respiratory pattern may be informative: patients with severe airflow obstruction often take slow, deep breaths; whereas rapid and shallow breaths are often seen with restrictive processes such as interstitial lung disease or kyphoscoliosis. Inspection of the chest and abdomen in the supine position may reveal the paradoxical inward movement of the abdomen indicative of respiratory muscle weakness (e.g., as in bilateral diaphragmatic paresis or paralysis). Thoracoabdominal discoordination during sleep raises the possibility of obstructive sleep apnea.

Palpation of the Chest

Over the years, the role of palpation in the examination of the chest has been considerably devalued. Nonetheless, palpation can provide helpful diagnostic clues as well as confirmatory evidence for other physical signs. For example, the position of

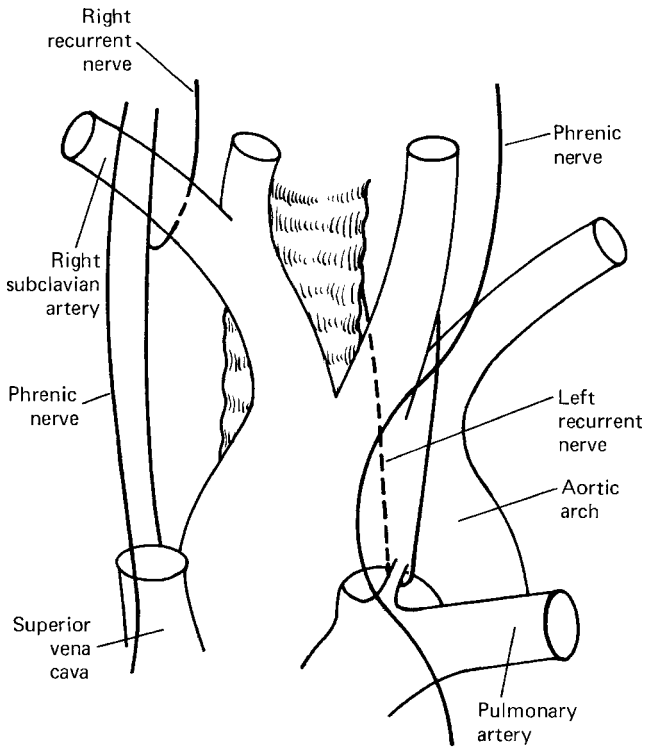

Figure 27-5 Courses of the recurrent laryngeal nerves. Invasion or compression of a nerve by a carcinoma of the lung causes paralysis of the vocal cord.

the trachea determined by palpation in the suprasternal notch can be helpful in detecting a lateral displacement of the upper mediastinum. Dislocation of the apical impulse and of cardiac dullness can be useful indices in detecting shift of the lower mediastinum. Tenderness over a rib may reflect a fracture, a metastasis, or an underlying pleuritis. Enlargement of the right ventricle can be more readily detected by palpation in the subxiphoid region than by other examination of the chest. Hoover's sign can be useful in disclosing a unilateral lag in motion of one side of the chest due to pleuritis or a pleural effusion. This sign is elicited by comparing the displacement from the midline during a patient's deep inspiration of the examiner's hands, each placed lightly over one hemithorax, with thumbs touching beneath the xiphoid at the start of the breath.

An abnormal mass or fullness palpated in the supraclavicular space may be a clue to the presence of a neoplasm or to an involved lymph node, and suggest a convenient location to obtain a biopsy for diagnosis.

Consolidation of the lung, which causes increased transmission of sound, can be detected as fremitus (i.e., as a palpable vibration) over the affected area while the patient repeats the traditional "one, two, three" as the examiner moves his/her palms systematically over the two hemithoraces. Conversely, impairment of sound transmission, as by a pleural effusion, diminishes vocal fremitus. In some instances, a pleural friction rub is palpable. Overall, the more seasoned the chest physician, the more likely is palpation to get its full due in the physical examination of the chest.

Percussion of the Chest

Percussion for physical examination has followed Auenbrugger's sounding of beer barrels to determine their fluid levels. The response to percussion is impaired whenever something other than air-filled lung lies directly beneath the chest wall. Common causes of dullness to percussion are consolidation or atelectasis of the lung, fluid in the pleural space, pleural thickening, and a large mass at the surface of the lung. Widespread hyperresonance can often be elicited in emphysema and circumscribed hyperresonance over a pneumothorax or large bulla. As a rule, a decrease in breath sounds, as over a large bulla, is more characteristic than an increase in resonance.

Auscultation of Lungs

Ever since the time of Laennec, physicians have applied the stethoscope to the chest in search of sounds of disease. Attention is focused on the intensity and quality of the sounds, as well as the presence of abnormal (often called adventitial) lung sounds.

Changes in the Intensity and Duration of Lung Sounds

The generation of lung sounds requires an ability to move air through patent airways. A global decrease in the intensity of breath sounds over the thorax or a hemithorax can be due to a variety of abnormalities: impaired movement of air due to airways disease (e.g., in emphysema), paralysis of a diaphragm, or complete obstruction of a bronchus. A decrease in audible breath sounds can also occur when the transmission of sounds to the chest wall is impaired (e.g., by a pleural effusion, pleural thickening, or a pneumothorax). A bulla gives rise to a more circumscribed diminution in breath sounds. In a patient with COPD, regional variations in breath sounds correspond to the distribution of ventilation.

An abnormal increase in intensity of breath sounds is accompanied by a change in their character (the sounds become either harsh or bronchial). The abnormal sounds are heard over consolidated, atelectatic, or compressed lung as long as the airway to the affected portion of the lung remains patent. Consolidated lung is presumed to act as an acoustic conducting medium that, unlike normal lung, does not attenuate transmission of tracheal sounds to the periphery.

Noting the duration of the inspiratory and expiratory phases of breathing can be useful. Inspiration is normally audible for a longer period, with little if any expiratory noise. A prolongation of expiration, often longer than inspiration, is found with obstructed airways.

Changes in the Transmission of Lung Sounds

Changes in voice sounds are often easier to appreciate than changes in breath sounds. Large pleural effusions, pneumothorax, and bronchial occlusion produce distant or inaudible breath sounds. Transmission of voice sounds is enhanced by consolidation, infarction, atelectasis, or compressions of lung tissue. Accompanying the increased transmission is a change in the character of the voice sounds that causes them to be higher pitched and less muffled than normal (bronchophony). When bronchophony is extreme, spoken words assume a nasal or bleating quality (egophony) and the sound "ee" is heard through the stethoscope as "ay." Egophony is most common when consolidated lung and pleural fluid coexist; sometimes it is heard over an uncomplicated lobar pneumonia or pulmonary infarction. Transmission of whispered voice sounds with abnormal clarity (whispered pectoriloquy) has the same significance as bronchophony.

Changes in the Quality of Lung Sounds

Normal breath sounds have a smooth, soft quality and are referred to as *vesicular*.

Adventitious Lung Sounds

Abnormal lung sounds have traditionally been resistant to meaningful clinical classification. The American Thoracic Society attempted to develop a rational and clinically useful classification based on acoustic analysis of tape recordings and the nomenclature introduced by Forgacs (Table 27-2). With this approach, lung sounds are categorized as continuous (wheezes, rhonchi, or stridor) or discontinuous (crackles).

Wheezes, rhonchi, and stridor are musical adventitious sounds. Wheezes originate in airways narrowed by spasm, thickening of the mucosa, or luminal obstruction. Although

Table 27-2

Classification of Common Lung Sounds

Acoustic Characteristics	American Thoracic Society Nomenclature	Common Synonyms
Discontinuous, interrupted explosive sounds; loud, low in pitch	Coarse crackle	Coarse rale
Discontinuous, interrupted explosive sounds; less loud than above and of shorter duration; higher in pitch than coarse crackles or rales	Fine crackle	Fine rale, crepitation
Continuous sounds longer than 250 ms, high-pitched; dominant frequency of 400 Hz or more, hissing sound	Wheeze	Sibilant rhonchus
Continuous sounds longer than 250 ms, low-pitched; dominant frequency about 200 Hz or less, snoring sound	Rhonchus	Sonorous rhonchus

Source: From Loudon R, Murphy RLH: Lung sounds. Am Rev Respir Dis *130:663–673, 1984.*

wheezes are more apt to occur during forced expiration, which further narrows airways, they may occur during both inspiration and expiration in asthma. Wheezes presumably originate through a combination of limitation to airflow and vibrations in the walls of the airways. Rhonchi are due to the presence of liquid or mucus in the airways; the quality and location may be readily changed by asking the patient to cough, thus moving the secretions. Stridor is predominantly inspiratory and best heard over the neck. Common causes of stridor are a foreign body in the upper intrathoracic airway or esophagus, an acquired lesion of the airway (e.g., carcinoma in adults), or a congenital lesion in children.

Crackles

Crackles are generally attributed to a rapid succession of explosive openings of small airways that closed prematurely during the previous expiration. Crackles have been subdivided according to their timing during inspiration (early or late) and by differences in their quality ("wet" or "dry"); at times they have been termed "rales". Noting differences in timing has been advocated as a way of distinguishing between possible causes (e.g., "dry" crackles in the fibrosis of interstitial lung disease vs. "wet" crackles in pulmonary edema). Unfortunately, wide variation in the interpretation of these sounds generally renders such attempts at classification of little value and often a cause of confusion. Crackles may accompany alterations in the elastic recoil of airways (emphysema), the presence of secretions (bronchitis or pneumonia), inflammation or fibrosis (interstitial lung disease) or fluid (pulmonary edema). Crackles can also be due to atelectasis, as in bedridden patients, and may clear with sequential deep breaths.

Pleural Rub

A pleural friction rub is a coarse, grating, or leathery sound that is usually heard late in inspiration and early in expiration; most often a pleural friction rub is audible low in the axilla or over the lung base posteriorly. The rub sounds close to the ear and usually is not altered by coughing.

DYSPNEA

Dyspnea is the medical term for breathlessness or shortness of breath. For the patient, dyspnea involves an experience of discomfort in breathing. It is alarming to most patients and can arouse great concern about a potential dire cause, making it one of the most frequent complaints that prompts patients to seek medical evaluation.

In the extensive medical, physiological, and psychological literature, dyspnea is used variously to designate a range of sensations from awareness of breathing on the one hand, to respiratory distress on the other. The wide range of meanings is understandable on several counts: (1) dyspnea is a subjective complaint without consistency in objective signs such as tachypnea; (2) few physicians have experienced the respiratory discomfort associated with chest disease, so that most interpretations of the complaint represent extrapolations from normal breathlessness (e.g., after strenuous exercise); (3) most experimental observations relating to dyspnea are based on the study of normal subjects or animals under artificial circumstances; and (4) most physicians apply the term loosely, based on their experience with the predominant patient population that they serve (e.g., patients with COPD or asthma). Despite this variability, in clinical medicine, the complaint of dyspnea almost invariably implies respiratory discomfort.

Because of its subjective nature, the sensation of dyspnea is an amalgam of two components. The *first* is the sensory input to the cerebral cortex, which consists of information from specialized receptors, predominantly mechanoreceptors, at various sites in the respiratory

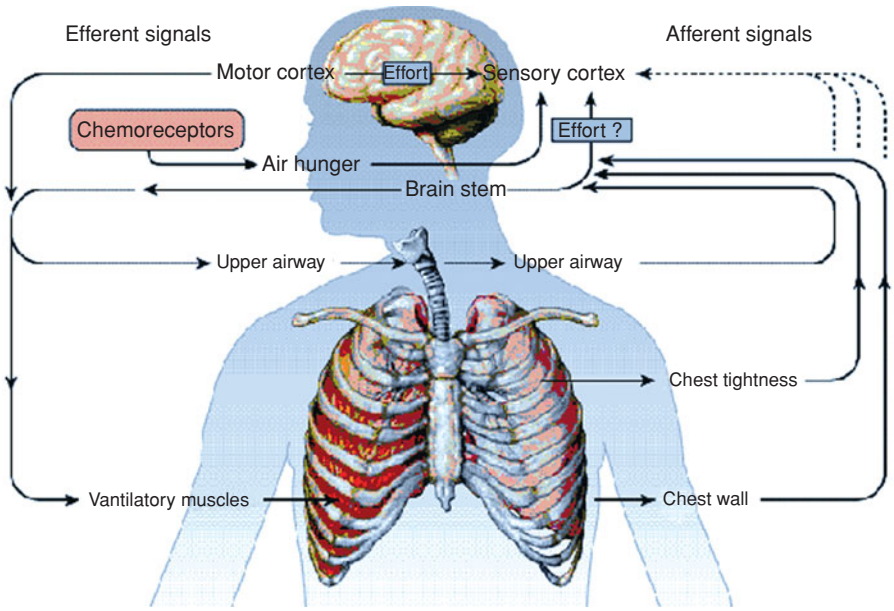

Figure 27-6 Pathways to the sensation of breathlessness. Respiratory effort is believed to originate as a signal transmitted from the motor cortex simultaneously to the sensory cortex and to the motor command to ventilatory muscles. The brain stem may also contribute to the sense of effort. The perception of air hunger is believed to arise, in part, from increased respiratory activity within the brain stem, whereas the sensation of chest tightness probably results from stimulation of vagal irritant receptors. Although afferent information from airway, lung, and chest-wall receptors most likely passes through the brain stem before reaching the sensory cortex, the dashed lines indicate uncertainty about whether some afferents bypass the brain stem and project directly to the sensory cortex. *(From Manning HL, Schwartzstein RM: Pathophysiology of dyspnea. N Engl J Med 333:1547–1553, 1995, with permission.)*

apparatus (predominantly the upper airways) and face (Fig. 27-6). The different sites of stimulation may contribute to the disparities in the sensation. Furthermore, no specific area in the central nervous system has been identified as the sensory locus for dyspnea. The input—from airways, lungs (via the vagus nerves), respiratory muscles, chest wall, and chemoreceptors—is processed at consecutive levels of the nervous system (i.e., spinal cord and supraspinal regions en route to the sensorimotor cortex). Additional sensory input, triggered by inadequate oxygen delivery or utilization, is poorly understood. The *second* component is the perception of the sensation, which rests heavily on the interpretation of information arriving at the sensorimotor cortex. The interpretation depends greatly on the psychological makeup of the person.

A variety of influences can modify the psychological component of dyspnea. During "Kussmaul breathing" (see below), "air hunger" may seem obvious to the observer, even though the patient does not feel short of breath. In contrast, patients with congestive heart failure or COPD frequently volunteer the complaint of "air hunger." Blunting of the sensorium, as by narcotics or by acute hypercapnia, can eliminate the sensation of breathlessness, even though the abnormal breathing pattern remains. Anxiety can heighten the sense of breathlessness. Indeed, anxiety can be responsible for the clinical syndrome of psychogenic dyspnea, in which the patient experiences "breathing discomfort" that eludes explanation on the basis of a somatic cause. Ill-defined sensations may accompany a full-blown hyperventilation syndrome consisting of light-headedness, tingling of the hands and feet, tachycardia, inversion of T waves on the electrocardiogram, and even syncope. Breathing discomfort at rest that decreases with activity is often seen when anxiety or other psychological issues are the cause, and is a distinctly unusual pattern for dyspnea due to a cardiopulmonary abnormality.

The quality of dyspnea can vary greatly. In normal persons, as well as in those with chest disease, dyspnea may simply signify the transition from an effortless process that is ordinarily conducted at a subconscious level to the awareness that muscular effort is being expended in breathing. The healthy athlete completing a dash experiences breathlessness that can be exhilarating rather than uncomfortable. The asthmatic often interprets breathlessness in terms of "tightness in the chest." The patient with COPD often complains of less-severe breathlessness than would be expected from the degree of airway obstruction, possibly reflecting adaptation either to the chronic obstructive airway disease or to CO_2 retention.

Patients may use different terms to describe breathing discomfort due to various causes. In some instances these descriptors may be useful in establishing a differential diagnosis and in assessing the response to therapy. Patients with asthma or myocardial ischemia often refer to "chest tightness." Patients with pulmonary edema may suffer a sensation of "air hunger" or "suffocation." Patients with COPD and hyperinflation of the chest often note an inability to take a deep, satisfying breath. Individuals who are physically out of

shape may complain of "heavy breathing." Unfortunately, no descriptor has sufficient sensitivity or specificity to be used alone in establishing the cause of a patient's dyspnea.

Clinical Presentations

Dyspnea may be acute, chronic, or paroxysmal (Table 27-3).

Table 27-3

Causes of Acute and Chronic Dyspnea*

Acute
Pulmonary edema
Asthma
Injury to chest wall and intrathoracic structures
Spontaneous pneumothorax
Pulmonary embolism
Pneumonia
Adult respiratory distress syndrome
Pleural effusion
Pulmonary hemorrhage
Chronic, progressive
Chronic obstructive pulmonary disease
Left ventricular failure
Diffuse interstitial fibrosis
Asthma
Pleural effusions
Pulmonary thromboembolic disease
Pulmonary vascular disease
Psychogenic dyspnea
Anemia, severe
Postintubation tracheal stenosis
Hypersensitivity disorders

**Many chronic processes (eg, left ventricular failure, asthma, and COPD) may have acute exacerbations.*

Acute

The usual causes of acute dyspnea in children differ from those in adults. In children, upper-airway infection (e.g., epiglottis, laryngitis, or acute laryngotracheobronchitis) is a common cause. In adults, the causes of acute dyspnea are much more varied (Table 27-3). Among the most common are an episode of acute left ventricular failure, a thromboembolic event, pneumonia, and spontaneous pneumothorax. Less common, but not unusual, is massive collapse of one lung due to inability to clear the airways of thick tenacious secretions (e.g., in chronic bronchitis or asthma) or the first attack of asthma.

Chronic (and Progressive) Dyspnea

Chronic dyspnea is almost invariably progressive. As a rule, this type of dyspnea begins with breathlessness on exertion—which, in time, progresses to dyspnea at rest. Pulmonologists encounter dyspnea in patients who have COPD; cardiologists more often deal with dyspnea in patients who are in chronic congestive heart failure. Especially in older patients, distinction between the heart and lungs in the etiology of dyspnea, or the relative contributions of each, can be difficult to establish.

Asthma is a common cause of recurrent bouts of dyspnea which are usually accompanied by cough and wheezing. Cardiac dysfunction is another cause of acute bouts of bronchospasm, especially in middle-aged or elderly persons. Another, much less frequent cause of paroxysmal wheezing and breathlessness is bronchopulmonary aspergillosis. Etiologies of asthma vary in different parts of the world; where schistosomiasis is endemic, an attack of asthma may accompany the migratory stage of schistosomiasis (i.e., larvae traversing the lungs).

Physiological Correlates of Dyspnea

Historically, attempts to understand the physiological bases of dyspnea have evolved along four separate lines: ventilatory performance, the mechanics of breathing, chemoreception, and exercise testing.

Ventilatory Performance

The earliest investigations related dyspnea to minute ventilation. Dyspnea was found to correlate with an excessive minute ventilation for the level of oxygen uptake. Most of the increase in ventilation was accounted for by an increase in respiratory rate, especially in patients with stiff lungs. In patients who continued to ventilate excessively for the level of oxygen uptake (e.g., those with chronic left ventricular failure), the sensation of breathlessness gradually diminished, suggesting adaptation to the continued stimulus.

A second ventilatory measurement that proved to correlate well with dyspnea is the maximum voluntary ventilation (MVV). MVV is decreased by diseases of the lungs, airways, or chest cage. The smaller the maximum breathing capacity, the more likely is dyspnea to occur.

A third time-honored approach to measurement is the "breathing reserve." This value is determined as the difference between the MVV and the actual minute ventilation. In principle, the sensation of breathlessness during the performance of any ventilatory task may be related to the fraction of the maximum breathing capacity that is used for force generation by the respiratory apparatus. Thus, the closer the minute ventilation is to the maximum breathing capacity, the more likely is the subject to complain of breathlessness. Indeed, when the actual level of ventilation reaches 30 to 40 percent of the maximum breathing capacity, dyspnea is inevitable. Unfortunately, the breathing reserve correlates better with the dyspnea of normal subjects during exertion than with the dyspnea of chronic bronchitis and COPD or of left ventricular failure. Thus, in COPD the minute ventilation may be a very large fraction of the MVV (greater than 50 percent) without eliciting dyspnea. In contrast, in acute left ventricular failure, a mild increase in ventilation and a nearly normal MVV may be associated with considerable breathlessness.

Mechanics of Breathing

One teleological way to regard dyspnea is as a sensation that prompts an unconscious effort to minimize the work, energy cost, or force of breathing. In this light, dyspnea protects the respiratory apparatus from overwork and inefficient operation. This approach has led to exploration of the relationships between dyspnea and the work or oxygen cost of breathing.

Work, Oxygen Cost, and Efficiency of Breathing

It has not been possible to identify a critical level for the work of breathing at which dyspnea will occur. However, a breakdown of the work of breathing into its elastic, resistive, and inertial components has helped to relate physiological disturbances to particular diseases. For example, in chronic mitral stenosis with pulmonary congestion, the elastic work is greatly increased (Fig. 27-7), whereas in obstructive airway disease, resistive work predominates. Moreover, such observations have reinforced the concept that patterns of breathing are automatically adjusted to minimize the work done by the respiratory muscles in breathing.

The relationship between ventilation and O_2 consumed by the respiratory muscles is curvilinear (Fig. 27-8). This O_2 cost of breathing can increase extraordinarily in patients with COPD or with abnormalities of the chest wall. Indeed, in patients with COPD, the quantity of O_2 delivered to the respiratory muscles during the large ventilatory effort may fail to satisfy their aerobic needs, leading to anaerobic metabolism and lactic acidosis. Although the greater the O_2 cost of breathing the greater the likelihood of dyspnea, the determination of O_2 cost provides no more useful insight into the mechanism of dyspnea than does the work of breathing. Calculation of the efficiency of breathing (i.e., the work of breathing related to energy cost) provides no further clarification.

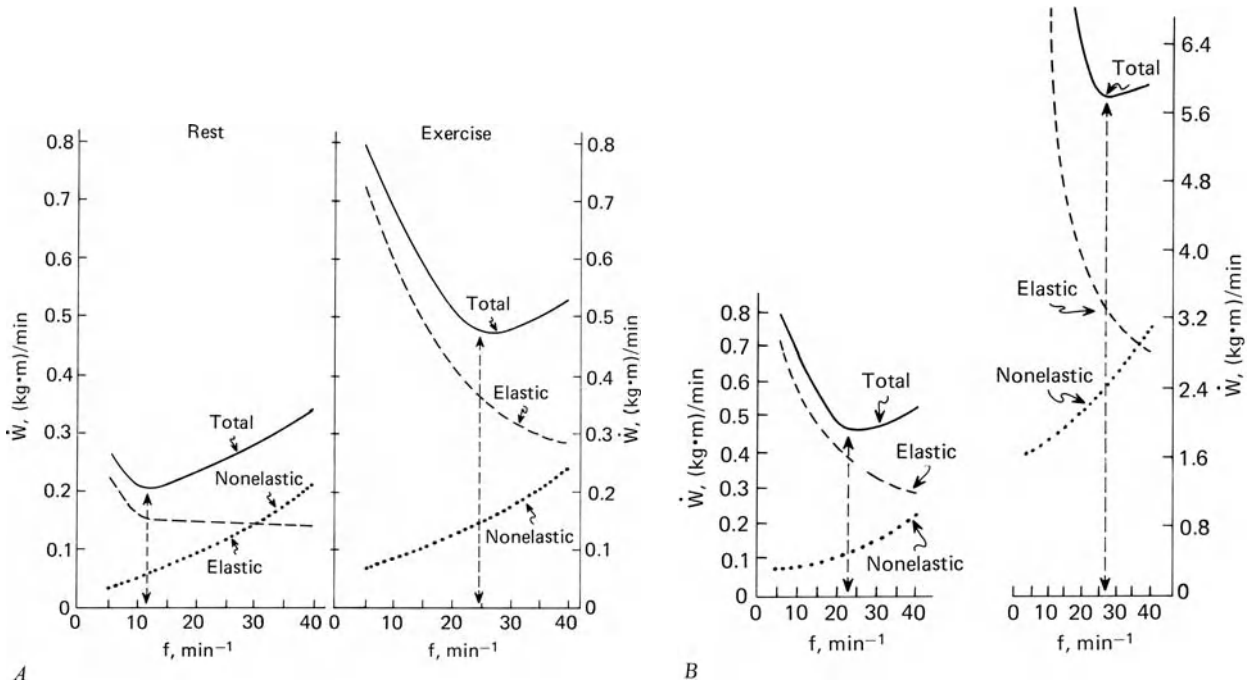

Figure 27-7 Partition of the work of breathing in pulmonary congestion and edema at rest and during exercise. *A.* Normal. The minimal work of breathing at rest was at a respiratory frequency of 12 breaths per min; during exercise, the minimal work was done at a higher frequency (25 breaths per min). *B.* Mitral stenosis. At rest, the frequency for least respiratory work was abnormally high (22 breaths per min); during exercise it increased further (to 28 breaths per min). The dashed vertical line (capped by arrowheads) in each frame indicates the respiratory frequency at which respiratory work was minimal. *(From Christie RV: Dyspnea in relation to the visco-elastic properties of the lung. Proc R Soc Med 46:381–386, 1953, with permission.)*

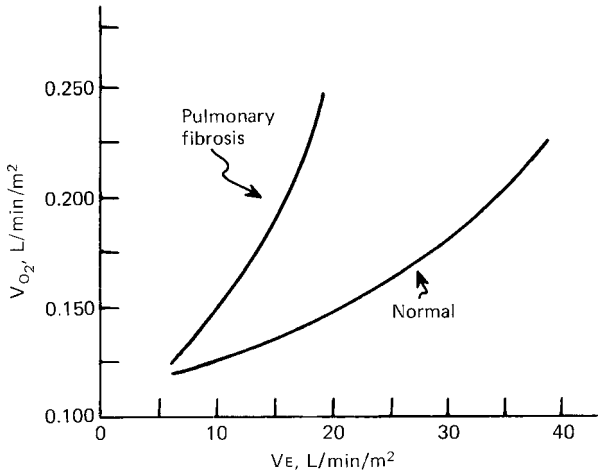

Figure 27-8 Oxygen cost of breathing in restrictive lung disease. Relationship between ventilation and O_2 consumption in pulmonary fibrosis. At each level of ventilation, the patient with pulmonary fibrosis does more work and expends more energy in breathing than does the normal subject.

Length-Tension Inappropriateness

The concept of "length-tension inappropriateness" explains dyspnea as a mismatch between the central motor command to the respiratory muscles (i.e., the motor signal emitted from the brain) and the suboptimal ("inappropriate") shortening of the respiratory muscles elicited by this command (e.g., suboptimal thoracic expansion for any level of central motor command). In essence, this concept pictures a decrease, instead of an increase, in the pressure-generating capacity of the respiratory muscles in the face of the increased need arising from the heightened respiratory drive.

Chemoreception

Chemoreceptors in the medulla respond to changes in pH and Pa_{CO_2}. Peripheral receptors in the aortic arch and carotid body also respond to alterations in Pa_{O_2}. Acute hypoxia, hypercapnia, and acidosis are the traditional stimuli for ventilation. For example, upon ascent to altitude, acute hypoxia can stimulate ventilation to the level of awareness that may progress to discomfort during exertion. The effects of these stimuli on breathing decrease if they continue unabated. In addition, side effects, such as blunting of the sensorium during chronic CO_2 retention, diminish the likelihood of dyspnea, even if the level of ventilation is increased. In patients with abnormal pulmonary mechanics, the onset of abnormalities in blood gas composition, as during exercise, can aggravate or contribute to dyspnea. In general, acute hypercapnia is a stronger stimulus for dyspnea than is acute hypoxia.

Scaling

A variety of scaling methods have been devised in the attempt to quantify dyspnea during exercise and various experimental conditions. Some, such as the Borg Category Scale (Table 27-4), use numbers and descriptive terms to depict a change in the intensity of the stimulus ("threshold stimulus detection methods"). Others rely on visual analog scales, which are straight lines, usually 10 cm long, that extend from "not breathless" at one end to "extremely breathless" at the other. The patient marks on this line the intensity of respiratory discomfort elicited by external stimuli, such as resistive loads or exercise testing. The score is measured as the length of the line between "not breathless" and the mark made by the patient. The Shortness of Breath Scale issued by the American Thoracic Society (Table 27-5) has also been used in one form or another, particularly in epidemiological studies. No single scale is applicable to all subjects or patients.

Table 27-4

Modified Borg Category Scale

Rating	Intensity of Sensation
0	Nothing at all
0.5	Very, very slight (just noticeable)
1	Very slight
2	Slight
3	Moderate
4	Somewhat severe
5	Severe
6	
7	Very severe
8	
9	Very, very severe (almost maximal)
10	Maximal

Dyspnea: Overview

In general, the sensation of dyspnea seems to be related to the intensity of afferent input from thoracic structures (especially the respiratory muscles) and from the chemoreceptors (central, peripheral, local). In patients with respiratory disease, dyspnea occurs most often when breathing is impeded, mechanics of breathing are abnormal, the lungs are stiffened, ventilatory musculature is weakened, and/or chemoreceptor input is increased.

Dyspnea in Chronic Pulmonary Disease

Two common types of pulmonary disease in which dyspnea features prominently are chronic obstructive airway disease and restrictive lung disease.

Table 27-5

American Thoracic Society Scale

Descriptions	Grade	Degree
Not troubled by shortness of breath when hurrying on the level or walking up a slight hill	0	None
Troubled by shortness of breath when hurrying on the level or walking up a slight hill	1	Mild
Walks more slowly than people of the same age on the level because of breathlessness or has to stop for breath when walking at own pace on the level	2	Moderate
Stops for breath after walking about 100 yards or after a few minutes on the level	3	Severe
Too breathless to leave the house; breathless on dressing or undressing	4	Very severe

Chronic Obstructive Pulmonary Disease (COPD)

COPD refers to a spectrum of airway diseases in which obstruction to airflow is the common denominator. Cigarette smoking is the leading cause of COPD. The outer limits of the spectrum are marked by chronic bronchitis at one end and emphysema at the other. Most patients with COPD fall into categories between those limits (i.e., they manifest mixtures of chronic bronchitis and emphysema which vary in degrees) (Fig. 27-9).

Asthma constitutes a different entity, not only in its clinical expressions but also because it is usually episodic and is often related to allergic manifestations, and generally affects younger individuals. Cystic fibrosis is another distinct entity because of its genetic basis, clinical and radiographic presentations, and nature of the airway obstruction (i.e., by inspissated mucus) and proclivity to superinfection. Dyspnea is a regular feature of each of these causes of chronic airways obstruction.

Patients with COPD suffer from disturbances in the mechanics of breathing, abnormal lung volumes, and derangements in gas exchange. The minute ventilation, which may be only slightly increased at rest, constitutes an abnormally large fraction of the maximum breathing capacity (i.e., the "breathing reserve" is low).

Abnormalities in the mechanics of breathing dominate the scene: resistance to airflow is high; the thorax assumes a hyperinflated position, placing the inspiratory muscles at mechanical disadvantage; the work of breathing is greatly increased. The O_2 cost of breathing is correspondingly high. Derangements in dead space ventilation and in alveolar-capillary gas exchange add to the afferent stimuli. As a result of the disturbances in mechanics and gas exchange, swings in pleural pressure (a measure of force applied to the lungs) are large, and a considerable muscular effort is expended in breathing; instead of the normal increase of about 1 ml of O_2 uptake per liter of ventilation per minute, the O_2 uptake increases enormously (up to 25 ml/min). Should O_2 delivery to the overworked respiratory muscles be insufficient, fatigue and exhaustion may send nervous and chemical signals of their own to the brain. Finally, if the patient accumulates excess water in the lungs, the juxtacapillary ("J") receptors provide additional sensory input to the central integrating mechanism. As noted above (see "Length-Tension Inappropriateness"), the convergence of these diverse stimuli upon the sensorimotor cortex may generate an inordinate motor command to the respiratory muscles, which cannot mobilize the thorax sufficiently to generate the pleural pressures needed for adequate ventilation.

One enigma is why some patients with COPD settle for a lower ventilation than others. For example, despite equal abnormalities in conventional pulmonary function tests, the "CO_2 retainer," with respiratory acidosis and arterial hypoxemia, often breathes less than does the non–CO_2 retainer in whom blood gas levels are near normal. One teleological explanation is that the lower ventilation in the CO_2 retainer causes less dyspnea. However, this explanation affords no insight into the physiological mechanism.

Treatment of the patient with COPD is directed at diminishing airways resistance and restoring arterial blood gases toward normal. Unfortunately, bronchodilators and corticosteroids generally exert little effect, and the basic abnormalities in the mechanics of the lungs and airways remain. Consequently, the load on the respiratory muscles is not readily alleviated by medical management. Accordingly, therapeutic interest in these disorders has turned to ways by which the performance of the respiratory muscles can be improved. These have generally taken the form of training exercises to facilitate adaptive changes and to increase both muscle strength and endurance. Exercise reconditioning in patients with COPD has been shown to diminish breathlessness, possibly owing to three interactive mechanisms: (1) increased mechanical efficiency of the exercising muscles, which decrease ventilatory requirements; (2) improved function of the respiratory muscles; and (3) increased tolerance of the "dyspneagenic" sensory input to the brain. Attempts to rest the respiratory muscles have no lasting effect on dyspnea.

Asthma

The mechanisms described above for COPD apply as well to asthma. However, these mechanisms do not account for the sensation of "tightness in the chest" or the inordinate sense of labored breathing that accompanies the breathlessness in asthma.

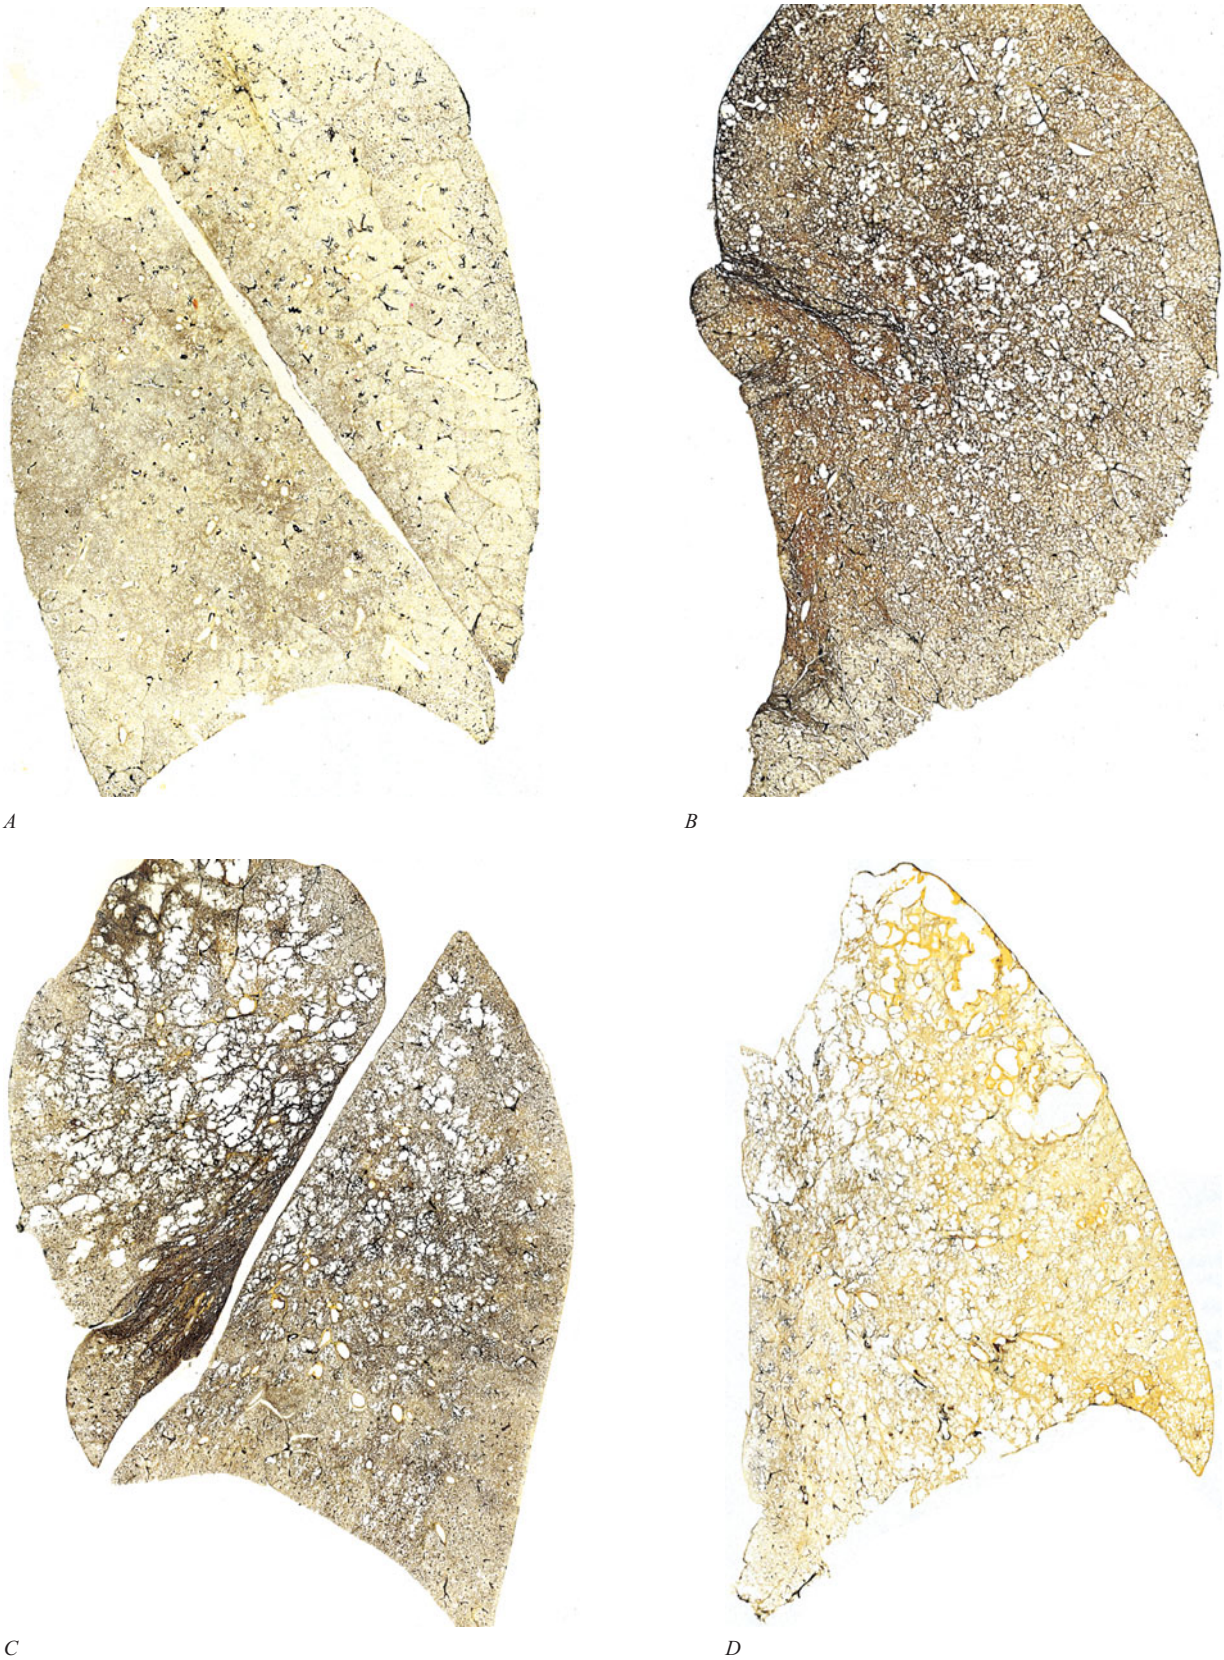

Figure 27-9 Chronic obstructive pulmonary disease (COPD). Sagittal sections showing patterns of emphysema. *A*. Normal lung from a patient who died of unrelated causes. *B*. Predominantly centrilobular emphysema. *C*. Predominantly centrilobular and panlobular emphysema. *D*. Predominantly panlobular emphysema. Centrilobular emphysema is less marked. The three patients with emphysema *(B, C, D)* also had clinical manifestations of chronic bronchitis confirmed by histological sections.

Table 27-6

Common Causes of Restrictive Lung Disease

Cause	Example
Interstitium	
Interstitial fibrosis and/or infiltration	Asbestosis
Pulmonary edema	Left ventricular failure
Pleura	
Pleural disease	Fibrothorax
Thoracic cage and abdomen	
Neuromuscular disease	Poliomyelitis
Skeletal abnormalities	Severe kyphoscoliosis
Marked obesity	Grossly overweight

Restrictive Lung Disease

Restrictive lung diseases can be due to different causes, but usually they have in common a reduction in lung volumes and diffusing capacity (Table 27-6). Diffuse interstitial disease, has many different causes and may be either acute or chronic (Table 27-7). Characteristically, in widespread interstitial disease, the diffusing capacity is low and accompanied by a considerable decrease in total lung capacity and in vital capacity accompanied by lesser decrements in functional residual capacity and residual volume. Similar findings occur in severe kyphoscoliosis or encasement of the lung by pleural thickening (Fig. 27-10). In contrast, in pulmonary vascular disease, such as idiopathic pulmonary arterial hypertension, a low diffusing capacity may be accompanied by normal lung volumes. Neuromuscular disease that affects the inspiratory muscles sufficiently to diminish maximum inspiratory pressures may only decrease the vital and total lung capacities, leaving the functional residual capacity and residual volume unaffected.

Patients with widespread pulmonary fibrosis breathe faster and maintain a higher minute ventilation than do normal subjects, both at rest and during exercise. The work and oxygen cost of ventilating the stiff lungs are increased. The maximum breathing capacity is well preserved. In these patients, dyspnea is attributable to the considerable effort by the respiratory muscles in ventilating the stiff lungs and in sustaining the high ventilatory rate. During exercise, dyspnea may become intolerable.

Dyspnea in Chronic Cardiac Disease

The mechanisms responsible for dyspnea in cardiac disease vary with the extent to which the lungs are stiffened.

Without Stiff Lungs

Dyspnea occurs in many forms of heart disease that are not associated with congestion of the lungs. Uncomplicated pulmonic stenosis is an excellent example. The symptom is probably related to an inadequate cardiac output during exercise. In tetralogy of Fallot, dyspnea is sometimes severe and often relieved by assuming a squatting position. In this and other forms of cyanotic heart disease, both dyspnea and fatigue appear during exertion when the arterial oxyhemoglobin saturation decreases appreciably below the resting level.

With Stiff Lungs

Cardiac dyspnea is associated with an increase in blood and water content of the lungs. It is a common occurrence in left ventricular failure and mitral stenosis, both of which are accompanied by increases in pulmonary venous and capillary pressures. The engorged pulmonary circulatory bed, coupled with interstitial and alveolar edema, stiffens the lungs (i.e., decreases their compliance) and stimulates the ventilation via "J" receptors. In chronic left ventricular failure, pulmonary fibrosis, consequent to long-standing interstitial edema, contributes to the stiff lungs. Edema of the tracheobronchial mucosa increases airway resistance.

As a result of the stiff lungs and increased airway resistance, the swings in pleural pressure during the respiratory cycle are large and the work and energy cost of breathing are increased. Arterial hypoxemia, generally mild, may add to the ventilatory drive. Exercise exaggerates the pulmonary congestion and edema, promotes arterial and mixed venous hypoxemia, and increases the dyspnea.

In patients with pulmonary congestion and edema, tachypnea is a regular feature at rest and increases during exercise. Although tachypnea is consistent, its degree is generally modest and probably not entirely responsible for the dyspnea. Fatigue is a common concomitant of low cardiac output and may stem from diminished O_2 delivery to the respiratory muscles, contributing to respiratory discomfort.

Orthopnea and Other Positional Forms of Breathlessness

Orthopnea signifies dyspnea in the recumbent, but not in the upright or semivertical position; it is usually relieved by two or three pillows under the head and back. Oppositely, platypnea signifies dyspnea induced by assuming the upright position and relieved by assuming the recumbent position. Platypnea can be seen when, due to gravity, increased blood flow worsens right to left shunting of blood through arteriovenous malformations at the lung bases. Orthopnea is a hallmark of pulmonary congestion that stiffens the lungs (i.e., decreases

Table 27-7

Some Types of Diffuse Interstitial Disease

Etiology	Example	Common Features
	Acute	
Infections	Miliary tuberculosis, histoplasmosis	Opportunity for exposure to organism
	Pneumocystis, cytomegalic inclusion virus, fungi	Immunosuppression
Pulmonary edema	Narcotic overdosage, nitrogen dioxide (silo-filler's disease), uremia	Distinctive history
Inhalation	Byssinosis	Monday morning asthma and fever
Aspiration	After loss of consciousness	History of alcoholism or epilepsy
Immunologic	Goodpasture's syndrome	Renal and pulmonary involvement
Carcinoma of lung	Alveolar cell carcinoma	
	Chronic	
Inhalation	Pneumoconioses	History of exposure to inorganic dust
Radiation therapy	After mastectomy	Gradual evolution after treatment
Lymphangitic spread	Carcinoma of breast, lung, stomach, pancreas	Evidence of primary carcinoma
Medications	Hexamethonium hydralazine, bleomycin, busulfan, nitrofurantoin	History, suggestive chest radiograph
Systemic disorders	Sarcoidosis, collagen, disorders, histiocytosis X, amyloidosis, tuberous sclerosis	Multi-organ involvement; biopsy
Idiopathic	Idiopathic pulmonary fibrosis	Exclusion of known causes

their compliance). The decrease in compliance on lying flat is attributable to the fact that more of the lung is located at or below the level of the heart. During recumbency, the swings in pleural pressure, the work of breathing, and the respiratory frequency increase. The increase in respiratory frequency appears to be automatically adjusted to minimize the work of ventilating the more rigid lungs.

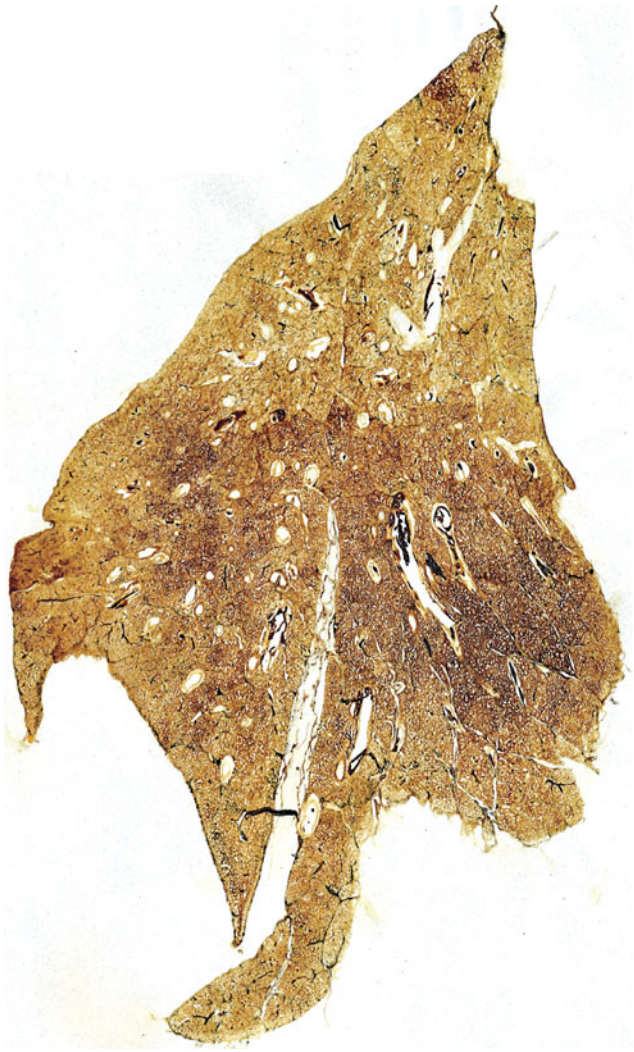
Some patients with chronic lung disease or asthma are also intolerant of recumbency. In these people, the discomfort is attributed to the greater difficulty of performing vigorous movements of the chest bellows in the recumbent position.

Paroxysmal Nocturnal Dyspnea

In an episode of paroxysmal nocturnal dyspnea, the patient is aroused from sleep gasping for air and must sit up or stand to catch his or her breath; sweating may be profuse. Sometimes the patient throws a window open wide in an attempt to relieve the oppressive sensation of suffocation. The chest tends to become fixed in the position of forced inspiration. Both inspiratory and expiratory wheezes, often simulating typical asthma, are heard. In some instances, overt pulmonary edema occurs, accompanied by many inspiratory crackles. The acute pulmonary edema is rarely fatal, however, the attacks occasionally recur several times a night, forcing the patient to sleep upright in a chair.

An episode of paroxysmal nocturnal dyspnea represents precipitous failure of the left ventricle caused by the factors that produce orthopnea (see above), abetted by pulmonary hypervolemia caused by a surge in systemic venous return. Mobilization of peripheral edema from the periphery as the extremities are elevated from the

A



B

dependent position may contribute to the increase in systemic venous return. The acute increase in pulmonary blood volume increases pulmonary capillary pressures, thereby promoting pulmonary edema, while the surge in venous return imposes an additional burden on the left ventricle.

A variety of factors can trigger an episode of paroxysmal nocturnal dyspnea: coughing, abdominal distention, the hypercapnic phase of Cheyne-Stokes respiration, a startling noise, or anything that causes a rise in heart rate and further increases the pulmonary capillary and venous pressures. Usually the attack is terminated by assumption of the erect position and a few deep breaths. Cough, an important manifestation of pulmonary congestion, frequently occurs during the attack.

Cardiac Asthma

Asthmatic wheezes, often audible in patients with pulmonary congestion, have given rise to the term *cardiac asthma.* The wheezes are a manifestation of tracheobronchial edema and often are accompanied by overt signs of pulmonary edema. In addition to the reduction in the lumen of the airways and thickening of bronchial walls by edema, the high intrathoracic pressures which are required to overcome the obstruction during expiration tend to narrow the airways even further. The resistance to airflow is increased during both inspiration and expiration, and the compliance of the lungs is greatly reduced, reaching values as low as one-tenth of normal. Upon recovery from the acute episode of pulmonary edema, airway resistance and pulmonary compliance return toward normal unless previous episodes have left a residue of pulmonary fibrosis.

Dyspnea in Anemia

Shortness of breath during exercise or excitement is a common complaint in severe anemia (e.g., hemoglobin concentration under 6 to 7 g/dl). It is more common in acute than in chronic anemia. Often the dyspnea is associated with dizziness or faintness, and invariably the patient manifests signs of a high cardiac output and low peripheral resistance (i.e., bounding pulse, warm skin, and systolic cardiac murmurs). Although the pathogenesis of the dyspnea is not entirely clear, inadequate O_2 delivery to the respiratory muscles has been proposed.

←

Figure 27-10 Restrictive lung disease. *A.* Asbestosis with markedly thickened pleura that encases and compresses the lungs. In addition, the lungs were afflicted with diffuse interstitial fibrosis. *B.* Compressed, distorted lung in patient with kyphoscoliosis. The lungs were otherwise normal, so that in this instance restriction was imposed by the chest wall rather than by intrapulmonary or pleural disease.

Metabolic Abnormalities and Drugs

Increases in CO_2 production demand a concomitant rise in ventilation to dispose of the metabolic load, and can thus result in dyspnea. To prevent acidemia, patients with diabetic ketoacidosis may require an enormous increase in minute ventilation in order to reduce Pa_{CO_2} to even single digits. Thyrotoxicosis, fever, infection, and pregnancy can also cause an increase minute ventilation; so can drugs, such as aspirin and progesterone.

Miscellaneous Disorders

Breathlessness is not uncommon in patients with musculoskeletal disorders. The usual explanation is the heightened motor drive that is needed to activate the weakened respiratory muscles. In the intensive-care unit, inadequate ventilator settings for flow and tidal volume may fail to satisfy the intrinsic ventilatory drive of the patient, generating the sensation of breathlessness.

ABNORMAL BREATHING PATTERNS

An important clue to the nature of a clinical problem in pulmonary disease is sometimes provided by bedside observation of a patient's breathing pattern. The pertinent features are the rate, regularity, depth, and apparent effort being expended in breathing. A normal person at rest breathes about 12 to 15 times per minute, with a tidal volume of 400 to 800 ml. As a result, minute ventilation is normally greater than 5 L/minute. The pattern is quite regular except for an occasional slow, deep breath, and the respiratory movements appear effortless. In the patient with lobar pneumonia, both the rate and depth of breathing accompany the increase in body temperature.

Severe skeletal deformity, as well as massive obesity, can limit chest excursions to cause alveolar hypoventilation. Neuromuscular weakness, as in myasthenia gravis or Guillain-Barré disease, can do the same, not only by diminishing ventilatory excursions as a result of generalized weakness of the respiratory muscles but also by causing overload of respiratory muscles (e.g., residual effects of poliomyelitis). Unilateral involvement of one pleural space by pneumothorax, effusion, or fibrothorax limits excursions on the affected side. Massive chest trauma can cause flail chest.

In COPD, a slow respiratory rate and large tidal volumes are characteristic. This pattern presumably serves to minimize the work of breathing. Pursed-lip breathing, a self-induced type of positive-pressure breathing, is often part of the picture. In contrast, persons with restrictive lung disease adopt a breathing pattern that is characterized by small tidal volumes and a rapid respiratory rate, often with little apparent effort. This pattern is seen in patients with a decrease in the distensibility of the lung or chest wall or with reduction of the vital capacity from any other cause. During exercise, minute ventilation increases inordinately with respect to the level of O_2 uptake and frequency increases more than tidal volume.

Fatigue of the diaphragm and intercostal muscles, sufficient to disturb their coordinated contractions, can give rise to paradoxical breathing which heralds the onset of respiratory failure.

Cheyne-Stokes Respiration

In the fourth century B.C., in a preterminally ill person with fever, sweats, and black urine, Hippocrates described a pattern of breathing in which "the respiration throughout [was] like that of a man correcting himself, and rare and large." Presumably he had observed Cheyne-Stokes breathing, which was described more graphically by William Stokes two millennia later (in 1854) as follows:

> The symptom in question (previously described by Dr. Cheyne) consists in the occurrence of a series of inspirating, increasing to a maximum, and then declining in force and length, until a state of apparent apnea is established. In this condition the patient may remain for such a length of time as to make his attendants believe that he is dead, when a low inspiration, followed by one more decided, marks the commencement of a new ascending and descending series of inspirations.

Cheyne-Stokes breathing is characterized by alternating periods of hypoventilation and hyperventilation (Fig. 27-11). In its typical form, an apneic phase, which lasts for 15 to 60 s, is followed by a phase during which tidal volume increases with each successive breath to a peak level and then decreases in a progressive fashion to the apneic phase. At the onset of apnea, CO_2 tension in brachial or femoral arterial blood is at its lowest. As apnea persists, CO_2 tension gradually increases, and respiration is stimulated. CO_2 tension continues to increase until maximum hyperventilation is attained, after which ventilation decreases until apnea again occurs. The arterial oxyhemoglobin saturation varies in an inverse manner, being highest at the onset of apnea and lower during mid-hyperpnea. During the cycle, CO_2 tension varies by as much as 14 mmHg and oxyhemoglobin saturation by as much as 18 percent.

In patients with congestive heart failure, the respiratory oscillations are attributable to slowing of the circulation so that the blood gases reaching the respiratory centers in the brain are 180 degrees out of phase with those in pulmonary capillary blood. This mechanism has been verified experimentally by eliciting Cheyne-Stokes breathing in dogs by prolonging the circulation time from heart to brain by way of an extracorporeal circuit.

Fluctuations in mental state and electroencephalographic patterns, and evidence of nervous system dysfunctioning, may occur during Cheyne-Stokes breathing because of swings in cerebral blood flow. In neurological disorders, Cheyne-Stokes breathing can be due to supramedullary

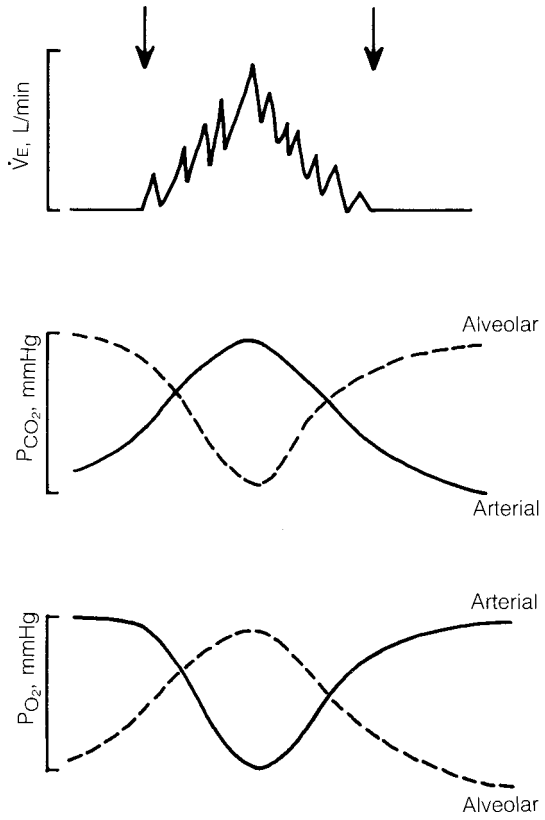


Figure 27-11 Cheyne-Stokes breathing, illustrating the relationship between the ventilation and the blood and alveolar gas tensions during the periods of apnea and hyperpnea. *(From Cherniack NS, Fishman AP: Abnormal breathing patterns. Dis Mon 3–45, 1975, with permission.)*

dysfunctions, particularly in patients who have destructive lesions in the tegmentum of the pons.

Less common than in heart failure or neurological disorders is the occurrence of Cheyne-Stokes respiration in normal infants, in healthy elderly persons, and in normal persons at high altitude. It is also seen occasionally after the administration of respiratory depressants (e.g., morphine) often accompanied by an increase in intracranial pressure, uremia, or coma. At one time, the respiratory center was believed to be depressed in Cheyne-Stokes respiration. This hypothesis has been proved to be in error, since it has been shown that the respiratory response to inhalation of CO_2 is greater than normal in individuals with Cheyne-Stokes respiration. Respiratory alkalosis is common and the arterial P_{CO_2} remains subnormal in both the apneic and hyperpneic phases.

Kussmaul Breathing

In 1874, Kussmaul described three patients with diabetic ketosis who manifested "air hunger": they were breathing with large tidal volumes and so rapidly that there was virtually no pause between breaths. In essence, they were breathing at rest as though they were exercising; breathing was accomplished with little apparent effort. Since then, this pattern of breathing has been observed in other types of severe metabolic acidoses (e.g., alcoholic ketoacidosis). The usual sequence leading to this type of breathing is renal failure with a progressive decrease in plasma bicarbonate and resultant acidosis. The "compensatory" increase in ventilation that Kussmaul described mitigates the fall in systemic pH caused by the fall in plasma bicarbonate.

Other Abnormal Patterns

Gasping respirations are characteristic of severe cerebral hypoxia. The pattern consists of irregular, quick inspirations associated with extensions of the neck and followed by a long expiratory pause. It is commonly seen in shock or in other conditions associated with severe reduction in cardiac output.

Hyperventilation is commonly seen in anxious patients without structural disease of the lungs. In some of these patients, striking deep sighs dominate the ventilatory pattern.

DIAGNOSTIC TESTING IN THE EVALUATION OF DYSPNEA

Attention to important history and physical examination findings as described in the preceding sections will help to focus the initial approach to diagnosis. In most cases, the initial diagnostic impression can be confirmed or excluded with only a few tests, and appropriate therapy instituted or the hunt for a cause continued (Table 27-8). In some instances, the response to a therapy instituted empirically on the basis of the history and physical examination findings is itself diagnostic. For example, the relief of dyspnea following the administration of diuretics given to a patient with progressive orthopnea, bilateral basilar inspiratory crackles, and a prominent third heart sound (S_3) is strong evidence of heart failure as the cause.

A plain chest radiograph is frequently useful in demonstrating changes suggestive of COPD (chest hyperinflation, bullous changes). Vascular engorgement, an enlarged cardiac silhouette, interstitial markings and pleural effusions may indicate left heart failure. Interstitial markings may also have a pattern consistent with an inflammatory or fibrotic process.

Spirometry is useful in identifying airways obstruction, at times noting a change in values following the administration of a bronchodilator. The measurement of lung volumes or the diffusing capacity may be reserved for when there is suspicion of an interstitial process or other cause of restriction (e.g., muscle weakness). Measurement of arterial oxyhemoglobin saturation both at rest and with exertion is important. While oxyhemoglobin desaturation may not itself indicate the etiology of the problem, its presence is always an important indicator of the severity of the disease and may itself warrant treatment with oxygen while the evaluation of its cause continues. An echocardiogram can be used to assess ventricular or valvular cardiac function or to estimate pulmonary arterial pressures.

Table 27-8

Common Tests in the Evaluation of Dyspnea

Test	Some Possible Abnormalities	Some Possible Diagnoses
Plain chest radiograph	Cardiac enlargement	Congestive heart failure
	Vascular enlargement	COPD
	Abnormal interstitial markings	Malignant pleural effusion
	Pleural effusions	Neoplastic disease
	Hyperinflation	Infection
	Nodules/masses	
Pulmonary function tests		
Spirometry	Obstructive ventilation defect (Decreased FEV_1/FVC ratio)	Asthma
		COPD
	Restrictive ventilatory defect	Interstitial lung disease
Diffusing capacity	Decreased	Interstitial lung disease
		Pulmonary vascular disease
	Increased	Alveolar hemorrhage
Inspiratory and expiratory maneuvers	Decreased values	Respiratory muscle weakness
Computed tomography	Abnormal interstitial markings	Interstitial lung disease
	Cystic changes	Congestive heart failure
	Lymphadenopathy	Atelectasis
	Vascular filling defects	Pulmonary embolism
	Ground-glass opacities	Neoplastic disease
Blood tests	Elevated white blood cell count	Infection
	Anemia	Anemia
	BNP	Heart failure
	Cr	Acidoses (respiratory or metabolic)
	HCO_3	
	ABG	Alkaloses (respiratory)

COPD, Chronic obstructive pulmonary disease; FEV_1/FVC, forced expiratory volume in 1s/forced vital capacity; BNP, brain natriuretic peptide; Cr, creatine; HCO_3, bicarbonate; ABG, arterial blood gas.

A complete blood count may reveal anemia or suggest an infection. Electrolytes may indicate the presence of an acidosis or renal dysfunction. Measurement of brain natriuretic peptide (BNP) has been useful in helping to exclude heart failure as an acute cause of dyspnea. Fewer than 5 percent of patients with BNP values below 50 pg/ml have heart failure as the acute cause of dyspnea.

Additional testing is usually not required unless the cause of dyspnea remains unclear following these more basic studies. Further tests often include computed tomography (CT) of the chest which may rarely reveal changes of emphysema or an interstitial process not suggested by plain radiographs or lung function testing. The CT may additionally help to better characterize an interstitial process identified on plain radiographs. Cardiopulmonary exercise testing may be helpful in differentiating between cardiac and respiratory causes of dyspnea, or in excluding a significant abnormality of either system and suggesting deconditioning as the culprit. Arterial blood gas measurements may be necessary to characterize the level of blood oxygenation or to identify hyperventilation or hypercapnia. More invasive testing, including cardiac catheterization or lung biopsy (by either bronchoscopy or surgery), is reserved for when the diagnosis remains unsettled and the results will be helpful in guiding therapy or discussions of prognosis.

COUGH

Cough is one of the most frequent causes of visits to the doctor's office. Patients are frequently anxious about the possibility of a serious malady as the cause. They may also be troubled by the complications of cough, including chest pain from intercostal muscle strain or even a fractured rib in patients with bone disease. They may be embarrassed by

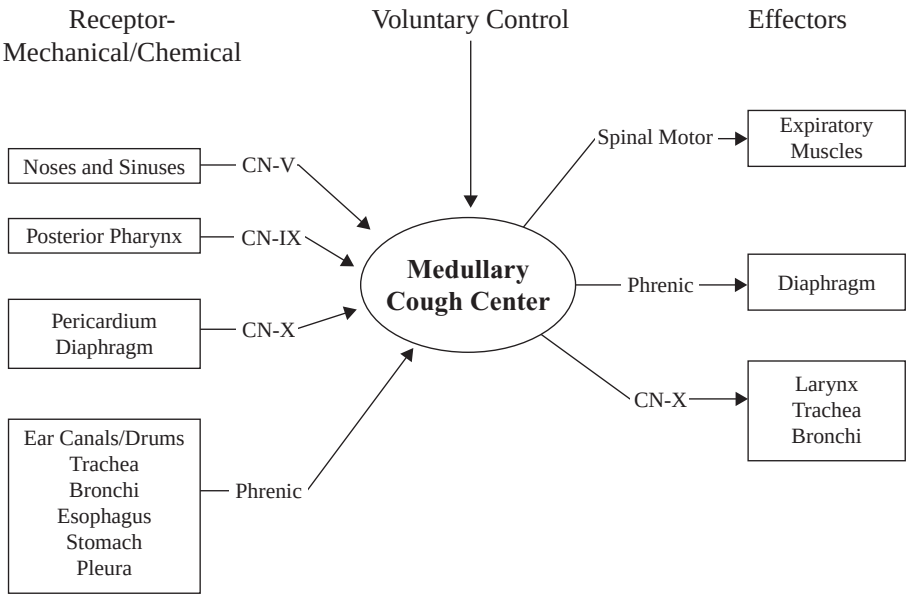

Figure 27-12 Signaling pathways in the development of cough. CN, cranial nerve. *(After Silvestri RC, Weinberger SE: Evaluation of chronic cough in adults. In Rose B (ed), UpToDate. Wellesley, MA, 2006.)*

cough-induced incontinence of the bladder or stool. Embarrassment, and even social isolation may also arise from the frequent fear of others that the patient's cough is infectious and communicable.

A cough is an explosive expiration that protects the lungs against aspiration and promotes the movement of secretions and other airway constituents upward toward the mouth. It is a critical element in the self-cleansing and protective mechanisms of the lungs—a reflex act that usually, but not invariably, arises from stimulation of the bronchial mucosa somewhere between the larynx and the second-order bronchi. On rare occasions the cause is remote: impacted cerumen in an external ear or an inflammatory process of the pleura (see "Mechanism" below) (Fig. 27-12). The stimuli that can elicit a cough are diverse: inhaled particles, mucus that has been elaborated by the lining of the airways, inflammatory exudate in airways or parenchyma, a new growth or foreign body in an airway, pressure on the external wall of the bronchus.

A cough may be voluntary, involuntary, or a combination of the two if the subject attempts to control an involuntary cough. Three categories of stimuli are commonly at work in producing an involuntary cough: mechanical, inflammatory, and psychogenic. Mechanical and chemical causes range from inhalation of irritants, such as smoke or dust, to distortions of the airways produced by pulmonary fibrosis or atelectasis. Most often, coughs are due to tracheobronchial inflammation. The cigarette smoker is particularly vulnerable to exacerbation of cough by inhaled particles and fumes because of underlying chronic pharyngitis, laryngitis, and tracheobronchitis. As a rule, cough represents organic disease. But on occasion, psychogenic influences are responsible for a dry cough that is related to anxiety. Psychogenic stress can aggravate cough due to organic causes.

The site and significance of a cough can sometimes be localized from telltale signs and symptoms (Table 27-9). For example, the cough of acute tracheitis is often associated with retrosternal "burning." Acute laryngitis is usually associated with hoarseness and sore throat as well as cough. Tuberculosis of the larynx is associated not only with painful swallowing but also with unequivocal evidence of pulmonary tuberculosis. In asthma, cough is part of a constellation of airway obstruction. Body position can influence the persistence of a cough. When the pathological process is changing, as in pneumonia or a neoplasm, the cough undergoes concomitant change, reflecting the evolution of the disorder.

Interpretation of the significance of a cough depends on the clinical company that it keeps. It has to be viewed in context: Is it acute or chronic? productive or nonproductive? How long has it lasted? What is the general condition of the patient, and what co-morbidities are present? For example, the acute onset of a hacking, nonproductive cough accompanied by coryza, sore throat, malaise, sweating, and fever generally heralds a viral upper respiratory infection. An episode of asthma may begin with cough and wheezing. In contrast, a persistent cough, even if virtually ignored by the patient, may be a harbinger of serious disease (e.g., carcinoma of the lung). In a cigarette smoker, in whom bronchi are chronically irritated, a change in the nature of the cough from nonproductive to productive may signify the onset of a serious tracheobronchial infection or pneumonia. Alternatively, a lung neoplasm may present with a dry cough that not only persists and intensifies but also gradually becomes associated with systemic manifestations (e.g., loss of weight).

The implications of dry cough are different from those of productive cough. Before a cough can be regarded as

Table 27-9

Some Causes and Characteristics of Cough

Cause	Characteristics
Sinusitis or nasopharygnitis	Cough following an upper respiratory syndrome or sinus symptoms; sensation of a need to clear the throat; postnasal drip
Acute infections of lungs	
Tracheobronchitis	Cough associated with sore throat, running nose and eyes
Lobar pneumonia	Cough often preceded by symptoms of upper respiratory infection; cough dry, painful at first; later becomes productive
Bronchopneumonia	Cough dry or productive, usually begins as acute bronchitis
Mycoplasma and viral pneumonia	Paroxysmal cough, productive of mucoid or blood-stained sputum associated with flulike syndrome
Exacerbation of chronic bronchitis	Cough productive of mucoid sputum becomes purulent
Chronic infections of lungs	
Bronchitis	Cough productive of sputum on most days for more than 3 consecutive months and for more than 2 years
	Sputum mucoid until acute exacerbation, when it becomes mucopurulent
Bronchiectasis	Cough copious, foul, purulent, often since childhood; forms layers upon standing
Tuberculosis or fungus	Persistent cough for weeks to months, often with blood-tinged sputum
Parenchymal inflammatory processes	
Interstitial fibrosis and infiltrations	Cough nonproductive, persistent, depends on origin
Smoking	Cough usually associated with injected pharynx; persistent, most marked in morning, usually only slightly productive unless succeeded by chronic bronchitis
Tumors	
Bronchogenic carcinoma	Cough nonproductive to productive for weeks to months; recurrent small hemoptysis common
Alveolar cell carcinoma	Cough similar to that with bronchogenic carcinoma except in occasional instances, when large quantities of watery, mucoid sputum are produced
Benign tumors in airways	Cough nonproductive; occasionally hemoptysis
Mediastinal tumors	Cough, often with breathlessness, caused by compression of trachea and bronchi
Aortic aneurysm	Brassy cough

(*Continued*)

Table 27-9

(*Continued*)

Cause	Characteristics
Gastrointestinal	
Gastrioesophageal reflux (GERD)	Nonproductive cough often following meals or with recumbancy; may (or may not) be accompanied by other symptoms of GERD (e.g., heartburn, a bitter oral taste, belching)
Foreign body	
Immediate, while still in upper airway	Cough associated with progressive evidence of asphyxiation
Later, when lodged in lower airway	Nonproductive cough, persistent, associated with localizing wheeze
Cardiovascular	
Left ventricular failure	Cough intensifies while supine, along with aggravation of dyspnea
Pulmonary infarction	Cough associated with hemoptysis, usually with pleural effusion
Medication-induced	
Angiotensin-converting enzyme (ACE) inhibitors	Nonproductive cough, more common in women, may occur at any time (following soon after drug initiation or with years of use)

nonproductive, the possibility should be weighed carefully that sputum has been produced but swallowed. Failure to probe deeply into this possibility once led to the notion that British and American patients suffered from different types of chronic bronchitis. Improved history taking and interviews discounted this idea.

A cough that is productive of purulent sputum is generally a reliable indication of infection in the tracheobronchial tree or lungs. When this symptom is associated with an acute illness, the characteristics of the sputum can be of considerable diagnostic help. Rust-colored sputum, which contains its distinctive coloration from the even dispersion of blood in yellow, purulent sputum was previously seen often in pneumococcal pneumonia but less so today due to the widespread use of antibiotics. The classic description of sputum in Friedlander's pneumonia is a resemblance to currant jelly; it also contains blood, but it is bright red and more translucent and viscid than the sputum of pneumococcal pneumonia. Purulent sputum with a foul odor usually indicates an anaerobic infection, commonly due to streptococci or *Bacteroides* in a lung abscess. A persistent cough that is productive of purulent sputum occurs in chronic bronchitis, bronchiectasis, and a variety of other suppurative disorders. Sputum that is mucoid can be a consequence of any long-standing bronchial irritant. Copious sputum production (bronchorrhea) may be a sign of bronchoalveolar carcinoma.

Mechanism

The cough begins with a rapid inspiration, followed, in rapid sequence, by closure of the glottis, contraction of the abdominal and thoracic expiratory muscles, abrupt increase in pleural and intrapulmonary pressures, sudden opening of the glottis, and expulsion of a burst of air from the mouth (Fig. 27-13). The high intrathoracic pressures, which often exceed 100 to 200 mmHg, increase the velocity of airflow through the airways, hastening the propulsion of the offending particles and producing the sound of a cough by setting into vibration airway secretions, the tracheobronchial walls, and the adjacent parenchyma (Fig. 27-14).

Afferent stimuli for a cough originate in irritant receptors and are conveyed centrally by the vagus, glossopharyngeal, trigeminal, and phrenic nerves (Fig. 27-12). In subjects with an idiopathic, persistent, nonproductive cough, increased sensitivity of the afferent nerves of the airways due to neuropeptides stored in them has been proposed. The vagus nerve carries impulses not only from the larynx, trachea, and bronchi but also from the pleura and stomach. Receptors in the airways are most concentrated in the larynx, diminish in density in the conducting airways, and are absent from the distal airways, enabling the pooling of secretions in the periphery. The glossopharyngeal nerve carries stimuli from the pharynx; the trigeminal nerve, from the nose and paranasal sinuses; the phrenic nerve, from the pericardium and diaphragm. The motor pathways are even more extensive,

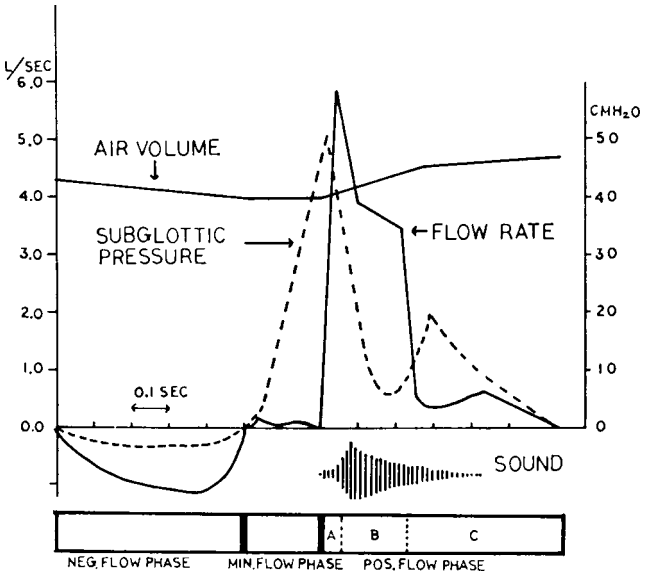

Figure 27-13 Sequence of events during a cough. Simultaneous recordings obtained during a single explosive cough by a normal subject. The three phases of a cough are identified by the boxes at the bottom of the figure. They correspond to (1) a deep initial inspiration, (2) compression of air in the lungs and airways by forceful contraction of the expiratory muscles coupled with tight closure of the glottis and opening of the larynx, and (3) sudden explosive expiration followed by narrowing of the glottis and return of the larynx to its normal inspiratory position. *(From Yanagihara, von Leiden, Werner-Kukuk: Acta Otolaryngol 61:495–510, 1965.)*

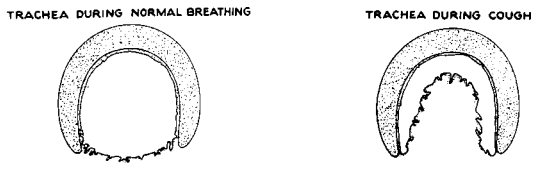
comprising not only the cranial and phrenic nerves but also the nerves to the muscles of the rib cage and the accessory muscles. Additional impulses from chemoreceptors are located in the esophagus and carried by the phrenic nerve.

The effectiveness of a cough is strongly influenced by the lung volume at which it occurs. As indicated elsewhere in this volume, cough only removes particles toward the mouth ("downstream" from the "equal pressure points"). In healthy persons at high lung volumes, the equal pressure points are located in the larger airways; they move toward the alveoli ("upstream") as lung volume decreases. A series of coughs without any intervening inspiration moves the equal pressure points even closer to the small airways, helping to clear the depths of the lungs.



Intrathoracic pressure, cm H_2O	−4	+150
Cross-sectional area, cm^2	1.5	0.25
Volume flow, L/sec	1	7
Linear velocity, cm/sec	667	28,000

Figure 27-14 Effects of tracheal narrowing during a cough. The forced expiratory effort during coughing causes invagination of the noncartilaginous part of the intrathoracic trachea by the high intrathoracic pressure. Air rushing with a high linear velocity through the exceedingly narrow trachea dislodges the material to be dispelled and propels it into the throat. *(From Comroe: Physiology of Respiration. St. Louis, Mosby-Year Book, 1965, p 122.)*

The cough reflex may be impaired by interrupting or blunting any step in the sequence. Irritant receptors can be damaged by a local destructive process (e.g., bronchiectasis), or their sensitivity can be diminished by narcotics or anesthetics.

The reflex pathways can be damaged as part of a neurological disease. Tracheostomy, which eliminates glottic closure, decreases peak intrapulmonary pressures. Contraction of the respiratory muscles can be impaired by weakness due to illness, age, or neuromuscular disease. In general, as long as the patient can achieve maximum expiratory pressures greater than about 60 cm H_2O, the peak flow will suffice to produce effective coughs.

Circulatory Consequences

The increase in intrathoracic pressure that is part of the cough mechanism exerts considerable circulatory effects. However, because the increase in intrathoracic pressure is accompanied by an equal rise in vascular (and cerebrospinal fluid) pressures, distending pressures on the vessels of the heart, lungs, and other vital organs are unaltered, so they are normally spared the ill consequences of marked swings in transmural pressures.

The increase in intrathoracic pressure is accompanied by reflex vasodilation of systemic arteries and veins. Both of these effects contribute to a decrease in cardiac output. In patients with cor pulmonale and right heart failure, cough impedes systemic venous return and may result in syncope.

Posttussive Syncope

Charcot recognized the syndrome of posttussive syncope in individuals without underlying cardiopulmonary disease 100 years ago. Originally conceived of as a form of epilepsy or a consequence of a laryngeal reflex, it is now attributed to the same circulatory consequences of raised intrathoracic pressures that coughing evokes in a normal person. However, the patient with cough syncope probably coughs more forcefully and longer than do normal persons.

The syncope usually develops within a few seconds after the onset of a paroxysm of coughing and ends quickly once the coughing has stopped. Return to consciousness is without sequelae unless the subject falls and is injured during the faint. Posttussive syncope nearly always occurs in men, probably because they generate a higher intrathoracic pressure and much more profound decrease in cardiac output than do women. It is not clear why this type of fainting occurs in the supine as well as the upright position; this occurrence suggests that the reduction in cerebral blood flow during posttussive

syncope reflects more than interference with cardiac output. The extent to which intense reflex vasodilation contributes to posttussive syncope is unclear.

Etiology

The most common causes of chronic cough (defined as lasting longer than 8 weeks) are postnasal drip (recently termed *upper airway cough syndrome*), gastroesophageal reflux disease (GERD), and asthma. In patients treated with angiotensin-converting enzyme (ACE) inhibitors, the drug is very often the cause of a chronic cough (even one developing after years of uncomplicated use). A deliberate evaluation can identify the cause in the vast majority of patients. Usually, the diagnosis is established only by the resolution of the cough following a specific intervention (Fig 27-15). For example, cough that disappears after antihistamines and inhaled nasal steroid treatment for allergic rhinitis can logically be attributed to postnasal drip. Similarly, cough may disappear after interventions for GERD (e.g., the use of H_2-blockers) or asthma (use of inhaled bronchodilators and steroids). A cough that resolves after discontinuation of an ACE inhibitor was presumably caused by the drug. Although the more common causes of chronic cough are usually benign, a chest radiograph is nonetheless warranted at the beginning of the evaluation of a chronic cough to assess for possible worrisome causes.

HEMOPTYSIS

The coughing up of blood is termed *hemoptysis*. The material and amount produced varies from mere blood streaking of expectorated sputum to massive volumes of pure blood. Massive hemoptysis has been variably defined according to the volume, but implies a life-threatening process requiring immediate evaluation and treatment.

An initial decision faced by the physician who is told that blood has been coughed up is whether to conclude that the blood is coming from the respiratory tract. Any portion of the respiratory tract can be the source of bleeding including a main bronchus, the lungs, or the nose or throat. On occasion, blood from the nose and throat is inhaled and then expectorated. As long as this possibility is kept in mind, bleeding that originates in the nose, throat, or larynx is not apt to be overlooked.

An additional consideration is distinguishing hemoptysis from hematemesis (vomited blood). Even if the blood is aspirated and then coughed up, the patient can usually tell if the blood originated in the respiratory or alimentary tract. The appearance of the bloody material also helps to distinguish between hemoptysis and hematemesis: blood that originates in the airways is usually bright red, is mixed with frothy sputum, has an alkaline pH, and contains alveolar macrophages that are laden with hemosiderin; in contrast, blood from the stomach usually is dark, has an acid pH, contains food particles, and often occurs in patients with a long history of gastric complaints.

Blood arising from the bronchial arteries is more often the source of massive hemoptysis, owing to its higher perfusion pressure than blood from the pulmonary circulation. The bronchial circulation may be the source of life-threatening bleeding, for example, in patients with bronchiectasis in whom the vessels frequently become distorted and easily ruptured.

The differential diagnosis of hemoptysis includes disorders arising within the airways and the pulmonary parenchyma. Inflammatory processes (e.g., bronchitis and bronchiectasis) and neoplasms are the most common causes of blood arising within the airways. Within the pulmonary parenchyma common causes are infections, such as tuberculosis, pneumonia, *Aspergillus*, or lung abscess. Inflammatory processes that involve the lung, such as Wegner's granulomatosis or Goodpasture's syndrome are also important causes of hemoptysis (Fig. 27-16). Bleeding may be iatrogenic, as for example, after a lung biopsy or when chemotherapy for bone marrow transplantation evokes diffuse alveolar hemorrhage. Vascular disorders, including pulmonary embolism, arteriovenous malfunctions, and mitral stenosis are also to be considered in the differential diagnosis.

The list of causes of hemoptysis is long and diverse (Table 27-10). The clinical setting is usually helpful in identifying the cause. Hemoptysis before middle age usually brings to mind infections; after 40 to 45 years of age or if there is a history of smoking, bronchogenic carcinoma heads the list. In patients left with a pulmonary cavity after pulmonary disease that has healed (e.g., tuberculosis), and in regions of the country where pulmonary fungal diseases are prevalent, a bout of hemoptysis is occasionally the first sign of the disease. In patients who have a predisposing cause, such as oral contraceptives or chronic heart failure, pulmonary embolism must be considered.

The evaluation of hemoptysis involves a careful history, physical examination, and a chest radiograph. Initial studies also include a complete blood count. The degree of anemia may influence the rapidity of further testing, and thrombocytopenia may be a contributing factor to hemoptysis. Rapid correction of anemia, thrombocytopenia, or coagulopathy with the transfusion of appropriate blood products may be required promptly depending upon the clinical status and degree of abnormality. Similarly, measurement of coagulation times are important. Studies of renal function and a urinalysis may be indicated when a systemic process which causes a pulmonary-renal syndrome is a possibility. Sputum should be zealously collected and, depending on the circumstance, microbiologic cultures and stains or cytologic examination should be performed. Depending on whether a cause is identified, and the risk factors for a serious cause of bleeding, the evaluation next involves additional studies to search for a source.

Because hunting for the cause and the source of bleeding is generally uncomfortable for the patient and often expensive, the intensity of the search depends on the circumstances. For example, rarely is a search for the bleeding site needed in a patient with acute bronchitis, pneumonia, or

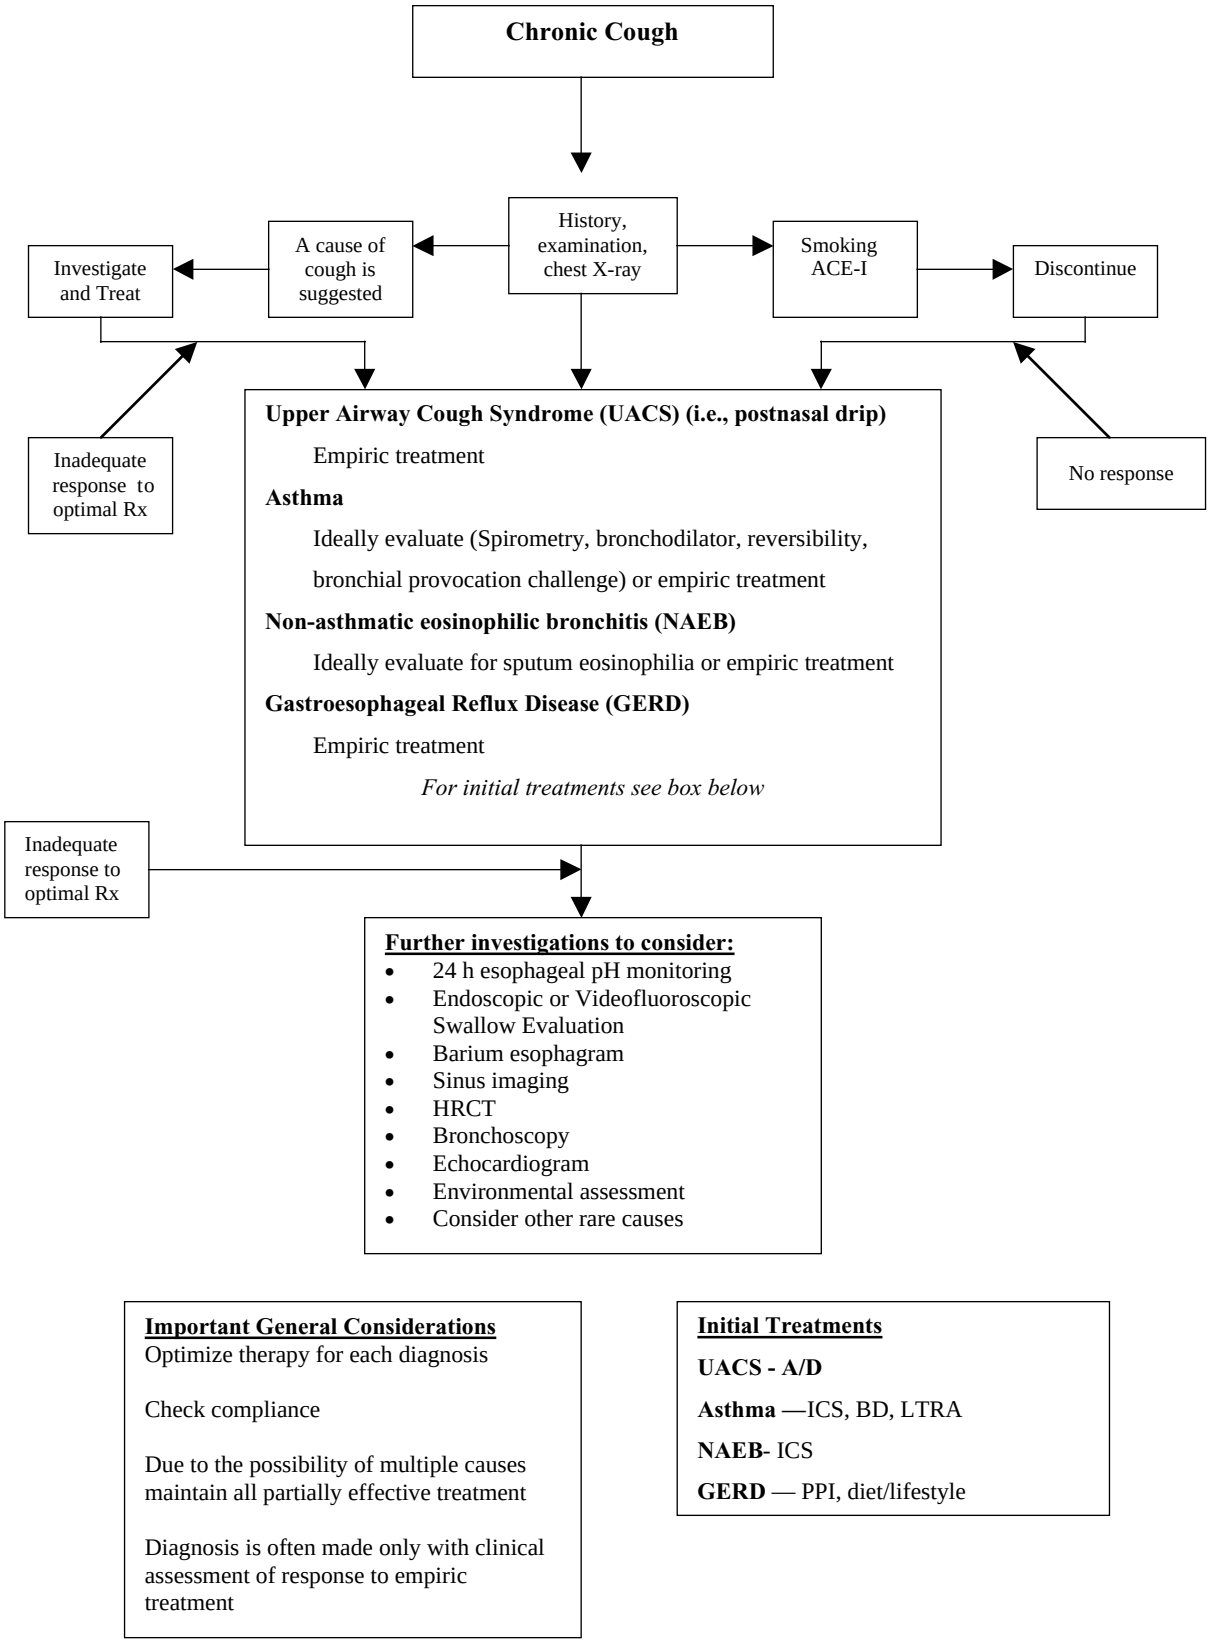


Figure 27-15 Algorithm for the evaluation of chronic cough lasting 8 weeks in adults. ACE-I = ACE inhibitor; BD = bronchodilator; LTRA = leukotrienes receptor antagonist; PPI = proton pump inhibitor; ICS = inhaled corticosteroid; A/D = antihistamine/decongestant; HRCT = high-resolution computed tomography. *(After Irwin RS, et al: Diagnosis and management of cough executive summary: ACCP evidence-based clinical practice guidelines. Blood dyscrasia
Goodpasture's syndrome

bronchopulmonary suppuration. But as a rule, unless the cause is evident, a full-scale investigation is mandatory, particularly if this is not the first episode.

Patients with hemoptysis and a history of tobacco smoking, individuals who are more than 40 years of age, or those who experience hemoptysis that lasts for more than 1 week are at greater risk for a worrisome cause and warrant additional studies. A high-resolution computed tomography (HRCT) of the chest is usually the next step if the patient has no history of tobacco use or if the plain chest radiograph suggests a parenchymal abnormality, such as bronchiectasis or arteriovenous malformation. Patients with a history of tobacco use or other risk factors for a malignancy warrant fiberoptic bronchoscopy. In practice, HRCT and bronchoscopy are often complementary for visualizing abnormalities that are not apparent on plain chest radiographs. Patients with chronic bronchitis and at low risk for malignancy, or in whom the chest radiograph is normal or identifies the cause of hemoptysis (e.g., epistaxis or pneumonia) can usually be treated initially for bronchitis with follow-up appraisals to show prompt resolution of hemoptysis. However, should hemoptysis recur, further evaluation is required.

Neoplasms

Nonmassive hemoptysis is common in bronchogenic carcinoma; less frequently it is the cause of massive hemoptysis. The likelihood of a neoplastic cause of hemoptysis is greatly increased in a cigarette smoker. Usually a troublesome cough and vague chest pain precede and accompany the hemoptysis. For hemoptysis to occur, the lesion must communicate with the airways. Most often the bleeding is a consequence of ulceration caused by an expanding tumor; sometimes it is due to a pneumonic process or to an abscess in the lung behind the obstructive lesion. Hemoptysis rarely complicates metastatic tumors of the lungs, since few (primarily renal and colon carcinomas) intrude on the airways until preterminal.

Not only malignant but also benign tumors of the lung cause bleeding. The classic example is bronchial carcinoid, which often causes bleeding that is generally difficult to arrest.

Infections

Hemoptysis can accompany a severe infection anywhere from the top to the bottom of the respiratory tract. It is uncommon in the usual viral or bacterial pneumonia. Conversely, it is not uncommon in the pneumonia that complicates bronchogenic carcinoma or in the pneumonia that is caused by staphylococci, influenza virus, or *Klebsiella.*

The infecting organism determines the appearance and composition of the material that is expectorated with the blood. As indicated above, in pneumococcal lobar pneumonia, the sputum at the onset is characteristically rusty-looking, but sometimes it is faintly or grossly bloody. In staphylococcal pneumonia, the blood is mixed with pus. In *Klebsiella* pneumonia, the bloody sputum often resembles currant jelly. Brisk bleeding is common in lung abscess; the blood is mixed with copious amounts of foul-smelling pus. In lung gangrene, blood is associated with necrotic lung tissue.

Bleeding is common in bronchiectasis. Because it usually originates in a bronchial artery, bleeding is often brisk. While most episodes stop spontaneously, it tends to recur and can be life-threatening.

Fungal infections of the lungs can cause hemoptysis (Fig. 27-16). As in tuberculosis, hemoptysis is generally a consequence of a continuing necrotizing and ulcerating inflammatory process or of bronchiectasis. The most common fungal disorder associated with hemoptysis is a "fungus ball" that resides either in a healed tuberculous or bronchiectatic area or in a cystic residue of sarcoidosis. *Aspergillus* is the usual fungal agent; less often another fungus (e.g., *Mucor*) is the cause.

The most common source of hemoptysis used to be an active tuberculosis cavity. But currently tuberculous pneumonia is a more common cause of hemoptysis than is active cavitation. Despite the increasing frequency of tuberculosis, hemoptysis is uncommon because of effective antituberculous therapy. If tuberculosis is allowed to progress to the point of extensive fibrosis and causation, or becomes complicated by bronchiectasis, hemoptysis can be troublesome and persistent. Hemoptysis from a Rasmussen's aneurysm involves the erosion of a small or medium-sized pulmonary artery into an adjacent tuberculosis cavity.

The "right middle lobe syndrome" is frequently associated with hemoptysis. It is due to a partial or complete

obstruction of the right middle lobe bronchus, resulting in atelectasis and/or pneumonitis in the right middle lobe. The obstruction is more often caused by scarring and/or inflammation than by physical compression of the lumen by an enlarged lymph node. The cause is usually infectious; the infection can be tuberculosis.

In parts of the world where amebiasis is endemic, hemoptysis follows perforation into the airways of an amebic lung abscess. The sputum resembles anchovy sauce.

Cardiovascular Disorders

Pulmonary congestion and alveolar edema sometimes produce blood-tinged sputum. In chronic pulmonary congestion, secondary to left ventricular failure or to mitral valve disease, alveolar macrophages in the sputum are often laden with hemosiderin ("heart failure cells"). In severe congestion and edema, the sputum is often pink and frothy. Usually there is no difficulty in recognizing that inadequate performance of the left ventricle is the cause of the bloody sputum.

Pulmonary thromboembolism can produce hemoptysis when associated with infarction (Fig. 27-17). The hemoptysis of pulmonary infarction is usually associated with pleuritic pain and often with a small pleural effusion because of the peripheral location of the infarct.

Tight mitral stenosis is sometimes first manifested by a bout of brisk, bright-red hemoptysis that is difficult to control. The source of the bleeding is the submucosal bronchial veins, which proliferate considerably in this disorder. Massive hemoptysis due to mitral stenosis is a medical emergency and is an indication for surgical intervention to relieve the obstruction at the mitral valve.

Figure 27-17 Hemorrhagic pulmonary infarcts. Several subpleural areas of infarction are clearly demarcated.

Hemoptysis from other circulatory disorders is much less common. Occasionally, an aortic aneurysm penetrates into the tracheobronchial tree, causing death by exsanguination and asphyxiation. An extraordinary event is the communication of an arteriovenous fistula with a small airway, causing bleeding that is exceedingly difficult to arrest.

Trauma

Hemoptysis follows a variety of chest injuries: puncture of a lung by a fractured rib, contusions of a lung by severe blunt trauma to the chest, and necrosis of the lining of the tracheobronchial tree by inhaled fumes or smoke. Blunt trauma from the steering wheel during an automobile collision sometimes lacerates or fractures the tracheobronchial tree. Stab or gunshot wounds often tear the lungs or airways. On occasion, mucosal lacerations in the course of severe coughing evoke hemoptysis.

After pneumonectomy or lobectomy, a large hemothorax occasionally empties into the airways. This is an alarming and ominous event. Its imminent occurrence is often heralded by the expectoration of blood-stained sputum after a paroxysm of coughing. The hemothorax must be promptly evacuated and the bronchus surgically repaired. Hemoptysis within a few weeks to months after pneumonectomy has different implications: recurrence of tumor, granulation tissue, or bronchial sutures. Prompt bronchoscopy is necessary for accurate appraisal of the situation.

Miscellaneous

Other causes of hemoptysis are listed in Table 27-10. They vary greatly in severity, urgency, and prognosis. Sometimes the cause is obscure, as in the occasional instance of hemoptysis that accompanies menstruation ("catamenial hemoptysis"). An aspirated foreign body produces bleeding by damaging the mucosa on impact; if allowed to remain in place, it sometimes causes bronchiectasis, which in turn may cause bleeding. Pulmonary calcific foci, either in the pulmonary parenchyma or in lymph nodes, sometimes cause hemoptysis by ulcerating into a bronchus.

Blood dyscrasias, notably thrombocytopenic purpura and hemophilia, and the therapeutic use of anticoagulants are occasional causes of hemoptysis. In areas where scurvy is endemic, vitamin C deficiency is a major cause.

Hemoptysis in Goodpasture's syndrome (Fig. 27-16) or in idiopathic hemosiderosis is life-threatening. This grim prospect has led to an aggressive therapeutic approach, including use of plasmapheresis and immunosuppressive agents.

Management of Massive Hemoptysis

The first priority in the care of a patient with life-threatening hemoptysis is to protect the airway and prevent asphyxiation. Intubation should be performed promptly, and consideration given to selective intubation of one lung in order to protect it from spillage of blood from the other. When the site of bleeding is known, one simple, initial bedside maneuver is to place the involved side in a dependent position in order to protect the uninvolved lung. Bronchoscopy should be performed promptly in order to identify the source. This may also allow bronchoscopic interventions such as the placement of a balloon catheter to isolate the involved segment, lavage with iced saline, or the application of topical epinephrine (1:20,000). Bronchoscopic localization may help to guide attempts at arresting the bleeding by angiographic embolization. If these modalities fail to stop the bleeding, surgical exploration may be required. Not surprisingly, emergency procedures are accompanied by a high mortality. None of the approaches has been rigorously studied and the choice is frequently dictated by the urgency, local experience, and availability of bronchoscopy.

CYANOSIS

Cyanosis refers to a bluish discoloration of the skin that is caused by increased amounts of reduced hemoglobin in the subcapillary venous plexus. The discoloration is most apparent in the lobes of the ears, the cutaneous surfaces of the lips, and the nail beds. In patients with dark skin, the mucous membranes and the retina are important sites to examine for cyanosis. Unless flow through the skin is slowed, as in heart failure, cyanosis implies arterial hypoxemia. Cyanosis does not appear in carbon monoxide poisoning or in severe anemia even though arterial O_2 content is extremely low. This is because there is an insufficient amount of reduced hemoglobin present for the cyanotic discoloration to be visible. The presence of abnormal pigments in blood, such as methemoglobin or bilirubin, complicates the detection of cyanosis.

Capillary O_2 Content

An increase in the amount of reduced hemoglobin in the capillaries of the skin, as elsewhere, results from inadequate oxygenation of arterial blood, excessive removal of O_2 from capillary blood (as when the circulation through a region is slowed by vasoconstriction or a very low cardiac output), or from a combination of the two. The concentration of reduced hemoglobin in the skin capillaries must reach about 5 g/dl before cyanosis becomes discernible. Thus, in severe pernicious anemia, in which hemoglobin concentrations are exceedingly low (on the order of 3 to 4 g/dl), although virtually all the hemoglobin can be reduced in traversing the skin capillaries, an insufficient amount of reduced hemoglobin remains to produce a visible discoloration. Oppositely, the polycythemic patient develops cyanosis at a higher arterial O_2 saturation than does the normal individual.

The combination of intense vasoconstriction and excess reduced hemoglobin is responsible for the distinctive gray or heliotrope color that is frequently seen in patients with circulatory collapse and severe pulmonary edema.

Causes of Cyanosis

Several types of cyanosis are usually identified according to the underlying mechanism. They include peripheral cyanosis, cyanosis arising from pulmonary disease, cyanosis from venous admixture, and cyanosis due to abnormal pigments in the blood.

Peripheral Cyanosis

This type is secondary to abnormally large extraction of O_2 from blood flowing through peripheral capillaries. The most common cause is a diminished cardiac output associated with peripheral vasoconstriction. Not only the hands and feet but also the tip of the nose becomes blue in severe heart failure. Indeed, in patients with intractable heart failure, necrosis occasionally develops at the tip of the nose.

Peripheral vasoconstriction per se, as in Raynaud's disease, also produces cyanosis of the nail beds.

Cyanosis in Pulmonary Disease

Patients with chronic bronchitis and emphysema characteristically manifest derangements in ventilation-perfusion relationships. In some, arterial hypoxemia results. In patients with diffuse interstitial fibrosis, normal arterial oxygenation at rest is succeeded by arterial hypoxemia, and sometimes by cyanosis, during exercise. Another cause of arterial hypoxemia is the syndrome of alveolar hypoventilation in patients with normal lungs. In any of these situations, cyanosis is intensified if heart failure supervenes and slows blood flow through the skin (i.e., decreases O_2 delivery).

Cyanosis Due to Venous Admixture

In patients with intracardiac right-to-left shunts, cyanosis arises from a mixture of venous and arterial blood. The effect of venous admixture is particularly striking if the O_2 content of mixed venous blood is inordinately low, as in some types of congenital heart disease and in severe heart failure. Often secondary polycythemia contributes to the cyanosis. On occasion, regional cyanosis is diagnostic. For example, in patent ductus arteriosus with reversal of blood flow, the lower extremities are deeply cyanotic, whereas the upper extremities are virtually normal in color.

Cyanosis Due to Abnormal Pigments in Blood

Methemoglobinemia is an occasional cause of cyanosis. Methemoglobinemic blood is chocolate brown, and spectrophotometric examination of blood reveals the characteristic pigment. Arterial blood examination discloses a normal P_{O_2}.

The cause of methemoglobinemia may be hereditary (i.e., due to the presence of hemoglobin M or a deficiency in methemoglobin reductase) or, more often, acquired (e.g.,

by exposure to chemical agents such as aniline dyes, chlorates, nitrates, and nitrites); or methemoglobinemia may result from drugs such as dapsone acetanilide, nitroglycerin, phenacetin, and primaquine. Nitrates are a common cause of methemoglobinemia. Nitrates are reduced to nitrites by bacteria in the intestinal tract. Excessive use of nitroglycerin, an organic nitrate, leads to methemoglobinemia.

In methemoglobinemia, the ferrous iron is oxidized to ferric iron, rendering the hemoglobin molecule incapable of binding O_2 or CO_2. Methemoglobin is formed continuously in the normal erythrocyte, but its level within the cell is kept low (less than 2 percent) by intracellular reductive mechanisms. High levels of methemoglobin result from hereditary abnormalities (e.g., a deficiency in methemoglobin reductase) or from exposure to drugs or chemicals that increase the rate of oxidation beyond the reductive capacity of the erythrocytes. Clinical manifestations of methemoglobinemia vary with the blood levels. Concentrations of methemoglobin between 10 and 25 percent usually cause asymptomatic cyanosis. When these levels are exceeded, dizziness, fatigue, and headache appear.

Because of the normal methemoglobin reductase and Nicotinamide adenine dinucleotide (NADH) generated during anaerobic glycolysis, treatment beyond discontinuation of an offending drug is often unnecessary unless serious manifestations occur (angina, stupor, or coma). Then methylene blue is given intravenously (1 to 2 mg/kg as a 1 percent solution) over 5 to 10 min. Cyanosis should disappear within 1 h; if not, the dose should be repeated. Larger doses of methylene blue engender the risk of aggravating the methemoglobinemia. Methylene blue should not be used in patients with glucose-6-phosphate dehydrogenase deficiency (common in certain African-American and Mediterranean populations) as it cannot be metabolized and may result in accidental toxicity.

CLUBBING

Clubbing of the digits is a classic finding in medicine that dates back to Hippocrates' awareness of the association between characteristic changes in the fingertips and empyema. Occasionally it constitutes a valuable clue to clinically unapparent disease of the lungs and pleura. Clubbing of the fingers designates the selective bulbous enlargement of the distal segments of the digits due to an increase in soft tissue (Fig. 27-18). Although most often it is painless, clubbing remains an important finding as its presence should signal an evaluation for potential serious causes.

When full-blown, clubbing is easy to recognize: (1) the nails, particularly the index finger, become abnormally curved in the longitudinal and coronal planes; (2) the hyponychial angle, viewed in profile, becomes blunted, often in conjunction with softening and sponginess of the base of the nail; and (3) the undersurface of the terminal digit becomes large and bulbous. Early stages of clubbing are subtle and generally difficult to diagnose. Clubbing often has to be distinguished from simple curvature of the nails and occasionally from chronic paronychia and Heberden's nodes. A variety of methods have been proposed for quantifying clubbing (e.g., measuring casts of the fingertips), but none has become popular.

Clubbing is generally acquired, but it may be hereditary. Acquired clubbing is seen in a wide variety of disorders, both extrathoracic and thoracic (Table 27-1).

It is important to recognize that clubbing is not caused by all forms of chronic lung disease. COPD, for example, does not cause clubbing. The presence of clubbing in a patient with COPD should alert the clinician to the possibility of a second process, commonly lung cancer. As a rule, clubbing is bilaterally symmetrical, affecting hands and feet; on occasion, local factors, such as injury of a finger or of the median nerve, may cause clubbing that is confined to a single finger. Rarely, clubbing may be confined to the digits of one hand (e.g., in an ipsilateral pulmonary sulcus tumor that has invaded the brachial plexus or following hemiplegia). In certain types of congenital heart disease, a telltale distribution of clubbing is of considerable diagnostic value. For example, in patent ductus arteriosus associated with reversal of shunt through the ductus, clubbing affects only the toes.

Pathogenesis

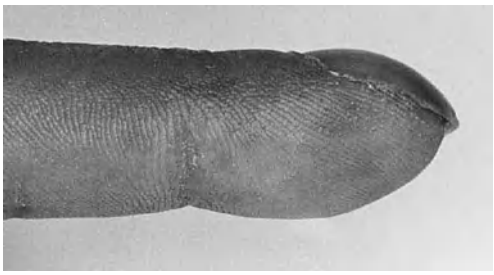
The pathogenesis of clubbing is unknown, and no suitable animal model of clubbed fingers has yet been developed, largely because so few species other than primates have fingers. A common denominator in the pathogenesis of clubbing appears to be vasodilation of vessels in the fingertip, including formation of the arteriovenous connections. As a result, hydrostatic pressures increase in the capillaries and venules, promoting the transduction of fluid into the interstitium. The reason for this preferential vasodilation is unclear. A popular notion is that a humoral substance escapes normal deactivation by pulmonary capillaries. This theory could account for clubbing in cyanotic congenital heart disease, in various pulmonary diseases in which proliferation of the bronchial circulation occurs, and in hepatic cirrhosis in which pulmonary arteriovenous anastomoses and right-to-left shunts are common. However, it is difficult to relate this theory to the high incidence of clubbing in subacute bacterial endocarditis.

At present, a single hypothesis that would account for the clubbing that occurs in such diverse disorders as subacute bacterial endocarditis, carcinoma of the lung, hemiplegia, chronic mountain sickness, and purgative abuse is not possible. Indeed, it seems likely that clubbing of the digits is a stereotyped consequence of diverse influences that have in common the capacity to induce marked digital vasodilation and interstitial edema of the soft tissue.

HYPERTROPHIC OSTEOARTHROPATHY

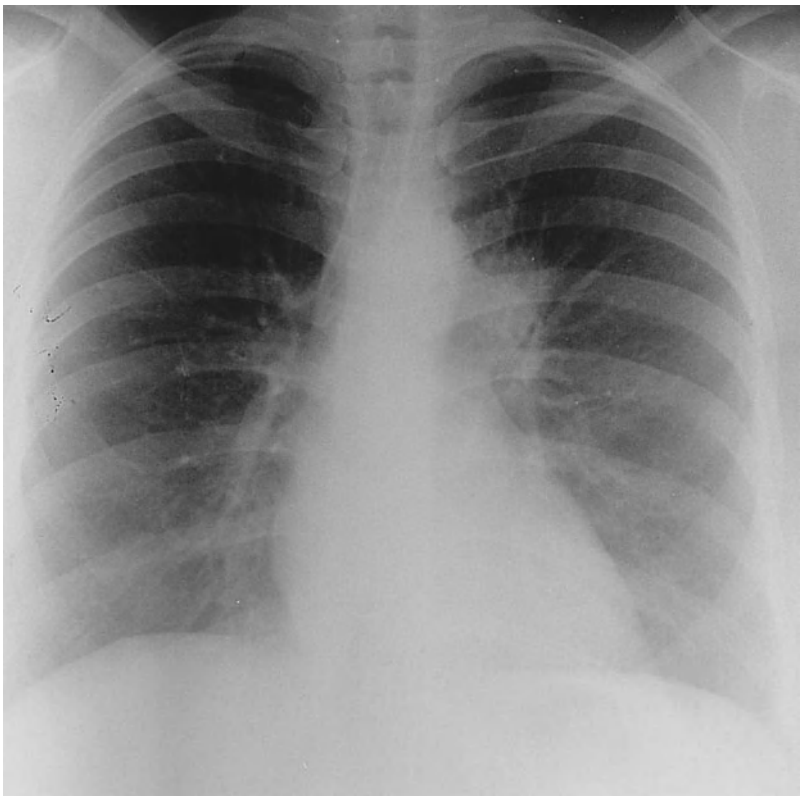
Occasionally, clubbing of the digits is accompanied by hypertrophic osteoarthropathy (HOA), a separate entity both

A

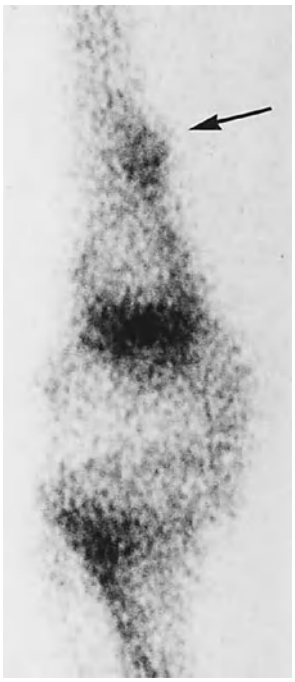


B

D



C



E

Figure 27-18 Clubbing of the digits and hypertrophic osteoarthropathy. A 40-year-old woman developed swelling and tingling of the fingertips in association with painful swelling of both knees. She was a heavy smoker (36 pack-years) and had an 8-month history of a dry cough. *A.* Clubbing of all fingers. *B.* Index finger. *C.* Left hilar mass that proved to be a primary adenocarcinoma of the lung. *D.* Subperiosteal formation of new bone on the medial aspect of the diaphysis of the femur. *E.* Bone scan, using ^{99m}Tc methylene diphosphonate. An abnormal accumulation of isotope is seen in the area of new bone (arrow).

clinically and radiographically. Clinically, HOA is manifested by pain and swelling of the soft tissues over the distal ends of the long and tubular bones. Radiographically, the distinctive feature of HOA is the formation of new bone beneath the periosteum of the distal diaphyses of the long bones of the extremities (Fig. 27-18).

The most common disorder associated with HOA is carcinoma of the lung. The incidence is about 5 percent and is unrelated to the cell type of the cancer, except that small-cell carcinoma is rarely implicated; a peripheral carcinoma of the lung is slightly more common than a central one. Joint symptoms precede the local signs of tumor in about one-third of the cases; the interval is sometimes as long as 2 years. Pulmonary metastases rarely cause HOA. Pulmonary tuberculosis is seldom, if ever, associated with HOA. Cystic fibrosis and idiopathic pulmonary fibrosis can be accompanied by HOA. Pregnancy can rarely be a cause of HOA, with symptoms resolving promptly with delivery.

As in the case of clubbing of the digits, theories about pathogenesis tend to focus on humoral factors generated elsewhere. However, a neurogenic theory has also been advanced on the basis of two types of observations: (1) in a few patients, vagotomy has relieved the symptoms of inoperable carcinoma of the lung and led to regression of the bony lesions; and (2) in keeping with the observations on the few patients, vagotomy in dogs is usually followed by a decrease in blood flow to the limbs. At present, neither theory has much convincing support, but both suggest future directions for exploration.

In contrast to clubbing of the digits, which is rarely painful, HOA associated with carcinoma of the lung often causes severe rheumatic symptoms. These symptoms vanish after resection of the carcinoma, even though clubbing usually remains. In patients who are treated with radiotherapy for unresectable carcinoma, pain in the vicinity of the joints usually decreases greatly and usually does not recur even if metastases develop to the lungs or elsewhere.

THORACIC PAIN

First thoughts about chest pain almost invariably turn to the pain of myocardial ischemia. However, cardiac pain is often distinguishable from other types of chest pain because of its viselike nature; its characteristic radiation to the left arm, shoulder, or neck; and its lack of relation to breathing. Extracardiac painful sensations can arise from various sites within the thorax, most often from the pleura, the lungs, and the chest wall. Pain may also be referred to the thorax as a result of GERD.

Pleuritic Pain

The most characteristic pain associated with the respiratory apparatus is pleural pain. It originates in the parietal pleura and endothoracic fascia; the visceral pleura is insensitive to pain. In contrast to the deep, oppressive substernal pain of myocardial infarction, pleuritic pain is identified by the patient as being close to the thoracic cage. It is predominantly an inspiratory pain reflecting the stretching of inflamed parietal pleura during movement of the thorax; coughing or laughing is exceedingly distressing; the patient often clutches the chest to minimize its excursion. The pain is usually local, but sometimes it spreads along the course of the intercostal nerves that supply the affected area. Irritation of the diaphragmatic pleura by an inflammatory process either below or above the diaphragm often causes ipsilateral shoulder pain when the central portion of the diaphragm is involved; sometimes the pain is referred to the abdomen when the outer diaphragmatic pleura is irritated.

As a rule, pleural pain is part of a syndrome of pleural inflammation that includes malaise and fever; an important exception to this generalization is the pleural pain of pulmonary infarction, which is often unassociated with any premonitory signs. In addition to inflammation and malignant etiologies, pleuritic pain occurs with pneumothorax.

Pulmonary Pain

A second distinctive type of respiratory chest pain accompanies a tracheitis or tracheobronchitis. The pain is searing and is most pronounced after cough. Invariably this central chest pain is associated with evidence of upper respiratory infection.

An uncommon type of chest pain is associated with pulmonary hypertension. It is usually absent at rest and appears during exertion. The pain is substernal and is invariably associated with dyspnea; it subsides promptly when exercise stops. It is often mistaken for left heart angina until the presence of pulmonary hypertension is uncovered. It may be due to right ventricular strain and ischemia.

Chest Wall Pain

Pain in the chest is a common clinical problem. It may arise from within the thorax (the heart, pericardium, lungs, pleura, chest wall) or be referred from elsewhere (e.g., from below the diaphragm). Characteristic patterns and associations may help to clarify the source of the pain.

Pleural pain is generally associated with fever or dyspnea. Most often it is abrupt in onset, unilateral, and incapacitating. As a rule, it affects the lower part of the chest, but occasionally it is referred to the shoulder or abdomen. Almost invariably, pleural pain is aggravated by deep breathing or coughing. The patient tends to splint the chest on the affected side. Tachypnea and shallow tidal volumes are a consistent pattern.

Musculoskeletal pain arising in the chest that is also aggravated by breathing may be confused with pleuritic pain. It is rarely severe and incapacitating, is often bilateral, and generally is intensified by changes in body position or flexing the thorax. The affected muscles are often tender to gentle pressure. A fractured rib is often identified as the source of pain by a history of a fall, injury, or trauma. Additional clues

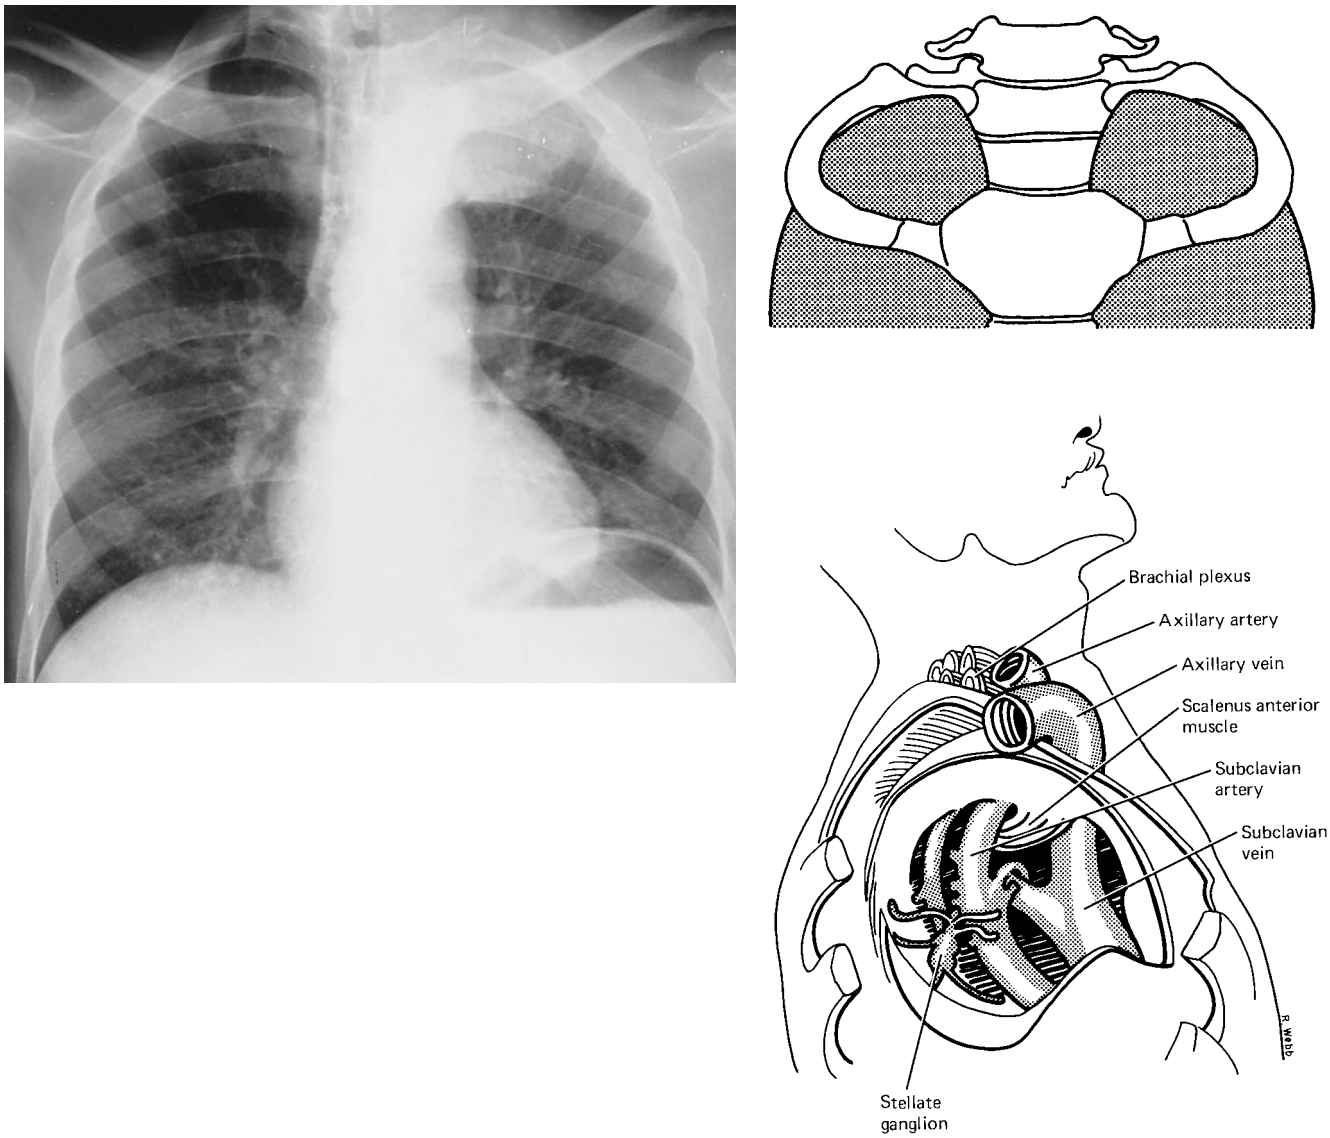


Figure 27-19 Pulmonary sulcus tumor. *A.* Chest radiograph. *B.* Relationships of apex of the lung to adjacent bony structures. *C.* Lateral view of area occupied by apex of lung, showing proximity not only to nerves of brachial plexus but also to sympathetic chain and to blood vessels. A mass that grows posteriorly and laterally can encounter sympathetic chain and bony structures; superiorly, the axillary vessels, brachial plexus, and bony structures; anteriorly, the subclavian vein and its tributaries. *(From Pernkopf: Atlas of Topographical and Applied Human Anatomy. Philadelphia, WB Saunders, 1964, p 22.)*

are point tenderness and crepitus of the affected area, reproduction of the pain upon manual compression of the chest, or radiographic evidence of the broken rib.

Pain arising from the large airways is usually burning in nature and retrosternal in location and is disturbing rather than incapacitating. It is aggravated by cough and is commonly accompanied by evidence of a bronchitis. Cold air may be intolerable.

The pain of a pulmonary sulcus tumor (Fig. 27-19) is quite distinctive. This unusual location of a carcinoma of the lung was originally described by Pancoast in 1932 as characterized by pain along the distribution of the eighth cervical and the first and second thoracic nerves, Horner's syndrome, local destruction of bone by the tumor, and atrophy of hand muscles. The chest radiograph is distinctive in showing a small, sharply defined shadow at one apex. Destruction of one or more of the upper three ribs posteriorly and of their adjacent transverse processes may also be observed.

Cardiac Pain

Attention was called above to the pain of myocardial ischemia. Another type of cardiac pain is that of pericarditis. Pericardial pain is often aggravated by deep breathing and, almost invariably, is accompanied by a telltale rub that is synchronous

with the heartbeat. The discomfort may be relieved by leaning forward.

The postcommissurotomy (postpericardiotomy) syndrome is characterized by chest pain that develops within a few days to weeks after cardiac surgery or pericardiotomy. The pain is usually sudden in onset and substernal, with radiation to the left side of the neck; often it is aggravated by deep breathing. Low-grade fever and a high sedimentation rate are regular concomitants. Chest pain can also be troublesome in patients who have undergone cardiac transplantation. The diagnosis is usually self-evident when account is taken of the antecedent history of cardiac surgery. Indeed, confusion is more apt to arise with the pain of myocardial infarction than with respiratory causes of chest pain.

Miscellaneous Pain

Other structures in the mediastinum can be the source of chest pain. Noteworthy are the types of pain arising from the esophagus (peptic esophagitis) and dissection of the aorta. Their patterns and intensity help to distinguish them from respiratory pain. Esophageal disease is typically accompanied by a burning pain, frequently after eating. Acid reflux may worsen with recumbency. Aortic dissection is often described with a sharp, tearing sensation of acute onset with radiation to the shoulder; these are often signs of impending cardiovascular collapse.

Arthritis of the cervical spine is a common cause of thoracic pain. Usually the cause is quite clear because of the characteristic distribution of the pain. Cervical spondylosis occasionally causes severe pain in the chest and arms, but it is more apt to mimic myocardial infarction than is respiratory pain. A metastatic tumor to the thoracic spine often causes bilateral symmetric pain; there is often discomfort to palpation over the affected area. Unilateral pain, along the distribution of an intercostal nerve, is characteristic of herpes zoster before the appearance of the skin eruption and is often described as an intense burning sensation.

Anxiety can produce or intensify chest pain. Usually, pain related to anxiety is accompanied by dyspnea and hyperventilation. Manifestations of vasomotor instability, such as excessive palmar sweating, flushing, and tachycardia, may accompany the complaint of chest pain due to anxiety. Rarely does the pain conform to a characteristic or consistent pattern. Anxiety also interferes with the quantification of pain originating in a somatic lesion and with its management.

FEVER

In the patient with lung disease, fever usually, but not invariably, signifies infection. When the lung disease is chronic, as in bronchitis and emphysema, a bout of acute bronchitis usually elicits only a modest fever, even though the sputum turns purulent. In contrast, an acute pneumonia of lung abscess may be associated with high fever.

The possibility that fever is due to infection lends urgency to the situation. Elsewhere in this book, the patterns of acute pulmonary infection are considered with particular attention to systemic effects, chest radiography, white blood cell count, sedimentation rate, and sputum examination. Often overlooked at the outset is miliary tuberculosis, which occasionally escapes detection on the initial chest radiograph. Favoring this diagnosis is a history of recent contact with a patient experiencing active tuberculosis, general malaise, easy fatigability, and anorexia during the previous few weeks. This insidious onset differs strikingly from the more sudden onset of acute pneumonia.

Neoplasms are also associated with fever. In certain neoplasms, such as carcinoma within a bronchus, the fever is generally a secondary effect attributable to infection distal to obstruction; necrosis within the tumor is a less common cause. In others, such as hypernephroma, fever and chills are striking, even though evidence of infection is absent. A mesothelioma of the pleura is often associated with fever. Presumably, in patients with neoplasms who have no evidence of infection, necrosis within the tumor leads to the elaboration of pyogenic substances within and around the tumor.

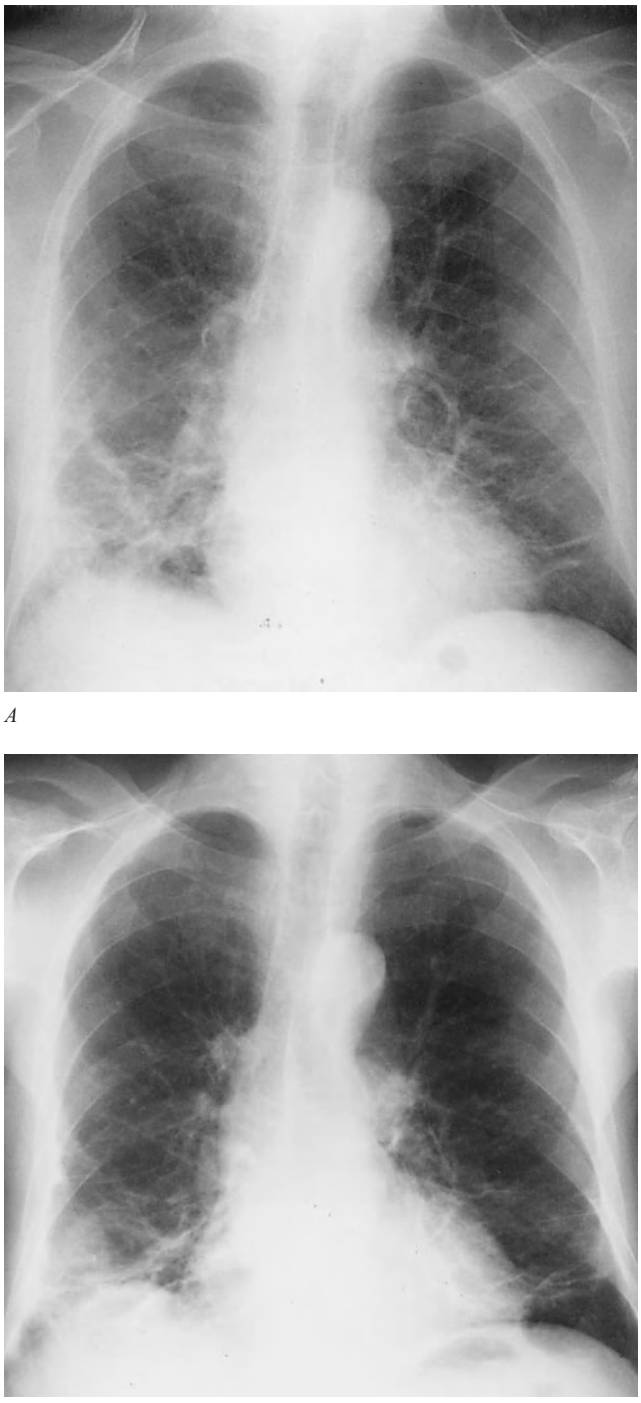
Hypersensitivity pneumonitis (extrinsic allergic alveolitis) is sometimes followed by fever as well as by pulmonary disability after exposure to the offending antigen.

In contrast to the pulmonary disorders in which fever is a characteristic feature, pulmonary sarcoidosis is uncommonly associated with fever unless there is extrapulmonary involvement, such as lymphadenopathy or erythema nodosum. Nor is pneumoconiosis associated with fever unless complicated by necrosis in the midst of conglomerate fibrosis or by superimposed tuberculosis. Among the other extensive disorders of the lungs that cause no fever (and few systemic complaints) are idiopathic pulmonary fibrosis, lymphangitic carcinomatosis, multiple pulmonary metastases, alveolar proteinosis, idiopathic pulmonary hemosiderosis, and alveolar microlithiasis.

RADIOLOGIC EVALUATION

The radiologic evaluation of the patient presenting with respiratory symptoms is dealt with in considerable detail elsewhere in this book (see Chapter 30). Over the years, the chest radiograph has become an invaluable tool, not only for diagnosis but also for following the result of treatment (Fig. 27-20) and for directing interventions. The value of routine screening films in asymptomatic subjects (e.g., as part of annual physicals or in chronic cigarette smokers to detect cancer) is still a matter of debate. The diagnostic yield of such studies has not been impressive. In contrast, the chest radiograph is an integral component of the initial evaluation of the patient with new respiratory symptoms.

In recent years, the conventional chest radiograph has been supplemented by a succession of imaging techniques, such as computed tomography, magnetic resonance imaging,



A

Pulmonary function tests improved dramatically along with clearing of the pulmonary lesions on the chest radiograph.

and positron emission tomography. Although these powerful tools are generally used as complementary techniques, they often assume primary roles (e.g., examination of the mediastinum for lymphadenopathy or invasion of the chest wall in a patient with carcinoma of the lung). As successive improvements in these techniques continue to be made, the future seems to hold even brighter prospects for these noninvasive methods.

COMMON CHRONIC PULMONARY DISEASES

The great majority of chronic pulmonary diseases that affect both lungs fall into four categories: chronic obstructive airway diseases, restrictive lung diseases, global alveolar hypoventilation, and obliterative pulmonary vascular diseases.

Chronic Obstructive Airway Disease

Obstruction of the airways generally occurs during expiration. Based on expiratory maneuvers, airway obstruction has been categorized by a wide variety of tests (see Chapter 50). But it is remarkable how much information about the obstruction can be obtained from the forced expiratory volume in 1 s (FEV_1; determined serially, before and after administration of a bronchodilator), inspection of the flow-volume loop, and arterial blood gas analyses. Preoccupation with expiration may obscure disorders characterized primarily by inspiratory obstruction. These are commonly overlooked because of failure to elicit stridor on the physical examination.

In asthma, generalized wheezing occurs during both inspiration and expiration. Except for attacks precipitated by specific antigens, two common mechanisms often precipitate an episode: a respiratory infection, usually viral rather than bacterial, and an emotional event. Between episodes, most asthmatics, even those who are symptom-free, can be shown to have heightened bronchomotor tone (Fig. 27-21). In a latent asthmatic, a brief period of hyperventilation generally suffices to induce a bout of asthma. In patients with left ventricular failure, a paroxysm of wheezing ("cardiac asthma") occasionally heralds the onset of acute pulmonary congestion and edema. The new onset of asthma in an elderly person should be carefully assessed with respect to the state of the left ventricle before vigorous bronchodilator therapy is initiated.

Restrictive Lung Disease

The diagnosis of restrictive lung disease usually begins with a complaint of dyspnea, reinforced by a telltale chest radiograph. Indeed, without abnormalities on the chest radiograph, detection of interstitial disease by pulmonary function testing is uncommon. The combination of tachypnea, the typical chest radiograph, concentric reduction in lung volumes, and the appearance of arterial hypoxemia during exercise almost invariably clinches the diagnosis; a low value for the

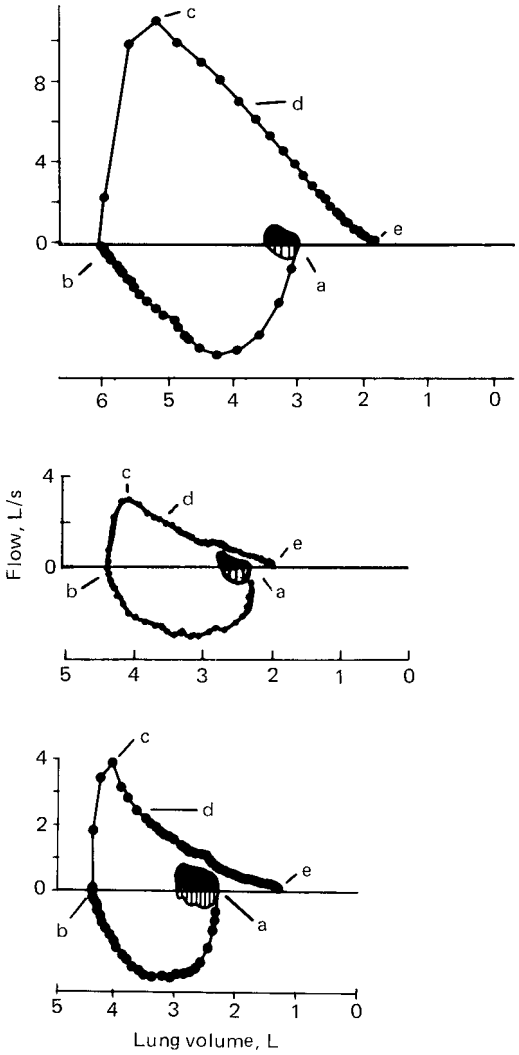

Figure 27-21 Simultaneous flow-volume curves in asthma. Top: Normal subject. Beginning at the end of a quiet expiration (a), the curves were recorded during a normal tidal breath (small, shaded loops) and during a forced expiration from peak lung inflation (b) to full expiration (e). Peak flow rates were reached at c. Expiration then continued along segment cde. In the record of the tidal breath, inspiration is hatched and expiration is solid black. The interval between each dot is 0.05 s. Center: Asthmatic subject. The vital capacity (be) is abnormally small, and flow rates along cde are diminished. Bottom: Same asthmatic subject 2 weeks after clinical recovery. Although flow rates are considerably higher than during the acute attack, the slope of segment de is still abnormally low, indicating that the resistance to airflow as lung volume decreases is still inordinately high. *(From Mellins R, Lord GP, Fishman AP: Dynamic behavior of the lung in acute asthma. Med Thorac 24:81–98, 1967, with permission.)*

diffusing capacity of the lungs is final proof and is useful in following the course of the disease. Much more troublesome is the identification of the cause (Table 27-6).

An important distinction at the outset is whether the disease is acute or chronic (Table 27-3). Some types of interstitial disease, such as asbestosis, take years to become symptomatic. Others, such as hypersensitivity pneumonitis can have a more fulminant onset.

Three weeks later. Reduction in size of cardiac silhouette and clearing of infiltrates after marked diuresis and treatment with antibiotics.

Another way to assist in categorization is the presence of systemic complaints. Sometimes, particularly in immunosuppressed patients, distinction between interstitial infection and interstitial edema may be difficult to make (Fig. 27-22). Persistent fever suggests infection. Lung impairment by a

systemic disease, such as scleroderma, is often suggested by telltale stigmas in extrapulmonary sites (Fig. 27-23). In some instances, the cause is self-evident. This relationship is striking in some occupational disorders (e.g., silo-filler's disease that occurs after exposure to moldy hay). Also, the chest radiograph in sarcoidosis or silicosis is sometimes so characteristic as to be virtually diagnostic (Fig. 27-24). But sometimes the cause remains enigmatic or idiopathic despite elaborate laboratory investigations, including lung biopsy.

In essence, uncovering the cause of diffuse interstitial fibrosis is often a matter of painstaking and discriminating medical detection. The flash of brilliant insight, in the tradition of Sherlock Holmes or Lord Peter Wimsey, is apt to

Figure 27-24 Sarcoidosis. Unilateral hilar adenopathy due to sarcoidosis in a 27-year-old asymptomatic man with left hilar adenopathy and interstitial lung disease of upper lobes. Bronchoscopic biopsy disclosed widespread noncaseating granulomas.

be less revealing about cause than is a meticulous, systematic account of lifestyle, habits, occupation, and background. The distribution and pattern of disease on the chest radiograph often provide clues to the next step in diagnosis. Sometimes the identification of abnormal constituents in sputum is diagnostically helpful (e.g., blood or blood products in the macrophages of the patient with Goodpasture's syndrome or eosinophils in the patient with a hypersensitivity disorder). In many instances, diagnosis rests on lung biopsy. Unfortunately, except in diseases such as sarcoidosis, biopsy is often deferred indefinitely, owing to a perceived lack of likely change in treatment. As a result, biopsy is usually performed at the stage of nonspecific interstitial fibrosis when scarring is so indiscriminate that neither etiology nor pathogenic mechanisms are decipherable.

As pointed out above, the physiological hallmarks of diffuse interstitial disease are those of restrictive lung disease (i.e., stiffening of the lung [low compliance] and concentric reduction in lung volumes [decrease in vital capacity, residual volume, and total lung capacity]). Accompanying the decrease in compliance is an increase in the work of breathing and a breathing pattern of rapid, shallow tidal volumes. The chest radiograph demonstrates the inability of the patient to expand fully the stiffened lungs. Dyspnea is evoked at first by mild exercise and later persists at rest.

The once-popular picture of widespread disease confined to the alveolar-capillary interstitium has been modified by the recognition that alveoli are generally implicated in the underlying process. In interstitial pulmonary edema, groups of alveoli are often flooded. In inflammatory processes, such as sarcoidosis or desquamative interstitial pneumonia, alveoli,

as well as the interstitial space, are commonly caught up in the process. In pneumonia caused by *Pneumocystis carinii (Pneumocystis jiroveci)*, the organisms are found in alveoli as well as in the interstitial spaces. Therefore, the designation of diffuse interstitial disease should not be misconstrued as being confined solely to the interstitium of the lungs, even though the term generally does identify the predominant seat of disease.

Syndromes of Alveolar Hypoventilation

The common denominator in disorders characterized by alveolar hypoventilation is an abnormally high value for arterial (and alveolar) P_{CO_2}. The most common cause is chronic bronchitis and emphysema (COPD), which produces hypercapnia by deranging ventilation-perfusion relationships. This "net" alveolar hypoventilation is conceptually different from the "generalized" alveolar hypoventilation that results from a disorder of respiratory control or of the chest bellows as occurs in kyphoscoliosis, respiratory muscle weakness, or obesity-hypoventilation. The usual manifestation of generalized alveolar hypoventilation is the combination of normal lung volumes and FEV_1, normal chest radiograph in conjunction with arterial hypoxemia, hypercapnia, and respiratory acidosis.

Obliterative Vascular Disease

Pulmonary thromboemboli usually affect large as well as small vessels. Occlusive vascular diseases, such as idiopathic pulmonary arterial hypertension, which are more confined to small ("resistance") pulmonary vessels, are much less common. More often, the pulmonary resistance vessels are caught up in the adjacent and surrounding diffuse interstitial disease. In pulmonary vascular disease that compromises the area available for gas exchange, the diffusing capacity becomes subnormal. Occlusive vascular diseases of the lung are usually recognized when the extent of the disease is sufficient to cause considerable pulmonary hypertension. The diagnosis is most often first suggested by the estimated pulmonary artery pressure in the echocardiogram. Additional testing is required to establish the cause (e.g., pulmonary function testing to rule out airways obstruction, a polysomnogram to assess possible sleep apnea); confirmation of pulmonary arterial hypertension requires right heart catheterization.

CHOOSING PULMONARY FUNCTION TESTS

In Chapter 34, pulmonary function testing is discussed in some detail. Often a combination of pulmonary function tests is needed to characterize a patient's abnormalities. Pulmonary function tests can be particularly helpful in obstructive diseases of the airways, in which chest radiographs are often normal. Some of the tests are simple; others require special facilities and personnel. For example, closing volume and closing capacity, previously popular as "sensitive" tests for obstruction of small airways, have proved to be of little clinical value. There is certainly no value to these tests once the FEV_1 is abnormal. Nonetheless, the possibility exists that such sensitive tests may be useful in special conditions (e.g., in assessing obstruction of small airways in occupational disease).

The battery of tests that is used experimentally to portray the full length and breadth of the patient's pulmonary disorder is rarely needed for clinical purposes. However, only a few physiological test patterns result from a wide variety of causes. Indeed, virtually all diffuse diseases of the lungs and airways that compromise pulmonary performance can be categorized into four distinctive patterns: (1) obstructive disease of the airways, (2) restrictive lung disease, (3) obliterative vascular disease, and (4) alveolar hypoventilation due to malfunctioning of the chest bellows or control mechanisms.

Skin Disease in Patients with Pulmonary Disease

Jeffrey P. Callen

Examination of the skin can provide important clues in the diagnosis and treatment of persons with pulmonary disease. Some skin lesions either accompany pulmonary disease or complicate its treatment; occasionally, systemic diseases that affect both skin and lung first manifest themselves in the skin. In this chapter we deal briefly with processes in which there is prominence of cutaneous manifestations that might impact the care of the patient with pulmonary disease. The diagnosis and development of a differential diagnosis of cutaneous lesions is beyond the scope of this chapter and can be found in general dermatologic texts.

ATOPIC DERMATITIS

Atopy refers to a group of disorders, including asthma, allergic rhinitis, and atopic dermatitis, in which immune and pharmacologic responses are abnormal. The atopic person usually has a family history of one or more of these disorders. Atopic dermatitis is a common disorder, affecting 1 to 3 percent of the population in the United States. In 85 percent of affected subjects, the skin lesions appear before 5 years of age. The dermatitis often resolves as the patient reaches adulthood; in

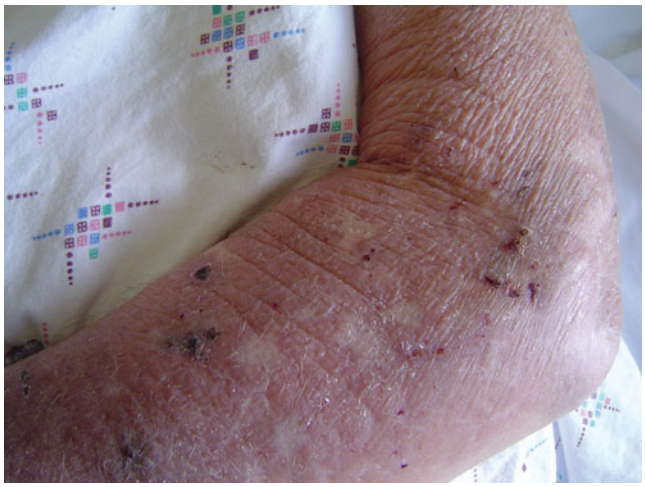

Figure 28-1 Atopic dermatitis is characterized by lichenification, excoriations and slight scale.

the adult, either the skin lesions or respiratory systems may predominate.

In infants, the skin lesions often begin as dry, erythematous plaques on the cheeks; excoriations and scaling may be prominent. In older children, the lesions localize in flexures; lichenification and excoriated papules are prominent features (Fig. 28-1). In adults, the lesions favor the hands and extremities. Atopic subjects also manifest prominent folds of the lower eyelids, periorbital hyperpigmentation with facial pallor, generalized dry skin, and white dermatographism. At any age, pruritus may be prominent and become secondarily infected, leading to bacterial impetigo within the lesions. In some patients, increased itching may be a prodrome to exacerbation of asthma.

The cause of atopic dermatitis is unknown. In all likelihood, the pathogenesis is multifactorial, probably including disordered immune regulation as a causative factor. In persons with atopic dermatitis, abnormalities in cell-mediated immunity and lymphocyte function increase the risk of disseminated viral and fungal skin lesions. The role of food or environmental antigenic challenge in flares of atopic dermatitis is unsettled, but it is known that asthma can be precipitated by such challenges.

The relationship between atopic dermatitis and lung disease is imperfect. Although hyposensitization is useful for asthma, it is either not helpful or is detrimental in atopic dermatitis.

Treatment of atopic dermatitis in adults is multifaceted. The patient should avoid irritants. Bathing can occur on a daily basis, but should be followed by the application of emollients. Patients with atopic dermatitis frequently harbor or develop infections, particularly *Staphylococcus aureus* and eradication of infection is useful in those instances. Topical therapy with corticosteroids of an appropriate strength and in an appropriate vehicle for the site on the body that is being treated is a standard form of therapy. Recently topical calcineurin inhibitors, including pimecrolimus and tacrolimus, have been used as an adjuvant or as a replacement for topical corticosteroids. Full discussions of the therapy of atopic dermatitis are available elsewhere.

COLLAGEN VASCULAR DISORDERS

Dermatomyositis

Dermatomyositis (DM) is an idiopathic inflammatory myopathy characterized by proximal, symmetrical, slowly progressive muscle weakness and characteristic cutaneous lesions. The skin lesions that are pathognomonic include a heliotrope eruption, which consists of erythematous to violaceous periorbital changes that may be accompanied by edema (Fig. 28-2). Gottron's papules are also pathognomonic for DM and consist of erythematous papules over the bony prominences on the dorsal hands (Fig. 28-3). In addition, patients might manifest a photodistributed poikiloderma

Figure 28-2 Heliotrope eruption of dermatomyositis.

Figure 28-3 Gottron's papules in dermatomyositis: Erythematous to violaceous lesions are most prominent over the joints. In addition, this patient demonstrates cuticular and periungual changes that are frequent in dermatomyositis.

Figure 28-4 Photodistributed poikiloderma in a patient with dermatomyositis.

Figure 28-5 Acrosclerosis characterized by marked contractures and sclerodactyly.

(Fig. 28-4), nail fold changes, and an erythematous to violaceous scaly alopecia. Patients with dermatomyositis frequently complain of marked itching. Patients with dermatomyositis may also have other systemic manifestations, including arthritis, esophageal disease, and cardiopulmonary disease. Some patients with dermatomyositis have a malignancy. Others with the characteristic cutaneous lesions of DM are not weak and do not have an increase in muscle-derived enzymes. These patients are said to have amyopathic dermatomyositis.

Pulmonary disease occurs in dermatomyositis and polymyositis (PM) in approximately 15 to 65 percent of patients. Interstitial pneumonitis is a primary process in DM/PM. Kang et al. have demonstrated that interstitial lung disease also occurs in patients with amyopathic dermatomyositis; in this subset of patients survival is poor. Pulmonary involvement is more frequent in patients with esophageal dysfunction. Lung disease may also occur as a direct complication of the muscle disease, such as hypoventilation or aspiration in patients with dysphagia, or may be a result of treatment, such as opportunistic infections or drug-induced hypersensitivity pneumonitis. In a retrospective review of 70 patients with myositis-associated interstitial lung disease seen at the Mayo Clinic between 1990 and 1998, most presented with either symptoms of lung disease or symptoms of myositis alone; in only 15 did the involvement occur simultaneously. The lung disease was originally felt to be a pneumonitis that was antibiotic resistant. Biopsy of the lung revealed non-specific interstitial pneumonitis or diffuse alveolar damage in a majority of those who were biopsied. Only two patients had bronchiolitis obliterans organizing pneumonia (BOOP). It is unclear how many of the patients had dermatomyositis; perhaps between 8 and 12. Therapy included corticosteroids with or without an immunosuppressive agent. However, the prognosis is poorer for these patients than for unselected patients with myositis, as demonstrated by a 5-year survival of 60.4 percent. Patients with Jo-1 antibodies (19 of 50 who were tested) had roughly the same features and prognosis as those who did not have these antibodies.

Scleroderma

Scleroderma refers to hard skin. This process may be localized to the skin or may be part of a systemic disease. Localized scleroderma may occur as limited plaques of morphea, generalized morphea, deep morphea, or linear scleroderma. Despite the fact that the disease occurs primarily on the skin, in rare instances pulmonary disease in the form of interstitial pneumonitis may complicate the course of the disease.

There are two principal forms of progressive systemic sclerosis (PSS): limited scleroderma (acrosclerosis) and diffuse scleroderma. Acrosclerosis is the more common of the two, and is characterized by sclerosis of the skin of the fingers (sclerodactyly) (Fig. 28-5) and Raynaud's phenomenon (Fig. 28-6). A variant known as the CREST syndrome includes esophageal dysfunction, telangiectasia, and calcinosis. In contrast, patients with diffuse scleroderma have widespread sclerosis beyond the acral areas of sclerodactyly. The prognosis for diffuse scleroderma is much worse than for acrosclerosis. Both types of scleroderma are often preceded by Raynaud's phenomenon, diffuse arthralgias, or arthritis. The skin manifestations begin with transient, recurrent swelling of the hands and progress to tapered fingers with shiny, hidebound skin (sclerodactyly). The feet, chest, face, and scalp are often involved in the sclerotic process. In time, the skin becomes taut, leading to contractures of the large and small joints that culminate in a claw-like deformity of the hand. A variety of pigmentary disturbances may occur in scleroderma, including generalized hyperpigmentation that resembles adrenal insufficiency, focal hyperpigmentation, and hypopigmentation, and areas of perifollicular pigmentation that resemble vitiligo (Fig. 28-7). Raynaud's phenomenon leads to small pitted scars at the fingertips or frank ulceration, with or without gangrene of the fingertips, toes, knuckles, and ankles, especially the malleoli.

Figure 28-6 Raynaud's phenomenon in this patient was so severe that autoamputation of the distal digits occurred.

The face often undergoes distinctive changes, leading to a fixed stare and inability to wrinkle the forehead. As the facial tissues shrink, the nose becomes pinched, the cheeks sunken, the mouth narrows, and the lips thin. In diffuse scleroderma, cutaneous sclerosis, accompanied by a yellowish-brown hue, spreads from the chest to the head and extremities. Sharply delineated, broad telangiectatic macules appear on the face, buccal mucosa, lips, and hands.

PSS is associated with interstitial pneumonitis. This is more common in patients with diffuse disease than in patients with limited disease. Pulmonary hypertension has been reported to occur in patients with CREST syndrome.

Treatments for the cutaneous disease are multiple, but few have been tested in double-blind, randomized trials. Raynaud's phenomenon is treated by avoidance of exposure to cold, and with calcium channel-blocking agents such as nifedipine, angiotensin-2 receptor antagonists such as lorsartan and most recently with phosphodiesterase type 5 inhibitors such as sildenafil or tadalafil. Ulcerations from scleroderma might be treated with the endothelin receptor antagonist bosentan. Localized scleroderma (morphea) might be treated with topical application of superpotent corticosteroids or calcipotriene. Systemic therapy with methotrexate seems promising in patients with progressive skin disease, although the therapy of systemic sclerosis is beyond the scope of this chapter. Over time the sclerosis that involves the skin seems to improve naturally; therefore, studies that suggest benefit based on improvement of the cutaneous disease should be interpreted cautiously.

Figure 28-7 Vitiligo-like dyspigmentation associated with progressive systemic sclerosis.

INFECTIONS

Blastomycosis

Skin lesions are as common as pulmonary lesions in patients with blastomycosis. Cutaneous disease usually represents dissemination from a pulmonary focus that is often small and may be inapparent. The typical presentation is as a solitary nodule or multiple papules or nodules on the face, wrists, hands, or feet, which subsequently ulcerate and discharge pus (Fig. 28-8). The lesions grow eccentrically at the periphery and atrophy centrally over a period of months, eventually forming an arciform or serpiginous contour with sharply elevated and verrucous borders. Miliary abscesses occur along the borders of the lesions. In addition to the cutaneous involvement, osteolytic lesions may occur in the bones. Patients with cutaneous blastomycosis should be treated with antifungal therapies such as itraconazole, fluconazole, ketoconazole, or amphotericin B.

Coccidioidomycosis

Coccidioidomycosis is usually manifest as a pulmonary infection. In its acute form, it is often associated with cutaneous symptoms; roughly 20 percent of patients develop erythema nodosum. Erythema nodosum is often accompanied by fever, arthritis, and eosinophilia. In patients with progressive pulmonary disease and eventual disseminated disease, the skin may be affected; subcutaneous granulomatous eruptions form and undergo necrosis and ulceration. After several months, the lesions tend to become verrucous. A third form is primary cutaneous disease, which occurs in farmers and laboratory workers as a chancriform lesion with sporotrichotic spread. This variant is extremely rare. Acute disease is often self-limiting and requires only symptomatic management; however, disseminated disease requires aggressive antifungal therapy and is associated with a poor prognosis.

Actinomycosis

The thoracic form of this disease presents as a pulmonary parenchymal process that sometimes forms multiple draining sinus tracts. Diagnosis is often difficult, but identification

A *B*

Figure 28-8 *A–B.* Blastomycosis: verrucous lesions on the face *(A)* and trunk *(B)*.

of sulfur granules in the draining exudates is helpful. Treatment with penicillin or tetracycline may eliminate the need for surgery.

Tuberculosis

Cutaneous involvement results from direct inoculation with the tubercle bacillus, via either the skin or mucous membranes or as a consequence of widespread organ involvement that begins in the respiratory tract.

When the tubercle is introduced via the skin or mucous membranes by a contaminated syringe or a wound in a previously unexposed host, a nodule usually develops at the site of injury. Within several weeks, the nodule evolves into a chancre, a well-circumscribed ulcer. Particularly if host defenses are impaired, these chancriform lesions, which are typically located on the extremities, develop associated regional lymphadenitis, followed by systemic dissemination of the organism.

A person who was previously infected with *M. tuberculosis* is apt to develop *tuberculosis verrucosa cutis* after receiving a cutaneous inoculation. The characteristic lesion in a sensitized person is a papule or a pustule, which becomes verrucous. On occasion, this disorder produces plaque-like lesions of the extremities consisting of verrucoid–indurated papules surrounded by an erythematous halo.

Lupus vulgaris is the most common form of cutaneous post-primary tuberculosis that follows inoculation or lymphatic or hematogenous spread of *M. tuberculosis.* Patients with this disorder typically present with reddish-brown plaques surrounded peripherally by yellowish nodules, especially on the neck or extremities. The skin lesions tend to spread centrifugally as the center becomes atrophic. Papillary growths also occur in the nasal, buccal, and conjunctival mucosa. Histologically, lupus vulgaris generally shows epithelioid tubercles with caseation necrosis. Chronic cutaneous eruptions tend to involute, leaving considerable scarring. Chemotherapy with the usual antituberculosis drugs is effective in treating these skin manifestations.

Disseminated miliary tuberculosis can result in macules, papules, or vesicles. In children, especially those who are debilitated, subcutaneous nodules or gummas appear, ulcerate, and eventually develop draining sinus tracts, especially in the extremities and trunk. *Scrofuloderma,* which occurs following the necrosis of cervical nodules, is associated with fistula and sinus tract formation in the overlying cutaneous tissues.

Tuberculids are skin lesions that are considered to represent either a hypersensitivity reaction to *M. tuberculosis* or an embolic response to atypical *Mycobacteria.* Erythema nodosum also occurs in association with primary tuberculosis.

NEOPLASTIC DISORDERS

Kaposi's Sarcoma

Early in the epidemic of HIV infection, the incidence of Kaposi's sarcoma (KS) increased. However, since the advent of HAART therapy, KS again became less common. KS can occur in any immune-suppressed individual whether the immune dysfunction is due to HIV infection, age, or iatrogenic immunosuppression in transplant recipients. Human herpesvirus-8 (HHV-8) has been identified and linked to all forms of KS. In addition, a recent report has documented that HHV-8 viremia is associated with progression on KS in both classic and endemic forms. In the elderly population, KS has an indolent course and occurs primarily on the lower extremities. At the outset, the lesions are dark-blue, purplish, or reddish papules, macules, and nodules (Fig. 28-9). After months to years, plaques evolve in association with thickening of the skin from midtibia to ankle and lymphedema. In patients with immune dysfunction, including AIDS, KS is more aggressive and is often widespread in its cutaneous manifestations.

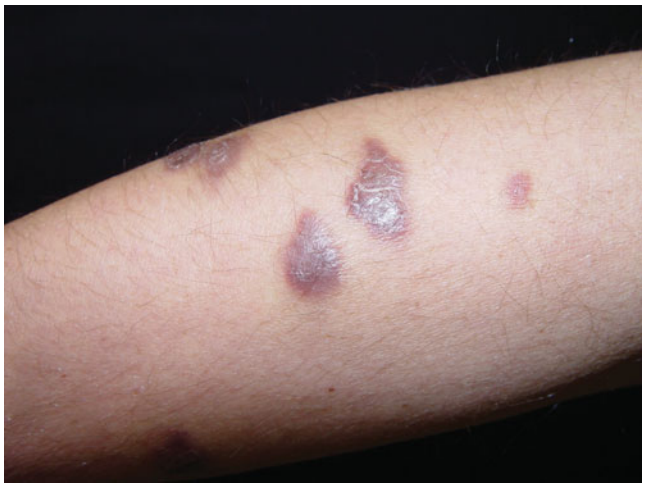

Figure 28-9 Kaposi's sarcoma in an HIV-positive patient.

Figure 28-10 Tripe palms. *(Courtesy of Dr. Jon Dyer.)*

The respiratory tract is second only to the gastrointestinal tract in frequency of systemic involvement. Tumors may involve the larynx, trachea, bronchi, pulmonary parenchyma, and pleura. Accordingly, local manifestations of respiratory tract involvement range from hoarseness, signs of airway obstruction, cough, and hemoptysis, to dyspnea. When the parenchyma of the lung is affected, chest radiographs usually show many small nodules; occasionally, parenchymal infiltration of the lung is massive. On bronchoscopic examination, bronchial and tracheal lesions appear as small bluish nodules. Bloody pleural effusions are rare.

Treatment of KS associated with immune suppression involves correction of the dysfunction by discontinuing immunosuppressive drugs when feasible or reconstitution of immune function in the HIV-infected individual. Local therapies for skin lesions include topical application of alitretinoin gel, liquid nitrogen cryotherapy, local irradiation, intralesional interferon, systemic interferon-α2a, or systemic chemotherapy. Liposomal doxorubicin or paclitaxel infusions are reserved for patients with extensive skin disease or systemic disease.

Lung Cancer and the Skin

Several paraneoplastic syndromes may occur in patients with lung cancers. In most instances the dermatosis is not specific for lung cancer; other sites may be involved. The following are some of the more ominous manifestations of potential pulmonary malignancy.

Tripe palms is a paraneoplastic condition that is manifest as rugose thickening of the palms and occasionally the soles (Fig. 28-10). Patients often have coexistent acanthosis nigricans (AN) and sometimes the sign of Leser-Trélat. Patients with tripe palms and AN usually have adenocarcinomas of the gastrointestinal tract; however, when tripe palms occurs in the absence of AN, patients often have squamous cell carcinoma of the lung. There is no known treatment for the cutaneous changes other than removal of the tumor.

Patients with *Bazex syndrome (acrokeratosis paraneoplastica)* develop an erythematous to violaceous psoriasiform eruption primarily on acral surfaces (Fig. 28-11). The ears, nose, cheeks, hands, feet, and knees are most often affected, but the nails may become dystrophic and the palms and soles may develop a keratoderma in later stages of the disease. The disorder may develop in stages, and is associated primarily with carcinomas of the upper respiratory and digestive tracts (larynx, pharynx, trachea, bronchus, and/or upper esophagus); the malignancy is often detected concurrently. If the tumor is effectively treated the eruption may resolve, but may return with tumor recurrence. There is no known effective treatment for the cutaneous eruption, although corticosteroids and keratolytic agents have been used.

Ectopic ACTH-producing tumors cause many of the typical signs and symptoms of Cushing's syndrome. Intense hyperpigmentation, present in only 6 to 10 percent of patients with Cushing's disease, is especially common in association with ectopic ACTH production and should alert the clinician to the possibility of a hormone-secreting tumor. Although

Figure 28-11 Acrokeratosis paraneoplastica (Bazex's syndrome). This patient was thought to have psoriasis prior to the diagnosis of a squamous cell carcinoma of the tonsillar pillar.

the cause of the hyperpigmentation is unclear, it may be related to tumor production of the peptide β-lipotropin, which contains within its sequence of 91 amino acids the 22–amino acid sequence of β-MSH. A myasthenia gravis–like syndrome, including profound proximal muscle weakness, may be a striking clinical feature and may reflect either underlying hypokalemia or polymyositis. Oat cell carcinoma of the lung is the tumor most often associated with ectopic ACTH production, although other malignancies have been reported.

The *carcinoid syndrome* is a second example of a hormonal syndrome associated with a nonendocrine tumor. The disorder is probably most often caused by the release of the enzyme kallikrein from tumor cells with subsequent conversion of kininogen to vasoactive kinin peptides, including bradykinin; in addition, increased blood levels of histamine may be important in the rare metastatic gastric carcinoid. The most striking cutaneous manifestations are episodes of flushing, initially lasting 10 to 30 minutes and involving only the upper half of the body; as the flush resolves, gyrate and serpiginous patterns may be noted. With successive attacks more extensive areas may be affected and the redness takes on a cyanotic quality, eventually leading to a more permanent facial cyanotic flush with associated telangiectasia, resembling rosacea. Persistent edema and erythema of the face may result in leonine facies. A pellagra-like picture, which has been noted in some patients, may be due to abnormal tryptophan metabolism. Systemic symptoms associated with the cutaneous flushing include abdominal pain with explosive watery diarrhea, shortness of breath, and hypertension.

Carcinoid tumors are usually found in the appendix or small intestine; extraintestinal carcinoid tumors may arise in the bile ducts, pancreas, stomach, ovaries, or bronchi. The carcinoid syndrome occurs primarily when an intestinal carcinoid tumor metastasizes to the liver or with extraintestinal tumors; flushing attacks can be provoked by palpation of hepatic or abdominal metastases or by alcohol ingestion, enemas, emotional stress, or sudden changes in body temperature. When the syndrome is associated with bronchial adenomas of the carcinoid variety, the flushing is more prolonged and often associated with fever, marked anxiety, disorientation, sweating, salivation, and lacrimation.

Migratory superficial thrombophlebitis and multiple deep venous thrombosis have been noted in cancer patients, especially those with tumors arising in the pancreas, lung, stomach, prostate, or hematopoietic system. The neck, chest, abdominal wall, pelvis, and limbs are most frequently affected.

Lymphomatoid Granulomatosis

The skin is the most commonly affected extrapulmonary site in lymphomatoid granulomatosis, occurring in 40 to 50 percent of patients. In 10 to 25 percent of patients, the skin lesions are the first clinical evidence of the disorder; the skin lesions precede involvement of the lungs by 2 weeks to 9 years. Because of the frequent occurrence of skin lesions, ease of biopsying the skin, and characteristic histology of these disease, careful dermatologic examination should be carried out in patients suspected of having lymphomatoid granulomatosis.

Figure 28-12 Lymphomatoid granulomatosis. This young woman developed the acute onset of multiple erythematous plaques on her face, accompanied by dyspnea and fever. She died within a month from pulmonary disease.

The characteristic cutaneous lesions in lymphomatoid granulomatosis are 1- to 4-cm erythematous-to-purplish dermal papules, or subcutaneous nodules, with or without ulceration. The lesions generally occur over the buttocks, thighs, and lower extremities (Fig. 28-12), but may occur anywhere. Healing is often accompanied by scarring and hyperpigmentation.

This histopathology of the skin lesions is similar to that of the lesions in the lungs, and is characterized by a marked angiocentric and angiodestructive lymphohistiocytic infiltrate composed predominantly of CD4-positive T cells. EBV-positive B cells are often present. This disorder is presumed to be a T-cell–rich B-cell lymphoproliferative disease.

The papules or nodules in lymphomatoid granulomatosis sometimes clear spontaneously; more often, they recur or progress. The skin lesions seem to respond to therapy with systemic corticosteroids and cyclophosphamide. Recently the use of rituximab has been associated with a favorable outcome in some patients. Localized radiation therapy has been used for some refractory skin lesions.

REACTIVE DERMATOSES

Clubbing and Hypertrophic Osteoarthropathy

Pachydermoperiostosis is a syndrome in which hypertrophic osteoarthropathy is associated with cutaneous changes of the face and extremities that are similar to those that occur in patients with acromegaly. Although this disorder is generally benign, it is occasionally associated with bronchogenic carcinoma.

Figure 28-13 Erythema nodosum. Red tender subcutaneous nodule on the leg.

Erythema Nodosum

A relatively common process, erythema nodosum (EN) is usually acute and self-limited. The typical clinical presentation is the sudden onset of one or more, tender, erythematous nodules on the anterior legs, which are more easily palpated than visualized (Fig. 28-13). The eruption is often preceded by a prodrome of fever, malaise, and/or arthralgias. As the lesions age, they may develop an ecchymotic appearance. Over a 4- to 6-week period they eventually heal without scar formation. Ulceration of the primary process is rare. Although EN is usually an acute process, patients with chronic or recurrent disease have been described using such terms as chronic EN, EN migrans, subacute nodular migratory panniculitis (Vilanova's disease), or septal granulomatous panniculitis. Chronic or recurrent EN most commonly occurs in middle-aged women. The disease is often present for several years, and is most common on the legs.

Etiologic or associated conditions are present in about 50 percent of patients with EN. The associated conditions can be divided into three broad categories: infections, drugs, or systemic diseases (usually inflammatory disorders). The infectious agents associated with EN tend to primarily affect the respiratory or gastrointestinal tract and are most often bacterial or fungal in origin. The most common drugs are antibiotics and oral contraceptives. Pregnancy, particularly in its second trimester, is a known association, and the EN will recur with subsequent pregnancies or with the administration of oral contraceptives. EN-like lesions may occur in Behçet's disease and are accompanied by oral and genital ulcerations, pathergy, uveitis, and/or central nervous system (CNS) disease or other systemic manifestations. A specific variant of sarcoidosis associated with EN is known as Löfgren's syndrome. This is an acute, self-resolving process in which EN occurs with bilateral hilar lymphadenopathy, arthritis, and anterior uveitis. Granulomatous colitis (Crohn's disease), regional enteritis, and ulcerative colitis have been associated with EN. In patients with inflammatory bowel disease, it appears that the EN parallels the activity of the bowel disease. At least half of the cases of EN are not found to have an associated or underlying process.

The treatment of EN first involves assessment of a causative disease and its treatment. In the absence of a treatable disorder, therapy is symptomatic. Acute EN is often self-limited, thus non-toxic therapies are advised. Bed rest and leg elevation are very helpful in controlling symptoms. In patients who need to continue to be ambulatory, support stockings or tights may be helpful. Aspirin or other NSAIDs may be helpful. Sometimes, however, treatment with aspirin does not produce results prior to toxicity; therefore, oral indomethacin (25–75 mg/day) is recommended.

In patients with chronic EN or frequent recurrences, oral potassium iodide 300 to 900 mg/day has been useful in open clinical trials. When the drug is stopped or the dose is lowered the disease often relapses, only to respond again to the reinstitution of therapy. Other therapies that may be considered include oral corticosteroids, colchicine, hydroxychloroquine, or an immunosuppressive agent.

Neutrophilic Dermatoses: Sweet Syndrome and Pyoderma Gangrenosum

Sweet syndrome (Fig. 28-14) and pyoderma gangrenosum (Fig. 28-15) are distinct dermatoses, but share common associations and are often managed with similar therapies. In addition, a condition known as neutrophilic dermatosis of the dorsal hands (Fig. 28-16) often has characteristics that overlap between a superficial variant of pyoderma gangrenosum (also termed atypical pyoderma gangrenosum) and Sweet syndrome. The associated diseases include inflammatory bowel disease, rheumatoid arthritis, and myelogenous malignancy and pre-malignancy. Extracutaneous neutrophilic inflammation has been reported in multiple organs, but the most frequently reported are the lungs. The inflammatory reaction can cause infiltrates including cavitary disease. It is critical that infectious diseases be excluded with appropriate culture prior to initiating therapy with corticosteroids with or without immunosuppressive therapy.

Figure 28-14 Acute febrile neutrophilic dermatosis (Sweet syndrome): erythematous plaque with what appears to be vesiculation on the surface.

Figure 28-15 Pyoderma gangrenosum: large ulceration on the leg with a violaceous, undermined border. This patient had active Crohn's disease.

Pruritus

Pruritus is a symptom that accompanies many dermatoses, but may also accompany systemic diseases. Patients without an obvious cause for their itching require a systemic evaluation, which usually includes a chest x-ray. Causes for pruritus are not commonly found, but Hodgkin's disease and other malignancies might be uncovered during the evaluation. Effective treatment of an underlying malignancy will result in a disappearance of the pruritus.

Urticaria

Urticaria is a reactive cutaneous disease manifest by transient urticarial skin lesions. Acute urticaria is almost always due to the ingestion of a food or medication and usually subsides within several days. The presence of chronic urticaria requires a thorough evaluation and at times the pulmonary evaluation might reveal an infectious, inflammatory, or neoplastic cause for the urticaria. This happens in less than 25 percent of patients.

Figure 28-16 Neutrophilic dermatosis of the dorsal hands (aka atypical pyoderma gangrenosum). Such patients often have a hematologic malignancy or pre-malignant process.

Vasculitic Syndromes

Churg-Strauss Syndrome

The clinical picture of allergic rhinitis, asthma, peripheral eosinophilia, and pulmonary infiltrates concomitant with systemic vasculitis has been designated the Churg-Strauss syndrome. However, the histologic finding of necrotizing granulomas and tissue eosinophilia is not unique to this clinical syndrome. Indeed, the same histologic appearance may be seen in a wide variety of systemic diseases, including allergic granulomatosis, Wegener's granulomatosis, rheumatoid arthritis, and lymphoproliferative disease.

One or more types of skin lesions develop in 70 percent of patients with Churg-Strauss syndrome. Most common is palpable purpura of the extremities; histologically, these lesions show necrotizing vasculitis without granuloma formation. In one-third of the patients, the cutaneous lesions are nonspecific—i.e., erythematous and urticarial. In another one-third, however, the skin lesions are distinctive—i.e., tender red to violaceous, indurated nodules, measuring 0.5 to 2 cm, which develop central crusting or become infarcted. These nodules occur most often over the scalp or symmetrically over the extensor surfaces of the extremities. It is these nodules that are most likely to have the histologic picture of necrotizing granulomatous vasculitis and eosinophilic infiltration; immunofluorescence staining may show vascular deposition of fibrin and complement. The skin lesions in Churg-Strauss syndrome generally respond to systemic corticosteroids or adjuvant cytotoxic therapy.

Wegener's Granulomatosis

About 45 percent of patients with Wegener's granulomatosis have cutaneous manifestations, most often small vessel vasculitis. Occasionally, biopsy of the skin lesions reveals a granulomatous vasculitis. In addition, the presence of cutaneous disease is usually indicative of active systemic involvement; therefore, such patients should be carefully evaluated and aggressively treated.

Polyarteritis Nodosa

Patients with polyarteritis nodosa frequently have cutaneous lesions. The skin disease may represent small vessel vasculitis as in Wegener's granulomatosis or may represent medium-sized vessel involvement. In the latter case the manifestation is livedo reticularis or ulceration. Treatment of polyarteritis should include corticosteroids along with an immunosuppressive agent.

Urticarial Vasculitis

Urticarial lesions can occur in patients as a manifestation of small vessel vasculitis. McDuffie et al. first described urticarial vasculitis in four patients with recurrent attacks of erythematous urticarial and hemorrhagic skin lesions associated with synovitis and, sometimes, abdominal distress. Their patients

did not have lupus erythematosus or paraproteinemia, but did have hypocomplementemia; two had nephritis.

Urticarial lesions may also be an early clinical manifestation of lesions that become typical palpable purpura. The spectrum of urticarial vasculitis has also grown, in recent years, to include the presence of lung disease characterized by asthma or obstructive lung disease. Patients with hypocomplementemic urticarial vasculitis often have or develop obstructive pulmonary disease, whereas most patients with normal complement levels, chronic urticaria and vasculitis have little or no systemic involvement.

The burning or itching of the lesions most often irritates patients with urticarial vasculitis. The patient should be first treated with antihistamines. Histamine 1 receptor (H_1) antagonists can be combined with H_2 antagonists, but the doses required often result in drowsiness. In some cases, the use of doxepin hydrochloride, which has effects on both H_1 and H_2 receptors, is effective. Lastly, the newer, less-sedating agent, cetirizine, or non-sedating agents such as fexofenadine or loratadine, can be used during waking hours and as a soporific agent before retiring.

Patients are also often treated with corticosteroids and/or immunosuppressive agents. Although these agents are useful in controlling the cutaneous lesions, they do not seem to have any impact of the progression of pulmonary disease.

Toxic Epidermal Necrolysis

Toxic epidermal necrolysis (TEN) is one of the true dermatologic emergencies. This disorder is most often due to drug administration and develops acutely. Patients often have a prodrome followed shortly by widespread skin involvement with a superficial blistering (Fig. 28-17). Multiple mucosal surfaces are affected (Fig. 28-18). Prognosis is dependent upon the extent of the blistering, age, and the presence of co-morbid diseases. Lung involvement is unusual, but these patients often are treated in an intensive care unit or burn unit and frequently end up on a ventilator. Infections are a frequent complication and can result in death. Pulmonary infection is one of the more frequent sites. Therapy of TEN is controversial, but in the United States treatment with high-dose intravenous immune globulin (0.75 g/kg per day for 4 days) has become a "standard" therapy. The use of corticosteroids or other immunosuppressive agents is controversial. Prophylactic antibiotics are contraindicated, but prompt therapy of an identified infection should occur.

Figure 28-18 Mucosal lesions of Stevens-Johnson syndrome/toxic epidermal necrolysis.

Yellow Nail Syndrome

Thick, yellow discoloration of all 20 nails occurs in the yellow nail syndrome (Fig. 28-19). The nails are thick, but there is no onycholysis and no subungual debris, allowing clinical differentiation from onychomycosis. The nails are not clubbed and there are no underlying bony abnormalities. This disorder is almost always associated with pulmonary abnormalities, including pleural effusions, lymphoma, and sleep apnea. There is no known therapy for the nail changes in this disorder, but improvement of the associated pulmonary disease can result in improvement of the nails.

Figure 28-17 Stevens-Johnson syndrome/toxic epidermal necrolysis.

Figure 28-19 Yellow nail syndrome. All 20 nails were affected in this patient.

MISCELLANEOUS DISORDERS

Inherited Congenital and Developmental Disorders

α_1-Antitrypsin Deficiency

α_1-Antitrypsin deficiency is regularly associated with pulmonary and hepatic disease. Cutaneous manifestations may also occur in some patients with this inherited disorder and most commonly manifests as a panniculitis or rarely as a cutaneous vasculitis. Although the panniculitis is a lobular panniculitis in contrast to the septal panniculitis that is found in erythema nodosum, the clinical disease is similar except that these patients' lesions might ulcerate. Therapy with replacement of the hormone will temporarily result in control of the panniculitic lesions.

Cutis Laxa

Cutis laxa is caused by a disorder in the formation of elastin that is transmitted as a dominant hereditary trait. In children with this disorder, skinfolds of the abdomen and face are large and pendulous. The pulmonary manifestations of cutis laxa are emphysema and pulmonary artery stenosis.

Cystic Fibrosis and the Skin

Cystic fibrosis (CF) is an inherited disorder that frequently affects the lungs and results in premature death. The skin is often useful for the diagnosis of this condition, but in addition there are patients in whom skin disease is due to CF. Specifically, cutaneous vasculitis seems to be more frequent in CF patients, probably due to the frequent formation of circulating immune complexes in the CF patient. Treatment of the patient with CF with cutaneous vasculitis is similar to other patients with cutaneous vasculitis.

Ehlers-Danlos Syndrome

The most important disorder of collagen affecting the skin and lungs is Ehlers-Danlos syndrome (cutis hyperelastica), a hereditary disorder of collagen in which the skin and blood vessels are unduly elastic and fragile and the joints are hyperextensible. The skin is smooth, rubbery, and bruisable; the joints are hypermobile. Associated systemic abnormalities include megaesophagus, megacolon, dissecting aortic aneurysm, and diaphragmatic and inguinal hernias. Among the pulmonary disorders are spontaneous pneumothorax, arteriovenous fistulas, mega-trachea, and bronchial ectasia.

Birt-Hogg-Dubé Syndrome

Birt, Hogg, and Dubé described an autosomal dominant condition that was manifest by multiple facial flesh-colored papules that were characterized histologically as trichodiscomas (Fig. 28-20). These patients have been subsequently found to have frequent renal cell carcinomas, particularly oncocytomas. In addition, these patients frequently develop spontaneous pneumothorax at a young age. Although there is no known therapy for BHD patients, their recognition can lead to discovery of renal tumors prior to spread to other organs. In addition to study of the patient, family members should be examined clinically and perhaps genetically.

Figure 28-20 Flesh-colored central facial papules in a patient with Birt-Hogg-Dubé syndrome.

Hereditary Hemorrhagic Telangiectasia

Hereditary hemorrhagic telangiectasia (HHT), also known as Osler-Rendu-Weber syndrome, is an autosomal dominant disorder that is manifested by vascular ectasia in various organs, including the skin and mucous membranes (Fig. 28-21). HHT often is first manifest as nosebleeds. Eventually lesions affect the lips, tongue, nasal mucosa, palate, and palms. On rare occasions, patients with HHT have arteriovenous malformations of the lungs or CNS. Epistaxis, melena, and hemoptysis are common in adults. There is no known therapy for HHT at present, but if an A-V malformation is found, surgical consultation is indicated.

Nephrogenic Systemic Fibrosis

Nephrogenic systemic fibrosis is a recently recognized disorder of the skin in which a rapid onset of skin hardening (Fig. 28-22) occurs in patients with some form of renal disease. Often the onset of the fibrosis is preceded by anasarca. The cause of this disease is not known, but possibilities include vascular

Figure 28-21 Mucosal telangiectasia in a patient with hereditary hemorrhagic telangiectasia.

Figure 28-22 Peau 'd orange changes in a patient with nephrogenic systemic fibrosis.

thrombosis and recent surgical interventions. Recent identification of gadolinium in tissue following its use for MRI or MRA has suggested that this radiocontrast agent may be implicated in the etiology of nephrogenic systemic fibrosis. Initial descriptions of the disease focused on the cutaneous findings, but it has become evident that patients may also have systemic fibrosis, including pulmonary fibrosis. There is no known effective therapy for these patients, but with time the fibrosis does seem to lessen.

Paraneoplastic Pemphigus

Paraneoplastic pemphigus (PNP) is a severe mucocutaneous disease with a specific pattern of immunofluorescence. It is a rare vesiculobullous disorder. Patients with PNP often present with severe oral erosions and polymorphous cutaneous lesions, including targetoid lesions, bullae, and erosions (Fig. 28-23). Patients with PNP often have a lymphoproliferative disorder with a high prevalence of Castleman's disease. In addition to the mucocutaneous disease, these patients frequently have bronchiolitis obliterans. There is no therapy for PNP that is uniformly effective; however, if a coexisting tumor is removed, the disease will remit. Suggested therapies include high-dose daily corticosteroids, cyclophosphamide, and rituximab.

Figure 28-23 Paraneoplastic pemphigus.

Sarcoidosis

Sarcoidosis is a multisystem disorder with protean manifestations. The pulmonary manifestations and other aspects of the disease are well covered elsewhere in this text and we focus solely on the cutaneous disease. Skin lesions occur in about 25 percent of patients with sarcoidosis and may be "histopathologically specific" or "non-specific." The most common nonspecific manifestation is erythema nodosum. Histopathologically, specific lesions are manifestations of granulomatous inflammation in the skin. Although associated with chronic disease in the past, it now appears that there are many patients with self-limiting granulomatous disease of the skin. Skin lesions are most commonly papules, plaques, or nodules. Rarely is there a great deal of surface change, and ulceration is uncommon. Several clinical variants are worth noting. Papular lesions on the knees (Fig. 28-24) are commonly associated with EN and are self-limiting. Lesions on the nasal ala (Fig. 28-25) are frequently associated with sarcoidosis of the upper respiratory tract (SURT) and a thorough otolaryngologic evaluation is indicated. Erythematous to violaceous plaques on the face are known as lupus pernio (Fig. 28-26) and residual scarring is possible. In addition, these patients tend to have accompanying chronic disease in the lungs. Finally, lesions of sarcoidosis frequently occur within scars or tattoos (Fig. 28-27). In this circumstance it may be difficult to distinguish sarcoidosis from foreign body granulomas.

Management of cutaneous sarcoidosis is often challenging. Patients with chronic disease are often treated with systemic corticosteroids, but at times these are ineffective or are associated with toxicity. Oral tetracyclines have been used in open-label studies and are at times effective. Oral hydroxychloroquine 200 to 400 mg/day (less than 6.5 mg/kg per day based on ideal body weight) has been effective for cutaneous disease in small case series, but when the therapy is discontinued the disease often relapses. Methotrexate is the most commonly reported immunosuppressive agent, although azathioprine, mycophenolate mofetil and other agents have also been utilized. With methotrexate in doses of 15 to 25 mg per week, about 80 percent of patients with cutaneous lesions respond; however, chronic therapy in sarcoidosis patients has been associated with hepatic abnormalities that limit the use of methotrexate. Anti-tumor necrosis factor-α therapy with thalidomide or biologic agents has been reported to be effective. Infliximab is regularly effective; the use of etanercept has rarely resulted in improvement and the use of adalimumab has only been reported in several individual cases.

Tuberous Sclerosis

Tuberous sclerosis is a hereditary disorder that is characterized by mental retardation, epilepsy, and skin lesions, including adenoma sebaceum, Shagreen patches, and ash leaf macules. Also seen as part of this disorder are retinal phakomas, calcification of basal ganglia, and ungual fibromas.

A

B

Figure 28-24 *A–B*. Sarcoidosis: acute onset of papular lesions *(A)* on the knees and feet *(B)* were associated with a self-limited course in these patients.

Approximately 9 percent of patients with visceral tuberous sclerosis have pulmonary manifestations; some of the pulmonary lesions are cystic and may be associated with recurrent spontaneous pneumothorax and hamartomas. Certain poorly understood diseases, such as fibrocystic pulmonary dysplasia, may represent a forme fruste of tuberous sclerosis.

TOXICITY OF MEDICATIONS

Cutaneous Toxicity from Therapies for Pulmonary Disease

Epidermal Growth Factor Receptor Inhibitors

Epidermal growth factor receptor inhibitors are now being used for the treatment of solid tumors, including lung cancers.

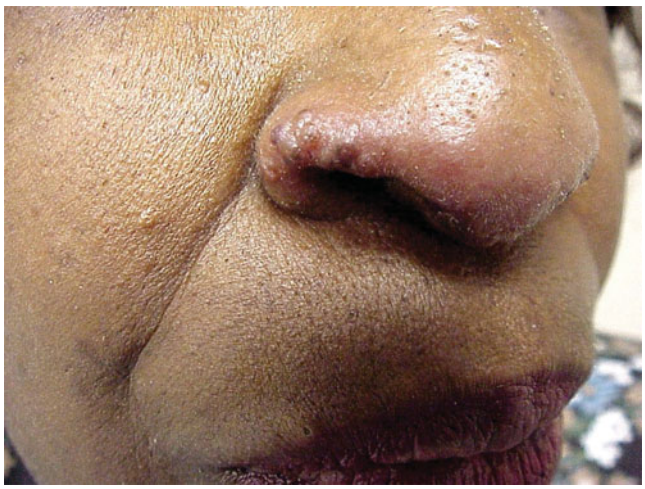

Figure 28-25 Sarcoidosis affecting the nasal ala is regularly associated with granulomatous disease in the upper respiratory tract (SURT).

These agents are regularly associated with the development of an acneiform eruption on the face. The presence and severity of this eruption appear to correlate with survival. A variety of therapies have been suggested for prevention or treatment of this eruption, including oral tetracycline, oral isotretinoin, topical corticosteroids, and topical sulfacetamide. None of these therapies has been regularly reported to be effective.

Consequences of Immunosuppressive Therapy in Lung Transplant Recipients

Patients who are organ recipients are regularly treated with corticosteroids in combination with various immunosuppressive agents. Therapy with corticosteroids has well-known dermatologic consequences, including striae, steroid-acne, and/or folliculitis, and an increased risk of superficial fungal infections. The intensity of the immunosuppression and duration of therapy are associated with increasing risk of cutaneous malignancy, specifically non-melanoma skin cancer (NMSC) and Kaposi's sarcoma. Squamous cell carcinoma is

Figure 28-26 Lupus pernio (sarcoidosis).

Figure 28-27 Sarcoidosis within tattoos.

overrepresented in comparison to basal cell carcinoma; in addition the tumors appear to be more aggressive in the presence of immunosuppressive therapy. Therefore, in patients who develop multiple squamous cell carcinomas immunosuppressive therapy should be less intense if possible or substitution of cyclosporin and azathioprine by other "less" toxic agents should be considered. In addition, the use of oral retinoids such as acitretin might lessen the frequency of NMSC.

Pulmonary Toxicity from Dermatologic Therapies

Methotrexate

Methotrexate is a common systemic therapy for patients with psoriasis. In addition, it is regularly used for cutaneous dermatomyositis, cutaneous sarcoidosis, and cutaneous lymphomas. Pulmonary toxicity is not common and is believed to be idiosyncratic. Most of the dermatologic use is for psoriasis vulgaris and psoriatic arthritis; fortunately, pulmonary disease appears to be quite rare in these patients. No specific monitoring is recommended.

Tumor Necrosis Factor-α Inhibitors

There are three available tumor necrosis factor (TNF) antagonists: infliximab, etanercept, and adalimumab. These therapies have revolutionized our approach to psoriasis, psoriatic arthritis, inflammatory bowel disease, and rheumatoid arthritis. All have been associated with an increased risk of infection, particularly pneumonitis. In addition, these agents may rarely cause or exacerbate cardiac failure.

Pulmonary-Systemic Interactions

Alfred P. Fishman

The lungs are incorporated into the body in such a way as to serve a variety of functions other than external gas exchange. These include hemodynamic, metabolic, endocrine, and immunologic activities. Inadequacy or failure on the part of any of these functions can have serious systemic repercussions. Moreover, as part of the total body fabric, the lungs share in diverse pathological processes, such as collagen vascular diseases, and inherit susceptibility to others, such as cystic fibrosis, in which a generalized defect in ion transport across epithelial surfaces affects the liver, gastrointestinal tract, and pancreas, as well as the lungs.

Because of its strategic location between the two ventricles and as the recipient of the entire output of the right ventricle, the pulmonary circulation is uniquely situated to transmit the products of pulmonary metabolism and injury to systemic organs and tissues. Its position at the exit of the right ventricle also enables the pulmonary vascular bed to serve as a filter for particulate matter arising in the systemic venous circulation (e.g., thromboemboli). Finally, the arrangement in series of the gastrointestinal tract, liver, and lungs enables interdependence in the handling of biologically active materials that release in health (Fig. 29-1) and disease (e.g., hepatic cirrhosis, gastrointestinal disorders, and splenic dysfunctions).

The diversity of cells that constitute the pulmonary parenchyma, the vasculature, and the airways, coupled with the ready access of blood constituents to the structures in the lungs, affords great opportunity for the lungs to influence systemic organs and vice versa. For example, the endothelial cells that line the enormous expanse of pulmonary vessels can release vasodilator or vasoconstrictor substances, anticoagulants, and a wide variety of enzymes and cytokines into the circulation. Mast cells in the vicinity of the pulmonary vessels can release a variety of substances that can influence both intrapulmonary and extrapulmonary vessels and structures. Chloride-secreting cells, not only in the airways but also in other glandular structures (e.g., sweat glands, pancreas), can suffer inherited defects that disturb different kinds of bodily functions. Immunologically competent cells in the lungs that are part of natural body defenses can open the way for serious systemic infections if their guard is dropped or if environmental pollutants are overwhelming.

The large pulmonary blood flow and the brief pulmonary transit time ensure virtually instantaneous exposure to biologically active substances originating in the lungs. Among these substances are hormones (e.g., angiotensin II), mediators (e.g., nitric oxide), and neurotransmitters. Disease,

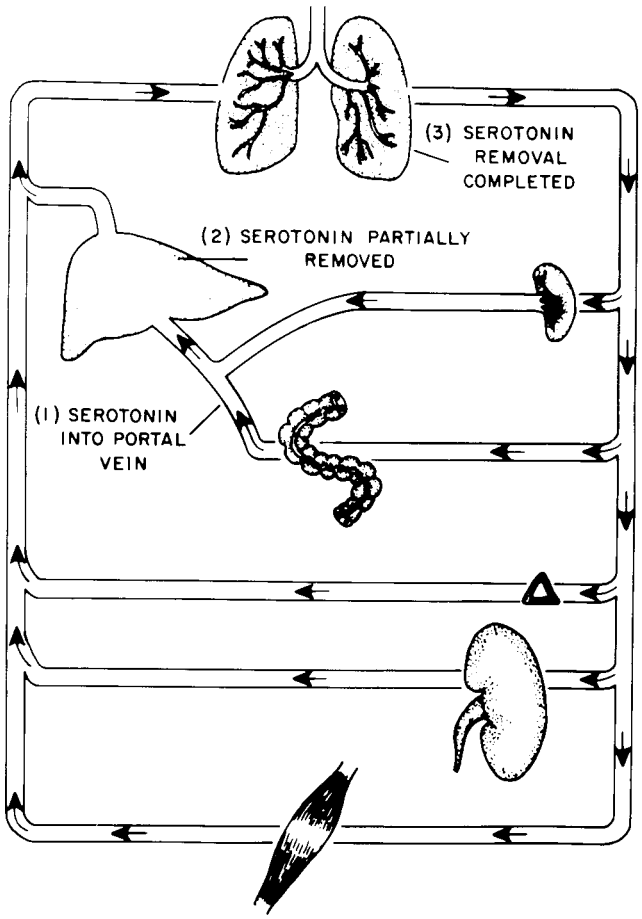

Figure 29-1 The sequential processing of serotonin.

such as pneumonia, can promote the release of inflammatory and immunologic mediators from both the resident cells and the migratory blood cells (e.g., leukocytes).

Another access route to the lungs is the bronchial circulation. This systemic blood supply can undergo remarkable proliferation in some diseases (e.g., bronchiectasis), but remain small in others (e.g., primary carcinoma of the lung). As is noted below, proliferation of the bronchial circulation often accompanies clubbing of the digits.

THE LUNG AS AN ENDOCRINE ORGAN

In addition to its roles in gas exchange and water exchange, the lung is active metabolically. The metabolic processes entail uptake, storage, and elaboration of substances, many of which (such as nitric oxide) function locally, whereas others, such as angiotensin II (Fig. 29-2), exert their effects on remote tissues and organs (i.e., they enter the bloodstream and influence systemic tissues and organs).

In addition to such chemical messengers, the lungs secrete amines and peptides, whose functions are far less well defined. These messengers are released by a system of epithelial cells (i.e., *pulmonary endocrine cells*) which are part of a widespread system that is contained within other organs as well as within the lungs. The so-called pulmonary endocrine cells have attracted the attention of clinicians more because of their potential for undergoing neoplastic transformation than because of recognizable biologic functions.

The Pulmonary Endocrine System

Pulmonary endocrine cells, or *pulmonary neuroendocrine cells*, have been found in a wide variety of species, ranging from the African lungfish to humans. These cells can be found in the respiratory epithelium from trachea to alveolar walls, where they may appear as single cells, as clusters associated with nerve terminals (*neuroepithelial bodies*), or in mounds (*tumorlets*). The typical pulmonary endocrine cell is usually argyrophilic and is characterized ultrastructurally by a dense-core vesicle surrounded by clear scant cytoplasm; within the core are granular chromatin bodies and prominent nucleoli. Histochemistry and immunochemistry have displayed a large spectrum of biologically active mediators, including serotonin, calcitonin, substance P, cholecystokinin, somatostatin, calcitonin gene-related peptide, and bombesinlike peptides. Although these substances have been identified in cells and in serum, few have yet proved to be of clinical significance, although a variety of physiological functions (i.e., vasomotor, bronchomotor, secretomotor, and inflammatory) have been attributed to them. The basal aspect of these cells is often closely related to nerve endings or nerve varicosities. Acute hypoxia has been shown to cause exocytosis of the dense-core vesicles in neuroepithelial bodies, presumably a reflection of a receptor or effector function.

Cells of the pulmonary endocrine system can give rise to neoplasms with endocrine characteristics. These endocrine tumors can be pictured as a continuum of neoplasms that range from benign to malignant (i.e., from carcinoid to small cell carcinoma). The carcinoids mark one end of the continuum: they are the more highly differentiated, and their endocrine features are the most marked. Toward the opposite end are the small cell carcinomas, which are poorly differentiated. Non–small cell carcinomas are less apt to show endocrine differentiation. In this continuum, carcinoids are generally indolent, whereas small cell carcinomas are very aggressive.

Paraneoplastic Syndromes

Pulmonary neoplasms are more commonly associated with paraneoplastic syndromes than are any other types of neoplasms. Three types of paraneoplastic syndromes illustrate the systemic effects of pulmonary neoplasms: the carcinoid syndrome, Cushing's syndrome, and the syndrome of inappropriate secretion of antidiuretic hormone (SIADH). Clubbing of the digits is considered below.

The carcinoid syndrome is attributed to the release of various mediators from the neoplasm, owing to either

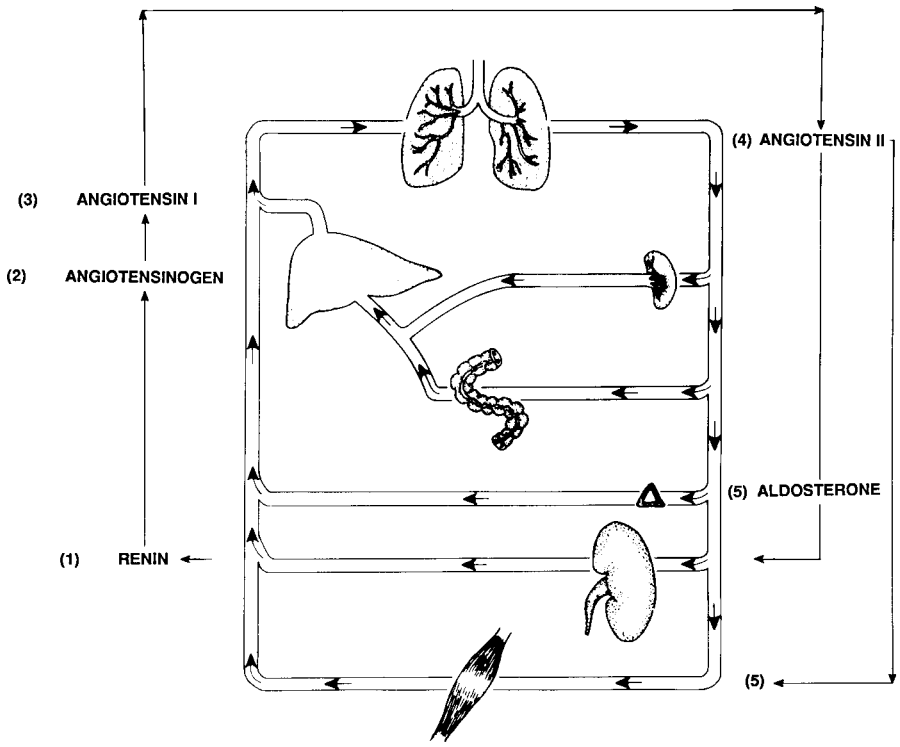

Figure 29-2 The renin-angiotensin system. The interplay among kidney, liver, and lungs results in the formation of angiotensin II. This hormone, generated in the lungs from precursors in the kidneys and blood, is active in the regulation of systemic blood pressure. It does so by way of its effects as a systemic vasoconstrictor and as a regulator of the circulating blood volume. The latter operates through the salt- and water-retaining effects of aldosterone.

a carcinoid tumor or, less often, a small cell carcinoma. Various mediators have been implicated, including serotonin, histamine kinins, and prostaglandins. The systemic effects include flushing, diarrhea, bronchospasm, and heart disease.

Cushing's syndrome is due to excessive secretion of adrenocorticotropic hormone (ACTH) or ACTH-like peptides by the neoplasm, generally a small cell carcinoma. The systemic effects are hypokalemic alkalosis, systemic hypertension, impaired carbohydrate tolerance, muscle weakness and wasting, edema, and weight loss.

SIADH generally occurs in association with pulmonary tuberculosis or bronchial carcinoma. The clinical syndrome, caused by inappropriate secretion of arginine vasopressin and antidiuretic hormone, is manifested by hyponatremia (not attributable to drugs), water retention, hyperosmolar plasma accompanied by disproportionately high hyperosmolarity of the urine, persistent natriuresis without volume depletion, and hypouricemia. These disorders may lead to altered mental state, lethargy, confusion, psychosis, or coma.

Other familiar syndromes involving pulmonary neoplasms in association with systemic effects are clubbing of the digits, gynecomastia, a variety of cutaneous disorders (e.g., acanthosis nigricans), neurological disorders (e.g., cerebellar degeneration), and autonomic disturbances (e.g., orthostatic hypotension).

PULMONARY VASCULAR ENDOTHELIUM

The lungs contain the largest expanse of endothelium in the body. This lining of the pulmonary circulation is engaged in a variety of vital functions (Table 29-1). Some, such as pulmonary vasodilation, are served by local mediators, such as nitric oxide and prostacyclin. Countering these effects are local vasoconstrictors, such as the endothelins. As noted above, other products, such as angiotensin II, exert their effects on remote functions (e.g., in the regulation of systemic blood pressure).

Endothelin (ET-1) is a powerful vasoconstrictor peptide which is synthesized by vascular endothelium. Increased circulating levels of ET-1 have been reported in pulmonary arterial hypertension. Endothelin contributes to setting pulmonary vascular tone by counterbalancing the vasodilatory effects of prostacyclin and other endothelium-derived relaxing substances. In addition to its vasoconstrictor actions, endothelin exerts a variety of other biologic effects depending on the cell type on which the receptors are found: positive inotropic and chronotropic effects on the heart, decrease in renal blood flow and filtration rate, and release of atrial natriuretic peptide (ANP). Among its deleterious effects are vasoconstriction, vascular hypertrophy, cell proliferation, fibrosis, and inflammation. ET-1 has been implicated in the

pathogenesis of systemic hypertension, pulmonary hypertension, and heart failure. Bosentan, a non-selective ET-1 receptor antagonist, is currently used in the treatment of pulmonary hypertension.

Nitric oxide is a highly reactive gas. It is synthesized within cells by nitric oxide synthase (NOS). The human genome contains three different genes that encode NOS, one of which, NOS-3, is found in endothelial cells. NOS is produced from arginine with the aid of molecular oxygen and nicotinamide adenine dinucleotide phosphate (NADPH). Nitric oxide acts as a vasodilator and anti-aggregator of platelets. The feasibility of direct measurements of the release of nitric oxide into expired air by vasoactive drugs has been demonstrated in both pigs and humans.

Thrombin is another interactive substance. It plays a key role in coagulant processes: on the one hand, it is procoagulant (i.e., it activates platelets, stimulates monocyte and neutrophil chemotaxis, cleaves fibrinogen, stimulates the endothelial release of tissue factors, and releases von Willebrand factor from Weibel-Palade bodies); on the other, it can serve as an anticoagulant molecule that stimulates protein C activity, promotes prostacyclin secretion, and causes the liberation of tissue plasminogen activators. Thrombin is also a potent growth factor that initiates proliferation of smooth-muscle cells at the site of injury. These diverse effects are due to the prevalence of thrombin receptors in many cell types. A variety of strategies to inhibit thrombin are being tested for therapeutic purposes: hirudin has been used to prevent the cleavage of fibrinogen and activation of thrombin receptors; peptides that act as antagonists for thrombin receptors are being tested; monoclonal and polyclonal antibodies are being developed that prevent activation of thrombin receptors; antisense oligonucleotides are being tried to block expression of thrombin receptors.

Chronic injury to the pulmonary vascular endothelium can evoke proliferation of the intima, invasion of the endothelial lining by underlying smooth muscle and adventitial cells, and accumulation of blood cells at the blood-endothelial interface. The end result is replacement of the single endothelial lining layer by occlusive heaps of endothelial, smooth-muscle connective-tissue cells (Figs. 29-3 and 29-4). How well the heaped-up endothelium preserves the functions of normal endothelial function (e.g., anticoagulation) is not clear.

The pulmonary circulation, like the systemic venous circulation, remains virtually free of atherosclerotic lesions unless pulmonary arterial blood pressures increase to hypertensive levels. Acute injury to endothelium can provide access of circulating proteins, such as fibrinogen, and blood cells to the pulmonary interstitium, thereby setting the stage for interstitial fibrosis. Aside from leakage, endothelial injury can stimulate a complex array of local reactions: circulating white blood cells and platelets are drawn to the injured site, undergo activation, and release factors that contribute to the response.

THE GUT-LIVER-LUNG AXIS

Perhaps nowhere is the principle of effluent from one organ influencing the behavior of its neighbor better illustrated than in the gut-liver-lung axis (Fig. 29-5). Misbehavior by any one of the series can seriously derange the workings of the next in line and the entire organism. For example, in liver failure, not only are noxious substances added to its effluent but also injurious substances from the gut, spleen, and other systemic organs, which are normally detoxified by the liver, gain access to the pulmonary circulation. The remote consequences of liver injury, such as clubbing of the digits in patients with liver cirrhosis, are considered below.

Dietary Pulmonary Hypertension

In 1974, the concept of *dietary pulmonary hypertension* was proposed. The idea stemmed from the ability of the drug

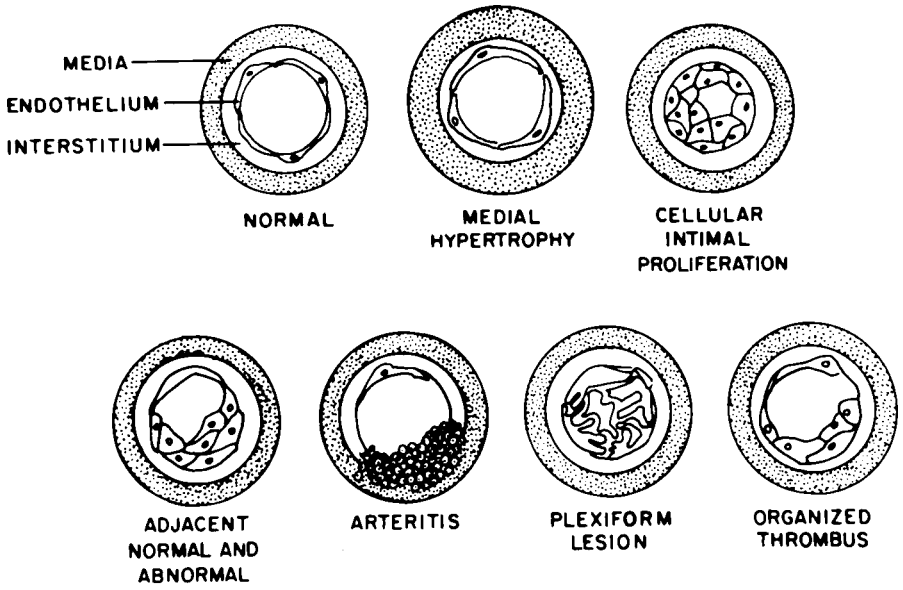

Figure 29-3 Normal and abnormal endothelium. Various endothelial abnormalities illustrating the different surfaces encountered by the perfusing blood.

aminorex in humans and the plant crotalaria in animals to elicit pulmonary hypertension. The generalization from this experience with drugs and plants taken by mouth was that other medications, foods, and herbs, taken by mouth, might injure the pulmonary circulation sufficiently to evoke pulmonary hypertension. Since then, ample evidence has accrued in support of this hypothesis (e.g., the toxic oil syndrome; fenfluramine derivatives; female "crack-cocaine" users).

The outbreak of primary pulmonary hypertension attributed to aminorex occurred in Austria, Switzerland, and Germany, and came to a close after the sale of the over-the-counter drug was stopped. Aminorex is a catechol derivative that acts by releasing norepinephrine at nerve terminals and synapses. One important lesson from the aminorex experience was that individual susceptibility was prerequisite for developing pulmonary hypertension: of the many thousands who used the drug, only a few developed the findings of primary pulmonary hypertension.

History repeated itself in April 1996, when another anorexigenic agent, dexfenfluramine, became available in drugstores throughout the United States. Its use spread widely. Dexfenfluramine exerts its pharmacologic effects by its enhancing effects on serotonin-mediated neurotransmission: it blocks serotonin reuptake, whereas its principal metabolite, dexnorfenfluramine, not only releases serotonin into synapses but also activates 5-HT_2 receptors.

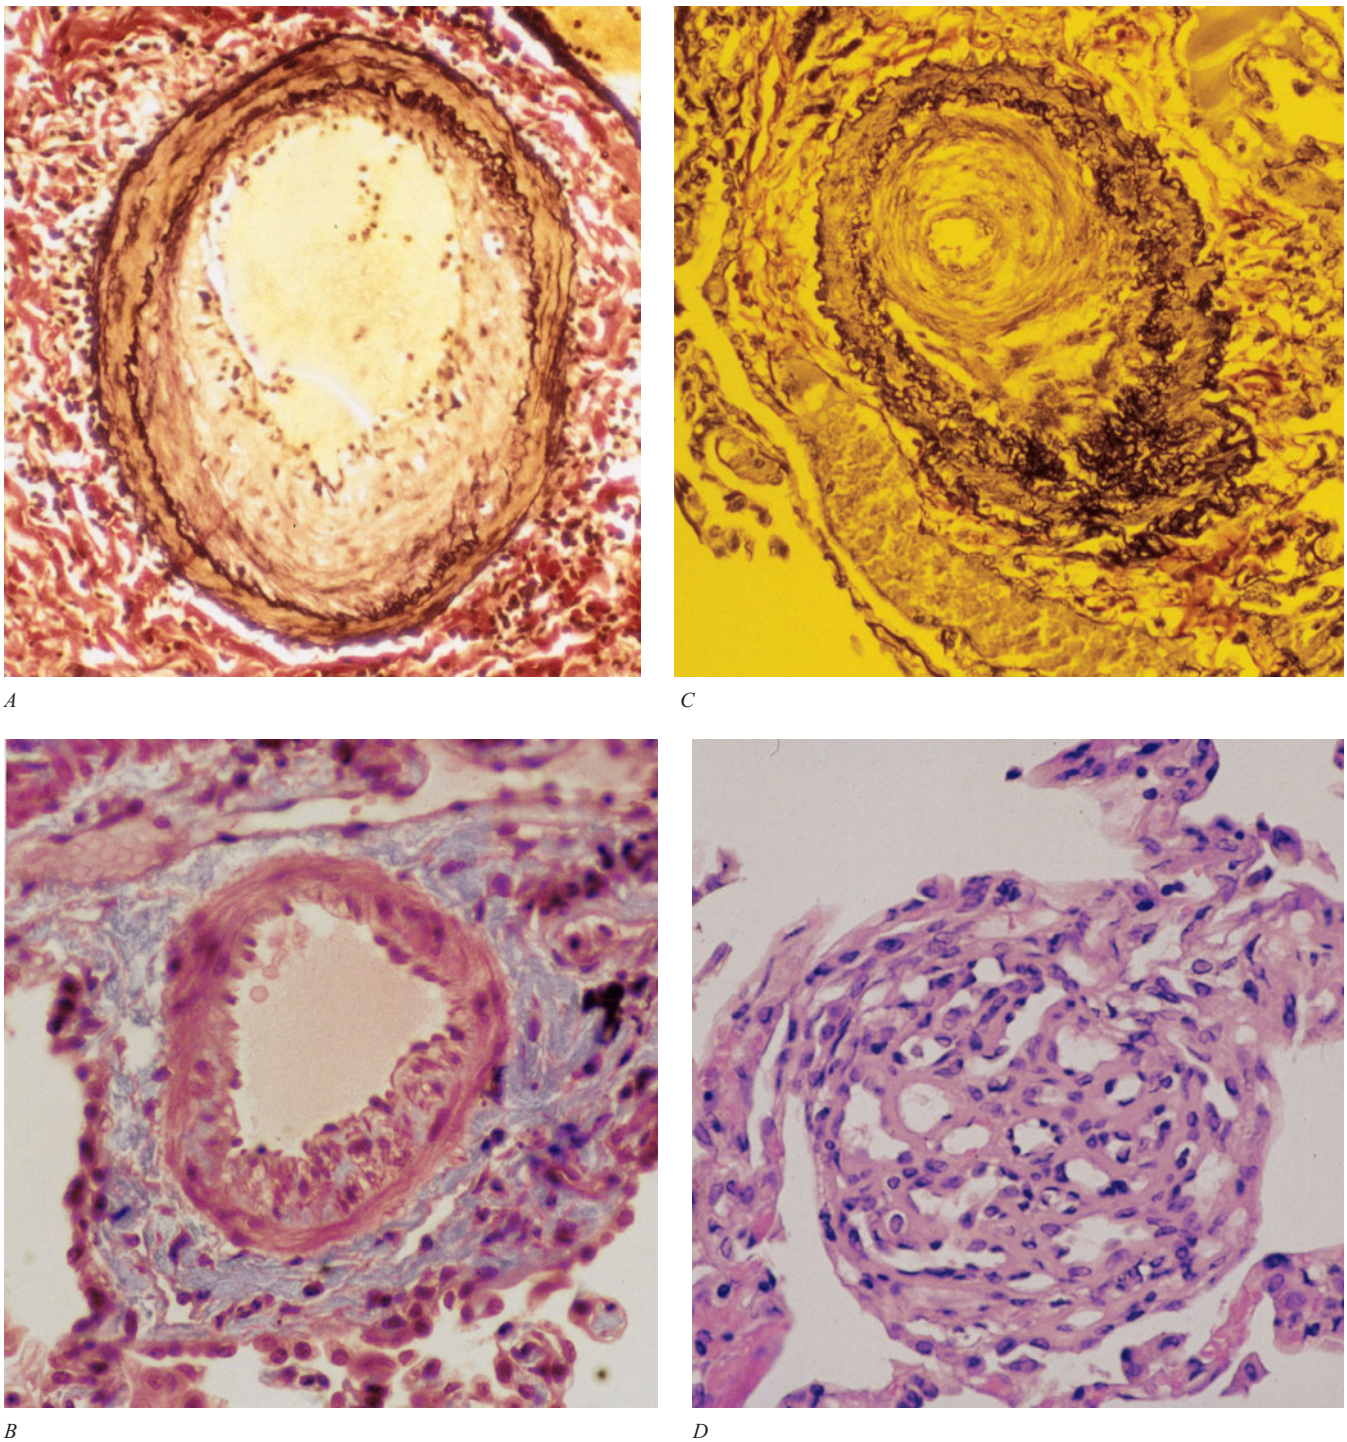
After sporadic case reports in the early 1980s of the association of pulmonary hypertension with the use of fenfluramine, Brenot and colleagues published a retrospective analysis that linked fenfluramine use with primary pulmonary hypertension. A follow-up, case-controlled study under the auspices of the Medical Research Council of Canada confirmed the higher incidence of primary pulmonary hypertension in people taking anorexigens, predominantly fenfluramine or dexfenfluramine. Moreover, the use of the anorexigen for more than a few months was associated with increased risk of primary pulmonary hypertension. Because of the widespread use of anorexigens, an outbreak of primary pulmonary hypertension seems inevitable. Indeed, a registry set up to keep track of such cases has already received reports of people in whom the use of anorexigens is associated with primary pulmonary hypertension.

Ventilation and Circulation in Liver Cirrhosis

Liver cirrhosis, and the accompanying portal hypertension, is often associated with striking changes in the pulmonary circulation. Some of these changes appear to be diametrically opposite. Thus, on the one hand the minute vessels of the lungs often show evidence of vasodilation in the pulmonary microcirculation (e.g., dilated arterioles and capillaries), whereas on the other hand the pulmonary microcirculation may be affected in obliterative vascular disease. The mechanisms at work are speculative. For example, the commonly held view that the obliterative pulmonary disease originates in pulmonary vasoconstriction, presumably because of some unknown vasoconstrictor mechanism, is unproven. Three aspects of the lung-liver relationship in liver cirrhosis have received special attention: pulmonary vasomotor control, pulmonary vasodilation, and pulmonary hypertension.

Ventilatory Responses to Hypoxia in Liver Cirrhosis

Hypoxic pulmonary vasoconstriction is blunted in patients with chronic liver disease, indicating a defect in intrinsic autonomic control. This blunting is in the face of the characteristic



A

C

B

D

Figure 29-4 Microscopic appearance of small pulmonary muscular arteries and arterioles, illustrating different degrees of intimal proliferation and vascular occlusion. Plexiform lesion is at bottom right.

high-cardiac-output state that is a feature of patients with liver cirrhosis. The mechanism responsible for both the high-output state and the blunted hypoxic pulmonary pressor response is unknown. Nitric oxide is the most recent candidate to explain the high-output state associated with liver cirrhosis.

CIRCULATORY ADAPTATIONS IN LIVER CIRRHOSIS

Mild arterial hypoxemia is found in 30 to 70 percent of patients with hepatic cirrhosis. This arterial hypoxemia is attributable to "anatomic" venous admixture (i.e., to anatomic shunts or to their equivalent; the rapid passage of unoxygenated blood past the gas-exchanging surfaces of the lungs).

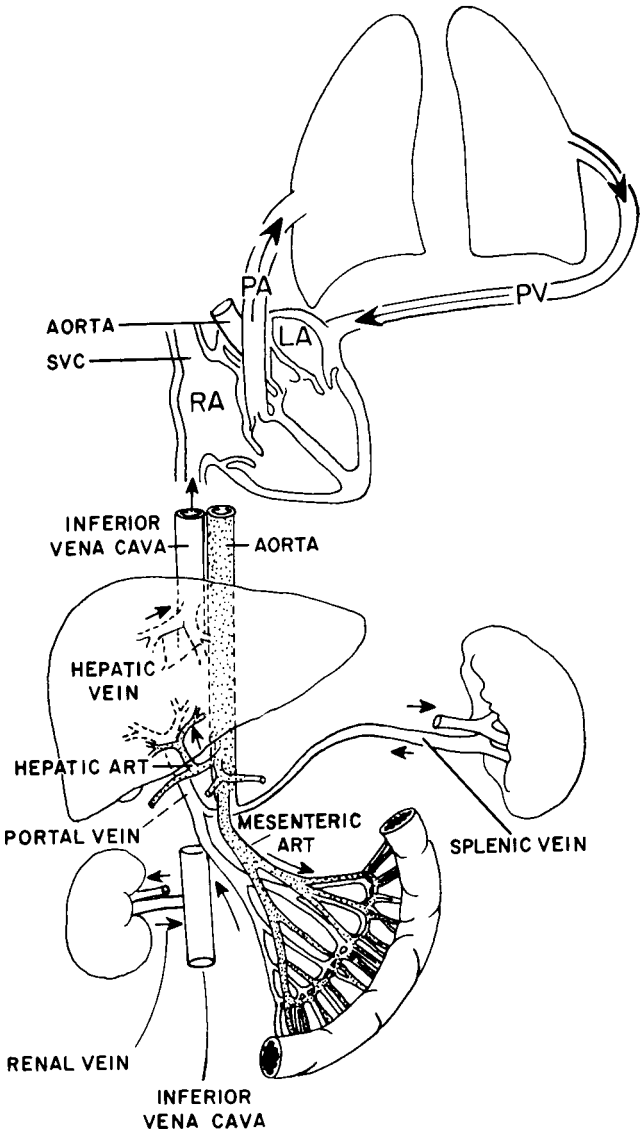


Figure 29-5 The gut-liver-lung axis.

This abbreviated transit time is, in turn, due to a combination of high-cardiac output and dilation of the pulmonary precapillaries and capillaries.

Dilatation of microvessels in liver cirrhosis is not confined to the lungs. Instead, it occurs throughout the body, including the skin and kidneys. In the fingers, it contributes to the rare occurrence of clubbing in patients with liver cirrhosis.

Inexplicably, the blood vessels on the pleural surface are more affected by dilatation than are the intrapulmonary vessels. The *spider nevi* on the pleural surface are fed by the pulmonary circulation. They are composed of short vessels, less than 1 mm in diameter, and are generally quite conspicuous. Although anatomic dilation of intrapulmonary microvessels has often been seen at autopsy, as a rule such dilatation is rare compared to that on the surface of the lung.

Portal-Pulmonary Hypertension

The association of pulmonary hypertension with liver cirrhosis has attracted considerable attention. The pulmonary hypertension is due to obliterative pulmonary vascular disease.

In the 1960s, the obliterative pulmonary vascular disease in patients with liver cirrhosis was attributed to organized pulmonary emboli that originated in thrombi in the portal vein. Since then, this possibility has largely been discounted, and it is now generally recognized that the pulmonary vascular lesions are identical with those of primary pulmonary hypertension.

The etiology of portal-pulmonary hypertension remains speculative. Among the possibilities being entertained is the prospect that vasoconstrictor substances or autoimmune substances, or other injurious agents, might start the obliterative process by injuring pulmonary vascular endothelium. The arrangement of the gut, liver, and lungs in series nurtures this hypothesis. One intriguing aspect of this proposition is why the endothelium of pulmonary resistance vessels should be extensively affected by the injury while the more extensive endothelium of the pulmonary capillary bed is spared.

SEPSIS-INDUCED MULTIPLE ORGAN FAILURE

Probably the most striking impact of the lungs on the rest of the body is exemplified by multiple-organ failure that complicates the adult respiratory distress syndrome (ARDS). Indeed, most patients who die of ARDS do so because of multiple-organ failure rather than from the lung disease. In recent years, the liver, as well as the kidneys, has been recognized to be a major determinant of the outcome of ARDS.

In its systemic effects, ARDS behaves like sepsis elsewhere in the body, overwhelming host defenses by the release into the circulation of inflammatory cytokines, such as tumor necrosis factor (TNF) and interleukin-1 (IL-1). TNF continues to be the major center of attention. Endotoxin is the most potent stimulus known for the production of TNF. Instead of acting directly to cause injury, endotoxin (or its lipopolysaccharide) prompts the formation of host factors that cause the damage. Macrophages are deeply implicated in generating these host factors. In addition to releasing injurious agents, sepsis interferes with the biologic inactivation of mediators of inflammation. Novel therapies have been directed at countering the role of TNF in the septic shock syndrome. These include anti-TNF monoclonal antibodies, soluble TNF receptors, and soluble TNF receptor-immunoglobulin G heavy-chain fusion proteins. These approaches are still under development.

Recently, attention has turned to attempts at blocking the production of nitric oxide, an endogenous vasodilator and immune modulator that may be active in inducing the systemic hypotension associated with sepsis. The target has been nitric oxide synthase (NOS), the enzyme that produces nitric

oxide. Blocking NOS affords promise not only of relieving systemic hypotension but also of favorably influencing other harmful processes that may contribute to organ failure, including direct tissue injury, myocardial depression, derangement of cellular metabolism, and release of inflammatory cytokines (e.g., TNF) from macrophages. However, the therapeutic role of inhibiting nitric oxide has not yet been settled because nitric oxide may have beneficial as well as harmful properties.

INJURY BY OXYGEN-DERIVED PRODUCTS

Mechanisms of Action

In recent years, mounting evidence has implicated oxidative injury in the pathogenesis of a wide array of biologic processes, ranging from the normal aging process to a variety of disease states, including atherosclerosis, carcinoma, and ischemia-perfusion injury. Oxidative injury has also been increasingly held responsible for diverse diseases of the lungs and airways, such as emphysema, interstitial pulmonary fibrosis, asthma, and ARDS. The relationship between cigarette smoking and the development of emphysema illustrates one pathway: oxygen-derived products, either contained in cigarette smoke or generated by activated leukocytes attracted to the lungs by smoking, oxidize the methionine residue of α_1-antitrypsin, an antiprotease, thereby inactivating it and enabling the destruction by proteases of alveolar walls (see Chapter 41). The abnormal pulmonary function that ensues exerts systemic effects by way of abnormal blood gases and mechanics of breathing, stimulation of respiratory control mechanisms, and the sensation of dyspnea. The oxidant injury may be aggravated by administration of supplementary oxygen in the form of O_2-enriched inspired air mixtures.

Sensitized asthmatics respond to an allergen by degranulation of mast cells, which causes the release of TNFα. In turn, TNFα prompts the migration of neutrophils and eosinophils to the site of the allergic reaction. At this site, the leukocytes release toxic oxygen products, which contribute importantly to the inflammatory response.

Most of the molecular oxygen entering the body is reduced sequentially to water via the respiratory chain. However, in the course of the serial reductions that are part of normal intermediary metabolism, superoxide anion (O_2^-) and hydrogen peroxide (H_2O_2) are generated as undesirable by products.

Generation of Toxic Reactive Oxygen Species

Cells that respire aerobically generate toxic reactive oxygen species. These reactive species are produced not only in the course of normal aerobic metabolism but also as by products of inflammatory reactions. The toxic reactive species known as free radicals include the superoxide anion and hydroxyl

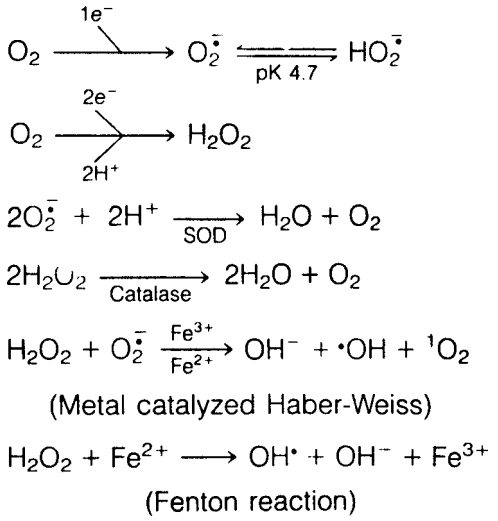

Figure 29-6 The generation of oxygen free radicals by the addition of electrons.

radicals and hydrogen peroxide (Fig. 29-6). Cellular damage is inflicted by these species on proteins, nucleic acids carbohydrates, and lipids. Damage to the lungs inflicted by free radicals (e.g., ARDS) can exert disastrous effects on systemic organs (e.g., renal failure). In turn, the cell damage causes the induction of antioxidant genes that prompt the elaboration of enzymes directed at scavenging the reactive oxygen species. Among the clinical situations in which free radicals feature prominently are reperfusion injury and the adverse immunologic responses elicited by organ transplant action.

In the lungs, reactive oxygen species from the environment can inflict damage. Oxygen toxicity, produced by breathing O_2-enriched inspired air, affords a traditional example of injury produced by O_2-derived products. Within 24 h of the start of oxygen breathing, the endothelium of the pulmonary microcirculation is damaged and becomes "leaky," enabling blood plasma to gain access to the interstitial spaces and alveoli. Along with excess fluid and serum proteins, inflammatory cells accumulate in the lungs. Should exposure to the O_2-rich inspired gas continue, the end point can be ARDS. One experimental strategy for mimicking the pathological and pathophysiological changes in the lungs induced by oxygen toxicity is the administration of endotoxin.

Another mechanism for causing oxidant injury involves nitric oxide (see Chapter 25). Nitric oxide, a mediator of signal transduction with diverse physiological functions, is categorized as a free radical because of its unpaired electron. Because of this property, it has biologically important reactivities with certain kinds of proteins, carbohydrates, and other free radicals (e.g., superoxide radicals). In its reactions with other free radicals, it can yield even more potent oxidants (e.g., peroxynitrite). Some toxic reactions, originally attributed to its chemical precursors, superoxide and nitric oxide, are now attributed to peroxynitrite. Oppositely, nitric oxide can also exert a protective action against free radicals, such as the superoxides. Thus, nitric oxide can either inflict damage or ward

it off, depending on the oxidative environment in which the reactions are taking place. An intense research effort is currently directed at unraveling the nature of reactions involving nitric oxide and peroxynitrite with proteins, lipids, carbohydrates, and gene expression in a variety of pathological processes.

The amino acid homocysteine is operative in another mechanism by which oxidative injury can damage endothelium. This mechanism is mediated primarily by autooxidation, which generates the superoxide anion radical (O_2^-) and H_2O_2 and the hydroxyl radical (OH·). Abnormally high levels of homocysteine in plasma blunt the responses of endothelium to endothelium-dependent vasodilators (e.g., nitric oxide) by way of the damage caused by products of homocysteine oxidation. The antithrombotic function of endothelium and the migration and proliferation of vascular smooth-muscle cells are also affected by high levels of homocysteine.

Two other clinical areas in which oxidant-produced injury features prominently are the inhalation or ingestion of oxidants (e.g., paraquat) and the chronic injury caused by smoking, which predisposes to low-level inflammation, pulmonary damage, and neoplasm.

GENERAL SYSTEMIC EFFECTS OF PULMONARY DISEASE

Pulmonary infections and neoplasms are notorious for the systemic effects that they can elicit (Table 29-2). Pneumonias caused by bacteria, mycoplasma, viruses, or fungi can cause a spectrum of disturbances, ranging from mild fever to bacteremia and circulatory collapse. Viral infections commonly induce leukopenia, anemia, and thrombocytopenia. Metabolic derangements are also the rule in these acute disorders; abnormal hepatic and bone marrow functions are the bases for common abnormalities (e.g., high erythrocyte sedimentation rate and leukocytosis). The span of disturbances is just as great for neoplasms, not only because they encroach on adjacent structures and functions but also because of derangements in remote bodily functions that they cause by releasing biologically active materials (Table 29-3; see also Chapter 134). The impact of pulmonary disease on the rest of the body rises exponentially when infectious organisms or neoplastic cells escape the confines of the lungs to enter the bloodstream.

Bacteremia, viruses, fungi, and other microorganisms can invade the bloodstream from the lungs. Such infections gain in virulence with increasing numbers of organisms and their products; the elderly are particularly vulnerable to the systemic effects of pulmonary infections. Among the common consequences of diseases that begin in the lungs and affect the rest of the body are fever and body wasting.

Table 29-2

General Systemic Effects of Nonrespiratory Diseases of the Lung

Disturbances in the control of body temperature (fever, chills, sweating)
Central nervous system abnormalities (euphoria, irritability, confusion, delirium)
Faintness, reduced alertness, syncope (postural hypotension, arrhythmias, decreased blood flow to the brain)
Anorexia, asthenia, cachexia
Remote organ failure

Pituitary gonadotropins
Thyroid-stimulating hormone
Vasoactive intestinal polypeptide
Insulin
Parathyroid hormone
Somatostatin
Renin
Gastrin
Prolactin
Bombesinlike peptides

Fever, Chills, Sweating

There are many causes of fever. Among the most common are infections, inflammation, injury to the central nervous system, thrombosis, hematoma, vasculitis, and necrosis. Fever is generally regarded as harmful. However, fever has enhancing functions. For example, in infections, it enhances neutrophil migration and the production of antibiotic substances by neutrophils.

The body is constructed to keep internal core temperature stable at about 37.1°C (corresponding to a rectal temperature of about 37.6°C) and equipped with automatic feedback devices that minimize fluctuations in the core temperature. Regulation of the core temperature is accomplished almost entirely by neural feedback mechanisms, virtually all of which are controlled by temperature-regulating mechanisms in the hypothalamus. Fever represents an upward shift in the thermostatic set point. The automatic attempt by the body to restore body temperature to normal includes cutaneous vasodilatation, sweating, decreased chemical thermogenesis, and a widespread decrease in muscle tone due to reflex inhibition of the *primary motor center for shivering*.

Chills are a response to an abrupt disparity between the set point of the thermostat in the hypothalamus and the temperature of the blood. Certain substances, notably pyrogens and products of tissue destruction (see next paragraph), can suddenly raise the hypothalamic set point without raising body temperature. Until the body temperature catches up, mechanisms to raise it are turned on, and the subject feels cold and experiences chills—even while the body temperature is increasing to match the hypothalamus set point: the cold sensation is a consequence of cutaneous vasoconstriction, whereas shivering causes the "shakes." When the body temperature reaches the higher set point, chills cease and the subject feels neither cold nor hot. Until the factor responsible for increasing the set point stops, the febrile state is maintained by the usual mechanisms. Precipitous discontinuance of the initiating factor results in widespread cutaneous dilatation and flushing and intense sweating (i.e., "the crisis").

Pyrogens feature prominently in causing clinical fevers. They do so, directly or indirectly, by raising the thermostatic set point in the hypothalamus. Particularly effective in this regard are endotoxins produced by gram-negative bacteria. Leukocytes and macrophages act as intermediaries in this process: these phagocytic cells, after digesting the bacterial products, release leukocyte or endogenous pyrogen, which, in minute amounts, stimulates the hypothalamus to raise its set point; prostaglandin E_1 is presumably the intermediary within the cells of the hypothalamus that effects the febrile response. Blockage of prostaglandin formation, as by aspirin, can prevent or reduce the febrile response.

Chills, fever, and sweating are familiar manifestations of the syndrome of pneumococcal pneumonia and its complications. Some infecting organisms tend to be associated with distinctive diurnal fever patterns. Although these patterns were once regarded as diagnostic clues to the etiological agent, not much clinical attention is now paid to patterns, although the peaks and valleys in the fever curves can suggest clues to origin, and undue persistence of fever may signal a complication.

Body Wasting

Progressive infection or the growth of a neoplasm often elicits anorexia, weight loss, and cachexia. Cachexia is characterized by an inexorable loss of weight that is inordinate for the degree of anorexia and the decrease in food intake. Both adipose tissue and muscle mass are depleted; death usually is the end result of progressive depletion of lean body tissue.

Anorexia and underlying metabolic abnormalities appear to be at work in the pathogenesis of cachexia. Anorexia regularly accompanies weight loss. Although the initiating mechanism for anorexia seems to relate to the infection or neoplasm, in time other mechanisms supervene. Among these are depression, continued immobilization, and comorbid conditions. Appetite suppression is often aggravated further by medications. Attempts to reverse cachexia by nutritional supplements are rarely successful.

Key factors in the production of cachexia fall into three categories: (1) metabolic products of the pathogen or neoplasm; (2) catabolic hormones and a lipid-mobilizing factor (LMF) produced by neoplasms that acts to cause breakdown of adipose tissue; and (3) cytokines, such as TNFα and interleukin-6 (IL-6), which seem to affect adipose tissue by inhibiting lipoprotein lipase. TNFα plays a pivotal role. It is produced by macrophages, monocytes, and T cells, and its toxic effects are exceedingly diverse: it is a pyrogen, directly damages endothelium, can suppress adipose-specific enzymes, and is a mediator of the inflammatory process.

Since the 1994 discovery of leptin, a hormone active in the control of body weight, interest in starvation has taken a new turn. Leptin is a hormone produced by the obesity gene (*ob*), manufactured by adipocytes, and delivered to receptors in the hypothalamus (arcuate nucleus and paraventricular nucleus). Leptin functions as a lipostat: when fat stores increase, adipocytes produce leptin, which tells the brain to decrease appetite and increase activity.

Leptin exerts its effects via a complex interplay that involves neuropeptide Y and the melanocortins, a family of peptides. Decreased leptin levels work through neuropeptide Y to deal with the stresses of starvation; high levels may work through melanocortins to resist overweight. One feature of starvation is altered endocrine activity (e.g., decreased production of thyroid and sex hormones and increased production of adrenal stress hormones). Low levels of leptin elicit starvation-induced changes in endocrine function. The components of the hormone-neuropeptide system and their interplay in the control of body weight are currently under intense investigation. Most studies have been conducted in the rat, however, and their implications for human disorders, such as starvation, are incompletely understood.

Some success in reversing cachexia has been accomplished by the use of two groups of agents: those that stimulate

intake of food (e.g., megestrol acetate, which can also stimulate tumor growth) and those that inhibit LMF (e.g., eicosapentaenoic acid).

SPECIFIC SYSTEMIC EFFECTS OF PULMONARY DISEASE

Certain systemic manifestations, although not unique to pulmonary disease, occur often enough to warrant special mention. Among these is clubbing of the digits.

Clubbing of the Digits and Hypertrophic Osteoarthropathy

The characteristic and preferential bulbous enlargement of the distal segment of the digits (Fig. 29-7) and the distinctive bony lesions of secondary hypertrophic osteoarthropathy are generally explained in terms of humoral mediators that cause selective vasodilatation of the digital precapillary vessels. As is noted in Chapter 108, this explanation seems to suffice in certain disorders (e.g., the clubbing of the digits and the hypertrophic osteoarthropathy that accompany carcinoma of the lungs) but not in others (e.g., subacute bacterial endocarditis). One other intriguing aspect of clubbing is its association both with chronic bronchiectasis, in which the adjacent collateral circulation of the lungs undergoes remarkable proliferation, and with carcinoma of the lung, in which the collateral blood supply is modest.

Circulation 33:143–145, 1966.)*

CONCLUSIONS

Once the metabolic functions of the lungs were fully appreciated, it became evident that interplay between the lungs and systemic tissues and organs was part of normal body functioning and that more than nervous connections is operative. This interplay became even more evident in clinical syndromes that involved the transport by the circulation (and possibly lymph) of products of inflammation from one part of the body to the other. Syndromes such as the hepatorenal syndrome and organ failure in ARDS underscored the interplay. Others, such as coexistent portal and pulmonary hypertension, remain enigmas to be resolved. With these insights came the realization that understanding of the interplay between the lungs and other organs is still in its infancy.

30
CHAPTER

Radiographic Evaluation of the Chest

Wallace T. Miller

Radiographic evaluation of the chest constitutes an important component in assessment of the patient with known or suspected pulmonary disease. In fact, the chest radiograph may provide the earliest or only clue to the presence of clinically significant respiratory disease. This chapter provides a brief overview of chest radiology. First, general aspects are covered; use of more specialized techniques, including computed tomography, nuclear magnetic resonance, and arteriography, is highlighted. Subsequently, radiographic manifestations of diseases that affect the distribution of pulmonary blood flow, the airways, and the lung parenchyma are considered. Finally, disorders are reviewed that are predominantly or exclusively confined to anatomically distinct areas of the thorax, including the mediastinum, diaphragm and chest wall, and pleura. Throughout the presentation, examples of radiographs are provided to highlight the principles and disorders discussed.

A *B*

Figure 30-1 The lateral view in uncovering a solitary nodule. *A*. PA view. No nodule is discernible. *B*. Lateral view. A small nodule (arrow) overlies the left hilus. The nodule proved to be a granuloma.

Although significant emphasis is placed on plain film findings, computed tomography has emerged as the most useful radiographic means of investigating chest disorders. Furthermore, although digital radiography is supplanting traditional film-based radiography in most departments, the descriptions provided about film-based radiography apply equally to digital studies.

GENERAL ASPECTS

In recent years, fresh concepts and new techniques have greatly expanded the diagnostic armamentarium of chest radiology. As a rule, the new approaches have strengthened the underpinnings of conventional methods and our diagnostic abilities. Evaluation invariably begins with routine chest radiographs, supplemented, as indicated, by more specialized techniques. Many of these specialized techniques are largely historical, since computed tomography (CT) and magnetic resonance imaging (MRI) produce a more detailed and sensitive evaluation of chest abnormalities.

Routine Examination

In asymptomatic patients, a posteroanterior (PA) chest radiograph may be used as the sole screening procedure. This projection is easiest to interpret, since the anatomy is quite familiar, and most pathological respiratory conditions are demonstrable in this view. Ideally, a lateral view should also be part of the routine examination. The lateral view adds valuable information about areas that are not well seen in the PA projection. This is particularly true of the anterior portion of the lung, adjacent to the mediastinum—an area that may be obscured by the overlying heart and aortic shadows (Fig. 30-1). The vertebral column is also seen to better advantage on the lateral view. A small pleural effusion is best seen, and often only seen, as blunting of a costophrenic sulcus posteriorly (Fig. 30-2).

In determining which costophrenic angle is blunted, correct identification of each hemidiaphragm on the lateral view is helpful. If the lateral radiograph is taken in the left lateral position, as is usual, the magnified ribs are on the right side; the unmagnified ribs are on the left side and are associated with the corresponding left hemidiaphragm (Fig. 30-2). In addition, the outline of the left hemidiaphragm is often obscured anteriorly because it merges with the heart shadow. Finally, the left hemidiaphragm may be recognized from its proximity to the stomach bubble, especially if the left hemidiaphragm is higher than the right.

Supplementary Plain Radiographs

In addition to the PA and lateral chest radiographs, other projections serve special purposes, although routine use of CT scanning has markedly diminished the frequency of use of these special films.

A

B

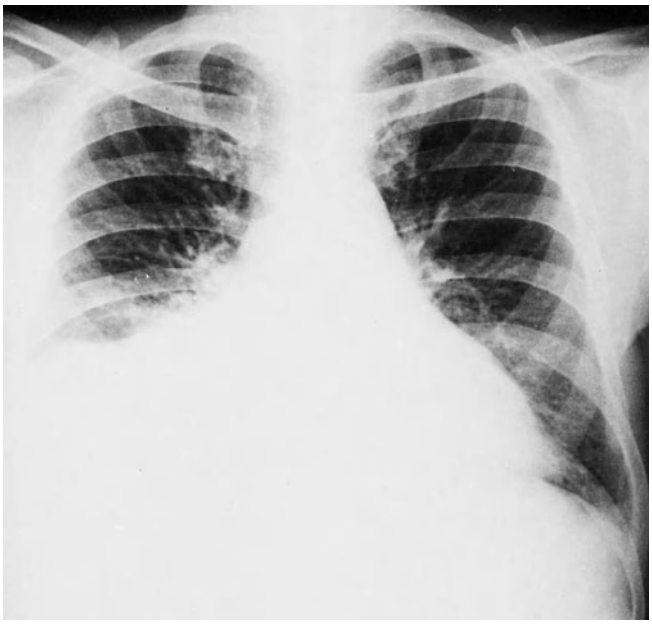
C

Figure 30-2 The lateral view in uncovering a small pleural effusion. *A*. PA view. No evidence of a pleural effusion. *B*. Lateral view. The right costophrenic sulcus is blunted (arrow). *C*. Lateral view. After treatment for heart failure, the effusion is gone. Note the magnification of the posterior (right) ribs.

Oblique views are sometimes invaluable in confirming or delineating a pulmonary mass or infiltrate from structures that overlie it on the PA and lateral views. Barium in the esophagus serves as a useful adjunct in clarifying the location of middle mediastinal lesions on oblique films.

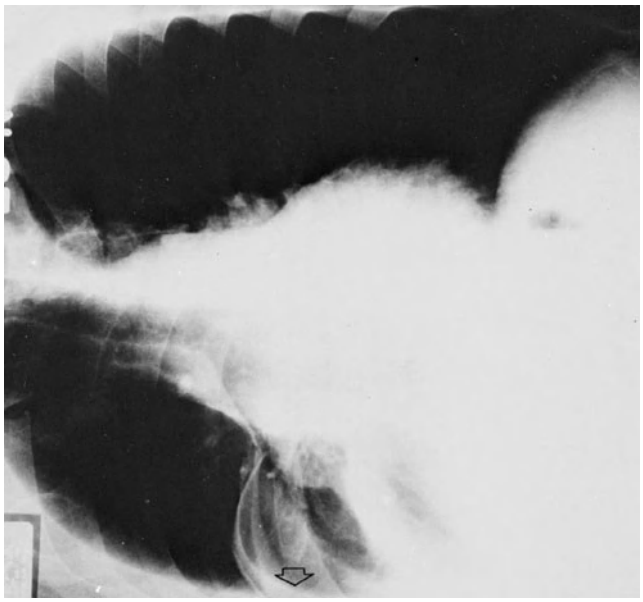
In interpreting oblique films, the clinician will find it useful to keep in mind that a pulmonary lesion that maintains a fairly constant relationship to the heart as the patient is rotated lies in the anterior portion of the chest; a lesion that maintains a constant relationship to the spine is in the posterior portion if the chest.

The *lateral decubitus* projection (Fig. 30-3*C*) is often used to identify the presence of a pleural effusion. As little as 25 to 50 ml of pleural fluid can be visualized, even though 300 ml may be required to blunt the costophrenic sulcus on the PA view. The decubitus view is particularly useful in determining if blunting of the costophrenic sulcus is due to a freely mobile pleural effusion or pleural thickening. Although a pleural effusion may be an important finding,



A

B



C

Figure 30-3 Infrapulmonary effusion. Neither the PA view (*A*) nor the lateral view (*B*) shows blunting of the costophrenic sulcus. However, elevation of the right hemidiaphragm suggests the presence of an infrapulmonary effusion. A right lateral decubitus film (*C*) shows the presence of a free pleural effusion on the right. The effusion was secondary to congestive heart failure.

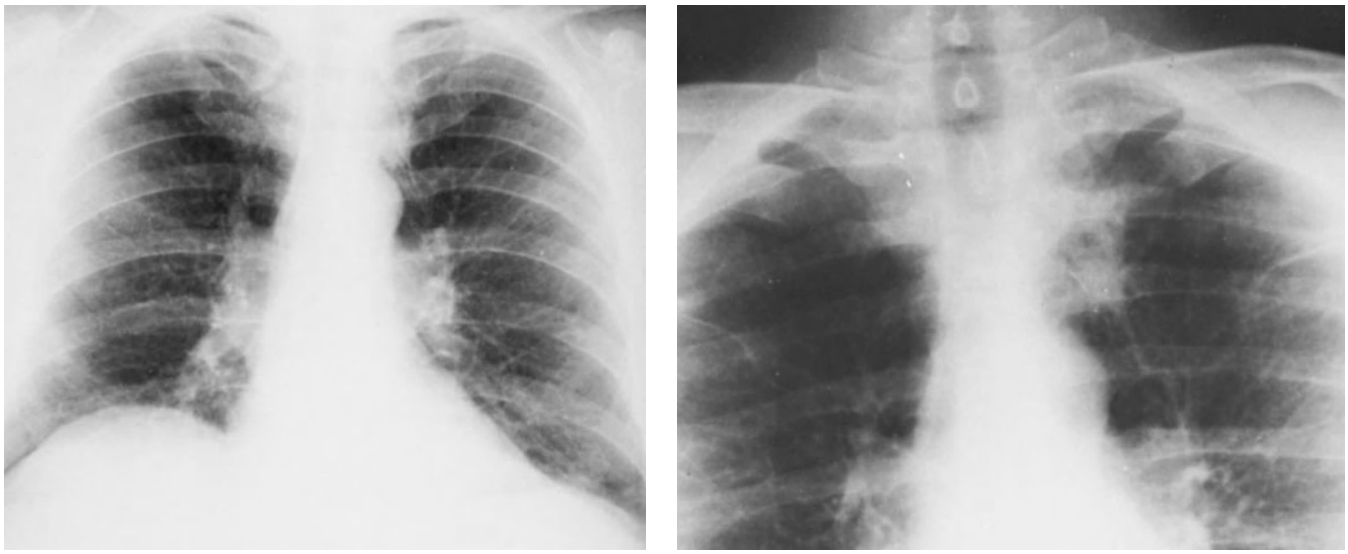
pleural thickening most often is a sequel to a remote exudate or blood in the pleural space; usually it is clinically unimportant. Distinction between pleural thickening and loculated fluid may be difficult.

On the PA film, shadows created by the first rib and clavicle may make interpretation of the lung apices difficult (Fig. 30-4*A*). The *lordotic* projection enables evaluation of the apices by displacing these overlying shadows (Fig. 30-4*B*). The lordotic view may also be useful in demonstrating collapse of the right middle lobe.

The *over-penetrated grid* radiograph (Fig. 30-5*A*) is useful for evaluating densities that lie behind the heart or diaphragm and are poorly seen on routine radiographs. Using digital imaging, the same effect can usually be obtained by appropriate windowing; hence, use of the over-penetrated grid radiograph is now seldom made. *Expiratory* films may disclose air trapping or a pneumothorax that is poorly shown on the inspiratory film.

Laminography

Historically, a technique known as *laminography* (also known as tomography, body section radiography, or planigraphy) utilized movement of the radiography tube and film about a fixed point to generate a radiograph of a tissue plane that is several millimeters thick; the designated plane is in focus, while surrounding anatomic details are blurred. In effect, this technique provided a view of a thin slice of lung and affords a "close look" at a suspected abnormality. It was useful in demonstrating the presence of calcification within a



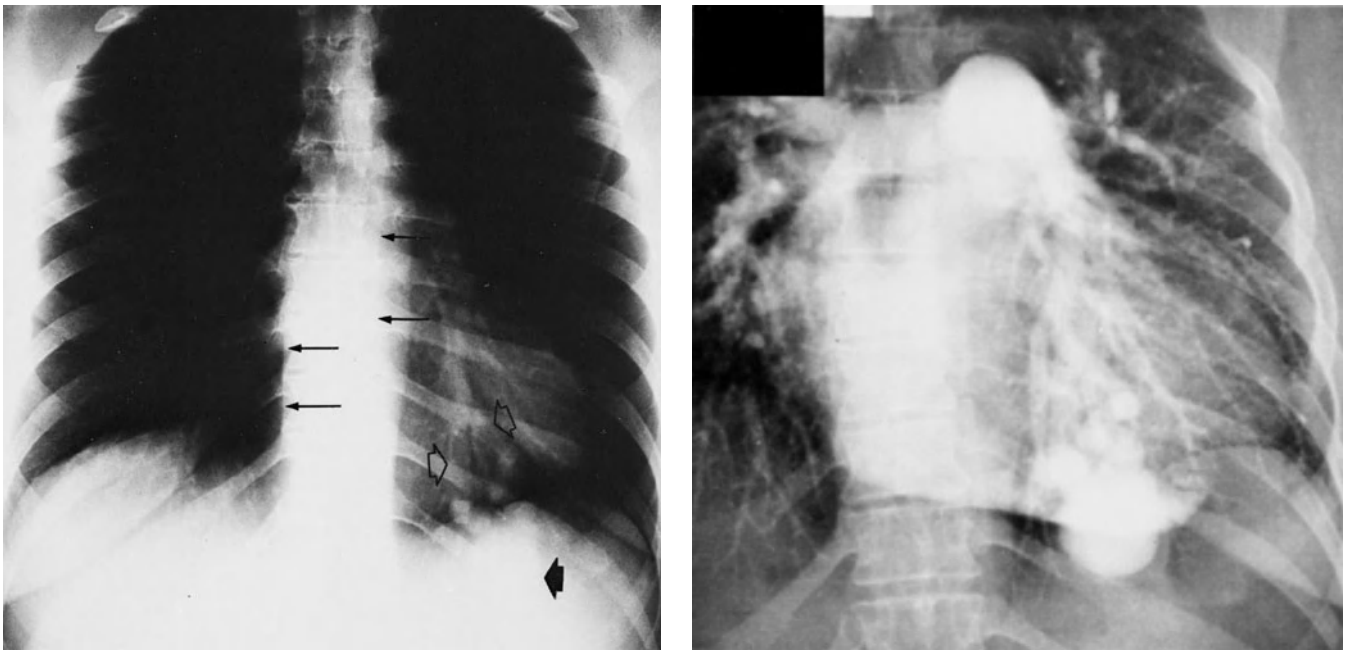
A *B*

Figure 30-4 Carcinoma of the left upper lobe. *A*. PA view. A small nodule is present in the left upper lobe adjacent to the mediastinum, just above the aortic knob. *B*. Lordotic view. The nodule is much more apparent. It proved to be a primary adenocarcinoma of the lung.

pulmonary nodule and, occasionally, in providing insight into its benign or malignant cause (e.g., the presence of scattered, "popcorn" calcifications, implying a benign process). Laminography has been supplanted completely by CT imaging.

Fluoroscopy

Fluoroscopy of the chest may be used for examining the movement of pulmonary and cardiac structures and for localizing a pulmonary lesion that is visible in only one of the two conventional radiographic projections. It is particularly



A *B*

Figure 30-5 Pulmonary arteriovenous malformation. *A*. Overpenetrated grid (Bucky) radiograph shows a nodule behind the diaphragm (closed arrow) with feeding artery in draining veins (open arrows). *B*. Pulmonary angiogram confirmed the diagnosis of arteriovenous malformation. Also visible bilaterally on the overpenetrated Bucky film are the posterior paraspinal lines (small arrows). The left posterior paraspinal line is medial to the aorta. The right paraspinal line is ordinarily not discernible; however, it can be seen in this patient because small osteophytes arising from the vertebral bodies displace the pleura laterally on the right.

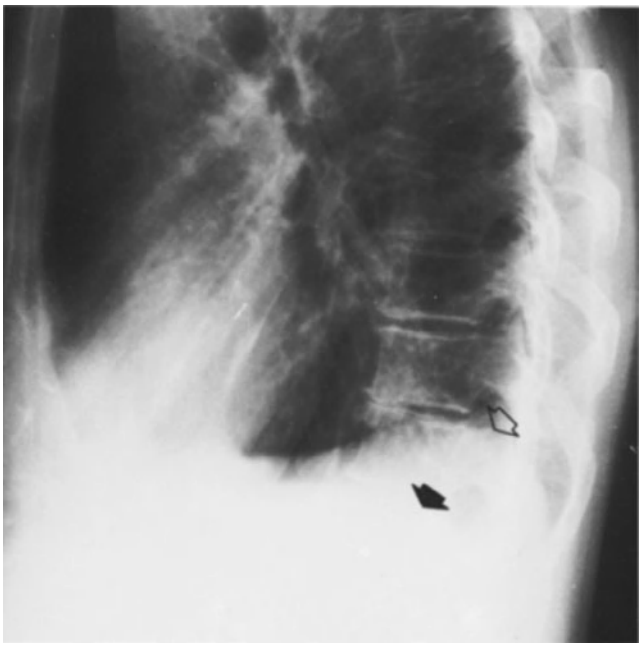


Figure 30-6 Partial eventration of the diaphragm. The lateral view shows elevation of the posterior portion of the right hemidiaphragm (open arrow). The normal contour of the left hemidiaphragm (closed arrow) appears immediately beneath. This partial eventration is due to a localized weakness in the posterior aspect of the right hemidiaphragm.

helpful for examining diaphragmatic motion. When one is searching for diaphragmatic paralysis, the patient is best fluoroscoped in the lateral projection, allowing motion of both hemidiaphragms to be observed simultaneously. A paralyzed hemidiaphragm moves paradoxically. This paradoxical motion may not be present during quiet breathing, but it usually becomes readily apparent during a quick, short "sniff" (*sniff test*). Localized weakness of part of one hemidiaphragm (i.e., *diaphragmatic eventration*) (Fig. 30-6) is often misinterpreted as diaphragmatic paralysis. This error can be avoided by performing fluoroscopy with the patient in the lateral projection; partial eventration is then readily observed as paradoxical motion of one portion of the hemidiaphragm, while the remainder of that hemidiaphragm moves normally. Eventration of an entire hemidiaphragm is impossible to distinguish from paralysis, since in both instances the entire hemidiaphragm moves paradoxically.

Fluoroscopy is sometimes useful in determining whether a nodule is truly in the lung. In an upright subject, nodules that are in the lung move in the caudal direction with inspiration, while nodules in the chest wall or ribs move in the cephalad direction. CT has largely supplanted fluoroscopy for this use; however, it is significantly more expensive, and fluoroscopy remains an option for evaluating certain pulmonary nodules.

Fluoroscopy of the heart may be useful in demonstrating calcifications in cardiac valves and in coronary arteries, but these areas are much better evaluated by CT or MRI. Fluoroscopy may suggest the presence of pericardial effusion much more convincingly than does the chest radiograph. However, fluoroscopy is rarely definitive for detecting a pericardial effusion, and other procedures, particularly ultrasound, CT, and MRI, are generally used to confirm a suspected pericardial effusion.

In the past, fluoroscopy was used as a screening procedure for routine examination of the chest. This is no longer acceptable for several reasons: (1) the patient's x-ray exposure is much greater during a short fluoroscopic examination than during the performance of standard chest radiographs; (2) small lesions in the lung fields are easily overlooked at fluoroscopy; and (3) no permanent record of the fluoroscopic examination is created.

Computed Tomography

Computed tomography (CT) is a radiologic technique for scanning cross-sections of the entire body. The underlying principle is the production of radiographic absorption profiles that are made at different angles in the same cross-sectional plane. A pencil-thin beam or beams of x-rays passes through the body as the radiographic tube rotates around the patient, and the transmitted radiation is detected by a sodium iodide crystal. By means of electronic transformation, the signals are fed into a computer, which synthesizes them into a radiographic image that displays the relative absorption coefficients of each small area in the plane of the scan. The technique is highly accurate, and its sensitivity to differences in density is considerably greater than that of the standard radiograph. Multidetector CT scanners now use multiple beams, so that 4 to 64 images are created simultaneously and at a much faster rate than when a single detector is used.

While the plain chest radiograph remains the primary radiologic technique in evaluating the chest, CT has added tremendous insight into disorders of the lungs, mediastinum, and chest wall. Cross-sectional images depicted by CT provide a huge added dimension in the investigation of chest pathology, and the increased resolution permits identification of many findings that are not visible on the plain radiograph (Fig. 30-7). This increased sensitivity is particularly true for small nodules, although the heightened sensitivity

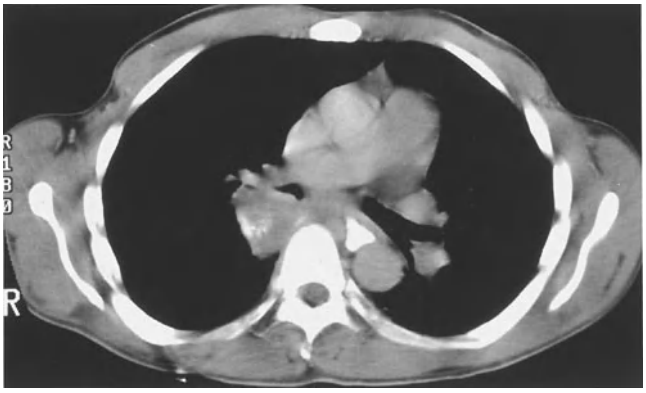

Figure 30-7 CT showing lung carcinoma not seen on routine chest radiograph. A large mass narrowing the right main stem bronchus can be seen in the right lower lobe. The mass contains some calcification.

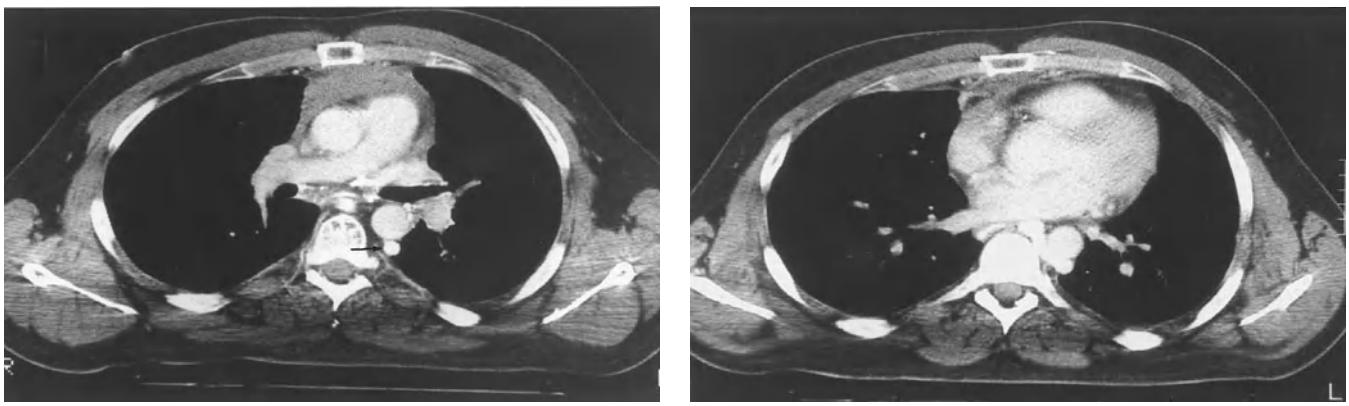

A *B*

Figure 30-8 CT demonstrating Hodgkin's disease obstructing the superior vena cava. *A*. A mass is seen in the anterior mediastinum, just beneath the sternum. The mass completely obstructs the superior vena cava, which cannot be seen. However, the accessory azygos vein (arrow) is unusually bright, since it is carrying blood that would ordinarily pass through the superior vena cava. *B*. A lower section shows contrast material crossing into the azygos vein, where it then enters the superior vena cava, adjacent to the right atrium.

for unimportant small nodules is the bane of chest CT. In addition, the mediastinum, which is somewhat of an "occult" area on the plain radiograph, is seen in wonderful anatomic detail. Lymphadenopathy may be readily seen, and mediastinal lesions of uncertain nature may be elucidated (Fig. 30-8). The use of intravenous contrast material as part of the examination permits separation of vascular from nonvascular mediastinal lesions and identification of vascular invasion by neoplasm (Fig. 30-9). The technique is also extremely useful in investigating chest wall lesions or the extension of pulmonary or pleural tumors into the chest wall (Fig. 30-10)—an important consideration, since the chest wall is not readily studied with the plain radiograph unless bone destruction is present.

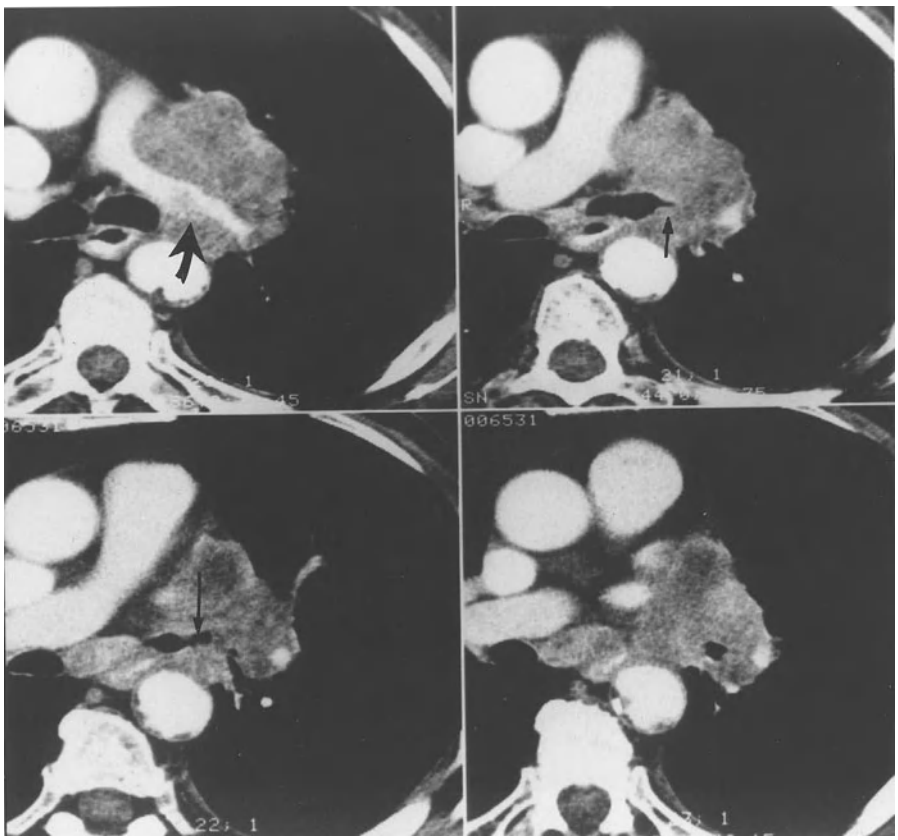

Figure 30-9 CT demonstration of extent of left upper lobe carcinoma. A mass is seen invading the pulmonary artery (large arrow) and left main stem bronchus (small arrows).

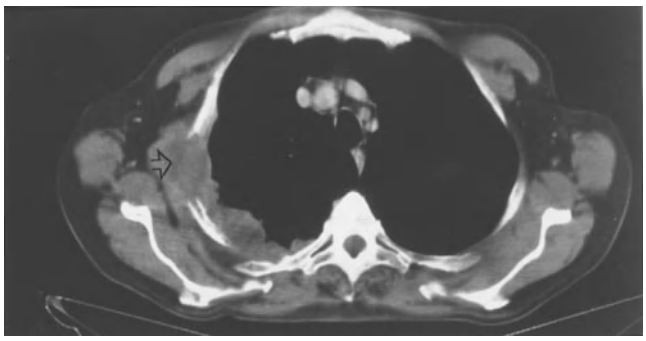

Figure 30-10 Mesothelioma extending into the chest wall. A pleural mesothelioma is seen on the right side; it directly invades the chest wall (arrow). The nodular character of the pleural involvement is characteristic of mesothelioma.

CT Angiography

CT angiography is an exciting application of helical (spiral) CT technology which has been made especially useful since the emergence of multidetector imaging. Axial, multiplanar, reformatted, and three-dimensional images of the vascular system are possible using this technique.

CT angiography has emerged as an excellent tool for identifying pulmonary embolism and has largely supplanted pulmonary angiography and scintigraphic ventilation-perfusion lung scanning. Direct visualization of pulmonary emboli by CT angiography carries a specificity similar to pulmonary angiography and a sensitivity similar to ventilation-perfusion scanning (Fig. 30-11). The technique is also useful in identifying chronic thromboembolic disease. Various aortic lesions, such as aortic dissection (Fig. 30-66), traumatic

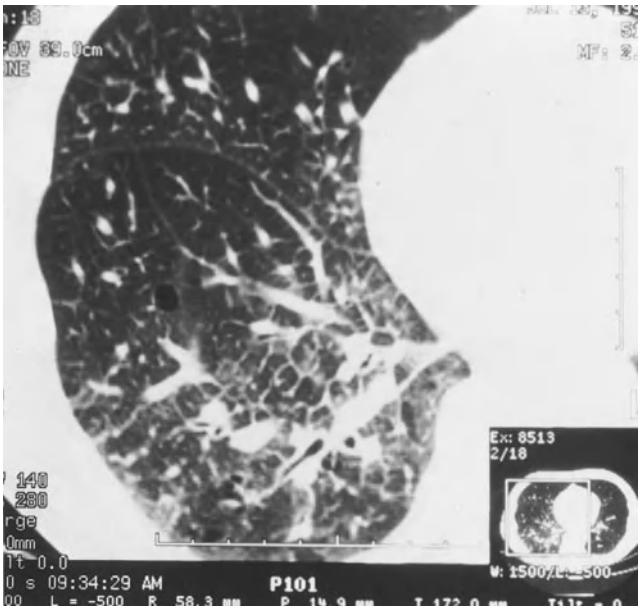

Figure 30-12 High-resolution CT of interstitial lung disease due to pancreatic carcinoma. Pulmonary lobules are nicely outlined by an interstitial process that affects the interlobular septae. This pattern is characteristic of lymphangitic spread of carcinoma, which, in this patient, was due to pancreatic carcinoma.

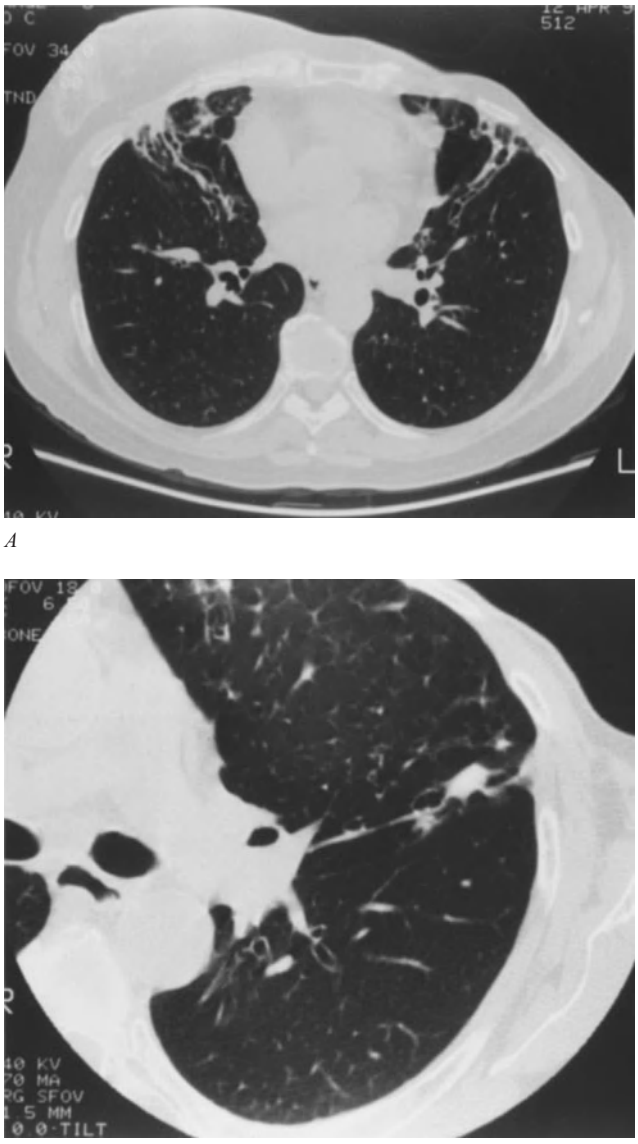
pseudoaneurysm, penetrating aortic ulcers, aortic aneurysms (Fig 30-24), and vascular anomalies of the aorta are well visualized using CT angiography. In addition, pulmonary venous malformations are readily recognized noninvasively. CT also has great usefulness in recognition and evaluation of cardiac disease.

High-Resolution CT

High-resolution CT is a special method for evaluating pulmonary pathology. The technique is based on generation of images of very thin anatomic slices (1 mm vs. 7 to 10 mm for the usual CT slice) and a special "bone algorithm" for reconstruction of the information obtained in each slice. The result is a very high-contrast image that provides excellent insight into certain pulmonary disorders.

High-resolution CT is primarily useful in identifying interstitial lung disease and bronchiectasis (Figs. 30-12 and 30-52). This technique has supplanted bronchography in evaluation of bronchiectasis (Fig. 30-13), as it is of comparable diagnostic accuracy and is noninvasive. In addition, high-resolution CT is helpful in identifying low-grade interstitial lung disease which may not be visible on the plain radiograph. While useful in stratifying differential diagnostic considerations in interstitial lung disease, high-resolution CT does not, at this time, completely supplant tissue biopsy. However, some clinicians will establish a diagnosis of usual interstitial pneumonitis (UIP) on the basis of clinical presentation and a characteristic CT appearance. In general, the technique serves mainly as an adjunct diagnostic method. While not ideal for studying mediastinal and chest wall lesions, high-resolution CT images are adequate to investigate these areas if the main



A

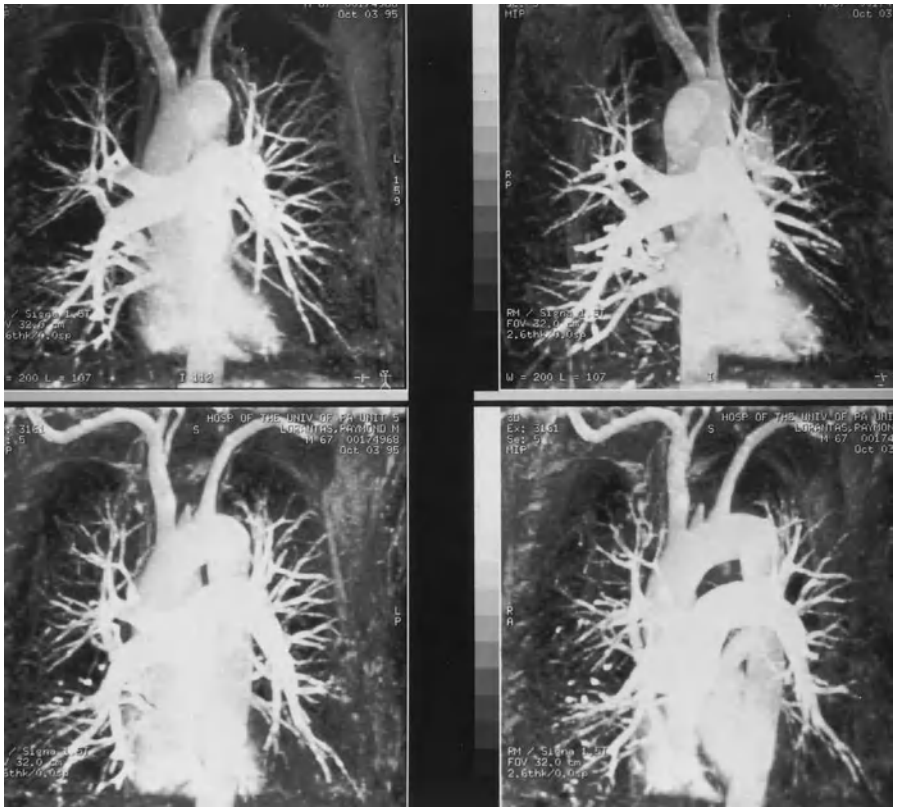
Figure 30-13 Bronchiectasis. *A*. Focal areas of tubular bronchiectasis are demonstrated in the middle lobe and lingula. This is a common manifestation of nontuberculous mycobacterial infection, in this case Mycobacterium avium intracellulare (MAI). *B*. High-resolution scan from another patient demonstrates more subtle bronchiectasis, with many small areas of invasion in the lingula. This was also secondary to MAI infection.

objective is delineation of the extent of the pulmonary process. In most instances, a routine, unenhanced CT study is performed prior to the high-resolution study to better evaluate the mediastinum, bones, and small pulmonary nodules that can be overlooked on the high-resolution images (since only *samples* of the lung are imaged, rather than consecutive contiguous slices).

Nuclear Magnetic Resonance

Magnetic resonance imaging (MRI) or nuclear magnetic resonance (NMR) is a technique that uses radiowaves modified by

A



B

Figure 30-14 Pulmonary embolus demonstrated by "time of flight" MRI. This technique shows the blood vessels in detail, rivaling images obtained with pulmonary arteriography. *A*. Pulmonary embolus can be seen in the right upper lobe (arrow). *B*. Reproductions in various degrees of obliquity show that the defect of the pulmonary embolus remains constant.

a strong magnetic field to produce a diagnostic image. The images generated are somewhat similar to CT images. However, using MRI, vascular structures are usually well seen without the use of contrast material, although intravenous gadolinium can be administered for better vascular evaluation. In addition, with MRI, different images and different information can be obtained by manipulation of the radiowave frequency and timing of the impulses delivered.

Although MRI has not had quite as great an impact as CT in the investigation of pulmonary lesions, it has great usefulness in the study of vascular lesions of the pulmonary vessels and mediastinum. In some institutions, MRI has

Figure 30-15 MRI demonstration of partial anomalous pulmonary venous return. Time of flight image shows the pulmonary arteries (straight arrow), pulmonary veins (curved arrow), and an anomalous pulmonary vein entering the superior vena cava (small arrow).

become the primary technique used in the study of aortic dissection (Fig. 30-62), although CT is equally good, somewhat faster, and much more readily available. MRI may also have a major role in the investigation of pulmonary embolism, either acute or chronic (Fig. 30-14). Finally, MRI has become a major means of investigation of congenital heart disease and shows great promise in the evaluation of myocardial ischemia.

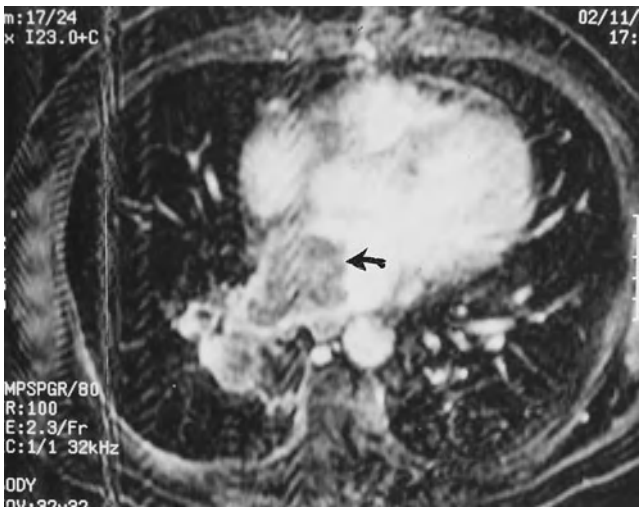
In addition to use of intravenous administration of gadolinium as a "contrast agent" to allow better visualization of vascular structures, a variety of MRI scanning techniques (e.g., "time of flight" imaging, etc.) further enhance the technique's utility (Figs. 30-15 and 30-16). Scanning can now be done extremely quickly, almost rivaling CT in rapidity of image acquisition.

MRI provides a unique feature in investigating the thorax and other body parts: the images obtained can be reconstructed in any one of several anatomic planes. While the standard MR image is usually an axial view, similar to that obtained with CT, sagittal and coronal images can be easily created from the information obtained at the time of the study (Fig. 30-14) and are usually routinely obtained. With the newer multidetectors, reformatted coronal and sagittal images with CT rival those of MRI.

Contrast Examinations

Air in the bronchi and alveoli is a superb contrast medium, outlining the pulmonary vasculature, heart, aorta and other mediastinal structures, diaphragm, and chest wall. In addition, pathological processes in the lung often produce characteristic changes in the pattern of the pulmonary vessels or air-filled alveoli. Hence, the plain chest film is a very useful

A



B

tool in the diagnosis of pulmonary disease, and more sophisticated radiographic techniques are often not necessary. Supplementary information can be gained by placement of contrast material into different components of the chest. Positive contrast material, such as barium sulfate suspension, is commonly introduced into the esophagus; other suitable media are used to visualize cardiac chambers, the trachea and bronchi, pulmonary vessels, vena cava and mediastinal veins, and mediastinal lymphatics. These techniques are very efficient in increasing the information that can be gained on a CT scan. Historically, carbon dioxide and nitrous oxide have been used to outline the right-sided cardiac chambers.

With CT, intravenous contrast material is especially useful in investigating mediastinal lesions and vascular structures. Oral contrast agents (e.g., Gastrografin) may be used to outline the esophagus and the gastrointestinal tract in the

Figure 30-17 Enlarged left atrium. The esophagus is displaced posteriorly by an enlarged left atrium (arrow).

upper abdomen. Similarly, using MRI, administration of intravenous gadolinium is frequently used to better depict vascular structures or highly vascular organs, such as the liver.

Of all the contrast examinations available, the barium swallow, generally carried out under fluoroscopic guidance, is the simplest to perform. A thick mixture of swallowed barium sulfate, with or without gas, outlines the esophageal contour, making it easy to detect displacement of the esophagus by adjacent mediastinal structures, such as tumor-containing lymph nodes or a large left atrium (Fig. 30-17). Abnormalities of the esophagus itself, such as achalasia or tumor, are also easily seen. While CT demonstrates most lesions of the esophagus, especially when oral contrast is administered, the barium swallow is much more sensitive for mucosal diseases, as it sometimes demonstrates esophageal carcinoma which is not well seen on CT.

Although the trachea and major bronchi are readily visualized in the mediastinum and hila on the plain film, bronchography or CT is necessary to better demonstrate the trachea, main stem bronchi, and peripheral bronchi. Historically, bronchography was performed with special contrast material to perform this function, but this has been replaced by CT and is no longer used. Figures 30-18 and 30-19 are bronchograms obtained using oily Dionosil as a contrast agent instilled in the airways.

Pulmonary Angiography

Pulmonary angiography and related interventional radiographic techniques are also discussed in Chapter 32. When used as a diagnostic tool, pulmonary angiography entails rapid injection of a radiopaque dye into the pulmonary circulation through a catheter introduced into the pulmonary arterial tree or into a large systemic vein leading into the right atrium. In the past, angiography, was the gold-standard in investigation of pulmonary thromboembolic disease (Figs. 30-20 and 30-21) (see Chapter 34); however, CT yields comparable information and is much less invasive. Ventilation-perfusion lung scans using radioactive isotopes are also useful in detecting pulmonary embolism (see Chapter 82), but they, too, are currently used less frequently than CT.

Congenital abnormalities of the pulmonary vascular tree, such as hypoplasia or agenesis of the pulmonary artery, arteriovenous malformation, pulmonary varix, or anomalous pulmonary venous return, are also identified using pulmonary angiography (Fig. 30-5*B*). These abnormalities are often suspected on the basis of routine radiographs, but angiography may be used for confirmation. As with pulmonary embolism, both CT and MRI have largely supplanted pulmonary angiography in investigating these lesions (Figs. 30-11 and 30-15).

Pulmonary angiographic procedures may also be used therapeutically (see Chapter 34). Arteriovenous malformations can be treated with pulmonary artery embolization using a variety of embolic materials, as can bleeding from the pulmonary or bronchial arteries. A strategically placed pulmonary artery catheter may be used to infuse streptokinase or other lytic agents to dissolve an acute pulmonary embolus. Similarly, techniques are available to fragment and extract pulmonary emboli through pulmonary artery catheters.

Aortography and Systemic Arteriography

Puzzling shadows in the vicinity of the middle (visceral) compartment of the mediastinum can be explored with aortography, a technique that takes advantage of the fact that the aorta is within the middle mediastinal compartment.

Opacification of the aorta using contrast material usually requires retrograde catheterization of the aorta for direct injection. Middle mediastinal masses frequently prove to be vascular (e.g., dissecting aneurysms of the aorta), saccular or fusiform aneurysms of the aorta (Fig. 30-22), or anomalies or unusual tortuosity of the aorta or great vessels. In current practice, CT or MRI usually makes arteriography unnecessary (Figs. 30-23 and 30-24).

Owing to the dual blood supply of the lung, pulmonary arteriography may not be rewarding in the evaluation of some pulmonary lesions; in these cases, bronchial arteriography may be more useful. In patients with massive hemoptysis due to tumor or infection (e.g., tuberculosis, bronchiectasis, or aspergillosis), the major pulmonary blood supply is usually the bronchial circulation. Embolization of feeding bronchial arteries may yield temporary, or even permanent, control of the bleeding.

Bronchial arteries supply most lung tumors. Infusion of various chemotherapeutic agents into these tumors via the bronchial circulation has been attempted for palliative control of nonresectable malignancies. So far, this has not been a very fruitful approach.

Venography can also be helpful in the diagnostic evaluation of pulmonary abnormalities. After injection of radiopaque material into a large vein of one or both upper extremities, displacement or obstruction of the superior vena cava by mediastinal masses or scarring due to inflammatory

processes can be identified (Fig. 30-25). The azygos vein can also be opacified, and visualization of this structure is occasionally helpful in evaluating mediastinal lesions or suspected bronchogenic carcinoma. Once again, these techniques have been largely supplanted by CT (Fig. 30-9) and MRI.

Air Contrast Studies

Historically, air has been introduced into various compartments of the chest for diagnostic purposes. For example, deliberate introduction of air into the pleural space (diagnostic pneumothorax) has been used to demonstrate pleural lesions. Diagnostic pneumothorax has fallen out of vogue because other methods, such as thoracoscopy, yield much more definitive and reliable information. Diagnostic pneumothorax and diagnostic pneumoperitoneum have been used to investigate masses in the vicinity of the diaphragm. Air in the peritoneal may also demonstrate a subphrenic abscess. CT or MRI is much less invasive and more definitive.

PULMONARY ARTERIES AND VEINS

The pulmonary arteries are recognized as structures that accompany the bronchi and branch in a similar fashion (Fig. 30-26 *A*). In contrast, the pulmonary veins take a somewhat different course (Fig. 30-26 *B*). In the lower lobes, the pulmonary veins are considerably more caudal than the corresponding arteries; the veins are situated at the level of the eighth to tenth ribs posteriorly, whereas the arteries are at the level of the seventh and eighth ribs. In the upper lobes, the pulmonary veins are lateral to the pulmonary arteries (Fig. 30-15).

On the plain film, the direction taken by a pulmonary vessel is the most useful basis for establishing its identity. Near the hili, particularly in the lower lobes, the pulmonary veins are more horizontal than the pulmonary arteries. At the hili, the pulmonary veins lie below and lateral to the arteries (Figs. 30-15 and 30-26). Although it is often possible to distinguish arteries from veins by plain film, this distinction is seldom useful, and the generic terms *pulmonary vessels* and *pulmonary vasculature* are used. CT and MRI more readily depict the pulmonary arteries and veins. The pulmonary arteries arise from the main pulmonary artery trunk, while the pulmonary veins enter the left atrium (Figs. 30-15 and 30-26).

Distribution of Pulmonary Blood Flow

Blood flow is not uniform in the normal, upright human lung. Moreover, the blood flow pattern shifts with changes in posture, during exercise, and in a variety of heart and lung diseases. In the normal pulmonary circulation, gravity is the predominant determinant of the pattern of blood flow. Under the influence of gravity, hydrostatic pressure in pulmonary arteries, capillaries, and veins decreases by approximately 1 cm H_2O per centimeter of distance from the bottom to the top of the lung. Accordingly, in the upright position, blood flow

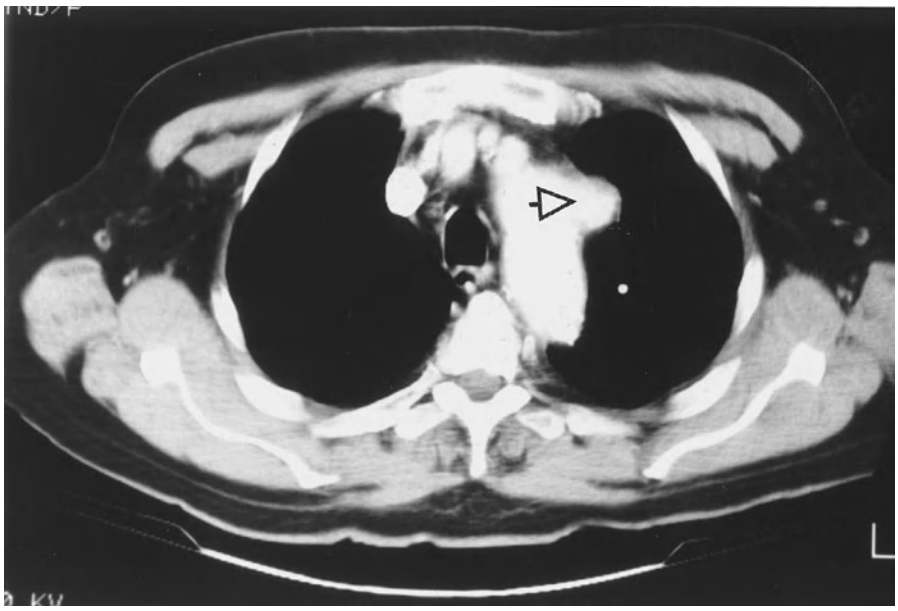

Figure 30-23 Aortic aneurysm shown by CT. A saccular aneurysm of the aortic arch (arrow) is readily demonstrated.

is minimal at the apex and maximal at the base. In the supine position, blood flow becomes much more uniform. If the lung is inverted, the normal pattern is reversed, so that flow to the apex, now dependent, increases considerably and exceeds blood flow to the base (Fig. 30-27). During walking or with any mild exercise in the upright position, total pulmonary flow increases, but flow to the lung apex increases proportionately more than flow to the base, resulting in a more uniform distribution.

If pulmonary arterial pressure at the top of the lung fails to exceed alveolar pressure, capillaries in the apices collapse. In the normal lung, pulsatile pulmonary blood flow suffices to perfuse the apices; but when pulmonary arterial pressure falls, as in hemorrhagic hypotension, the normal marginal perfusion of the apices may give way to cessation of blood flow. Gravity plays less of a role once an increase in pulmonary vascular resistance has raised pulmonary arterial pressure to hypertensive levels.

Lung disease often modifies the pattern of pulmonary blood flow by mechanical means and by development of pulmonary vasoconstriction (Fig. 30-28). Heart disease may also affect the pattern of flow. For example, in left-to-right intracardiac shunts, pulmonary blood flow not only increases but also becomes more uniform than normal. The pattern

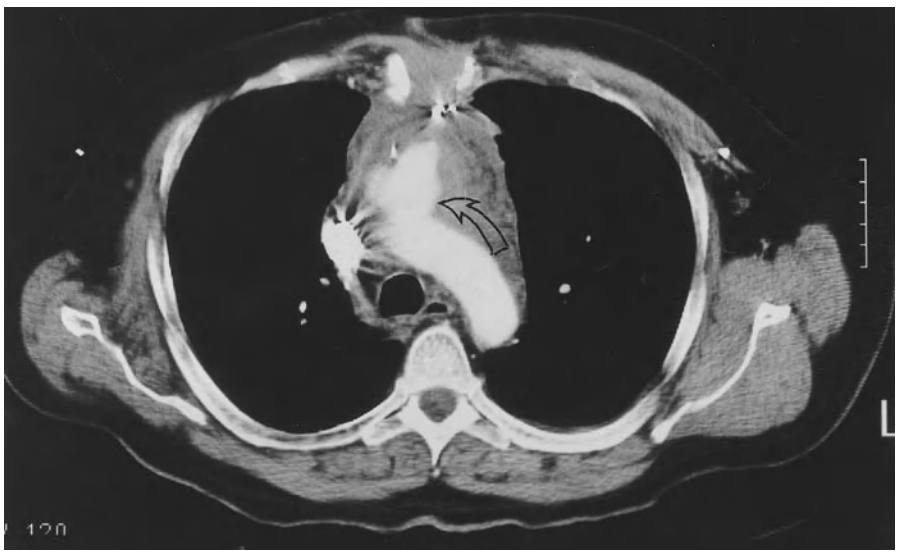

Figure 30-24 Aortic pseudoaneurysm demonstrated by CT. Anterior mediastinal infection led to development of a pseudoaneurysm at an aortotomy site. The CT not only demonstrates the pseudoaneurysm (arrow) but also shows masses caused by infection in the anterior mediastinum and chest wall.

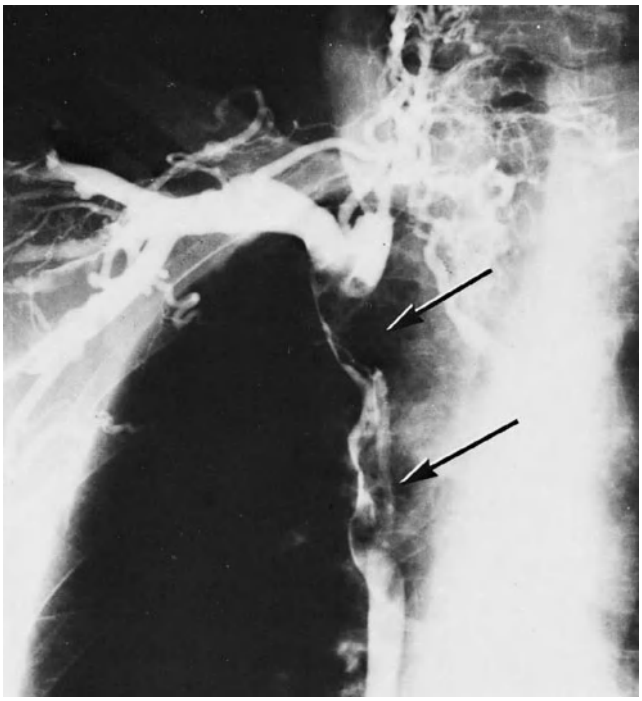

Figure 30-25 Superior vena caval invasion by metastatic tumor. A superior venacavogram shows invasion of the superior vena cava in several places (arrows) by metastatic tumor involving the mediastinal lymph nodes. Today, this would be identified by CT.

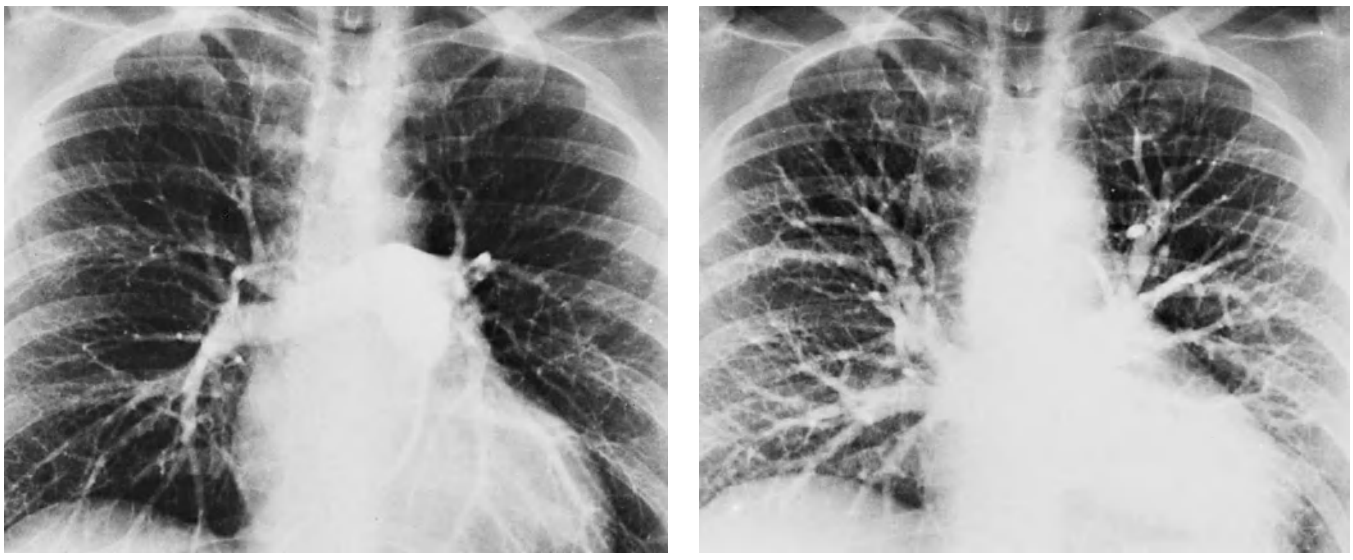
is quite similar to that in exercise. In heart disease associated with high pulmonary venous pressure (e.g., chronic left ventricular failure or mitral stenosis), the distribution of blood flow tends to become more uniform early in the disease. In time, the apices become relatively hyperperfused as a result of interstitial edema, pulmonary fibrosis, and hypoxic vasoconstriction of the lung bases. As a consequence, pulmonary vascular resistance at the lung bases is increased in the setting of pulmonary venous hypertension, and blood flow is directed toward the apices (Fig. 30-29). In prolonged, severe pulmonary venous hypertension, further constriction of the pulmonary vasculature occurs diffusely through the lungs, resulting in the "pruned tree" appearance of pulmonary arterial hypertension. Chronic lung disease or idiopathic pulmonary hypertension (Fig. 30-30*A*) may also result in the radiographic findings of pulmonary arterial hypertension. In general, the diagnostic accuracy of the plain film is much greater for pulmonary venous hypertension than for pulmonary arterial hypertension.

CT and MRI may suggest the presence of pulmonary arterial hypertension. Ordinarily, the aortic diameter is greater than the pulmonary artery, but in pulmonary hypertension, the situation is reversed (Fig. 30-30*B*).

The influence of gravity on the distribution of blood flow bears on the interpretation of the chest radiograph. The mainstay of the concept, illustrated in Fig. 30-31, is that in the normal upright lung, although gravity causes pulmonary arterial and venous pressures to increase from top to bottom of the lung, alveolar pressure remains virtually constant (see Chapter 11). Alterations in the normal relationships among pulmonary arterial, pulmonary venous, and alveolar pressures from top to bottom of the upright lung cause derangements in the pattern of blood flow. For example, a regional increase in alveolar pressure may arise because of "ball-valve" physiology as a result of bronchoconstriction or bronchial obstruction by a foreign body or mucus plug. In chronic obstructive airway disease, this mechanism contributes to



A *B*

Figure 30-26 Pulmonary arteries and veins. *A*. The early phase of the pulmonary angiogram depicts the normal course of the pulmonary arteries. *B*. The late phase shows the normal course of the pulmonary veins. The veins have a more horizontal course than the arteries and enter the hilus below the arteries.

A

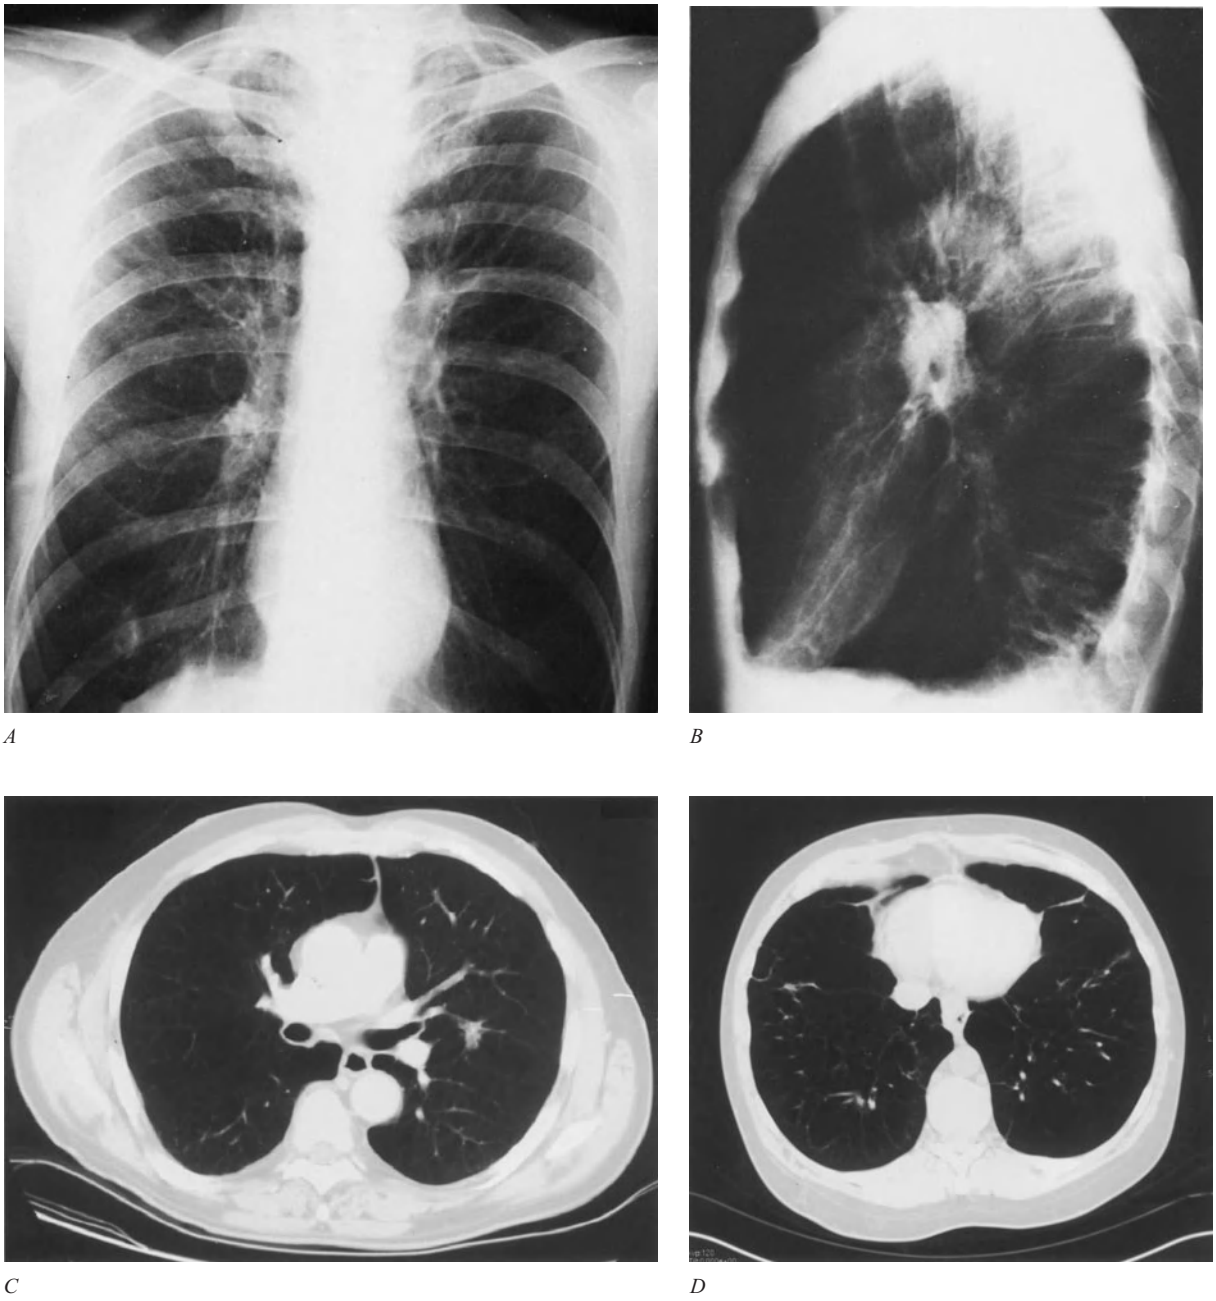
B

C

Figure 30-27 Effect of gravity on the pulmonary vasculature. Vascular patterns are compared in a normal subject in the erect, supine, and upside-down positions. *A*. Erect posture. The vascular pattern is more prominent at the bases. *B*. Supine position. The vascular pattern is more uniform. *C*. Upside-down position. The vascular pattern is more marked at the apices.

rearrangement of blood flow, adding a functional component to the anatomic effect of obliteration of parts of the pulmonary vascular bed by disease.

Other disease processes also cause a characteristic redistribution of pulmonary blood flow. For example, although uncommonly seen, the oligemic pattern distal to a large pulmonary embolus (Westermark's sign) is of great diagnostic value (Fig. 30-32). In primary pulmonary hypertension, the peripheral vessels are small and the central vessels are quite large, resulting in the pruned-tree appearance of the pulmonary vasculature described earlier (Fig. 30-30*A*). In emphysema, local destruction of pulmonary vasculature results in bizarre and unpredictable patterns of pulmonary blood flow (Fig. 30-28*A*).



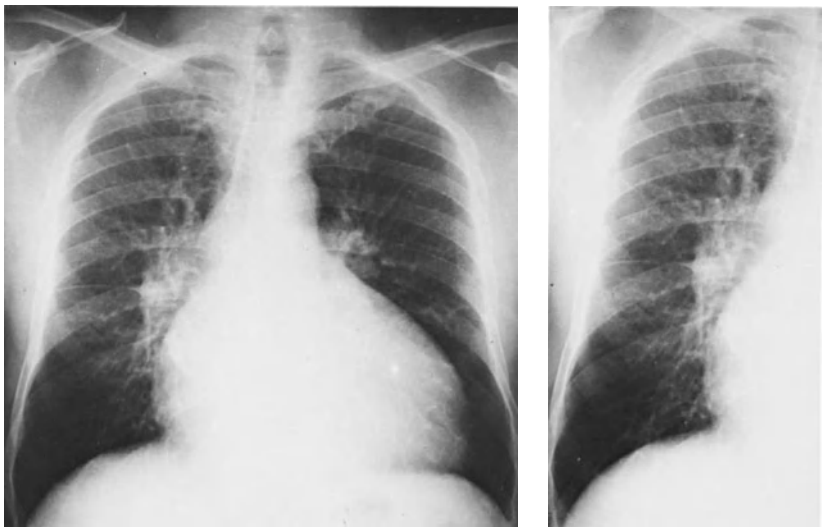
A *B*

C *D*

Figure 30-28 Severe pulmonary emphysema. *A*. PA view. Both lungs appear to be hyper-radiolucent. Blood flow to the left lower lobe is particularly reduced. *B*. Lateral view. The marked hyper-radiolucency is associated with a flat diaphragm, a wide anteroposterior diameter of the chest, and an increase in the retrosternal space. These changes represent advanced emphysema. In mild emphysema, the chest radiograph is usually normal. *C*. CT showing moderate centrilobular emphysema with incidental left upper lobe carcinoma. Multifocal, asymmetric hyperinflation is present. A small nodular infiltrate in the left upper lobe proved to be a primary lung carcinoma. *D*. CT showing panlobular emphysema in α_1-antitrypsin deficiency. Diffuse emphysematous changes are present, primarily at the lung bases.

DISTRIBUTION OF AIR WITHIN THE LUNGS

Just as is the case for pulmonary blood flow, the distribution of ventilation is affected by gravity. Normally, ventilation to the base is greater than to the apex because of the greater alveolar distention caused by gravity and a higher transpulmonary pressure at the apex (see Chapter 11). Changes in ventilation from top to bottom of the upright lung are much more modest than are changes in blood flow. When the lung is supine, ventilation, as well as blood flow, is much more uniform. If the lung is turned upside down, the normal pattern is reversed, so the apex is better ventilated than the base.



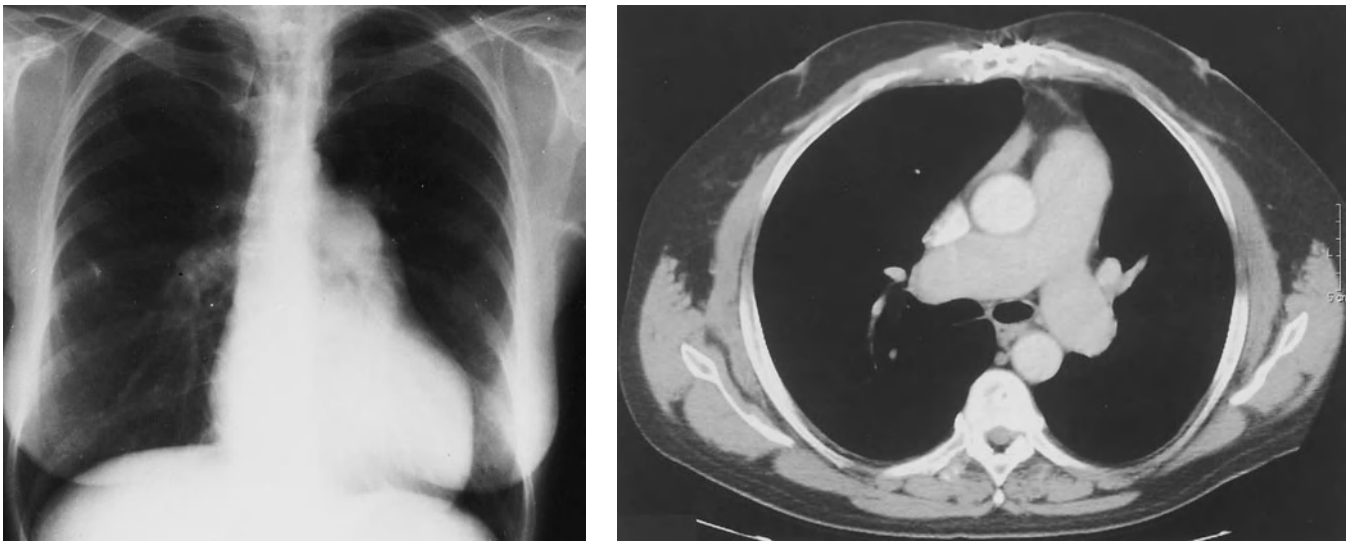
A *B*

Figure 30-29 Pulmonary vasculature (venous hypertension) in mitral stenosis. *A*. PA view. The enlarged left atrium is seen as a double density within the cardiac shadow. Cephalization of the pulmonary blood vessels is also present as a result of an increase in blood flow to the apices, in conjunction with a decrease in flow to the lung bases. *B*. Close-up view. The increase in vascular markings at the apices is more striking.

Radiographic techniques can be of considerable value in providing information about the distribution of air within the lungs. For example, fluoroscopy of the chest and comparison of chest radiographs taken during inspiration and expiration are useful in detecting and localizing air trapping; blebs and bullae appear as avascular, excessively radiolucent areas. Expiratory CT is much more sensitive in demonstrating air trapping, especially in small airways disease and is also much more sensitive in showing disproportionate blood flow to the two lungs. Extensive pleural encasement of one lung often is associated with a disproportionately small hemithorax and diminished ventilation and perfusion of the affected side. Marked reduction in pulmonary vascular markings also occurs in unilateral hypoventilation or hypoplasia of the pulmonary artery (Swyer-James or Macleod's syndrome); the hemithorax on the affected side is also usually small. Syndromes associated with unilateral hypoplasia often show air trapping on the affected side.

Obstructive Airway Disease

The plain film generally has little to offer in the early diagnosis of obstructive disease of the airways, but CT, especially high-resolution expiratory CT, can be quite useful. Chest radiographs are nearly always normal in patients in whom the airway obstruction is reversible. For example, in asthma, the chest radiograph is usually normal except during an acute episode, when the lungs often appear hyperinflated.



A *B*

Figure 30-30 *A*. Primary pulmonary arterial hypertension. The pulmonary trunk and its right and left main bronchi are markedly enlarged. In contrast, the peripheral vasculature is sparse. *B*. Pulmonary hypertension by CT. Note that the pulmonary artery is much larger than the aorta. This is the reverse of the normal situation and is characteristic of pulmonary hypertension.

Zone		Behavior of capillary	Flow depends on
I $P_A > Ppa > Ppv$		Collapsed	No flow*
II $Ppa > P_A > Ppv$		Starling resistor	$Ppa - P_A$
III $Ppa > Ppv > P_A$		Open or distended	Ppa – Ppv

*Except for flow through corner vessels.

Figure 30-31 Schematic representation of the behavior of small vessels in different parts of the lung. The lung is pictured as consisting of three vertical zones. In zone I, alveolar pressure is greater than arterial pressure, so collapsible vessels in the pulmonary microcirculation close; there is no blood flow. In zone II, arterial pressure exceeds alveolar pressure, which exceeds venous pressure. The pulmonary arterial-alveolar pressure difference determines the blood flow. Microvessels in this zone behave like Starling's resistors. The arterial-alveolar pressure difference increases linearly from top to bottom of the lung and produces corresponding changes in blood flow. In zone III, blood flow is determined by the difference between pulmonary arterial and venous pressures, since venous pressure exceeds alveolar. The collapsible vessels are open, and the pressure difference is constant throughout the zone (*From West JB: Regional Differences in the Lung. New York, Academic, 1977.)*

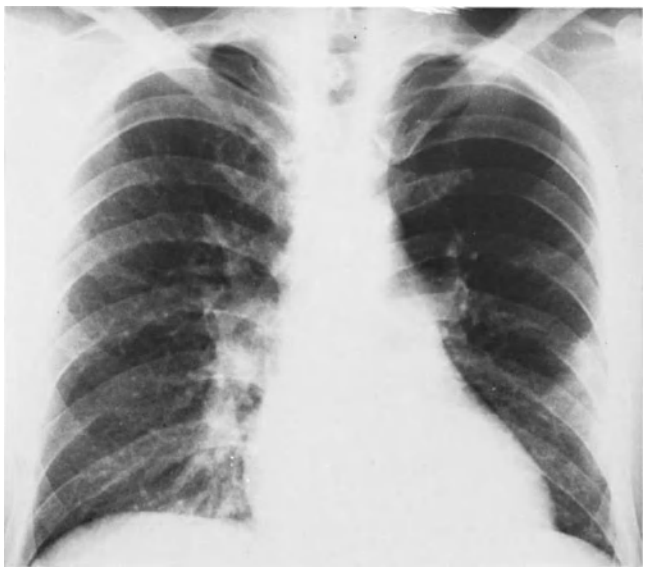


Figure 30-32 Massive pulmonary embolus. The PA view demonstrates marked diminution of the pulmonary vasculature to the left lung, secondary to a chronic massive pulmonary embolus in the left main pulmonary artery (Westermark's sign).

Expiratory CT may show localized air trapping or a "mosaic" perfusion pattern.

Similarly, the diagnosis of chronic bronchitis is a clinical one, based upon a history of chronic sputum production (see Chapter 40) and supplemented by characteristic abnormalities in pulmonary function tests (see Chapter 34). The radiograph rarely provides substantive help. Vascular markings throughout the lung fields are sometimes prominent, but this finding is nonspecific. Once again, expiratory CT may show air trapping which is indicative of small airways disease.

The classic radiographic appearance of more advanced emphysema is hyperinflation and diminution of vascular markings (Fig. 30-28). Hyperinflation is manifested by increased radiolucency of the lungs; low, flat diaphragms; exaggerated verticality of the heart; increased anteroposterior diameter of the chest; and widening of the retrosternal space. Of all these criteria, diaphragmatic flattening is probably the most reliable in supporting a diagnosis of chronic obstructive airway disease, but is seen only in patients with severe emphysema.

Hyperinflation can be simulated radiographically when a normal, robust person exerts a maximal inspiratory effort. The lungs also appear hyperinflated in very slender persons. Therefore, it is unwise to make the diagnosis of emphysema solely on the basis of the radiographic finding of hyperinflation.

CT shows characteristic changes in centrilobular, panlobular, and paraseptal emphysema. In centrilobular emphysema, focal areas of hyperlucency are scattered throughout the lungs, often with an apical dominance. As emphysema

Figure 30-33 Increased markings pattern. The vascular markings are prominent throughout the lung fields. The patient has chronic bronchitis and emphysema. Hyperaeration is minimal.

becomes worse, more lung is involved and bullae may be evident.

In panlobular emphysema, there is diffuse hyperaeration of the lungs, often with a basilar predominance. This pattern is characteristic of α_1-antitrypsin deficiency.

In paraseptal emphysema, there are focal areas of hyperlucency in the periphery of the lungs. Paraseptal emphysema usually coexists with centrilobular emphysema. CT is especially useful in demonstrating the presence and location of bullae when bullectomy or lung reduction techniques are planned (see Chapter 53).

Supplemental plain film evidence for the diagnosis of emphysema can be afforded by examination of the pulmonary vessels. Two distinctly different vascular patterns have been identified in patients with chronic bronchitis and emphysema: arterial deficiency and increased lung markings. Patients who show the arterial deficiency pattern (Fig. 30-28) often have panlobular emphysema and manifest the clinical syndrome of the "pink puffer." Those who have the pattern of increased lung markings (Fig. 30-33) often have centrilobular emphysema and manifest the "blue bloater" syndrome (see Chapter 40). Notably, these radiographic findings occur relatively late in the clinical course of emphysema.

Patients with chronic bronchitis and emphysema who develop pulmonary hypertension usually show the characteristic features of hyperinflation and an abnormal vascular pattern. In addition, they may show distinctive enlargement of the main pulmonary artery and of the hilar pulmonary arteries and oligemia of the peripheral lung fields. These findings constitute important evidence of the existence of pulmonary hypertension. Using CT, pulmonary hypertension is readily recognized when the diameter of the pulmonary artery is greater than the aorta, a reversal of the normal situation.

Attempts have been made to use radiographic techniques to determine lung volumes in patients with chronic bronchitis and emphysema. Numerous measurements made on PA and lateral chest radiographs and on CT have served as the basis for the calculations; results have compared favorably with those obtained directly using body plethysmography. Recently, the radiographic approach has been reinforced by the availability of sophisticated computer techniques, especially with CT. These methods have not been widely adopted, however, because of the availability and accuracy of body plethysmography (see Chapter 34).

Heart Failure Complicating Chronic Bronchitis and Emphysema

Both right and left ventricular failure may occur in the patient with chronic obstructive airway disease, but the underlying mechanisms and radiographic appearances are different. Right ventricular failure in chronic obstructive airway disease is generally a consequence of pulmonary hypertension—which, in turn, is secondary to severe hypoxia and respiratory acidosis. As a consequence of right ventricular failure, lung water increases, but rarely to the point of overt pulmonary edema. In contrast, left ventricular failure is generally caused by unrelated disease of the coronary circulation or left ventricular myocardium; as a result, pulmonary venous pressure is abnormally high, resulting in the formation of hemodynamic pulmonary edema.

Recognition of left ventricular failure in patients with chronic obstructive airway disease is difficult. The low diaphragm and rarefied lungs obscure enlargement of the heart. Changes in pulmonary vasculature that are associated with left ventricular failure are difficult to recognize in the patient with a pattern of increased lung markings. Moreover, pulmonary edema often assumes unusual appearances in patients with underlying structural lung disease. Most helpful is comparison of recent and old chest radiographs, with particular attention focused on changes in cardiac size and vascular pattern. Frequently the presence of left ventricular failure is recognized retrospectively, as heart size decreases and vascular markings become attenuated following diuretic therapy. Comparison with prior CTs is also useful in recognizing heart failure on CT.

DISEASES AFFECTING THE PULMONARY PARENCHYMA

In sorting out the many diseases that can affect the lung parenchyma, knowledge of whether the process involves

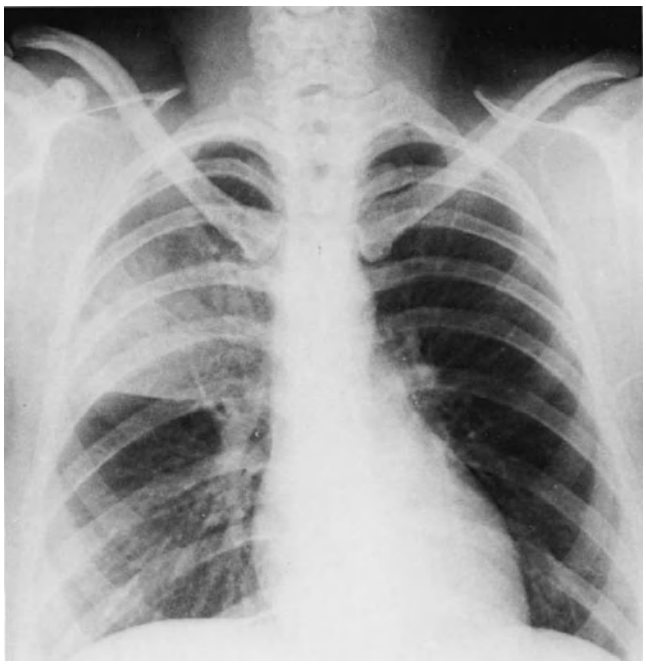

Figure 30-34 Right upper lobe pneumonia. The PA radiograph shows diffuse consolidation of the right upper lobe. The alveolar pattern is characteristic. The radiolucent streaks that run through the consolidation represent air in the bronchi (air bronchogram).

primarily the alveoli or the interstitium is useful. Frequently, but not invariably, this distinction can be made on the chest radiograph.

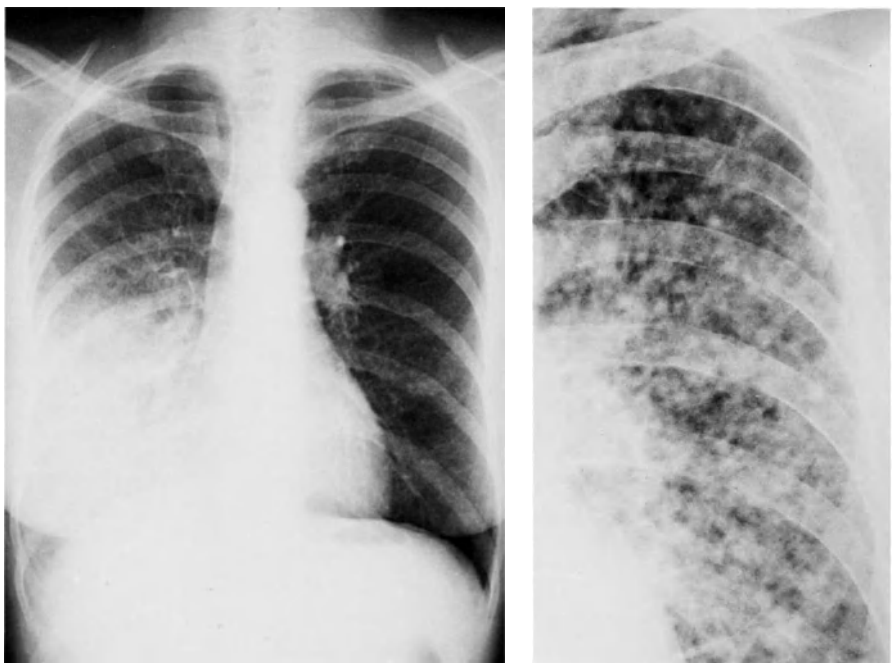
An alveolar radiographic pattern is created when alveolar airspaces are filled with material (e.g., blood, pus, or fluid). Characteristic radiographic features of alveolar filling diseases are exemplified in Figs. 30-34 through 30-36. These features include coalescence of densities and creation of large homogeneous shadows; presence of air bronchograms (i.e., visualization of peripheral bronchi due to consolidation of surrounding alveoli); fluffy, irregular margins of localized areas of consolidation; and usually rapid change in the areas of consolidation.

Localized Alveolar Disease

Localized alveolar disease assumes two primary patterns on the chest radiograph: patchy consolidation of airspaces without a decrease in the volume of the affected area, and consolidation of airspaces associated with a decrease in the volume of the affected area (atelectasis). The differential diagnosis depends largely on the extent to which lung volume is decreased. However, assessment of the magnitude of volume loss is not always useful. For example, while pneumonia usually is associated with minimal or no volume loss, occasionally, volume loss is considerable. On the other hand, atelectasis usually has moderate or severe loss of volume, but in some instances, there may be little or no loss of volume.

Localized consolidation of alveolar airspaces without loss of lung volume, or with minimal loss, is usually a sign of pneumonia (Fig. 30-34). Consolidation may be localized to a lobe (Fig. 30-35) or a pulmonary subsegment, or it may be more diffuse (Fig. 30-36). Consolidation of a pulmonary subsegment causes a characteristic radiographic pattern (Figs. 30-37 and 30-38). Other causes of consolidation without loss of volume include pulmonary edema (which occasionally occurs as local consolidation, even though more often it is diffuse) and pulmonary infarction (Fig. 30-11*C*).

In most instances, localized pulmonary consolidation without loss of lung volume indicates an acute inflammatory process. If consolidation persists without change for several



A *B*

Figure 30-35 Patterns of alveolar cell carcinoma. *A*. A large area of consolidation in the right lower lobe. The alveolar pattern suggests pneumonia, but was due to lobar alveolar cell carcinoma. *B*. The more distinctive pattern for alveolar cell carcinoma consists of multiple alveolar nodules. The nodules have irregular or fuzzy margins that are characteristic of alveolar, rather than interstitial, nodulation.

Figure 30-36 Pulmonary edema. Pulmonary edema may be either localized or diffuse. *A*. Most distinctive, but not most common, is a "bat wing" pattern of central alveolar consolidation. *B*. Occasionally, pulmonary edema affects one or more areas of the lung and appears as patchy alveolar consolidation. *C*. CT of diffuse pulmonary edema secondary to acute respiratory distress syndrome (ARDS). In this instance, the pattern is indistinguishable from that of other causes of severe pulmonary edema. In some cases of ARDS, the pulmonary edema is very patchy.

weeks, however, a less common pathological process should be suspected, including alveolar cell carcinoma (Figs. 30-35 *A* and 30-39); lymphoma; metastatic carcinoma, particularly from a breast primary; bronchiolitis obliterans organizing pneumonia; fungal infection; eosinophilic lung disease; or granulomatous vasculitis, such as Wegener's disease.

CT is frequently useful in distinguishing between the various causes of localized alveolar disease, although it may not be able to distinguish between atelectasis and pneumonia. The technique is especially useful in depicting the extent of the process (Fig. 30-39). CT is extremely useful in identifying cavitation (Figs. 30-40 and 30-41) and in demonstrating mediastinal adenopathy, which may not have been suspected on plain films.

Loss of volume is also associated with localized consolidation of the lung. In most instances, atelectasis detected radiographically is lobar in distribution, since collapse of anatomic pulmonary units smaller than a lobe (e.g., segments) is prevented by collateral air drift. Lobar patterns of atelectasis are illustrated in Figs. 30-42 through 30-46.

The various patterns of lobar atelectasis are extremely important to recognize, since this radiographic finding is a very common manifestation of carcinoma of the lung or, occasionally, some other endobronchial neoplasm. Atelectasis is also common in the postoperative patient, presumably because of hypoventilation of dependent parts of the lungs and inadequate clearing of respiratory secretions. In this instance,

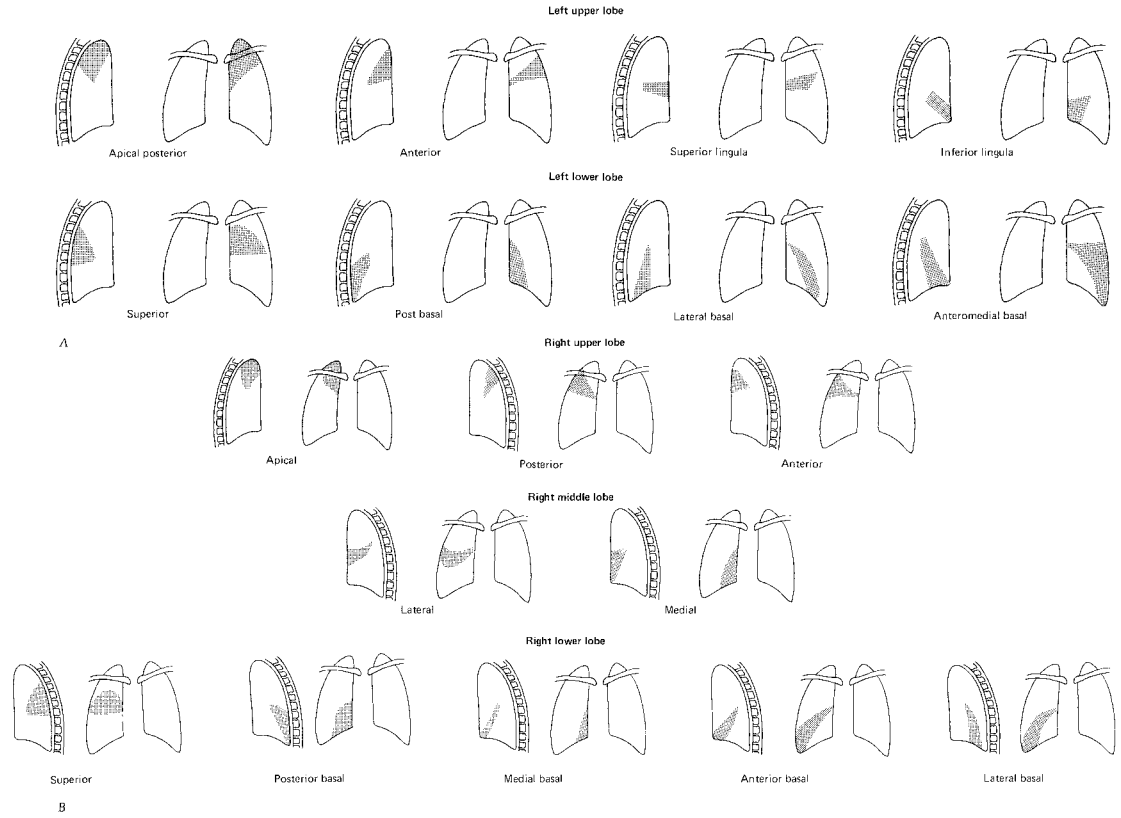

Figure 30-37 Radiographic anatomy of the pulmonary subsegments. Schematic representations of characteristic patterns of consolidation for each of the pulmonary subsegments are shown. *A*. Left lung. *B*. Right lung.

loss of volume may be minimal or absent. Atelectasis may also occur as a consequence of inflammatory disease of the airways or aspiration of a foreign body.

CT is extremely useful in the evaluation of atelectasis, since the technique may clearly demonstrate the cause—for example, a primary carcinoma of the lung. Conversely, CT may demonstrate an open bronchus, strongly suggesting that the atelectasis is not due to an endobronchial tumor. In this regard, it is important to note that some tumors (e.g., alveolar cell carcinoma and lymphoma) may cause consolidation with an open bronchus.
