Pharyngitis may be the presenting or predominating symptom in more generalized viral infections. Pharyngitis is a significant complaint in approximately one-half of cases of the acute mononucleosis syndrome due to Epstein-Barr virus. Pharyngitis in this syndrome is generally exudative and is accompanied by cervical and generalized lymphadenopathy, as well as fever, hepatosplenomegaly, and other systemic symptoms. The heterophile antibody test is typically positive in the second week of illness. Cytomegalovirus can cause an identical syndrome that is monospot negative. Cytomegalovirus may be associated with pharyngitis more commonly in children than in adults. An acute mononucleosis-like syndrome with pharyngitis may also be the presenting manifestation of primary HIV infection. Viruses in the hemorrhagic fever group produce an acute pharyngitis that occurs early in the disease, before skin lesions appear. Also, exudative pharyngitis is a common clinical manifestation in Lassa fever.

The differential diagnosis of acute pharyngitis generally centers upon the differentiation of streptococcal from viral etiologies. Features suggestive of streptococcal pharyngitis include tonsillar swelling, moderate to severe tenderness on palpation, enlargement of lymph nodes, presence of scarlatiniform rash, and absence of coryza. The presence of nasal symptoms or of conjunctivitis favors a viral etiology, and as described, some viral syndromes may present with distinguishing characteristics that help in their identification. Generally, acute pharyngitis in children less than 3 years of age is predominantly viral in origin. The presence of exudate is suggestive of bacterial etiology, but exudates may also be seen with adenovirus or EBV.

Pathogenesis

As described, pharyngitis in the common cold is probably the result of chemical mediators of inflammation, which are potent stimulators of pain nerve endings. Potentially similar mechanisms may account for pharyngitis in other viral syndromes as well. Direct viral damage and other host inflammatory responses may also contribute. Pharyngitis occurs most often as part of the common cold syndrome and thus is usually associated with the same viruses that cause colds. In some cases, pharyngeal symptoms predominate to a degree that overshadows other complaints. The kinins are potent stimulators of pain nerve endings, and high levels of bradykinin and lysyl bradykinin are present in nasal secretions of patients with rhinovirus colds. Intranasal application of bradykinin promotes sore throat and nasal symptoms in volunteers, supporting a role for these agents in the pathogenesis of cold symptoms.

Diagnostic Tests

Identification of viral causes of pharyngitis is generally possible through isolation in cell culture, but is seldom attempted in clinical practice. Rapid antigen detection tests are available for respiratory syncytial virus and influenza A virus.

Rapid diagnostic tests are widely available for the office identification of group A streptococci, and are indicated in most cases in which the etiology is uncertain. When highly sensitive tests are used, backup cultures are generally not necessary. Routine studies for other bacterial and nonbacterial pathogens are usually not obtained. When guideline recommendations for the selective use of throat cultures are used with antibiotic treatment based only on positive rapid test or throat culture, results can reduce unnecessary use of antibiotics for treatment of pharyngitis.

Treatment and Prevention

The treatment of most cases of viral pharyngitis is symptomatic, as noted in the section on common colds. Patients suspected of having influenzal pharyngitis who are seen within the first 2 days of illness can be treated with antiviral therapy (see the discussion on influenza virus). In immunosuppressed patients with chronic herpetic pharyngitis or normal hosts with primary gingivostomatitis, acyclovir therapy is recommended (see the discussion on herpes simplex virus).

Treatment of group A streptococcal infections with antimicrobial agents is generally initiated to prevent rheumatologic complications of this infection, and because treatment of acute streptococcal pharyngitis is associated with more rapid resolution of symptoms, although the absolute benefits are rather modest.

TRACHEOBRONCHITIS (CROUP)

Clinical Features

Croup, or viral laryngotracheobronchitis, is a clinically distinct illness that predominantly affects children under the age of 3. The illness typically begins with upper respiratory tract symptoms of rhinorrhea and sore throat, often with a mild cough. After 2 or 3 days, the cough deepens and develops a characteristic brassy, barking quality, which is similar to a seal's bark. Fever between 38 and 40°C is common, although those with croup due to respiratory syncytial virus may have normal temperatures. The child may appear apprehensive and most comfortable sitting forward in bed. The respiratory rate is elevated, but usually not over 50; this contrasts with bronchiolitis, in which more severe tachypnea is often seen. Chest wall retractions, particularly in the supraclavicular and suprasternal areas, may be observed. Children with this finding on presentation have a higher risk of hospitalization or of requiring ventilatory support.

The characteristic physical finding of croup is inspiratory stridor. Inspiration is prolonged, and in very severe cases, some degree of expiratory obstruction may also be seen. Rales, rhonchi, and wheezing, which reflect the characteristic involvement of the lower respiratory tract, may be heard on physical examination. A fluctuating course is typical for viral croup, and the child may appear to worsen or improve within an hour. The typical duration of croup is 3 to 4 days.

Hypoxemia occurs in 80 percent of children with croup severe enough to require hospitalization. The degree of hypoxia is generally difficult to ascertain clinically, but pulse oximetry provides a reliable and noninvasive means to monitor the state of oxygenation. Children who develop respiratory insufficiency as a result of increasing fatigue also may have elevations in Pa_{CO_2}.

Children with croup characteristically exhibit subglottic narrowing of the tracheal air shadow on PA films of the neck, the so-called "steeple" sign). This finding may be useful in differentiating croup from epiglottitis. However, radiographs are limited in accuracy, and when the diagnosis is uncertain, radiologic and pharyngeal examination should be avoided because of the risk of cardiorespiratory arrest in acute epiglottitis. Emergency assessment by an otolaryngologist or an anesthesiologist is indicated in this situation. Chest x-rays may reveal parenchymal infiltrates which are part of the characteristic involvement of the lower respiratory tract in this syndrome.

Viral Etiologies and Differential Diagnosis

Parainfluenza viruses type 1 and 2 are the most common viruses responsible for croup, accounting for about 75 percent of cases, and the seasonal incidence of croup reflects the seasonal variations in parainfluenza virus incidence. Less common causes of croup include respiratory syncytial virus, influenza A or B viruses, measles, rhinoviruses, and adenoviruses as well as *Mycoplasma pneumoniae*. Parainfluenza virus type 2, influenza A viruses and measles are associated with more severe disease, but generally, the clinical presentation of the croup syndrome due to individual agents is similar. Specific viral diagnosis can be made by viral culture, but is not routinely performed, since the clinical syndrome is sufficient for diagnosis, and management generally does not depend on identification of the specific agent.

The majority of cases of inspiratory stridor in children are caused by viral croup. However, it is critical to distinguish these syndromes from other, potentially more serious causes of airway obstruction such as bacterial epiglottitis and tracheitis early in clinical management. Epiglottitis is an acute cellulitis of the epiglottis and surrounding structures. Patients present with acute respiratory distress and drooling, but the barking cough of croup is absent. Since the introduction of effective vaccines for the major bacterial cause or epiglottitis, *Haemophilus influenzae* type b (Hib), the incidence of epiglottitis in children has also declined considerably. In adults, and rarely in children, epiglottitis may be caused by a variety of other bacterial agents such as *Haemophilus parainfluenzae* or alpha hemolytic streptococci, which may spread from a contiguous focus of infection. Bacterial tracheitis is a relatively rare syndrome that mimics croup. Abundant purulent sputum is often present. Bacterial tracheitis is usually caused by *Staphylococcus aureus* or Hib; other bacteria such as *Streptococcus pneumoniae* have also been associated with this syndrome. Other infectious causes of stridor, including peritonsillar or retropharyngeal abscess, or diphtheria, should be considered. Evidence of noninfectious causes of stridor such as trauma or aspiration of a foreign body, should also be sought in the history and physical examination.

Pathogenesis

The severity of clinical symptoms in parainfluenza virus croup appears to be directly related to the level of virus replication. The viral infection in croup produces inflammation both in the upper respiratory tract, and in the lung parenchyma. The classic signs of croup, including the barking cough and inspiratory stridor, arise mostly from inflammation occurring in the larynx and trachea. Inflammatory changes are seen by histology in the epithelial mucosa and submucosa of the larynx and trachea. The cellular infiltrate includes histiocytes, lymphocytes, plasma cells, and polymorphonuclear leukocytes. The inflammation and obstruction are greatest at the subglottic level, which is the least distensible part of the airway because it is encircled by the cricoid cartilage. Consequently, localized inflammation and edema lead to obstruction to airflow. The impeded flow of air through this narrowed area produces the classic high-pitched vibration. Obstruction is greater during inspiration because it occurs in the extrathoracic portion of the airway, and is enhanced in small children because the walls of the airways in these individuals are relatively compliant. Obstruction of airflow results in an initial decline in tidal volume, which is compensated by an increase

in respiratory rate to maintain adequate alveolar ventilation. However, if the obstruction increases, the work of breathing may increase until the child tires, and as the respiratory rate declines, the child develops hypercarbia and respiratory failure.

Involvement of the lower respiratory tract with resulting hypoxia is integral to the pathophysiology of croup. Inflammatory changes are noted throughout the respiratory tract, including the linings of the bronchi, bronchioles, and even the alveoli. Although some degree of hypoxia can be explained on the basis of hypercarbia, the major pathophysiologic mechanism is ventilation-perfusion mismatching.

Pulmonary edema may complicate severe croup and upper airway obstruction. The onset of pulmonary edema often is immediately following intubation. Pulmonary edema in these cases does not appear to be due to pulmonary artery hypertension, but to local hypoxia, and increased alveolar-capillary transmural pressure.

In addition to these anatomic pathophysiologic events, immunologic mechanisms may also play a role in some manifestations or in determining the severity of disease. Virus-specific IgE responses appear earlier and are of greater magnitude in patients with parainfluenza virus-associated croup than in age-matched controls with simple upper respiratory illness. Histamine is also detectable in upper respiratory tract secretions in this condition. There also appears to be a relationship between croup and subsequent reactive airways disease and/or heightened responsiveness to bronchodilators, particularly in children with recurrent croup.

Diagnostic Tests

Parainfluenza viruses and other viruses associated with croup can be isolated in cell culture, but specific viral diagnosis is generally not indicated in the management of croup.

Treatment and Prevention

Because the majority of hospitalized children are hypoxic, oxygen is the mainstay of treatment for severe disease, and should be given to all hypoxemic patients. Use of helium as the carrying gas, rather than air, may decrease the work of breathing. However, this approach requires use of 70 percent helium to be effective and limits the amount of oxygen which can be delivered. Humidified air, or mist therapy is commonly used, and has several potential roles. Desiccation of the inflamed epithelial surfaces is decreased, and the viscosity of the exudate is reduced. However, the value of mist therapy has not been proven, and it should be recognized that water from the standard home-use vaporizer cannot reach the lower respiratory tract because of the large particle size. In addition, removal of the child from the parents and placement in a mist tent can be more distressing to the child than beneficial.

Administration of nebulized racemic epinephrine generally gives rapid, symptomatic relief in croup. It is believed that alpha-adrenergic stimulation by this drug causes mucosal vasoconstriction, leading to decreased subglottic edema. Several randomized trials have demonstrated a rapid beneficial effect on airway obstruction. The onset of action is rapid, often within minutes, but the duration of relief is also limited, lasting 2 hours or less. Therefore, treated subjects should be observed closely for clinical deterioration. Although symptomatic relief is considerable, use of epinephrine is not associated with improvements in oxygenation, probably because the defect in oxygen is associated with ventilation perfusion mismatching due to lower respiratory tract involvement. In addition, tachycardia may occur. Thus, inhaled epinephrine is generally reserved for children who fail to respond to more conservative management, although some centers use it routinely.

Steroids have been shown to confer significant benefits in the management of mild, moderate, and severe croup, including more rapid improvement in symptoms, reduced length of hospital stay, and reduced rates of intubation. Administration of intramuscular, oral, or nebulized steroids appears to be equally effective. Administration of single-dose steroid therapy in this setting has not been associated with significant side effects, and should probably be used in any patient with illness significant enough to require an emergency room or clinic visit.

Antiviral agents effective against some of the viruses responsible for croup are available, but have not been tested for efficacy in this situation. However, the potential benefit of the use of antiviral agents in the typical self-limited course of croup would likely be limited. Since croup is a viral illness, antibiotic therapy is of no benefit.

Effective prevention of croup will largely depend on development of vaccines for the individual viral agents responsible for this syndrome. Vaccines are currently available for both measles and influenza. There are currently no vaccines available for parainfluenza virus, although a live vaccine for type 3 is in clinical development.

TRACHEOBRONCHITIS

Clinical Features

In addition to causing croup and bronchiolitis, viral infection of the trachea and bronchi may cause tracheitis or tracheobronchitis. The diagnosis of acute bronchitis is usually applied to cases of acute respiratory disease with severe and prolonged cough that continues after other signs and symptoms of the acute infection have subsided. Cough occurs during the first week of illness in 30 percent of rhinovirus colds in young adults and in 80 percent or more of cases of influenza A virus infection, in which it is often prolonged. Adenovirus infections characteristically involve the tracheobronchial tree, with resultant bronchitis that in military populations is part of the syndrome of acute respiratory disease. Tracheitis is characterized by tracheal tenderness, which can be elicited by gentle pressure on the anterior trachea just below the cricoid cartilage. Substernal discomfort on inhalation,

and nonproductive paroxysmal cough are noted. Paroxysmal nonproductive cough is also characteristic of tracheobronchitis, and is usually much more severe at night. Later in the course of illness, small amounts of clear or whitish sputum may be produced. Accompanying symptoms may include fever, headache, myalgias, malaise, and anorexia. After several days of coughing, chest wall or abdominal discomfort that is muscular in nature may be noted. Physical findings are generally nonspecific; examination of the chest may reveal no adventitious sounds, but more commonly diffuse rhonchi and occasional wheezing. Physical signs such as egophony, pleural friction rubs, or areas of dullness to percussion, are not present.

Pathogenesis

The mechanisms of cough production in viral infection are not well understood but may include direct damage to the respiratory mucosa, release of inflammatory substances in response to the infection, increased production and/or decreased clearance of respiratory secretions, and stimulation of airway irritant receptors. Intranasal application of several prostaglandins also produces cough in uninfected volunteers. Infection may also enhance airway reactivity, leading to increased sensitivity to cold air and pollutants such as smoke.

Viral Etiologies and Differential Diagnosis

Tracheobronchitis is most typically caused by influenza A or B virus. In adults other common respiratory viruses such as parainfluenza virus or respiratory syncytial virus may present with prolonged cough. Herpes simplex has been associated with necrotizing tracheobronchitis in nonimmunocompromised hosts. This syndrome is often accompanied by refractory bronchospasm.

The differential diagnosis of acute bronchitis includes nonviral infections and noninfectious etiologies such as cough-variant asthma. *Mycoplasma pneumoniae* and *Chlamydia pneumoniae* infections cause prolonged cough. *Bordetella pertussis* infection should also be considered in the differential diagnosis. In otherwise healthy persons, workup of acute cough should be directed toward determining the presence of pneumonia.

Diagnostic Tests

Influenza viruses can be isolated in cell culture, as can many of the other viruses associated with bronchitis. In addition, rapid antigen tests or nucleic acid tests are available for some of these viruses. Specific viral diagnosis is generally not necessary for appropriate management of bronchitis.

Treatment and Prevention

Treatment in adults is best effected by prescribing rest, aspirin for headache and fever, cold water vapor inhalation; and a cough syrup such as guaifenesin with dextromethorphan. For children, a cough suppressant may be helpful. In the absence of signs of pneumonia, treatment of prolonged cough with antibacterial agents is of no benefit.

BRONCHIOLITIS

Clinical Features

Bronchiolitis is a fairly characteristic syndrome whose presenting symptoms are dominated by the major pathophysiologic defect, obstruction to expiratory air flow. The onset of lower respiratory symptoms is usually preceded by rhinitis, often with nasal congestion and discharge. More severe symptoms characteristically occur 2 to 3 days later, but in some cases are concurrent with the onset of upper respiratory symptoms. In many instances, there may be a history of exposure to an adult or sibling with a cold or other minor respiratory illness, or history of exposure to other cases of bronchiolitis in the day care setting.

The hallmark of disease is wheezing, which can be quite marked, with flaring of the nostrils and use of accessory muscles of respiration. Cough may or may not be prominent initially, and when cough is present, it may be paroxysmal in nature. Slight cyanosis is often observed, but the presence or absence of cyanosis is not a reliable indicator of the degree of oxygenation or of the severity of disease. Physical findings are generally confined to the chest, with development of rales, which are usually musical in the beginning, and then become moister. Hyperresonance of the chest may be observed, and the liver may be displaced downward. The respiratory rate is elevated, with rates of from 50 to 80 breaths per min. Fever is frequently present at the beginning of the illness, but may no longer be present at the time lower respiratory tract involvement develops. Among hospitalized infants, one-third or more are afebrile, but have marked lower respiratory tract disease. Thus, the presence or absence of fever does not indicate the severity of the child's illness. Mild conjunctivitis is noted in about one-third of cases, with pharyngitis of varied severity in about one-half, and otitis media in 5 to 10 percent. The hospital course is variable, but most infants show improvement in 3 to 4 days.

Radiologic findings are generally nonspecific, with reported findings including air trapping, consolidation, and collapse. Air trapping is particularly indicative of RS bronchiolitis and may be the only radiologic finding. However, there is no correlation between the chest x-ray findings and the clinical course. Chest x-rays should be obtained to rule out alveolar filling defects suggestive of bacterial pneumonia and in those infants with severe disease, sudden deterioration, or underlying disorders. Results of routine laboratory tests are generally unremarkable. The peripheral white blood cell count is usually not elevated. Electrolyte disturbances, most notably, hyponatremia, may be seen with severe disease, particularly if excessive amounts of hypotonic fluid are administered. Acute disease may be associated with elevations in pulmonary artery pressure, but echocardiographic studies

are usually unremarkable in infants with structurally normal hearts.

Bronchiolitis is a disease predominantly of infancy, and the peak age incidence is between 2 and 6 months of age, with over 80 percent of cases occurring in the first year of life. The risk of hospitalization and severe bronchiolitis is particularly high in infants with congenital heart disease, chronic lung disease, or immunodeficiency. In addition, infants born prematurely, and those who are less than 6 weeks of age at the time of presentation are also at increased risk of hospitalization. More severe disease has also been documented in children with a family history of asthma, and those exposed to cigarette smoke in the family setting.

Viral Etiologies and Differential Diagnosis

Respiratory syncytial virus (RSV) causes the majority of cases of bronchiolitis and during the RSV epidemic season, essentially all cases are due to this virus. Overall, RSV is recovered from about three-fourths of all infants admitted to the hospital with bronchiolitis. Several other respiratory viruses are associated with bronchiolitis, including parainfluenza viruses, influenza virus, mumps, and rhinoviruses. The epidemiology and pathophysiology of parainfluenza bronchiolitis is similar to that of RSV, and particularly severe disease may be associated with parainfluenza virus type 3. Adenoviruses types 3, 7, and 21 are relatively uncommon causes, but may be associated with more severe disease, including the development of bronchiolitis obliterans. Rhinoviruses represent a small but significant proportion of cases of bronchiolitis, and may mimic RSV infection in infants with bronchopulmonary dysplasia. Rhinoviruses and *Mycoplasma pneumoniae* become more important causes of infection-induced wheezing as children become older. Surveys of bronchiolitis in various parts of the world have suggested a similar pattern of viral etiologies.

Recently, it has been recognized that a significant number of cases are associated with the newly discovered human meta pneumovirus (hMPV). hMPV appears to be responsible for a spectrum of acute respiratory illnesses ranging from very mild or asymptomatic infection to severe bronchiolitis and pneumonitis. The clinical picture most closely resembles that of RSV, and bronchiolitis is the major manifestation in children. Clinical features include wheezing and hypoxia. There are no clinical features that can distinguish between disease caused by hMPV and RSV, although generally those due to RSV may be more severe. Novel human coronaviruses, such as NL-63, have also been associated with lower respiratory tract disease in infants. An additional recently described human parvovirus, the human Boca virus, has been found in as many as 20 percent of cases of acute wheezing in young children. This virus is often detected in the presence of other viruses, and the exact role it plays in this syndrome has not been determined completely.

The differential diagnosis of diseases characterized by expiratory airflow obstruction in infants is relatively small. Pertussis can occasionally be confused with bronchiolitis; however, more frequent vomiting and more paroxysmal cough would be clues to the diagnosis. Anatomic defects such as vascular rings can cause obstruction of the airway. Foreign bodies should be considered strongly, especially in young infants. Gastroesophageal reflux is an additional consideration. The major differential diagnostic consideration is asthma, which is uncommon under the age of 1 year.

Pathogenesis

The pathophysiology of infectious bronchiolitis has been described most completely in the case of infection with RSV. The average incubation period is 4 to 5 days, with a range of 2 to 8 days. Virus replication is limited to the respiratory tract mucosa, which may be involved through its entire length. Involvement of the lower respiratory tract probably occurs by cell-to-cell spread through the respiratory epithelium or aspiration of upper respiratory secretions. Pathologic findings in RSV bronchiolitis include necrosis of bronchiolar epithelium, loss of ciliated epithelial cells, and marked peribronchiolar mononuclear inflammation. Virus-induced cytopathology and associated submucosal edema leads to obstruction of smaller bronchioles, particularly in infants, with distal collapse or air-trapping.

Viral infection of epithelial cells of the bronchioles leads to destruction and necrosis of the ciliated epithelium. Lymphocytes can be seen in increased numbers in the peribronchial tissues. The submucosa becomes edematous, and there is increased production of mucus. Ultimately, dense plugs of alveolar debris and strands of fibrin form within small bronchi and bronchioles, which may partially or completely obstruct airflow. The pathogenic basis for respiratory difficulty in bronchiolitis is related to obstruction of these small airways. Hypoxemia is the major abnormality of gas exchange, with ventilation-perfusion imbalance the major cause of the hypoxemia. In addition to hypoxia, hypercarbia and respiratory acidosis have been observed in some severely ill infants.

Infants are particularly susceptible to the consequences of viral infection for several reasons. The peripheral airways are disproportionately narrow in the early years of life. In addition, collateral channels of ventilation, such as the pores of Kohn, are deficient both in number and size in the infant lung. Finally, the airways of infants are intrinsically more reactive to bronchospastic stimuli than are the airways of older children.

The possibility that immune responses are involved in the pathogenesis of RS bronchiolitis has received considerable attention. The presence of preexisting infection-induced antibody does not appear to play a role in enhancing the severity of disease because maternal antibody, or passively transferred antibody is protective. It has also been postulated that cellular immune responses may be involved in the pathogenesis, since infants infected with RSV who have clinical bronchiolitis have higher levels of cell-mediated immunity to RSV than those with uncomplicated upper respiratory tract disease. Immediate hypersensitivity type reactions have also been postulated to play a role in the pathogenesis of wheezing in bronchiolitis. Production of virus-specific IgE

and subsequent release of mediators of bronchoconstriction have been documented with RSV and PIV bronchiolitis. Leukotriene C4, a potent stimulant of airway smooth muscle constriction and mucus secretion, is also released into the airway in acute bronchiolitis. Elevated levels of histamine and prostaglandin $F_2\alpha$ metabolite have been found during acute bronchiolitis and increased levels of eosinophilic cationic protein in nasopharyngeal secretions, suggesting that release of chemical mediators of inflammation in response to viral antigens is one factor contributing to the development of severe bronchiolitis.

The innate immune response also plays an important role in the pathogenesis of RSV disease in infants, and it has been recognized that single nucleotide polymorphisms in several genes that control the inflammatory response have an important impact on the severity of RSV disease. Examples include polymorphisms in the genes for IL-4, IL-8, and IL-13, and in TLR-4 and the CCR5 receptor, among others.

Following recovery from acute bronchiolitis, some children experience continued episodes of wheezing, especially during viral upper respiratory infections. Estimates are that from 5 to 50 percent of children diagnosed as having bronchiolitis in infancy go on to develop recurrent episodes of wheezing. Generally wheezing episodes wane in frequency over the next several years. After clinical bronchiolitis, some individuals also may demonstrate increased bronchial responsiveness to histamine or cold challenge, which generally decreases over time. The mechanism by which RSV or other viral infection might lead to increased episodes of wheezing is unclear. Some individuals develop elevated levels of viral specific IgE, which may play a role in triggering bronchospasm upon reexposure. In some studies, persistent wheezing correlates with a family history of asthma, and with higher levels of IgE.

Diagnostic Tests

Rapid viral diagnosis can be made by identification of viral antigens in nasopharyngeal secretions. Both immune-based assays, such as immunofluorescence or enzyme-linked immunosorbent assay (ELISA), and nucleic acid-based techniques, such as hybridization or polymerase chain reaction (PCR), have been developed. Immune-based techniques are generally preferable for routine diagnostic purposes, and several kits are commercially available. The sensitivity of such techniques is dependent on the quality of the nasopharyngeal specimen, with nasopharyngeal aspirates superior to brushings or swabs. Commercially available immunofluorescence or ELISA antigen detection has a sensitivity of about 75 to 90 percent relative to culture for specimens collected from children, who shed large quantities of virus. The sensitivity of such tests in adults, who shed lower quantities of virus, is much lower (generally less than 20 percent). In transplant patients with suspected RSV pneumonia, samples of the lower respiratory tract by bronchoalveolar lavage are more sensitive than throat swabs for detection of RSV antigens.

Respiratory syncytial virus grows well in several human cell lines, in which it causes formation of characteristic syncytia. Because the virus is thermolabile, freezing of clinical specimens should be avoided. Bedside inoculation of monolayers or transport of specimens on wet ice to the laboratory helps assure maximal isolation rates. Virus can be detected as early as 2 days and usually within 7 days on primary isolation from specimens collected from children.

Treatment and Prevention

Recommendations regarding the treatment and prophylaxis of bronchiolitis have been summarized recently. Correction of hypoxemia is the most important aspect of managing RSV lower respiratory tract disease. Oxygenation should be monitored by pulse oximetry, and oxygen administered to infants whose oxygen saturation consistently falls below 90 percent. Since bronchiolitis is a viral disease which is infrequently complicated by bacterial superinfection, routine treatment with antibiotics is not warranted. Because of the dehydrating effect of tachypnea and reduced oral intake in some hospitalized infants, parenteral rehydration is often needed, but care must be taken to avoid inducing hyponatremia. Fluid intake and electrolyte concentrations should be carefully monitored in all infants with severe bronchiolitis, as hyponatremia and syndrome of inappropriate secretion of antidiuretic hormone (SIADH) may occur.

Data concerning the potential benefits of bronchodilator therapy are somewhat conflicting. Generally, bronchodilators produce modest short-term improvements in clinical scores, but do not improve oxygenation, rates of hospitalization, or duration of hospital stay. In addition, bronchodilating drugs may contribute to increased restlessness and cardiovascular stress. Because some children do respond to these drugs, a reasonable strategy is a short trial of nebulized bronchodilator with continued therapy only in selected children who respond.

The majority of studies of systemic corticosteroids have also failed to demonstrate a beneficial effect in acute bronchiolitis, and oral corticosteroids do not appear to have a beneficial effect in terms of long-term outcomes, either. Steroids may also be associated with evidence for delayed viral clearance. Although a recent meta-analysis suggested that systemic steroids have a small but statistically significant effect in decreasing length of stay, the clinical significance is minimal; therefore, corticosteroids should not be used routinely.

Antiviral therapy is available for some of the viruses responsible for bronchiolitis. The use of such therapy for the most common etiology, RSV, remains controversial. Ribavirin (1-β-D-ribofuranosyl-1,2,3-triazole-3-carboxamide) is a broad spectrum antiviral agent with antiviral activity against RSV in a variety of cell culture systems and animal models. It does not achieve suitable levels in respiratory secretions when administered systemically, so that therapy of bronchiolitis has used aerosolized drug. Although initial randomized placebo-controlled trials of ribavirin small particle aerosol showed benefit in treatment of bronchiolitis, subsequent experience with use of the drug in clinical practice did not confirm this clinical benefit. These findings, and the

expense of this drug, suggest that ribavirin should be considered only in selected infants and young children with severe illness or at high risk for serious RSV disease.

Bronchiolitis due to RSV can be prevented by passive transfer of antibody against this agent. A humanized neutralizing monoclonal antibody to the RSV F protein, palivizumab (Synagis) has significant protective efficacy in a population of infants with prematurity or bronchopulmonary dysplasia, as well as in children with hemodynamically significant congenital heart disease. Current recommendations for the use of passive antibody prophylaxis are to consider use in infants and children less than 2 years of age with chronic lung disease or congenital heart disease, and in infants born at 32 weeks of gestation or earlier (who would be expected to receive little placental transfer of maternal antibody). Palivizumab may be considered for infants born between 32 and 35 weeks who have at least two additional risk factors, such as exposure to second-hand smoke or attendance at day care. Palivizumab is not effective for therapy of RSV disease.

Interruption of nosocomial transmission may be facilitated by thorough handwashing, decontamination of surfaces and inanimate objects, and isolation or cohorting of infected infants. Use of disposable eye-nose goggles by pediatric staff reduces the risk of nosocomial RSV infection in both staff and patients. Regular use of gowns, gloves, and possibly masks by hospital staff caring for infected children may also reduce the risk of nosocomial RSV spread. Protective isolation of high-risk infants or deferring their elective admission has been recommended during institutional outbreaks of RSV.

Vaccines are available to prevent bronchiolitis due to influenza virus and mumps, but there is no vaccine currently available for prevention of bronchiolitis due to RSV. There are multiple significant hurdles to the development of such a vaccine, including the very young age at which the disease presents, the suppressive effect of maternal antibody on vaccine responses, and the potential for enhanced disease in vaccine recipients. However, several promising live vaccine candidates are in clinical development, and it has been demonstrated that it is possible to prevent RSV lower respiratory tract disease with such a vaccine.

INFLUENZA

Clinical Features

The onset of influenza is typically abrupt, and the illness is characterized by the predominance of systemic symptoms, including fever, prostration, myalgias, and malaise. Respiratory symptoms may be relatively minimal, particularly early in the course, and include nasal complaints, sore throat, hoarseness, and nonproductive cough. Because of the involvement of tracheal epithelium in infection, complaints of burning throat and substernal pain may be seen. Among healthy adults, the best clinical predictors of influenza virus positivity are the presence of cough and fever in patients presenting during epidemics.

Other than fever, there are usually few findings on physical exam. Affected individuals may exhibit rhinitis, pharyngitis, conjunctival injection, and tracheal tenderness. The chest is usually clear in uncomplicated cases. Most acute symptoms resolve in 3 to 5 days, but complete recovery may take weeks. The clinical features of influenza A and B virus infection are similar.

Influenza is an important cause of acute febrile illness in children during epidemics. Generally symptoms of influenza are similar to those in adults, although children may have higher fever with febrile seizures. As described, influenza may be associated with otitis media or croup in children. Pneumonia represents the most severe complication of influenza virus infection in both normal and compromised hosts. Primary influenza viral pneumonia is characterized by rapid progression of dyspnea, cough and cyanosis, and development of respiratory distress syndrome acute (ARDS). Chest roentgenographs reveal bilateral interstitial infiltrates, sputum production is scanty, and gram stain reveals few organisms. Secondary bacterial pneumonia may present 1 to 2 weeks after apparent recovery from an acute influenza episode with recurrence of fever, and signs and symptoms of typical lobar pneumonia.

Recently, human infections with avian influenza viruses have been described, and infections with H5N1 viruses have been particularly alarming. The available data regarding the signs and symptoms of H5N1 infection is mostly from hospitalized patients. The frequency of subclinical and mild forms of infection is currently unknown. Most patients present with the nonspecific complaints of a fever greater than or equal to 38°C along with cough and shortness of breath. In many patients, there is a progression of symptoms leading to respiratory failure requiring ventilation and other supportive measures. Atypical symptoms such as nausea, vomiting, encephalopathy, bleeding gums and nose have been reported. Watery diarrhea may be present prior to the onset of respiratory symptoms. The majority of patients have an abnormal chest x-ray with diffuse and multifocal or patchy infiltration, but pleural effusions are rare.

Epidemiology

After any given strain has caused widespread infection within a population, the presence of high levels of antibody in the population against that strain provides selective pressure that favors the emergence of viruses with amino acid changes in key antibody binding epitopes of the HA and NA. These antigenically variant viruses become the predominant strains in subsequent influenza epidemics, a process referred to as antigenic drift. As new strains emerge, they tend to replace previous strains so that in any given season there is usually one predominant influenza A H1N1, A H3N2, or influenza B strain.

Occasionally, influenza A viruses emerge with more radical antigenic changes in the HA and/or NA, a process referred to as antigenic shift. Antigenic shift is defined by the presence of a new HA or NA subtype, and only occurs in influenza A viruses. Antigenic shift has been noted three times

in the twentieth century. In 1918, H1N1 viruses emerged and replaced previous H3N2 viruses, in 1957 H2N2 viruses replaced H1N1 viruses, and in 1968 H3N2 viruses replaced the H2N2 viruses. Because there is little or no population immunity to the new viruses, antigenic shift typically results in rapid spread and high attack rates, resulting in worldwide epidemics, or pandemics. Thus, influenza epidemiology is characterized by two patterns: reliable yearly epidemics of greater or lesser severity depending on the degree of antigenic drift (seasonal influenza) and rare cataclysmic events with high mortality and morbidity resulting from antigenic shift (pandemic influenza).

Influenza is typically associated with seasonal epidemics of greater or lesser severity, which occur during the winter months in temperate climates in both the northern and southern hemispheres. Outbreaks in the northern hemisphere are usually noted between the months of November and March or April, and typically last for from 4 to 6 weeks in any given community. The reasons for the seasonal behavior of influenza are not known but have been the subject of much interest. Some suggested mechanisms have included the seasonal effects of heat and humidity on the viability of virus in the environment, behavioral patterns that facilitate transmission, such as attendance at schools, or sunlight effects on baseline immune function.

Seasonal influenza epidemics are regularly associated with excess morbidity and mortality, and both influenza A and B can be associated with severe illness. During interpandemic years, influenza is characterized by a "U-shaped" epidemic curve, in which attack rates and medically attended illness rates are generally highest in infants and young children, whereas mortality is generally highest in the elderly. Excess morbidity and mortality are particularly high in those with underlying medical conditions, including chronic cardiovascular or pulmonary disease, chronic metabolic disease including diabetes mellitus, renal dysfunction, hemoglobinopathies, or immunodeficiency, including HIV. Women in the second and third trimesters of pregnancy also have increased rates of cardiopulmonary hospitalizations during influenza epidemics. For this reason, these groups are targeted for special efforts toward prevention and therapy.

Young children are generally more susceptible to influenza infection than are adults, and shed higher levels of virus for longer periods. Influenza is a significant cause of medically attended illness in children, and is the most common cause of physician visits for febrile illness in children during influenza epidemics. Healthy children younger than 1 year of age are hospitalized for influenza at rates comparable to those of older children and adults with chronic high-risk conditions and are special targets of prevention measures.

Pathogenesis

The mechanisms responsible for transmission of influenza viruses from person to person have never been completely defined, and it is likely that both large particles (i.e., droplet) and small particles (aerosol) released from the airway during coughing and sneezing play a role. Once virus is deposited on the respiratory tract epithelium, it can attach to and penetrate columnar epithelial cells if not prevented from doing so by specific secretory antibody (IgA), by nonspecific mucoproteins to which virus may attach, or by the mechanical action of the mucociliary apparatus. The duration of the incubation period to the onset of illness and virus shedding varies from 18 to 72 h depending in part on the inoculum dose. Viral shedding in the respiratory tract is first detected just before the onset of illness (within 24 h), rapidly rises to a peak and remains elevated for 24 to 48 h, and then rapidly decreases to low titers. Usually influenza virus is no longer detectable after 5 to 10 days of virus shedding. Both the duration as well as the level of virus shedding is typically longer in young children than in adults. In general, the course of the clinical illness correlates temporally with the pattern of virus shedding, and severity is correlated with the quantities of virus shed.

Bronchoscopy of individuals with typical, uncomplicated acute influenza has revealed diffuse inflammation of the larynx, trachea, and bronchi, with mucosal injection and edema. Histologic findings on autopsy of more severe cases show extensive necrotizing tracheobronchitis, with ulceration and sloughing of the bronchial mucosa, extensive hemorrhage, hyaline membrane formation, and a paucity of polymorphonuclear cell infiltration. Abnormalities of pulmonary function are frequently demonstrated in otherwise healthy, nonasthmatic young adults with uncomplicated (nonpneumonic) acute influenza. Demonstrated defects include diminished forced flow rates, increased total pulmonary resistance, and decreased density-dependent forced flow rates consistent with generalized increased resistance in airways less than 2 mm in diameter, as well as increased responses to bronchoprovocation. In addition, abnormalities of carbon monoxide diffusing capacity and increases in the alveolar-arterial oxygen gradient have been seen. Of note, pulmonary function defects can persist for weeks after clinical recovery.

Aberrant cytokine responses have also been implicated in the pathogenesis of influenza, particularly in recent human cases of H5N1 disease. In vitro, the levels of TNF-α and other proinflammatory cytokines are higher in cells infected with the H5N1 virus when compared to cells infected with H3N2 and H1N1 viruses. Autopsy findings in humans have revealed changes of a reactive hemophagocytic syndrome, ARDS and multi-organ failure, findings typically associated with production of high levels of cytokines like TNF-α and interferons.

Viral Etiologies and Differential Diagnosis

The influenza viruses are classified into three distinct types: influenza A, influenza B, and influenza C viruses. Both influenza A and B viruses can cause the typical syndrome of influenza, and both are responsible for seasonal epidemics associated with increased morbidity and mortality. However, influenza A viruses differ from influenza B viruses by having a significant animal reservoir (birds) and by the development of numerous antigenic subtypes, which may be responsible

for pandemics. Influenza C viruses cause relatively minor respiratory disease, mostly in children.

The typical nomenclature for influenza viruses include the type (A, B, or C), the geographic origin of the specific viral strain, and strain number, and the year of isolation. In addition, the viral subtype, based on the hemagglutinin (H) and neuraminidase (N) are also given. Thus, the current influenza A virus of the H3N2 subtype is referred to as influenza A/Wisconsin/03/06 (H3N2). Since influenza B viruses, influenza A (H1N1) viruses, and influenza A (H3N2) viruses may all cause disease in any given year, the influenza vaccine contains recent examples of all three strains.

Diagnostic Tests

Viral culture is highly sensitive and specific, and also has the advantage that after isolation the virus is available for further characterization. However, it may take several days for the culture to become positive; the results are not available during the time when decisions regarding management and therapy of an individual case must be made. Thus, there has been considerable interest in the development of rapid, point-of-care tests for influenza diagnosis.

The most widely used tests are based on immunologic detection of viral antigen in respiratory secretions. In these tests, a sample of respiratory secretions is treated with a mucolytic agent and then tested, on a filter paper, in an optical device, or with a dipstick in which reaction with specific antibody results in a color change. All of the tests are designed to detect both influenza A and B, but only some of the tests differentiate between the two. Some of the tests that are minimally complex may be eligible for waivers that allow them to be used in the office setting. In general, sensitivities in adults and elderly patients tend to be lower than reported in young children, who tend to shed much larger quantities of virus in nasal secretions and therefore have much higher concentrations of antigen in their samples. Although all types of respiratory samples can be used in such tests, the sensitivity appears to be better with nasopharyngeal swabs and aspirates than with throat swabs or gargles.

Treatment and Prevention

Vaccines for Influenza

Two types of vaccines, inactivated and live, are currently available for prevention of influenza (Table 134-3). Inactivated influenza vaccines are designed to induce primarily serum antibody to the hemagglutinin and neuraminidase. The viruses selected to be contained in the vaccine are grown in embryonated hen's eggs, and the virions are chemically inactivated, and then chromatographically purified. Because influenza A (H1N1), A (H3N2), and influenza B viruses are all circulating in human populations, current formulations of influenza vaccine are trivalent; that is, they contain one example of H1N1, H3N2, and B viruses thought to be the most likely to cause disease in the upcoming influenza season. Live attenuated influenza vaccines have as their primary goal the induction of mucosal antibody in the respiratory tract, which appears to play a critical role in prevention of influenza infection. The vaccine is a so-called "cold-adapted" vaccine, generated by genetic reassortment between circulating wild-type strains and cold-adapted, attenuated master donor viruses. These vaccines are also generated in embryonated hen's eggs and are administered nasally as a trivalent formulation.

Influenza vaccine can be used in any individual who wishes to reduce his or her risk of developing influenza. Efforts at vaccination are generally targeted at two groups of individuals: persons who, for reasons of age or medical conditions, are at increased risk for developing complications, hospitalization, or death due to influenza, and contacts who may transmit infection to these high-risk individuals. Currently, high-risk groups are considered to be those 5 years of age or under, and those 50 years of age or older, as well as individuals with chronic heart or lung conditions, immunosuppressive diseases including HIV, persons with diabetes and other endocrine disorders, pregnant women, and others. Persons who may transmit to high-risk persons include family members, out of family caregivers, and especially health care

Table 134-3

Features of Influenza Vaccines

	TIV	CAIV
Produced in	Eggs	Eggs
Administration	Intramuscular infection	Intranasal spray
Immune response	Serum antibody	Mucosal immunity
Formulation	Inactivated	Live, attenuated
Storage	4C	4C
Side effects	Sore arm at injection site In some years, increased risk of Guillain-Barré syndrome	Runny nose Increase in wheezing in children <1 yr
Indications	Any person >6 mo	Healthy persons >1–49 yrs
Efficacy		
Children	++	++++
Healthy adults	++++	++++
Elderly	+++	+

Table 134-4

Antivirals Active Against Influenza

Drug	Dosage in Adults	Dosage in Children	Comments
Oseltamavir	75 mg PO bid for 5 d	≤15 kg: 30 mg twice daily >15–23 kg: 45 mg twice daily >23 kg: 60 mg twice daily >40 kg: 75 mg twice daily	Controlled trials available in adults, elderly, and children Approximately 1–2 d earlier resolution of symptoms, reduced otitis in children Other effects demonstrated include earlier return to work, decreased diagnosis of bronchitis Meta-analysis shows reduced hospitalization rates Well tolerated, main adverse event is nausea
Zanamavir	10 mg via inhalation bid for 5 d	≥7 y: 10 mg via inhalation twice daily <7 y: not recommended	Similar safety and efficacy profile as oseltamivir, without nausea Reports of exacerbations of reactive airways disease
Amantadine	<65 y: 100 mg twice daily for 5 d >65 y: 100 mg once daily	1–9 y: 5 mg/kg/d, not to exceed 150 mg/d in two divided doses 10–12 y: 100 mg twice daily	High levels of resistance in current influenza A viruses
Rimantadine	100 mg twice daily for 5 d >65 y: 100 mg once daily	≤12 y: not recommended	High levels of resistance in current influenza A viruses Not approved for use in children

workers. However, it is important to note that the recommended groups continue to expand, and as the supply of vaccine increases, it is likely that a universal recommendation for all individuals to receive yearly vaccination will eventually be made.

Antiviral Therapy

Two classes of antiviral agents have been developed with efficacy against influenza A in humans (Table 134-4). The adamantina (amantadine and rimantadine) are referred to as the M2-inhibitors, because their mechanism of action is the result of inhibition of the viral M2 protein, an ion channel involved in viral uncoating. M2 inhibitors are only active against influenza A viruses, because influenza B viruses do not contain an M2 protein. Although the M2 inhibitors are highly effective drugs for the prophylaxis and therapy of influenza A, resistant viruses are generated quite readily in treated individuals, and can be transmitted to, and cause disease in contacts. Currently, the great majority of influenza A (H3N2) viruses worldwide, as well as most Clade 1 H5N1 viruses, are completely resistant to M2 inhibitors. Therefore, M2 inhibitors are no longer recommended for use as antiviral agents against influenza.

A second class of agent is referred to as the neuraminidase inhibitors, because they are potent and selective inhibitors of the neuraminidase enzymes of both influenza A and B viruses. In cell culture, inhibition of neuraminidase function is predominantly manifested as inhibition of cell-to-cell spread of virus. The results of clinical trials of the two licensed drugs, oseltamivir and zanamivir, have been very similar, and although no head to head trials have been performed, their clinical efficacies appear equivalent. Both drugs also have an excellent safety profile. Since licensure, there has been considerably greater use of oseltamivir than zanamivir, reflecting the relative ease of administration of the oral tablet compared to oral inhalation mode of delivery.

As a general principle, it is clear that early initiation of therapy is critical to the effectiveness of antiviral therapy of acute influenza. This general observation is consistent with the typical pattern of viral shedding in an immunologically primed individual in which the peak of virus shedding is in the first few days of illness, and is rapidly controlled by the immune system. Therapy initiated beyond 48 h of symptoms does not appear to be useful in immunocompetent adults and children, and the greatest benefit is seen when therapy is begun within 12 or 24 h after the onset of symptoms. Relatively little controlled data are available related to the use of

antivirals in immunocompromised individuals with influenza or in primary influenza infections, and it is unclear whether these same constraints would apply in these situations.

Antiviral Prophylaxis

Although not a substitute for vaccination, antiviral drugs can be used for prevention as well as treatment. Generally, two strategies for antiviral prophylaxis have been evaluated. Seasonal prophylaxis refers to the strategy of administration of drug throughout the entire period of potential influenza exposure, i.e., the influenza season, typically 6 to 8 w in any given community. The second strategy administers prophylaxis for a relatively shorter period of time to a person who has close contact with an index case known or suspected to have influenza. Examples of this strategy include administering prophylaxis to family members of a person with influenza, and administering prophylaxis to patients who may be exposed during a nosocomial outbreak at a health care institution such as a nursing home or hospital.

VIRAL PNEUMONIA

Clinical Features

As described, viral infections of the lower respiratory tract represent a wide spectrum of clinical entities including croup and bronchiolitis, tracheobronchitis, and reactive airways changes. The development of pneumonia is defined by inflammation of the lung parenchyma, often associated with visible changes on chest x-ray or abnormalities of other radiologic studies such as gallium scanning and accompanied by the development of abnormalities of alveolar gas exchange. Although there can be considerable variety to the presentation of this syndrome depending on the age and immunologic competence of the host and the specific viral pathogen, there are certain general features that are described in the following.

Viral pneumonia in adults is usually associated with nonproductive cough, although production of frothy, pink-tinged sputum is seen in some severely ill individuals. Cyanosis and hypoxemia are prominent features of severe primary viral pneumonia. Physical findings are often nonspecific. The patient may appear acutely ill, conjunctivitis and rhinitis may be noted, and the trachea may be somewhat tender if accompanied by viral tracheitis. There is an increased respiratory rate, and diffuse rales and wheezes. A variety of chest x-ray patterns have been described, including lobar infiltrates, but most typically primary viral pneumonia presents with diffuse, bilateral interstitial infiltrates. However, there are really no x-ray patterns that reliably differentiate between bacterial and viral pneumonia. The sputum is relatively scant, generally shows few polymorphonuclear leukocytes, and gram stain reveals minimal numbers of bacteria.

The basic presentation of viral pneumonia in children is similar. The clinical presentation varies considerably with the specific causative agent, but typically includes fever and lower respiratory tract signs and symptoms, such as difficulty breathing, nonproductive cough, and physical findings of wheezing or increased breath sounds. Young infants may present with apneic episodes with minimal fever. The clinical presentation may be dominated by the associated croup or bronchiolitis, which are frequently present.

Underlying cardiopulmonary diseases, such as valvular heart disease or COPD, are well recognized risk factors for viral pneumonia in adults and children. Pregnancy, particularly in the second and the third trimester, has been recognized as a risk factor for cardiopulmonary hospitalizations associated with influenza epidemics.

Bacterial superinfection is a common complication of viral lower respiratory tract infection, particularly in adults. The classic presentation is that of a typical episode of viral illness with more or less complete recovery, followed 2 to 14 d later by a recurrence of fever and development of cough and dyspnea. CXR reveals lobar infiltrates, and the clinical course is typical of bacterial pneumonia. In addition, combined bacterial and viral pneumonia, with clinical features of each, are common in adults and with certain viruses in children. Bacterial superinfection of viral pneumonia can occur with many bacteria, but the most common bacteria responsible for bacterial pneumonia complicating influenza is *Streptococcus pneumoniae*. There are also increases in the relative frequency of staphylococci and *Haemophilus influenzae*.

Viral Etiologies and Differential Diagnosis

Evaluation of the specific cause of acute pneumonia, and in particular, attribution of pneumonia to a particular viral etiology, is complicated by difficulty in obtaining appropriate samples for culture, in isolating or detecting certain pathogens, and the frequent asymptomatic shedding of some viruses, such as herpes viruses or adenoviruses. Serologic diagnosis essentially establishes a temporal, but not causal, relationship between viral infection and a clinical syndrome, which may be misleading during times of high prevalence of a particular viral agent. With these qualifications in mind, it is reasonable to make several broad generalizations regarding the role of viruses in acute pneumonia. The impact of viral pneumonia and the spectrum of associated viral agents is highly dependent on the age group and immune status of the host. Viruses are clearly important and frequent causes of pneumonia in young children. The role of viruses becomes less apparent in older children, and in healthy adults, pure viral pneumonia is rare, and is predominantly due to influenza. Elderly adults may experience more significant lower respiratory tract signs and symptoms following infection with agents which normally cause upper respiratory tract illness in younger adults, but generally have similar rates of viral pneumonia as do healthy young adults. Finally, viral pneumonia is an important cause of morbidity and mortality in individuals with compromised immune systems, with a broader spectrum of viral agents than seen in immunologically intact individuals.

Immunologically Intact Adults

Influenza

The majority of cases of viral pneumonia in immunocompetent adults are probably due to or associated with influenza viruses, which typically cause disease during the winter months in temperate climates. In addition, lower respiratory tract involvement with severe viral pneumonia is a characteristic feature of human infection with avian influenza A (H5N1) viruses. The features of influenza are described in the preceding. In addition, multiple other viral pathogens are associated with a similar syndrome of viral pneumonia in otherwise healthy adults, and are described in the following.

Respiratory Syncytial Virus

Respiratory syncytial virus frequently causes detectably altered airway reactivity in adults, and on occasion, lower respiratory tract involvement becomes clinically manifest as pneumonia in otherwise healthy adults. RSV is being increasingly recognized as a cause of significant lower respiratory tract disease in the elderly. It has been estimated that 2 to 4 percent of pneumonia deaths among the elderly in the United States may be due to RSV.

Parainfluenza Virus

The parainfluenza viruses are most typically associated with viral pneumonia in children, particularly serotype3 (PIV3). However, occasionally these viruses may be associated with pneumonia in adults. Frequent contact with small children is probably a risk factor. Parainfluenza viruses have occasionally been reported as causes of pneumonia in adults and in the elderly.

Adenovirus

Adenovirus was first recognized as a cause of viral pneumonia in military recruits and has since been recognized as a rare cause of pneumonia in civilian adults and children. Outbreaks in institutionalized populations occur. The clinical characteristics of adenovirus pneumonia are similar to those of other pneumonias, so that it is difficult to make an accurate etiologic diagnosis on the basis of clinical features. In fatal cases there has been extensive pulmonary damage, with death occurring 2 to 3 weeks into the illness. Intravascular coagulopathy has also been a late feature of some cases, and a septic shock picture has been described. Bacterial superinfection, particularly with *N. meningitidis*, may occur. Since 1996, a specific variant of adenovirus type 7 (Ad7d2) has been responsible for several civilian outbreaks and a large military outbreak. The appearance of new Ad 7 genotypes may herald a shift in the predominant strains with greater disease impact.

Measles

Measles can be complicated by clinically severe pneumonitis in a small percentage of healthy adults, and bacterial superinfection is common.

Varicella Zoster Virus

Viral pneumonia is the major complication of varicella zoster virus (VZV) in normal adults, in whom it occurs with an estimated 25-fold higher frequency than in children. Smoking is a significant risk factor. Pneumonia associated with varicella is usually apparent 1 to 6 d after the onset of rash. Symptoms include cough, dyspnea, pleuritic chest pain, and hemoptysis. Physical findings other than fever and tachypnea are often modest. The intensity of the rash does not necessarily correlate with the severity of pneumonia. The characteristic radiographic pattern is that of diffuse nodular (1–10 mm) infiltrates, which may resolve with miliary calcific densities. Hilar adenopathy, pleural effusions, and peribronchial infiltrates are frequently present. Pulmonary infarction may complicate the clinical picture. Pulmonary function studies have found normal spirometric values but decreased carbon monoxide diffusing capacity, which may persist for months. One prospective radiologic study of military recruits with varicella found abnormalities in approximately one in six patients, but only one-fourth of those with radiographic changes had cough, and none experienced severe disease.

Emerging Viruses

In addition to these viruses, which have a widespread distribution and cause sporadic cases of viral influenza, two novel emerging pathogens have caused severe outbreaks of respiratory disease in previously healthy adults.

Hantavirus Pulmonary Syndrome

Clinical features of the Hantavirus pulmonary syndrome (HPS) include onset of severe pulmonary dysfunction after a 2- to 3-d prodrome of nonspecific influenza-like symptoms of fever, myalgias, cough, gastrointestinal symptoms, and headache. Laboratory abnormalities included leukocytosis, increased hematocrit due to hemoconcentration, and thrombocytopenia with coagulopathy. However, clinical bleeding is unusual, in contrast to other systemic Hantavirus syndromes. Moderately elevated levels of serum lactate dehydrogenase and aspartate aminotransferase are typically seen. A variety of radiographic abnormalities have been described. Radiographic findings that may help to distinguish HPS from ARDS include early, prominent interstitial edema, and nonperipheral distribution of initial airspace disease.

Presentation of HPS begins with a prodrome of fever, chills, and myalgias, occasionally accompanied by abdominal discomfort and gastrointestinal symptoms, and generalized malaise. Upper respiratory symptoms are usually absent. After a variable period of several days, the patient presents with mild, nonproductive cough and progressive dyspnea resulting from leakage of high-protein edema fluid into the alveoli. On physical exam patients are febrile, with tachypnea and tachycardia with mild hypotension. Examination of the chest may reveal rales but is otherwise unremarkable.

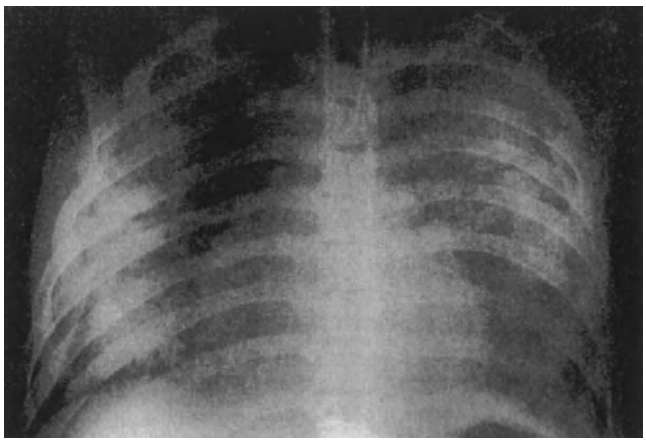

Figure 134-1 Chest radiograph showing diffuse interstitial and alveolar infiltrates in a patient with Hantavirus infection. *(From Duchin et al.,: Hantavirus pulmonary syndrome.* N Engl J Med *330: 949–955, 1994. with permission.)*

Laboratory studies generally reveal hemoconcentration, mild thrombocytopenia, and mildly elevated lung function tests (LFTs). The triad of thrombocytopenia, left shift with circulating myeloblasts, and circulating immunoblasts, is highly suggestive of HPS. Multivariate analysis has identified dizziness, nausea, and the absence of cough as clinical symptoms predictive of HPS, as well as thrombocytopenia, elevated hematocrit, and decreased serum bicarbonate as features which help distinguish HPS from other causes of acute respiratory distress such as pneumococcal pneumonia and influenza. Mild renal abnormalities may be detected, but unlike hemorrhagic fever with renal syndrome (HFRS), do not progress to renal failure.

Chest radiograph typically shows both interstitial and alveolar infiltrates and resemble noncardiogenic pulmonary edema (Fig. 134-1). Pleural effusions are present in most cases. Early in the course of HPS these effusions are transudative, while later they develop higher fluid protein content and in severe cases have the protein characteristics of plasma. Cardiopulmonary manifestations in severe cases include a shock state with low cardiac index, low stroke volume index, and high systemic vascular resistance. Typically, the pulmonary artery wedge pressure is normal or low. Progression is associated with worsening cardiac dysfunction and development of lactic acidosis. The case-fatality rate averages approximately 30 to 40 percent. In those patients who survive, recovery is usually complete, but some patients have manifested long-term pulmonary dysfunction. The syndrome in children and adolescents is similar to that in adults.

Severe Acute Respiratory Syndrome

Epidemics of SARS initially in southern China and subsequently in multiple locations in Asia and elsewhere in the early spring of 2003 were associated with the emergence of a novel coronavirus, referred to as the Human SARS Coronavirus (HuCoV-SARS). After an intense epidemic associated with 8096 cases and 774 deaths, the disease disappeared, largely due to aggressive infection control practices.

Extensive sequence data strongly suggests that HuCoV-SARS was introduced into human populations from an animal species, likely the palm civet or a related animal. Subsequent transmission took place largely in the health care setting. Transmission appeared to be by droplet spread and required close contact. Virus shedding was at its peak at the time that illness was most severe, which may account for the preponderance of transmission occurring in the hospital setting. Generally, the reproductive number in the absence of infection control measures was estimated to be about 3, i.e., each case transmitting to an estimated three additional individuals. In addition, a poorly explained phenomenon in which certain individuals appear to be responsible for an extraordinarily large number of transmissions, or so-called "super spreaders" was described.

Generally, SARS has a nonspecific presentation that is difficult to distinguish on clinical grounds from other forms of viral acute respiratory illness, particularly influenza. The most common symptoms on presentation are fever, chills and/or rigors, and myalgias. Cough and dyspnea are the predominant respiratory symptoms but may not be present initially. Upper respiratory symptoms, such as rhinorrhea or sore throat are infrequent. In addition, about one-third of patients have diarrhea at some point in the clinical course. Respiratory disease is progressive and becomes more severe over 4 to 7 d, leading to significant hypoxemia. About 20 percent of patients require respiratory support. The overall case fatality rate is about 10 percent, but is much higher in older adults.

Laboratory abnormalities on presentation include elevations in lactate dehydrogenase, transaminases, and creatine kinase, and hematologic abnormalities, particularly lymphopenia, as well as thrombocytopenia. The lymphopenia includes depletion of both CD4 and CD8 cells.

Radiologic abnormalities have included unilateral or bilateral ground-glass opacities or focal unilateral or bilateral areas of consolidation. In hospitalized patients the abnormalities tend to progress to bilateral airspace consolidation. In most patients, peripheral involvement is seen, often involving the lower lung zones. However, the initial chest radiographs have been normal in about 10 percent of cases. Thin-section chest CT is more sensitive at detecting radiologic abnormalities in SARS. Common findings include ground-glass opacification, and interlobular septal and intralobular interstitial thickening. Pulmonary fibrosis may develop after recovery from the acute illness.

Features associated with a higher risk of intubation and death include older age, and the presence of comorbid conditions, particularly diabetes. However, even relatively healthy young health care workers may have very severe disease. Clinical features predictive of a worse outcome have included the presence of bilateral disease at presentation and the peak level of lactate dehydrogenase.

For reasons that are unclear, children have been reported to have milder disease than adults. SARS in children has a similar presentation to that in adults, including fever, cough, and alveolar infiltrates. However, younger children

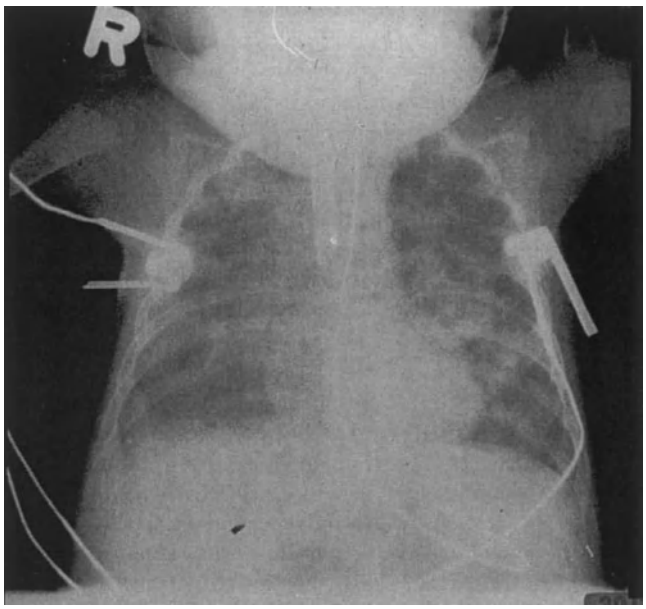

Figure 134-2 Premature infant at 3 months of age with respiratory syncytial virus pneumonia. *(Courtesy of Dr. Janet Englund, Baylor College of Medicine.)*

generally do not require oxygen therapy, and have a relatively benign clinical course.

Children

Respiratory Syncytial Virus

In most series, RSV has been associated with the largest proportion of viral pneumonia in young children, particularly if accompanied by bronchiolitis. It should be noted in this regard that bronchiolitis and pneumonia represent a spectrum of lower respiratory tract involvement with RSV, frequently coexist, and are not clearly distinguishable. The most typical finding is diffuse interstitial pneumonitis (Fig. 134-2). Lobar or segmental consolidation are evident by CXR in about one-fourth of children with RSV lower respiratory tract disease.

Parainfluenza Virus

The parainfluenza viruses are second only to RS virus as causes of pneumonia in this age group. As described, lower respiratory tract involvement is integral to the pathophysiology of croup, but pneumonia with pulmonary infiltrates is most commonly associated with parainfluenza virus type 3.

Influenza Virus

Influenza A and B viruses are both significant causes of pneumonia in children, especially during periods of epidemic prevalence. In infants and children, the most frequent manifestation of influenza pneumonia is an interstitial pneumonitis similar in appearance and course to those of the other predominant viral agents of pneumonia in this age group, except that a secondary bacterial pneumonia may occur more frequently than with RS or parainfluenza viruses.

Adenovirus

Adenoviruses are frequently isolated from children with respiratory disease and are implicated in about 10 percent of childhood pneumonias. However, the true impact of adenoviruses as causes of pneumonia in this age group is difficult to assess because of the long and intermittent asymptomatic respiratory shedding of these viruses in children. Hilar adenopathy on CXR is somewhat more common with this form of pneumonia than other types.

Measles

Pneumonia is the most frequent serious complication of measles. The prodrome of typical measles lasts 2 to 8 d and is characterized by fever, malaise, anorexia, cough, coryza, and conjunctivitis. Koplik's spots, which are erythematous macular lesions with central white-yellow or gray puncta, appear on the buccal or labial mucous membranes toward the end of the prodromal period. The maculopapular, erythematous eruption begins about the face and neck and progresses to involve the upper body, trunk, and extremities. The rash typically disappears after 5 to 6 d in the order in which it appeared. Defervescence and symptom improvement occur several days after the appearance of the rash, although persistent cough is common. Leukopenia is common during the prodromal and early exanthematous stages of measles. Pronounced leukopenia (less than 2000 cells/mm^3) is associated with a poor prognosis. The development of neutrophilic leukocytosis suggests the possibility of bacterial superinfection or other complications.

Cytomegalovirus

Respiratory distress is part of the clinical picture in infants with congenital cytomegalovirus (CMV) disease. Older infants and children may exhibit prolonged respiratory disease with bronchitis or pneumonia associated with CMV carriage.

Rhinovirus

Rhinoviruses have also been associated with a significant proportion of community acquired pneumonias in children, despite the relative inability to grow efficiently at body temperature. Other viruses that may occasionally cause viral pneumonia in children include enteroviruses, rubella virus, and herpes simplex virus.

Immunocompromised Individuals

Individuals with diminished host immunity may develop severe, life-threatening pulmonary infections with the entire spectrum of RNA and DNA viruses, including both viruses that are typical causes of lower respiratory tract disease in normal hosts, and other, more opportunistic viral pathogens. DNA viruses have received the most recognition in this regard.

Cytomegalovirus

CMV is a frequent, severe pneumonitis in immunosuppressed individuals, particularly transplant recipients, or individuals infected with the human immunodeficiency virus (HIV).

The highest risk in the transplant population is 1 to 3 mo posttransplantation, with the peak incidence at 8 w posttransplant. Diffuse interstitial pneumonitis is the most frequent presentation, but multiple other CXR presentations have been reported, including nodular infiltrates resembling nocardia. Multiple associated findings are present in severe infection, and reflect the disseminated nature of the infection; the presence of neutropenia, abnormalities of liver function tests, and mucosal ulcerations may be clinical clues to the diagnosis.

Characteristically, patients with CMV pneumonia have sustained fever, nonproductive cough, and dyspnea. Rales and tachypnea are often present, and marked hypoxemia is an indicator of life-threatening infection. Pneumonitis may be accompanied by mild neutropenia, thrombocytopenia, and elevated liver enzymes, which may be helpful in differential diagnosis. Chest radiographic changes are usually bilateral, with diffuse or focal haziness involving the mid and lower lung fields. Both miliary and interstitial radiographic patterns have been described. Often the perihilar distribution of the infiltrate is suggestive of pulmonary edema. Common CT scan findings include small nodules, consolidation, and ground-glass attenuation.

Herpes Simplex Virus

HSV infection of the lower airway may occur either as the result of direct extension of infection from the tracheobronchial tree to the lung or as the result of hematogenous dissemination of virus from mucocutaneous lesions of the upper airway or genitourinary tract. Dyspnea, cough, and hypoxemia are usually seen, but the clinical features of the pneumonia do not permit an etiologic diagnosis to be made antemortem. Focal or multifocal infiltrates were seen on chest roentgenograms of patients with the pattern of direct extension, whereas diffuse bilateral infiltrates were found in patients with pneumonia due to presumed hematogenous dissemination of virus. CT scan findings include multifocal segmental and subsegmental ground-glass opacities, but are not distinctive. In one study, more than one-half of the patients had concomitant pulmonary infection with other microorganisms, including bacterial, candidal, and *Aspergillus* species, and cytomegalovirus. Histologic evidence of herpetic esophagitis was present in 10 of 16 patients with herpes pneumonia in whom esophageal examination was performed.

Herpes simplex virus infection of the lower airway has also been found in association with ARDS. The relationship of HSV infection to ARDS is unclear, but the presence of HSV in the lower respiratory tract was associated with the need for prolonged respiratory support and an increased late mortality. Isolation of HSV from lower respiratory tract secretions has also been common in mechanically ventilated patients and may be associated with a poor outcome.

Varicella Zoster Virus

VZV is an important problem in individuals with hematologic malignancies and others with iatrogenic immunosuppression, with the greatest risk seen in organ transplantation. Prolonged fever and/or recurrent crops of lesions are predictors of visceral dissemination, and pneumonia is generally seen in this setting. Pulmonary manifestations may include pleuritic chest pain due to vesicular lesions of the pleura, and, as is also true in normal hosts, the CXR may demonstrate nodular lesions.

Adenoviruses

Adenoviruses are significant causes of morbidity and mortality in immunocompromised patients, particularly after transplantation. In contrast to infection in normal hosts, infection in immunocompromised subjects tends to be disseminated, with isolation of virus from multiple body sites including lung, liver, gastrointestinal tract, and urine. In addition, the spectrum of serotypes includes both those found in immunocompetent individuals as well a markedly increased frequency of isolation of higher-numbered serotypes found rarely in immunologically normal subjects.

RNA Viruses

RNA viruses have also received increasing recognition as potential causes of significant morbidity and mortality in this population. RSV has been well recognized as a cause of pneumonia in recipients of bone marrow and solid organ transplantation. Nosocomial transmission of RSV in this setting has been well documented, and may be the source of many infections in this susceptible population. The illness typically begins with nondescript upper respiratory symptoms that progress over several days to severe, life-threatening lower respiratory tract involvement. Mortality rates of 50 percent or higher are typical, particularly if disease occurs in the preengraftment period. Parainfluenza viruses have also been reported as an infrequent lower respiratory tract pathogen in both solid organ and bone marrow transplantation. PIV-3 has been most commonly serotype isolated, but all four serotypes have been implicated. Influenza may also cause severe disease in transplant recipients, but most subjects have survived. Rhinovirus infections in this population are also common, but tend to be associated less frequently with lower respiratory tract disease. However, chronic rhinovirus infection, with graft rejection, has been described in lung transplant recipients.

Measles giant cell pneumonia is a severe, usually fatal form of pneumonia associated with measles infection in immunosuppressed individuals. Most cases have occurred in those with hematological or other malignancies, or individuals with AIDS. Recent outbreaks of measles worldwide, coupled with the increasing incidence of HIV infection, has increased the frequency and impact of measles giant cell pneumonia. Giant cell pneumonia also occurs in significantly malnourished individuals. Multinuclear giant cells with intranuclear inclusions are seen, and may be demonstrable in fluid obtained by bronchoalveolar lavage. An important feature of measles pneumonia in immunocompromised hosts is that many patients present without rash or other typical manifestations of measles, and a high index of

suspicion must be maintained. It has been speculated that such hosts may not mount the cellular immune responses involved in the pathogenesis of rash in immunologically intact individuals. In hospitalized patients, mortality rates are approximately 70 percent in oncology patients and 40 percent in HIV-infected patients.

Pathogenesis

The pathogenesis of viral infections of the lower respiratory tract can conveniently be considered in terms of infections initiated in and primarily confined to the respiratory tract, or so-called primary viral pneumonia, such as with influenza or RSV; processes in which infection is initiated in the respiratory tract with subsequent systemic manifestations, such as in measles or varicella, and processes in which respiratory tract involvement is secondary to a systemic infection, such as with CMV. Each of these situations may lead to what is recognized clinically as a viral pneumonia. In this discussion, the general features of primary viral pneumonia are discussed using influenza as a model, and pathogenesis of other forms of viral pneumonia are discussed briefly in comparison.

In primary influenza viral pneumonia, virus infection reaches the lung either by contiguous spread from the upper respiratory tract, or inhalation of small particle aerosols. Infection initially occurs in ciliated respiratory mucosal epithelial cells of the trachea, bronchi, and lower respiratory tract, and leads to widespread destruction of these cells. The trachea and bronchi contain bloody fluid, and the mucosa is hyperemic. Tracheitis, bronchitis and bronchiolitis are seen, with loss of normal ciliated epithelial cells. Submucosal hyperemia, focal hemorrhage, edema, and cellular infiltrate are present. The alveolar spaces contain varying numbers of neutrophils and mononuclear cells admixed with fibrin and edema fluid. The alveolar capillaries may be markedly hyperemic with intra-alveolar hemorrhage. Acellular, hyaline membranes line many of the alveolar ducts and alveoli.

The pathologic changes in the lower respiratory tract in children with viral pneumonia due to RSV and parainfluenza virus are nonspecific and include epithelial necrosis with bronchiolar mucus plugging and widespread inflammation and necrosis of lung parenchyma, and severe lesions of the bronchial and bronchiolar mucosa as well. In fatal cases of RSV pneumonia in children, hemorrhagic pneumonia with peribronchial mononuclear infiltration and cytoplasmic inclusion bodies in epithelial cells are seen.

Bacterial superinfection is a well-recognized complication of viral pneumonia and accounts for a large proportion of the morbidity and mortality of viral lower respiratory tract disease, especially in adults. Consequently, the spectrum of disease and pathophysiology of bacterial superinfection has been studied intensively, and a number of factors identified in viral respiratory disease which could play a role in increasing the risk of bacterial infection. The disruption of the normal epithelial cell barrier to infection, and loss of mucociliary clearance undoubtedly contribute to the enhancement of bacterial pathogenesis. The physiologic consequences of these alterations have been demonstrated as markedly decreased mucociliary clearance of labeled particles in human subjects with acute, naturally acquired influenza. In addition, increased adherence of bacteria to virus-infected epithelial cells has been demonstrated. Polymorphonuclear leukocytes and mononuclear cells are susceptible to abortive infection by some respiratory viruses with resulting decreased function that may also contribute to enhanced bacterial infection. Finally, bacteria themselves may enhance the replication of some viruses such as influenza viruses by the release of proteases that cleave the viral hemagglutinin.

The Hantavirus pulmonary syndrome represents an additional example of a viral infection that involves the lung as part of a systemic infection. The pathogenesis of HPS involves extensive infection of endothelial cells throughout the body, which is particularly intensive within the endothelial cells of the lung. Abundant viral antigen and nucleic acid can be detected within these cells. Microscopic examination of the lung reveals mild to moderate interstitial pneumonitis with variable degrees of congestion, edema, and mononuclear cell infiltration. The cellular infiltrate is composed of a mixture of small and large mononuclear cells, which consist predominantly of T lymphocytes, and macrophage/monocyte cells. The picture is one of immune mediated capillary leak and not of cell necrosis or inflammatory pneumonitis. High levels of cytokines have been detected in the blood and likely mediate the endothelial damage.

Cytomegalovirus pneumonia is a problem predominantly in individuals with compromised immune systems, particularly after transplantation, and also represents a systemic infection that involves the lung secondarily. There are several features of this disease in the transplant setting that suggest that both host and viral factors interact in pathogenesis. CMV pathogenicity is enhanced in transplant recipients and frequently occurs at the site of the transplanted organ. The risk of CMV pneumonitis is highest in individuals at the highest risk for graft-versus-host disease. Finally, treatment with antivirals alone is ineffective, while treatment with antivirals and immune globulin, which serve to mitigate the graft-versus-host component, is effective.

The pathogenesis of CMV pneumonia is partly related to viral replication but also is thought to have an immunopathologic basis. The development of CMV pneumonitis reflects a complex interaction between viral infection and graft-versus-host disease, particularly in marrow transplant recipients. Two patterns of histopathology have been described in the lung tissue of bone marrow transplant patients with serious pneumonia. One is a miliary pattern, with multiple focal lesions showing extensive cytomegaly with localized necrobiosis, alveolar hemorrhage, fibrin deposition, and neutrophilic response. The other is of interstitial character, with alveolar-cell hyperplasia, interstitial edema, lymphoid infiltration, and diffusely distributed cytomegalic cells.

Diagnostic Tests

Epidemiologic or clinical features of the presentation of viral pneumonia, such as the time of year, history of exposures,

or, in some situations, presence of systemic signs or symptoms, such as rash, may be very useful in establishing the potential viral etiologies in specific cases of viral pneumonia. However, the clinical presentation is rarely distinctive enough to allow a specific viral diagnosis to be made on clinical grounds alone. Specific diagnosis generally depends on isolation of viral agents from appropriate respiratory specimens. Many of these viruses can be isolated from nasopharyngeal swab or wash specimens, or from lower respiratory tract secretions. Rapid antigen detection tests are available for detection of RSV and influenza A virus in respiratory secretions. Definitive attribution of pneumonia to viruses that are typically shed asymptomatically in the upper respiratory tract, such as herpes simplex virus, is more difficult and requires detection of virus in the lower respiratory tract, usually in association with pathologic evidence of invasive disease.

Differentiation between viral and bacterial forms of pneumonia on clinical grounds can be difficult in children, and radiologic criteria do not always distinguish these entities well and mixed viral and bacterial pneumonia may be present. However, in normal infants and children with RS or parainfluenza virus pneumonia, bacteria do not appear to play an important role, and routine addition of antibacterial agents is not useful. The exception to this observation is in developing countries, where mixed viral and bacterial pneumonias in children are frequent and severe.

Treatment and Prevention

Therapy of viral pneumonia is dependent on the severity of disease, the age and immune status of the host, and the specific causative viral agent. General supportive measures, particularly the management of hypoxia, are critically important, and some patients have required high frequency ventilation or extracorporeal membrane oxygenation. Since mixed viral-bacterial infections or bacterial superinfections are common, antibacterial agents may be required, for example, in patients with lobar pneumonia or productive sputum.

Antiviral therapy is generally indicated for severe disease and in immunocompromised hosts, and should be guided by the results of diagnostic tests. As described above, the neuraminidase inhibitors zanamivir and oseltamivir have mostly been studied in uncomplicated influenza in healthy adults, but it seems reasonable to use antiviral agents if the patient is still virus positive at the time of presentation. Because of widespread resistance, use of the drugs amantadine or rimantadine is no longer recommended.

The only option available for the other RNA viruses is ribavirin, but there is little evidence of efficacy of this agent for any viral pneumonia. In immunocompromised hosts, treatment of established RSV pneumonia has not been successful. One approach that appears promising is treatment with ribavirin, possibly in combination with immunoglobulin, early in the illness when predominantly URI symptoms are present. Controlled trials in parainfluenza virus infection are not available, although anecdotal reports suggest potential efficacy. Limited controlled trials have suggested that aerosolized ribavirin may reduce the severity of symptoms in children with measles, and some immunocompromised patients with measles pneumonia have done well following treatment with aerosolized or intravenous forms of the drug. Intravenous ribavirin is effective in the treatment of several human Hanta-virus diseases, including Lassa fever and HFRS, but was not effective in a controlled trial of therapy of hantavirus pulmonary syndrome.

Antiviral agents with proven clinical usefulness for human coronavirus infection are currently unavailable. However, the severity of the SARS coronavirus epidemic has led to an extraordinary effort to discover and develop effective antivirals, and it is likely that multiple agents will be reported in the near future. The most promising to date appears to be the type I interferons (alpha and beta), which are highly active in cell culture. Treatment with parenteral interferon at doses used typically to treat hepatitis C virus infection appeared to lead to clinical improvement in a small series of patients in the Toronto epidemic.

Acyclovir is active in vitro against herpes simplex virus types 1 and 2; it is approximately ten-fold less active against VZV and does not have clinically useful activity against cytomegalovirus or Epstein-Barr virus. Although controlled clinical trials of this drug in herpes simplex pneumonia have not been conducted, the drug has proven clinical efficacy in other herpesvirus infections and would be indicated in any serious HSV lower respiratory tract infection. Acyclovir is also effective in the therapy of varicella, and intravenous acyclovir has been effective when initiated early in the course of varicella pneumonia. The related drugs famciclovir and penciclovir are similar to acyclovir in their spectrum of activity against herpes viruses. Viruses resistant to the activity of these drugs have been isolated from treated patients, and may be susceptible to the antiherpes drug phosphonoformic acid (foscarnet).

Once CMV pneumonitis is established, particularly in allogeneic bone marrow transplant patients, it is very difficult to treat. Ganciclovir is highly active against CMV in vitro but monotherapy is not effective in pneumonitis in BMT recipients. The combination of ganciclovir therapy and intravenous CMV immune globulin can reduce mortality from approximately 90 to 50 percent or lower in these patients. The effect of the immune globulin in this situation may be mostly to ameliorate graft-versus-host disease. Whether combination therapy is required in solid organ transplant recipients with CMV pneumonia is uncertain. Cidofovir and foscarnet are other antiviral drugs with activity against CMV. Both have been used to successfully treat CMV retinitis, but their effectiveness for treating CMV pneumonia has not been established. All of the available CMV antivirals have serious side effects that limit their usefulness.

Guidelines for reducing the risk of CMV disease in stem cell transplant recipients have recently been published. Transplant candidates should be screened for evidence of CMV immunity, and CMV-seronegative recipients of allogeneic stem cell transplants from CMV-seronegative donors should receive only leukocyte-reduced or CMV-seronegative RBCs and/or leukocyte-reduced platelets. In mismatched

solid organ transplant recipients (donor+/recipient–), post-transplant prophylaxis with oral ganciclovir or its prodrug valganciclovir significantly reduces the risk of CMV disease, although late-onset disease still occurs. Another strategy is preemptive therapy with ganciclovir or another anti-CMV agent when screening detects infection, but before disease develops. This strategy requires the use of sensitive and specific laboratory tests for diagnosis.

Antiviral treatment of proven value for adenovirus infection is not available. Both the broad spectrum antiviral agents ganciclovir and cidofovir are active in vitro, and an increasing number of reports indicate that intravenous ganciclovir may be useful in seriously ill patients, although at the expense of significant renal toxicity. Cidofovir has also been used for preemptive therapy in high-risk immunocompromised patients.

Various forms of intravenous immunoglobulin have also been evaluated in viral pneumonia. As mentioned, IVIG is important in the treatment of CMV pneumonia in bone marrow transplant recipients; the effect is unrelated to the titer of CMV neutralizing antibody contained in the preparation, and may act through modulation of the immune response. Intravenous immunoglobulin is effective for the prevention of measles after exposure of susceptible individuals, and may be useful in the treatment of measles pneumonia, especially when combined with ribavirin. As described above, a humanized, neutralizing monoclonal antibody directed against the F protein of RSV (palivizumab) is highly effective for the prevention of severe RS disease in at-risk infants, but is not effective for therapy of established disease.

Protozoan Infections of the Thorax

Louise C. Ivers • Edward T. Ryan

AMEBIASIS

Entamoeba histolytica

Entamoeba histolytica is a protozoan infection of humans that is found worldwide and is globally responsible for up to 100,000 deaths annually. It is endemic in most temperate and tropical areas of the world, particularly in areas with poor socioeconomic development and limited sanitation. Serological evidence of prior or current infection with *E. histolytica* is present in 5 to 50 percent of individuals in impoverished populations. *E. histolytica* is infectious in its cyst form. Transmission usually occurs as a result of contamination of food or water, but may also occur by means of oral-anal contact. Infection is common in developing countries. In Europe and the United States, infection is most commonly seen in individuals who have lived in endemic areas of the world. Institutionalized individuals are also at increased risk of infection. Sexually active men who have sex with men are also at increased risk of infection, although recent studies suggest that this group is not necessarily at increased risk of invasive disease. There does not appear to be an increased risk of invasive disease in persons with HIV infection.

A morphologically identical, but non-pathogenic protozoan, *Entamoeba dispar*, also infects the human gastrointestinal tract. It has recently been distinguished from *E. histolytica* by antigenic, genetic, and immunologic methods. Infection is 10 times more prevalent with *E. dispar* than with *E. histolytica*; however, the former does not cause invasive disease. In the United States, infection with *E. histolytica* or *E. dispar* is estimated at 4 percent. Many older epidemiological studies relied on microscopic diagnosis alone, and inadvertently incorporated both pathogenic and nonpathogenic species in estimates of prevalence of infection.

E. histolytica has a simple life cycle involving an infectious cyst and an ameboid trophozoite phase. Cysts may survive in the external environment for several weeks to months, especially in damp conditions and temperatures between −5°C and 40°C. After ingestion by humans, cysts excyst in the small intestine, each forming eight daughter trophozoites. These motile trophozoites can adhere to the intestinal wall; it is in this form that they may invade the mucosa, causing symptomatic invasive disease. In the colon, trophozoites encyst to complete the life cycle and are excreted. Trophozoites do not survive outside the human host.

Clinical Manifestations

The incubation period for intestinal amebiasis is usually 1 to 4 weeks, but ranges from a few days to months. Infection with *E. histolytica* is asymptomatic in up to 90 percent of cases, but may cause a range of gastrointestinal symptoms from mild diarrhea to severe colitis with bloody diarrhea. Symptoms result from penetration of the trophozoites through the mucosal barrier with invasion of the colon wall. In the absence of frank blood, stool is usually positive for occult blood. Fever is present in less than half of cases. Fecal leukocytosis is usually less marked than in bacterial colitis. Rarely, progression of invasive intestinal disease may lead to severe colitis and bowel perforation. On occasion, granulation tissue formation surrounding a localized area of invasive disease may form an inflammatory mass (an "ameboma") and manifest as a tender abdominal mass.

Extraintestinal disease most commonly occurs in the liver, and manifests as a liver abscess. In this instance, trophozoites migrate to the liver via the portal veins, and infection results in inflammation, necrosis, and ultimately an abscess. Eighty percent of amoebic hepatic abscesses are solitary, and 80 percent occur in the right lobe of the liver. Extraintestinal disease may present years after residence in an endemic area and should be considered in all patients with an appropriate travel history and suggestive symptoms. Liver abscesses occur more frequently in men than women, and usually in the age range of 18 to 50 years.

Thoracic manifestations of *E. histolytica* infection are rare; they have been reported in 2 to 3 percent of cases of invasive amebiasis. They can be considered chiefly as either pleuropulmonary or pericardial. A case of *E. histolytica* osteomyelitis of the rib has been reported, as has a case of pulmonary amebiasis presenting as superior vena cava syndrome.

Pleuropulmonary Disease

Amoebic pulmonary disease may occur by a number of mechanisms. It most often occurs as the result of a concomitant liver abscess. The abscess may result in a sympathetic pleural effusion that does not require specific therapy. A liver abscess may alternatively rupture through the diaphragm into the pleural space, causing respiratory distress, empyema, and subsequent parenchymal lung abscesses (Figs. 135-1, 135-2, 135-3). Pulmonary parenchymal disease in the form of lung

abscesses and consolidation less often occurs in the absence of hepatic disease, but may occur if there has been hematogenous spread of trophozoites to the lung.

Most patients with extraintestinal amebiasis have not had symptomatic intestinal disease, so the absence of preceding gastrointestinal symptoms does not exclude the diagnosis. Patients with liver abscess often present with insidious onset of fever, right upper quadrant pain, and hepatic tenderness on palpation. Pleuritis, respiratory symptoms such as cough, dyspnea, and/or physical examination consistent with pleural effusion further suggest involvement of the pleuropulmonary system. Sputum production may range from scant to copious, and sputum may contain purulent material, particularly if a hepatobronchial fistula has developed. Classically, the purulent material of amoebic abscess is reddish "anchovy paste." Jaundice is uncommon. Leukocytosis may be present, but eosinophilia is not a feature of the disease.

Pericardial Disease

Pericardial disease can result from either sterile inflammation of the pericardium as a result of a contiguous liver abscess in the left lobe of the liver, or may be a purulent infection as a result of rupture of a hepatic amoebic abscess into the pericardial space (Fig. 135-4). Chest pain, pericardial friction rub, and symptoms and signs of pericarditis may be presenting features. Presentation may be acute and severe, with symptoms and signs of pericardial tamponade.

Diagnosis of Pleuropulmonary and Pericardial Disease

Stool microscopy may reveal the presence of *E. histolytica* trophozoites or cysts, but microscopy is neither a sensitive nor a specific method for diagnosis of amebiasis. Microscopy is unable to distinguish *E. histolytica* from non-pathogenic *E. dispar*, and extraintestinal disease is associated with presence of the pathogen in stool in only a minority of cases. Stool may be concentrated and stained with iodine to evaluate for the presence of cysts. Trophozoites are best seen on a fresh smear with iron hematoxylin and trichome stain. Microscopy of abscess fluid occasionally may reveal presence of trophozoites. Diagnosis of extraintestinal disease is best made by a combination of microscopic examination of samples, antigen detection, and serology tests.

Antigen Detection

Antigen detection methods are increasingly commercially available to detect *E. histolytica.* These tests are able to distinguish *E. dispar* from *E. histolytica.* Stool antigen tests are over 95 percent sensitive and specific for the diagnosis of intestinal disease. Antigen detection assays are also highly sensitive and specific when applied to abscess fluid.

Serology

Most patients infected with *E. histolytica*, but not *E. dispar*, develop a serum antibody response. Amoebic serology is positive in over 90 percent of patients with extraintestinal disease. Serological analysis may be negative in early infection. The presence of IgG antibodies does not always indicate active disease; IgG may persist for many years after active infection.

Treatment

Metronidazole or tinidazole is effective in the treatment of individuals with intestinal and extraintestinal amebiasis. To

prevent a relapse, a luminal agent such as iodoquinol or paromomycin also should be administered. Sympathetic pleural effusions do not need specific therapy, other than treatment of the underlying liver abscess. Amoebic empyema and amoebic pericarditis are best treated with aspiration or percutaneous drainage, in combination with administration of antiamoebic microbial therapy.

FREE-LIVING AMOEBA: *ACANTHAMOEBA*

Free-living amoeba are rarely associated with human infection; however, when infection does occur, disease tends to be progressive and difficult to treat.

Acanthamebiasis

Acanthamoeba species are ubiquitous, and have been isolated from a wide variety of locations, including the nasal passages of healthy adults, water sources, soil, and contact lens fluid. Infection in humans usually manifests as either keratitis or systemic disease. Systemic disease usually involves the central nervous system, manifesting as granulomatous amoebic encephalitis. Amoebic infection of skin also has been reported.

Clinical Features

Acanthamoeba sp. keratitis is usually a disease of healthy individuals, often contact lens wearers. Infection is thought to result from direct deposition of amoeba into the eye. In contrast, systemic disease results from hematogenous dissemination of amoeba, which are thought to first enter the human host via the respiratory tract or skin. Systemic disease is primarily a disease of immunocompromised or debilitated persons, including individuals with the acquired immunodeficiency syndrome (AIDS), and those who have undergone bone marrow transplantation, organ transplantation, or are otherwise immunosuppressed. Pulmonary nodular infiltrates and pneumonitis have been reported in cases of systemic disease.

Diagnosis

Diagnosis of systemic acanthamebiasis is usually made late in the clinical course, and unfortunately, very often at autopsy. Evaluation of cerebrospinal fluid from individuals with granulomatous amoebic meningoencephalitis may disclose hypoglycorrhachia and elevated protein, but amoeba are not usually seen. Evaluation of biopsies of lesions of skin or brain usually provides the definitive diagnosis. *Acanthamoeba* spp. can be identified on histopathology, and may be cultured on nutrient agar overlaid with *E. coli*. Radiographic imaging of the central nervous system is often helpful.

Treatment

No single drug is effective against systemic *Acanthamoeba* spp. infection. Combinations of treatment with amphotericin B, azithromycin, fluconazole, 5-fluorocytosine, pentamidine, and sulfadiazine have been attempted, with success in some cases and failure in other cases that used similar regimens. Most individuals with systemic amebiasis do not survive, irrelevant of therapy. Individuals with acanthamebic keratitis are usually treated topically and may require corneal grafting.

SYSTEMIC COCCIDIOSIS

Toxoplasmosis

Toxoplasmosis is caused by *Toxoplasma gondii*. Asymptomatic disease is common. Symptomatic disease usually occurs in persons with suppressed cell-mediated immunity and infants born with congenital infection.

Epidemiology and Life Cycle

Understanding the life cycle of *T. gondii* is important in the understanding the disease process. The parasite is found worldwide. It has both sexual and asexual stages, the latter being the pathogenic stage in humans and other animals. Cats are the definitive host, and in the feline, oocysts develop after an intestinal intraepithelial sexual cycle. Oocysts are then passed in cat feces, and after 2 to 3 days become infectious. They may persist in soil. If ingested by humans or other animals (sheep, pigs, rodents, or cats), oocysts produce rapidly dividing tachyzoites. Tachyzoites invade varying cell types, and result in cell death and tissue necrosis. Eventually the host immune response curtails this process, and tachyzoites give rise to slowly dividing bradyzoites, which encyst and persist indefinitely in host tissues. Bradyzoites are infectious if ingested, giving rise to tachyzoites in the new host. Bradyzoites may also revert to tachyzoites if a host becomes immunocompromised, leading to "reactivation" of disease. Humans and other animals may be infected, not only by ingestion of oocysts, but also by ingestion of tissue cysts, such as following the consumption of undercooked infected meat. Toxoplasma infection may also be acquired by transplacental passage of tachyzoites, resulting in congenital infection, or by organ transplantation.

Serologic studies demonstrate a wide geographic variation in prevalence of infection between 10 and 90 percent. In the United States, rates range from 3 percent in Denver, Colorado, to 17 percent in Massachusetts, and 30 percent in Birmingham, Alabama.

Clinical Features

Infection may be primary or due to reactivation. After ingestion of infectious oocysts or tissue cysts, tachyzoites disseminate and invade organs, replicating intracellularly. Acute infection may result in tachyzoites being found in all organs, especially muscle, lymphatic tissue, and the central nervous system. Primary infection may be subclinical or asymptomatic. If symptomatic, the most common manifestations of acute disease include fever, painless lymphadenopathy, and a mononucleosis-like syndrome. More rarely pneumonitis, myocarditis, and myositis may occur.

Congenital infection is usually the result of primary infection in the mother, with transplacental passage of tachyzoites resulting in infection of the fetus. Infected infants may be symptomatic at birth, or may have hepatosplenomegaly, pneumonitis, myocarditis, rash, or jaundice. Congenitally infected children may be asymptomatic initially, but may subsequently develop central nervous system or ocular manifestations.

Reactivation disease occurs in persons who are immunocompromised, particularly those with deficiency in cell-mediated immunity. Patients with HIV infection and CD4 cell counts less than 100 cells/mm^3 are at particular risk of life-threatening disease, and although primary infection may occur in these individuals, reactivation disease is most common. Reactivation disease may be prevented in those at particular risk with the prophylactic use of trimethoprim-sulfamethoxazole. Necrotizing central nervous system disease is the most common manifestation of reactivation toxoplasmosis in AIDS patients. Affected individuals usually present with altered mental status, fever, headache, and clinical findings suggestive of focal CNS disease, and neuro-imaging often reveals multifocal, ring-enhancing lesions.

Pulmonary-Thoracic Disease

Pulmonary involvement in toxoplasmosis is common, and is usually reported in patients with AIDS or in individuals who have undergone bone marrow or solid organ transplantation (Fig. 135-5). Cases may also occur, albeit less frequently, in individuals without evidence of immunosuppression. Shortness of breath and cough are the most common presenting symptom, of pulmonary involvement during toxoplasmosis. In one review, immunocompetent patients with toxoplasmic pneumonitis were more likely than immunocompromised individuals to have evidence of hepatosplenomegaly at presentation, but clinical findings were otherwise similar. Bilateral interstitial pulmonary infiltrates are most often evident in radiography; however, a variety of other findings, from discrete pulmonary opacities to cavitary disease, also have been described. Severe disease or the acute respiratory distress syndrome (ARDS) may develop. *T. gondii* organisms can invade myocytes, and during acute or reactivation disease, myocarditis may occur and may be severe.

Diagnosis

In primary toxoplasmosis, the differential diagnosis is broad, but IgM-specific antibodies will usually be present. During reactivation of toxoplasmosis, IgM and IgG anti-toxoplasma antibodies are usually present in serum. Absence of anti-toxoplasma IgG antibodies makes the diagnosis of reactivation toxoplasmosis unlikely, but the presence of the antibody itself does not differentiate between latent and active disease.

Biopsy can confirm the diagnosis. Polymerase chain reaction (PCR) analysis of tissue samples or cerebrospinal fluid is sensitive, and PCR analysis of amniotic fluid is particularly helpful in the antenatal diagnosis of congenital infection. PCR has been used to detect toxoplasma in sputum specimens, but the sensitivity of this method for diagnosing pulmonary toxoplasmosis has not yet been determined. In pulmonary disease, microscopic or molecular analysis of bronchoalveolar lavage fluid or open lung biopsy may be required for confirmation of the diagnosis.

Treatment

Except in the case of pregnant women or individuals with severe or persistent symptoms, primary toxoplasmosis in immunocompetent individuals usually does not require treatment. Reactivation disease in immunocompromised individuals is usually treated for the duration of the period of immunosuppression, as therapy does not fully eradicate the parasite. Standard therapy is pyrimethamine and a sulfonamide, usually sulfadiazine. Leucovorin is added to overcome the bone marrow suppressive effects of pyrimethamine. Clindamycin may be used as an alternative in those intolerant of sulfonamides. After acute disease has been controlled, secondary suppressive therapy should be continued for the duration of immunosuppression to prevent relapse. Unfortunately, mortality in immunocompromised patients with toxoplasma pneumonia diagnosed antemortem has been as high as 40 percent.

INTESTINAL COCCIDIOSIS

Cryptosporidiosis

Cryptosporidium parvum is an intracellular protozoan that mainly causes intestinal pathology (Fig. 135-6). Disease may occur in immunocompetent hosts, but is more common and severe in immunocompromised individuals, particularly in patients with AIDS, in whom cryptosporidiosis may result in severe and persistent diarrhea. The organism also causes infection in a variety of animals, and fecal contamination of water or food is a common source of infection in humans, although person-to-person transmission also occurs.

The life cycle of *Cryptosporidium parvum* begins when the infectious oocyst is ingested. These organisms, which are 4 to 5 μm in diameter, may remain viable in the environment for months. After ingestion, they excyst in the small intestine, and release four motile sporozoites, which invade epithelial cells of the intestinal wall. Asexual maturation then results in merozoites being released back into the intestinal lumen. These merozoites either result in re-invasion of epithelial cells, or undergo maturation to become oocysts. The oocysts may then be excreted, or may excyst while still in the lumen to "auto-infect" the host.

Clinical Features

Cryptosporidial infection may be asymptomatic, or may be associated with a range of illness from mild diarrhea to severe gastroenteritis. Invasion of the intestinal epithelium results in secretory diarrhea. The biliary tree may be infected, causing cholangitis, and hepatitis and pancreatitis also have been

described. Infection may be associated with systemic symptoms such as malaise, nausea, and abdominal cramps. In some patients, diarrhea is voluminous and has been described as "cholera-like." In patients with a normal immune system, cryptosporidial diarrhea usually resolves within 2 weeks. In immunocompromised individuals, especially those with HIV infection and CD4 cell counts less than 100 cells/mm^3, symptoms often continue until the immune status of the individual is restored. In such individuals, cryptodoridiosis may result in a severe wasting syndrome.

(*Courtesy of J.A. Fishman, Massachusetts General Hospital.*)

Pulmonary Cryptosporidiosis

Respiratory infection with *C. parvum* is rare, but has been reported, usually in patients with AIDS (Fig. 135-7). Pulmonary involvement, as with other extraintestinal manifestations of cryptosporidiosis, usually occurs in the setting of intestinal disease. At least one case of pulmonary infection, however, has been reported with no apparent evidence of intestinal infection. Pulmonary involvement may appear as an interstitial infiltrative process or as areas of focal consolidation. Some authors suggest that the prevalence of pulmonary cryptosporidiosis is underestimated, and one study reported a prevalence of 17 percent in HIV positive patients with respiratory symptoms.

Diagnosis

Cryptosporidium may not be cultured in vitro, and diagnosis of cryptosporidiosis relies largely on demonstration of pathological findings in tracheal or bronchial tissues, and visualization of cryptosporidial cysts by microscopy. The cysts may be best seen by acid-fast staining of specimens. Oocysts have been detected in bronchoalveolar lavage, open lung biopsy, and sputum specimens.

Treatment

Nitazoxanide decreases diarrhea in immunocompetent individuals with intestinal cryptosporidiosis. However, reliable efficacy has not been demonstrated in individuals with disseminated cryptosporidial disease, or those who are immunocompromised. Thus, in most individuals, treatment is predominantly supportive while attempts are made to restore immune function; in AIDS patients, this is chiefly through the use of antiretroviral therapy. In addition to nitazoxanide, other agents have been administered to individuals with cryptosporidiosis, although efficacy has not been demonstrated. Administered agents have included paromomycin, trimethoprim-sulfamethoxazole, and metronidazole. Anecdotally, azithromycin has been successfully combined with paromomycin in the therapy of pulmonary infection.

CYCLOSPORIASIS

Cyclospora cayetanensis is a protozoan organism, usually associated with diarrheal illness in humans. It is ubiquitous,

and transmitted usually as a result of contamination of food or water. The protozoan is usually detected as an approximately 10-μ organism on acid-fast stains of specimens. Infection usually responds to trimethoprim-sulfamethoxazole. A single case report of possible pulmonary cyclosporiasis has been reported. A 60-year-old Brazilian man with a history of treated tuberculosis was found to have *C. cayetanensis* organisms in sputum specimens examined for evaluation of respiratory distress and pulmonary infiltrates. No other organisms were detected, and the patient's symptoms resolved following administration of trimethoprim-sulfamethoxazole (and treatment of concomitant intestinal parasitosis).

MALARIA

Malaria in humans is the result of infection by one of four species of plasmodia: *P. falciparum, P. vivax, P. ovale,* and *P. malariae.* Human malaria is endemic in parts of sub-Saharan Africa, India, Southeast Asia, the Caribbean, and Central and South America. Over 1 million deaths annually are attributed to malaria, usually among pregnant women and children under the age of 5 years who live in endemic areas. The majority of malaria-related fatalities are a result of infection with *P. falciparum.*

Malaria is acquired by the bite of an infective female *Anopheles* sp. mosquito. In non-endemic areas, malaria cases are found largely in travelers who have returned from malaria endemic areas, but the parasite also may be transmitted by contaminated blood products, in utero from mother to child, and by organ transplantation. Malaria infection in persons co-infected with HIV is associated with increased HIV viral load, and increased symptoms in the setting of parasitemia.

Life Cycle

When bitten by an infective mosquito, malarial sporozoites enter the host and travel to the liver, where they invade hepatocytes and divide, forming tissue schizonts in an asymptomatic stage. These schizonts then rupture, releasing thousands of daughter merozoites into the bloodstream. These merozoites invade erythrocytes, and develop to form mature ring forms and ultimately erythrocytic schizonts. A small percentage of merozoites develop into sexual forms called gametocytes. Gametocytes do not cause symptoms, but when another mosquito bites an infected human host, the gametocytes are ingested by the feeding mosquito, permitting the malarial life cycle to continue. *P. falciparum* may infect red blood cells of all ages, resulting in the potential for very high levels of parasitemia.

Infection with *P. vivax* and *P. ovale* may result in a dormant liver phase in which parasites remain in the liver in the form of hypnozoites, potentially causing relapse many months after first infection. *P. falciparum* and *P. malariae* do not have such a dormant stage, and do not cause late relapsing disease.

Pathogenesis

Malaria related morbidity and mortality occurs predominantly in children and pregnant women. Most individuals who live in endemic areas develop partial immunity to symptomatic disease as they age. This immunity does not prevent infection, but reduces the frequency of symptoms and severity of disease despite ongoing parasitemia. Infection with any of the four human-specific species of malaria causes hemolysis, resulting in anemia that may be severe.

Certain genetic traits associated with hemoglobin structure or erythrocyte surface antigens are associated with decreased infection rates or decreased symptomatic disease. For example, absence of the Duffy antigen on the surface of erythrocytes protects against *P. vivax* infection, and sickle cell trait is protective against severe *P. falciparum* infection. *P. falciparum* also causes the formation of "sticky knobs" on the surface of infected erythrocytes. These knobs are comprised of host cell and parasite antigens, and mediate binding of infected erythrocytes to endothelial surfaces. This binding results in sequestration of infected erythrocytes, and may result in "sludging" of blood flow. This sequestration and sludging contributes to micro-vascular obstruction that can result in organ dysfunction.

Clinical Features

Patients with malaria typically present with fever and a constellation of other nonspecific symptoms such as headache, chills, and myalgias. Vomiting, nausea, diarrhea and cough also may be present. Anemia, thrombocytopenia, and hepatosplenomegaly may be present. Sequestration of infected erythrocytes in the brain may cause cerebral malaria. Individuals with cerebral malaria may present with altered mental status, seizures, focal neurologic findings, or coma. Even with treatment in modern intensive care units, mortality during cerebral malaria is high. Other organ-specific complications of infection are also largely related to microvascular sequestration of parasitized red blood cells in specific tissues, and may manifest as placental, renal, or pulmonary dysfunction (Fig. 135-8).

Pulmonary Features

Pulmonary symptoms such as cough and increased respiratory rate are common during malaria. In African children, malaria frequently presents with symptoms and signs suggestive of pneumonia. Metabolic acidosis is an important cause of respiratory distress in these children, but pneumonitis as a result of sequestered parasitized red blood cells is also responsible. In more severe disease, noncardiogenic pulmonary edema may develop. Initial acute lung injury may progress to acute respiratory distress syndrome (ARDS) (Fig. 135-9). Tachypnea and dyspnea, followed by hypoxemia and respiratory failure may develop. Studies have confirmed the development of impaired alveolar-capillary membrane function in patients with severe malaria. Lung injury in severe disease is postulated to be not only the result of pulmonary

(*Reproduced with permission from Martinez S, et al.: Thoracic manifestations of tropical infections: A pictorial review*. RadioGraphics *25:135–155, 2005.*)

microvascular sequestration, but also a consequence of the inflammatory response to infection.

In a recent study of uncomplicated symptomatic malaria, altered pulmonary physiology, including increased airflow obstruction, decreased gas transfer, impaired ventilation, and increased pulmonary phagocytic activity were found in both *P. vivax* and *P. falciparum*-associated infections, but were worse in cases of *P. falciparum* malaria. ARDS has also been reported in cases of malaria caused by *P. vivax*, and one case of pulmonary edema has been reported complicating a case of *P. ovale* malaria; however, significant pulmonary morbidity is largely confined to infection by *P. falciparum*, and usually occurs in the context of multisystem involvement. The principal differential diagnosis for pulmonary disease in malaria infection is metabolic acidosis and bacterial pneumonia.

Diagnosis

The diagnosis of malaria should be considered in any symptomatic patient who has had exposure to the parasite in a malaria endemic area. Rare cases of transmission by blood products, organ transplantation, or congenital infection also have occurred. Individuals with malaria caused by *P. falciparum* usually develop symptoms within 3 months of the mosquito bite, and usually within 1 month. Since *P. vivax*

and *P. ovale* have potentially dormant liver phases, individuals infected with these parasites may not develop symptoms for many months after exposure (usually within 1 year of the mosquito bite).

Malaria is usually diagnosed through microscopic examination of blood smears. A thick smear examined by an experienced microscopist is highly sensitive for detecting infection. Review of a thin smear provides further detail to allow identification of the infecting species. Antigen detection assays identifying falciparum-specific histidine rich protein 2 (HRP-2), or parasite lactate dehydrogenase (pLDH, which is present in all four species), are also commercially available.

Treatment

Appropriate treatment of individuals with malaria depends on the infecting species, severity of disease, age and pregnancy status, and the ability of the patient to take drugs by mouth. Non-falciparum malaria is generally susceptible to chloroquine phosphate, although to date, resistance has been reported in parts of Indonesia, Papua New Guinea, India, Myanmar, and Brazil. Non-severe cases of chloroquine-resistant falciparum malaria can be treated with oral atovaquone-proguanil or mefloquine, or quinine sulfate in combination with either doxycycline or clindamycin. Severe cases of falciparum malaria should be treated parenterally with quinine dihydrochloride, quinidine gluconate, or artesunate. Therapy with artemisinin-based combinations of drugs is increasingly being recommended, particularly in endemic areas; however, artemisinin derivatives are not commercially available in many countries, including the United States.

Individuals with malaria caused by *P. vivax* or *P. ovale* also should be treated with primaquine to treat the hypnozoite form of disease. Primaquine should not be administered to individuals deficient in glucose-6-phosphate dehydrogenase or pregnant women. Pulmonary manifestations and other organ-specific complications of severe infection are treated supportively. Mechanical ventilation may be required. Early institution of renal replacement therapy may prevent subsequent development of ARDS in severe malaria. Exchange transfusion has been recommended for patients with severe falciparum-associated disease with parasitemia levels over 5 percent, although data on efficacy are controversial.

BABESIOSIS

Babesiosis is a tick-borne infection usually caused by *Babesia microti* in the United States, and *Babesia divergens* in Europe. In the United States, the disease has been reported from Minnesota, Maryland, Virginia, California, Washington State, Georgia, Wisconsin, and Indiana; however, most cases occur in the Northeastern states. Transmission also may occur as the result of infected blood transfusions.

Babesia parasites invade, multiply within, and lyse red blood cells. In immunocompetent hosts, disease is most commonly asymptomatic or relatively mild, and characterized by fever, flulike illness, myalgias, and nausea. More severe manifestations may include thrombocytopenia, hemolytic anemia, jaundice, meningismus, non-cardiogenic pulmonary edema, disseminated intravascular coagulation, hypotension, and shock. Severe disease is most common among the elderly or individuals with compromised immunity. Asplenic individuals are at particular risk of severe disease, and individuals infected with HIV are at particular risk of persistent disease. Pulmonary disease in babesiosis occurs in association with multisystem disease, and usually presents as ARDS or non-cardiogenic pulmonary edema.

The diagnosis of babesiosis should be considered in any patient with appropriate exposure history who presents with fever or a sepsis syndrome. Diagnosis is usually confirmed by microscopic examination of peripheral blood. Atovaquone, azithromycin, quinine and clindamycin all have anti-Babesia activity; combination therapy is usually administered.

TRYPANOSOMIASIS

American Trypanosomiasis (Chagas' Disease)

Chagas' disease is caused by infection with *Trypanosoma cruzi*, a protozoan parasite transmitted to humans most often via the feces of an infected reduviid bug. The disease is endemic in certain South and Central American countries. Clinical manifestations may occur acutely after initial infection. More commonly, clinical manifestations may not become evident until years or decades after initial infection. When acute symptoms do occur, they may include fever, peripheral edema, hepatosplenomegaly, and myocarditis. Chronic sequelae may occur in up to one-third of infected individuals, and usually involves the heart, esophagus, or large bowel (Fig. 135-10).

Cardiac disease usually manifests clinically as congestive-dilatory cardiomyopathy. Chronic dilatation of the esophagus or colon resulting from denervation of the gut may result in Chagasic mega-esophagus or mega-colon. Acute myocarditis may result in pulmonary edema. Pulmonary involvement during Chagas' disease is usually secondary to cardiac or intestinal disease, and may include pulmonary edema secondary to congestive heart failure, pulmonary hypertension secondary to right-sided dilatory cardiomyopathy, or aspiration pneumonia secondary to vomiting and regurgitation associated with mega-esophagus or mega-colon. Recurrent aspiration and pneumonitis may lead to lung abscesses, fibrosis, scarring, and bronchiectasis. The debilitation of chronic Chagas' disease may lead to cachexia, and may be associated with a higher rate of tuberculosis. In an autopsy review of 69 adult cases of Chagasic mega-esophagus in Brazil, 35 percent of patients had pneumonia, and 22 percent had pulmonary tuberculosis—rates that were higher than in a cohort of patients in the same study who had Chagasic cardiac disease, but no mega-esophagus.

Scale is in centimeters. *C.* Low-power photomicrograph (original manifestation, ×10; Giemsa stain) shows *T. cruzi* amastigotes within a myofiber (arrow). D. Chagasic achalasia in a 13-year-old girl with Chagas' disease. Barium esophagogram shows diffuse and severe dilatation of the esophagus. Histologic analysis demonstrated *T. cruzi* amastigotes within the esophageal wall. (*Reproduced with permission from Martinez S, et al.: Thoracic manifestations of tropical infections: A pictorial review*. RadioGraphics *25:135–155, 2005.*)

Congenital Chagas' disease has been associated with pneumonitis; and in an autopsy review of 10 congenital cases, pathologic finding have included diffuse pulmonary interstitial edema and endothelial swelling in lung tissues.

Diagnosis in acute Chagas' disease may be made by detecting parasites on blood smear. Culture of parasites from specimens is possible using specialized media, although the usefulness of this method is limited because culture may take several weeks. In chronic disease, parasites are not usually visualized. Diagnosis is usually based on serologic analysis, suggestive radiology, and, more rarely, pathological examination of tissues. Treatment in acute disease and in patients

with immunosuppression is warranted, and nifurtimox and benznidazole are the mainstays of therapy. The utility of treating individuals with established, chronic disease with antiparasitic agents is currently unclear.

African Trypanosomiasis (African Sleeping Sickness)

Trypanosoma brucei gambiense and *Trypanosoma brucei rhodesiense* are the causative agents of African trypanosomiasis (African sleeping sickness). African sleeping sickness is usually transmitted by the bite of an infective tse tse fly. East African trypanosomiasis is caused by *T.b. rhodesiense*. Individuals with East African trypanosomiasis are often acutely ill with fever, lymphadenopathy, headache, and myalgia. Disease may be fulminant, and individuals may develop disseminated intravascular coagulopathy, ARDs, hypotension, and shock. The most common pulmonary manifestations during acute disease is non-cardiogenic pulmonary edema and ARDS. West African trypanosomiasis is caused by *T.b. gambiense*. Individuals with West African trypanosomiasis usually do not develop severe disease during the acute stage. Rather, months or years after initial infection, infected individuals present with mental status changes, personality changes, recurrent fever, lymphadenopathy, weight loss, and disorders of circadian rhythm. The most common pulmonary manifestation during late stage disease is pneumonitis second to recurrent aspirations associated with inanition and altered mentation. Direct pulmonary involvement is not common in West African trypanosomiasis. A single case report describes an African child who presented with severe respiratory symptoms, and was later found to have African trypanosomiasis.

LEISHMANIASIS

Leishmaniasis is caused by an intracellular protozoa parasite in the Leishmania genus. The Leishmania parasites are widely distributed, and are usually transmitted through the bite of an infective sand fly. Infection of humans may be asymptomatic, or may involve the skin (cutaneous leishmaniasis), the mouth or nose (mucocutaneous leishmaniasis), or be systemic (visceral leishmaniasis). Human infection is most common in South and Central Asia, the Middle East, the Mediterranean, Balkans, North Africa, sub-Saharan Africa, and Central and South America. Specific organisms are often responsible for specific clinical syndromes, although overlap occurs. Disease is often considered as "New World" or "Old World," based on geographic location. The parasite exists as an intracellular organism (amastigote) in host macrophages, and as an extracellular promastigotes in the sandfly gut—being inoculated into the host's skin during the bite of the fly.

Clinical Features

Cutaneous syndromes may range from localized disease, usually on exposed areas of skin, to widespread cutaneous involvement. In localized disease, painless ulcers develop and most often resolve spontaneously over months. Classically, "Old World" cutaneous leishmaniasis is caused by *L. major, L. tropica, L. aethiopica,* or *L. infantum*; ' "New World" cutaneous disease is usually caused by *L braziliensis* or *L. mexicana*-complex organisms. Some New World species are associated with development of mucocutaneous disease months to years after resolution of the initial skin lesions. Severe destruction and disfiguration of the face with resultant aspiration pneumonitis may occur.

Visceral leishmaniasis is usually caused by *L. donovani, L. infantum,* or *L. chagasi*. Individuals with visceral leishmaniasis usually present with fever, hepatosplenomegaly, weight loss, pancytopenia, and hypergammaglobulinemia. Lymphadenopathy is commonly present. Gastrointestinal symptoms are common in advanced disease, and individuals with untreated visceral leishmaniasis develop a wasting syndrome. Pneumonia and tuberculosis may be the cause of death.

Pulmonary Disease

Pulmonary involvement from leishmaniasis in immunocompetent hosts is rare, but interstitial pneumonitis has been reported. However, immunosuppressed patients, particularly those with HIV infection, are at increased risk of atypical disease. In areas surrounding the Mediterranean, where seroprevalence for *L. infantum* in young adults may be as high as 30 percent, an increase in the incidence of HIV infection has caused an increase in the number of advanced cases of visceral leishmaniasis; a result either of new infections or reactivation of old infections. Patients with leishmaniasis and HIV infection may present with cough, dyspnea, hemoptysis, granulomatous mediastinal lymphadenopathy, solitary pulmonary nodules, or pleural effusions.

Treatment of leishmaniasis depends on type of disease (cutaneous vs. mucocutaneous vs. visceral), infecting species, parasite resistance patterns, severity of disease, and status of the host. Therapeutic options include amphotericin B, liposomal preparation of amphotericin, pentavalent antimony (sodium antimonylgluconate or N-methylglucamine antimonate), pentamidine, and miltefosine.

CILIATE INFECTIONS

Balantidium coli

Balantidium coli is the only ciliated protozoa that infects humans. Infection of humans usually occurs in individuals with contact with pigs, and human disease usually manifests as an infectious colitis very similar to amebiasis. Rare cases of pulmonary infection have been reported in humans: in a leukemic patient who presented with pulmonary lesions, in a 71-year-old woman with anal cancer and pneumonia, and a patient with chronic colitis and an intrapulmonary mass. Diagnosis is usually made through histological examination of

tissue samples. Treatment with tetracycline, metromedozole, or iodoquinol is usually effective.

FLAGELLATES

Trichomonas sp.

Trichomonads are flagellated protozoa. Pulmonary disease has been attributed most commonly to *Trichomonas tenax*, an organism that is most often considered a commensal in the human oropharynx, especially in individuals with poor oral hygiene. In one study of symptomatic patients, prevalence of *T. tenax* by PCR among 100 immunocompromised and 100 patients with chronic pulmonary disease was 10 percent. Diagnosis is most often made by examination of a wet mount of sputum or bronchoalveolar lavage specimen. Chronic purulent, necrotic pulmonary disease has been described, often thought to be a result of aspiration. Affected individuals have responded to metronidazole therapy.

Giardia Lamblia

Giardia lamblia is a pathogenic intestinal flagellate of humans. In humans, it usually causes chronic diarrhea and malabsorption. There is one case report of uncertain significance of recovery of *G. lamblia* trophozoites from bronchoalveolar lavage fluid.

MICROSPORIDIOSIS

Microsporidia is the name given to a group of spore-forming obligate intracellular organisms from the phylum *Microsporidia*. These organisms have been variously considered with the protozoa and fungi. Over 1200 microsporidia species occur worldwide, but the most common human pathogens are *Enterocytozoon, Encephalitozoon, Nosema, Pleistophora*, and *Septata* spp.

The microsporidia spore is the infective form of the organism, and when ingested or inhaled, it extends a polar tubule that infects the host cell. Within the host cell, replication occurs and more spores are formed. When spores sufficiently fill the cell, the cell membrane ruptures and spores are released; they may then proceed to infect nearby cells, or be passed into the environment in stool, urine, or respiratory secretions.

Most clinical cases of microsporidiosis in humans occur in immunocompromised hosts. In immunocompetent patients, infection with *Enterocytozoon bieneusi* can be asymptomatic or may cause acute and very rarely chronic diarrhea. In patients with HIV infection, symptomatic microsporidiosis tends to occur in advanced disease, such as when CD4 cell counts are less than 100 cells/mm^3. *Enterocytozoon bieneusi* and some species of Enterocephalitozoon (*E. hellem, E. cuniculi,* and *E. intestinalis*) have come to be recognized as major causes of diarrheal enteritis and disseminated infection in patients with AIDS. Disseminated disease caused by *Trachipleistophora* also has been described. Microsporidial species have been associated with disseminated disease including biliary tract disease, sinusitis, myositis, respiratory infection, and keratoconjunctivitis.

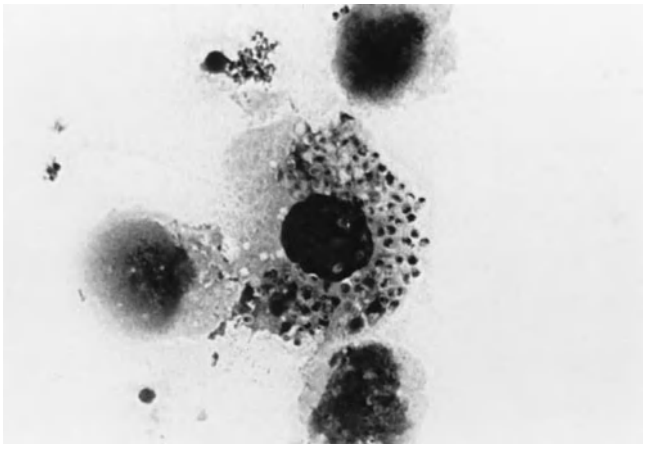

Figure 135-11 Pulmonary microsporidiosis. Tiny organisms (~1μm) within a pulmonary macrophage obtained via bronchoalveolar lavage (Giemsa-Wright stain, ×1000). (Courtesy of Dr. C. Wanke.)

Pulmonary Disease

Microsporidial disease with specific pulmonary involvement has been described in cases of patients with HIV infection, and in individuals who have undergone bone marrow or organ transplantation (Fig. 135-11). Pulmonary disease usually occurs in the setting of concomitant intestinal infection. In one retrospective review of 42 patients with HIV and microsporidial infection, 24 percent had respiratory symptoms, and four of six patients who had specimens examined had sputum or bronchoalveolar lavage positive for microsporidia.

Diagnosis

Diagnosis of microsporidiosis is based on identification of organisms in specimens of tissue or stool. Modified trichome staining allows detection of organisms on light microscopy, but electron microscopy is currently the definitive diagnostic method. Tissue culture, serologic assays, and PCR testing are used in research settings, but are not yet commercially available.

Treatment

Albendazole has activity against *Encephalitozoon* species, but is only partly effective against *E. bieneusi.* In immunocompromised individuals, treatment is directed at enhancing the immune status of the patient, i.e. antiretroviral therapy in patients with HIV infection, and decreased immunosuppression in transplant recipients. Duration of albendazole therapy depends on the severity of illness. *E. bieneusi* infections may be refractory to treatment.

Helminthic Diseases of the Lungs

Jay A. Fishman

Parasitic helminths are a distinct group of infectious agents that are among the most prevalent causes of morbidity and mortality in humans worldwide. Billions of people harbor parasitic worms. People with helminthic infections of the lungs often seek medical advice because of one or more common chest complaints—cough, pain, or breathlessness. They may also have unexplained laboratory abnormalities, including eosinophilia or pulmonary nodules. They often pose a diagnostic challenge, particularly in areas where helminthic infections are not endemic. Other, more common causes of chest complaints have to be excluded, a history of residence in certain geographic locations or of dietary or other exposures has to be elicited, and the proper procedures for making the diagnosis of helminthiasis selected.

The helminths that parasitize humans include the nematodes (roundworms) and platyhelminths (flatworms), with the flatworms divided into the cestodes (tapeworms, segmented worms) and trematodes (schistosomes and other flukes). The biology of each of these groups is distinct. Ectoparasites are uncommonly associated with lung disease (e.g., leeches or Annelida or segmented worms) and are not discussed here.

In humans, worms produce a variety of pulmonary parenchymal and vascular diseases (Table 136-1). Because several stages in the life cycle of the parasite are found in humans, and pulmonary lesions occur at a particular phase of the life cycle, familiarity with the biologic behavior of the organisms is essential for proper diagnosis and treatment.

BIOLOGY AND IMMUNOLOGY

Biology of Helminths

Worms are multicellular organisms that vary considerably in size, from a few millimeters to several meters. They are covered by a tegument cuticle that protects them from the environment. Reproductive organs, both sexual and hermaphroditic, take up a large portion of the body. They are among the most developed and elaborate of human parasites. Their parasitic capabilities are such that they often parasitize more than one host and survive different hostile environments. Despite their relatively large size, the infective stages of worms invade human tissues by ingestion, penetration of skin, or the bite of insect vectors. Furthermore, parasitic helminths have developed a myriad of mechanisms by which they can evade the protective mechanisms of the host.

The life cycle of the helminths includes an egg form, larval stages, and an adult form. Human infection is by ingestion of the eggs or larvae, penetration of the skin by larvae, or insect

Table 136-1

Pulmonary Parenchymal and Vascular Diseases Produced by Worms

Major Pulmonary Presentation	Infection	Causative Organism	Infective Stage	Pathogenic Stage
Loeffler-like syndrome	Ascariasis	*Ascaris lumbricoides*	Embryonated eggs in soil	Migrating larvae
	Hookworms	*Ancylostoma duodenale*, *Necator americanus*	Larvae in soil Larvae in soil	Migrating larvae
	Strongyloidiasis rhabditiform	*Strongyloides stercoralis*	Larvae in soil	Migrating larvae
	Hyperinfection with filariform	*S. stercoralis* *S. stercoralis*	Larvae in bowel	Migrating larvae
Pulmonary eosinophilia	Lymphatic filariasis	*Wuchereria bancrofti*, *Brugia malayi*	Larvae in mosquito	Microfilariae
Eosinophilia, cough	Visceral larva migrans	*Toxocara cani*, *T. catis*	Egg ingestion	Larvae
Space-occupying lesions	Echinococcosis	*Echinococcus granulosus*	Eggs in soil	Hydatid cysts
	Paragonimiasis	*Paragonimus westermani*	Metacercariae	Adult worms
	Schistosomiasis	*Schistosoma mansoni*, *S. japonicum*, *S. haematobium*	Cercariae in fresh water	Eggs

transmission of larvae. Humans may be the only host, an accidental host, an intermediate host (asexual reproduction), or a definitive host (with sexual reproduction in humans). A basic biologic generalization about helminthic infections is that the worms, as a rule, cannot multiply within the mammalian host. This phenomenon is important to the understanding of the dynamics of helminthic infection and the relationship between the intensity of a particular worm load within the host and its pathologic consequences. However, there are exceptions to this rule. For example, *Strongyloides stercoralis* and *Echinococcus granulosus* can increase their numbers within a host even though the host is not exposed to additional infective forms. This ability of *S. stercoralis* to autoinfect the same subject and cause a hyperinfection syndrome is of considerable clinical significance, especially in immunosuppressed patients, which may be fatal. A different example is that of echinococcosis, in which dissemination is usually a consequence of leakage or rupture of a hydatid cyst—thereby releasing its contents, which seed sites elsewhere and initiate similar lesions.

Another biologic characteristic of worm infections, particularly those migrating in host tissues such as the lungs, is the association with eosinophilia in the peripheral blood and tissue. When eosinophilia is marked, this association provides a clinically useful sign of a migratory worm infection. The prominent peripheral blood eosinophilia of tissue migratory worm infections contrasts with no eosinophilia in persons in whom the worm infection is confined to the gut lumen or in whom the infection is due to other agents (e.g., viruses or bacteria). The mechanism and specificity of this eosinophilic response depend on the integrity of the *cellular* immune response of the host: Sensitized T lymphocytes produce mediators that induce differentiation in the bone marrow or progenitor cells into mature eosinophils; this is done either directly or via other cell products from mononuclear phagocytes. Eosinophilia does not occur in athymic nude mice infected with *Trichinella spiralis* or *Schistosoma mansoni.* Similarly, eosinophilia often does not feature prominently when strongyloidiasis occurs in immunosuppressed persons. Eosinophil production appears to be affected by interleukin 3 (IL-3), GM-CSF, and IL-5. Only IL-5, however, is specific for the maturation of eosinophils and basophils. The cytokine interact with eosinophils through a cell surface–specific receptor. It induces a state of metabolic as well as functional activation of eosinophils. In contrast, the specific helminthic antigens responsible for initiating this response are unknown. It should be noted that corticosteroids may lyse eosinophils and complicate diagnosis.

Investigations have suggested that the increased eosinophil level that occurs in experimental animals or

humans with helminthiasis is related to their biologic role as an integral component of host defenses. In vitro, eosinophils along with antibodies or complement kill the larval forms of several helminths. The killing of parasites is accompanied by a respiratory burst in these cells and evacuation of the contents of their granules onto the surface of the helminth. In vivo, depletion of eosinophils in experimental animals leads to loss of their acquired resistance to infection from several helminths, such as *T. spiralis* and *S. mansoni.* Both oxidative and non-oxidative products of eosinophil granules have been implicated in target killing.

Host-Parasite Relationship in Pulmonary Helminthiases

Human disease caused by pulmonary helminthiases results from various factors. Most classes of helminths can reside in human lungs during one or more of their parasitic stages, including nematodes, trematodes, and cestodes. The stage of the life cycle that causes human pulmonary disease also varies—e.g., larvae of nematodes, eggs of schistosomes, and adult worms in paragonimiasis, and cestodes. The multiplicity and complex structure of these etiologic agents lead to a heterogeneous set of responses, both immunologic and nonimmunologic. Moreover, disease may result from the mechanical presence of worms (space-occupying lesions) and the associated inflammatory responses or as a byproduct of the host immune responses, or both. For example, in echinococcosis, hydatid cysts displace lung tissues, but in pulmonary schistosomiasis, the vascular obstructive lesions are predominantly the outcome of the delayed-hypersensitivity granulomatous response of the host. Therefore, the understanding of the host-parasite relationship in pulmonary helminthiasis is based on an appreciation of the heterogeneity of etiologic agents and corresponding host responses.

An additional and biologically relevant factor concerning helminthic infections and their role in the etiology of human disease is the intensity of infection. Since most worms that infect humans cannot increase their population without additional exposure to the infective stages, the worm load largely determines the degree of pathologic sequelae. For example, the number of schistosome eggs reaching the pulmonary circulation is an essential determinant of the severity of the induced disease. Although the number of eggs reaching the lungs may be influenced by several factors, the most important determinant is the number of adult worms in the infected person.

The immune responses of the host often feature prominently in shaping the pathologic consequences of helminthic infection of the lungs. In experimental animals, the degree of tissue injury and host responsiveness to several helminthiases has been shown to be regulated by modulatory antibody, cellular, and cytokine responses.

Whether humans acquire resistance to helminthic infection and resistance can be induced have not been settled. Resistance against several helminths occurs in experimental animals after primary infection, and can be induced by defined antigens.

APPROACH TO THE PATIENT WITH HELMINTHIC INFECTION OF THE LUNGS

As indicated, the major symptoms and signs of pulmonary disease are common to most etiologic agents, non-infectious as well as infectious. Although in general helminth infections are particularly common in temperate and hot areas of the world, some are transmitted in the United States and other colder and developed areas. A history that the patient has lived overseas or in certain parts of the United States is helpful in alerting the examiner to the possibility of a helminthic infection. The geographic distribution of the major helminthic infections is roughly known. Also, some infections, such as those with *E. granulosus,* are common in sheep-raising countries and in certain sheep-raising areas in the United States. Knowledge of the immunologic status of the patient is valuable in suggesting helminthic infection—e.g., the hyperinfection syndrome caused by *S. stercoralis.*

Eosinophilia in peripheral blood, sputum, or pulmonary tissue is a helpful clue in directing the diagnostic workup. Although increased eosinophil counts do occur in several other pulmonary diseases, the close association with helminthic infections necessitates appropriate diagnostic procedures to determine whether a worm is implicated. Definitive diagnosis of helminthic infections of the lungs requires isolation and identification of diagnostic stages in the life cycle of the parasite that routine examination of appropriate specimens may miss. Therefore, the appropriate laboratory personnel should be alerted to the possibility of a worm infection so that proper samples can be obtained and preserved for special examinations. Serologic testing for helminthiasis is particularly useful in nonendemic areas. It should always be considered an adjunct and important diagnostic procedure.

DISEASES DUE TO NEMATODES (ROUNDWORMS)

Ascariasis, Hookworms, and Strongyloidiasis

Human infections with *Ascaris lumbricoides,* the hookworms *Ancylostoma duodenale* and *Necator americanus,* and *S. stercoralis* are among the most prevalent helminthiases worldwide. Transmission also occurs in the southeastern United States.

Etiology

Human ascariasis (Fig. 136-1) results from ingestion of embryonated *A. lumbricoides* eggs that are contained in feces-contaminated soil. Ingestion of contaminated vegetables and fruits that have not been properly washed is the most frequent transmission vehicle. *Ascaris* eggs hatch in the gastrointestinal

Pulmonary Diseases and Disorders. New York, McGraw-Hill, 1980, pp 1182–1201). B. Strongyloides stercoralis.* Rhabditiform larvae. *(Courtesy of Dr. Stanley H. Abadie.)*

tract, producing larvae that penetrate the gut wall and migrate via venous blood and the right side of the heart to the lungs. Hookworms (*A. duodenale* and *N. americanus*) and *S. stercoralis* infect humans when infective larvae, found in soil, penetrate intact skin. Larvae of hookworms or of *S. stercoralis* travel via the bloodstream to the lungs (Table 136-1). The parasite larvae migrate via pulmonary capillaries into alveolar spaces. They then ascend toward the trachea to be swallowed en route to their final habitat in the small intestine. Although larvae are sometimes found in the sputum of infected persons, more often the eggs (*A. lumbricoides, A. duodenale,* and *N. americanus*) or the larvae *(S. stercoralis)* are found in stools. Passage to the outside environment, where the stool forms develop into stages infective for humans, completes their life cycle.

Pathogenesis and Pathology

In nematode infections, the most prominent pulmonary pathologic changes occur in persons with ascariasis or with the hyperinfection syndrome of strongyloidiasis. *Ascaris* pneumonia may occur in 1 to 2 weeks after infection. Portions of larvae are seen in the pulmonary parenchyma, surrounded by patchy infiltrate of neutrophils and eosinophils. The alveoli contain a serous exudate; the production of bronchial mucus is increased. Later, migrating larvae are destroyed within aggregates of eosinophils. The nature of the inflammatory process in *Ascaris* pneumonia suggests hypersensitivity. The intensity of the reaction depends on the number of parasite larvae and previous sensitization. In areas in which transmission of *Ascaris* eggs occurs seasonally, pulmonary reactions are usually more in evidence during these periods.

In *immunocompetent* subjects, pulmonary disease caused by hookworms or *S. stercoralis* is unremarkable. It should be recalled that infection with *Strongyloides* is lifelong and that reactivation with suppression of cell-mediated immunity can occur decades after initial exposure. As a result, life-threatening infection with *S. stercoralis* seems to relate to the premature development of filariform larvae in immunocompromised persons and invade across the gut wall or perianal skin, carrying intestinal bacteria into the peritoneum and bloodstream. Tissue migration occurs through most body organs, including the lungs. Gram-negative meningitis and sepsis are components of this syndrome. Initially, the pulmonary lesions resemble those of *Ascaris* pneumonia. In some patients, bronchopneumonia and lung abscesses develop. The lungs of fatal cases show intra-alveolar hemorrhages and inflammatory changes.

Clinical Features

The major clinical manifestations caused by infection of the lungs with the larval forms of intestinal nematodes resemble those of Loeffler's syndrome; these manifestations occur typically in patients with seasonal or *Ascaris* pneumonia. The symptoms include persistent, irritating, and nonproductive cough, substernal pain, and in the severely ill, hemoptysis and dyspnea. Eosinophilia is the most consistent laboratory finding. Radiographic signs—e.g., patchy or miliary infiltrate—are sometimes seen.

The onset of the Loeffler-like syndrome caused by intestinal nematodes usually occurs 2 to 3 weeks after infection, coincident with larval migration from the pulmonary circulation to the alveoli. This coincidence was illustrated by the occurrence of the syndrome in a group of students exposed to eggs of the pig roundworm *(A. suum)*. Typical symptoms occurred 10 to 15 days later; some of the students developed marked respiratory failure. In locations in which transmission of ascariasis is cyclic because of environmental factors, pneumonitis occurs seasonally. Mild symptoms are occasionally encountered in persons with hookworm infection or in immunocompetent subjects who have strongyloidiasis.

The most clinically significant pulmonary syndrome induced by intestinal nematodes is caused by hyperinfection with *S. stercoralis* (Fig. 136-2). As a rule, the syndrome occurs in patients with compromised cell-mediated immunity, although it is occasionally encountered in normal persons. Immunosuppression is usually caused by neoplastic diseases, such as Hodgkin's, other lymphomas and leukemias, or nonmalignant conditions that are being treated with corticosteroids—e.g., organ transplantation. The sequence of events in immunosuppressed patients indicates that a change has occurred in the reproductive cycle of the parasite: In non-immunosuppressed subjects, the rhabditiform larvae have to go to the outside world to transform into the infective filariform organisms; in immunosuppressed patients, the change to infective larvae occurs within the host. The organisms penetrate the intestinal mucosa—resulting in massive invasion of almost every organ, including the lungs. The major clinical features include asthma, pulmonary opacities and cavitation, consolidation, and diffuse focal infiltrates. Usually, widespread dissemination of the nematode is accompanied by secondary infection caused by gram-negative organisms carried along with *S. stercoralis*. Eosinophilia is often absent in patients with the *S. stercoralis* hyperinfection syndrome, due to either defective cell-mediated immunity or the use of corticosteroids in many patients. The *S. stercoralis* hyperinfection syndrome is often fatal: mortality occurs in up to 77 percent of people with such infections.

Management

Diagnosis of infection with intestinal nematodes that causes a Loeffler-like syndrome can be difficult. Only occasionally is the search for parasite larvae in sputum rewarding. Indeed, not infrequently, definitive diagnosis is delayed for weeks, until the adult worms mature in the small intestine. At this stage, fecal examination discloses the characteristic eggs of hookworms or *Ascaris* or the larvae of *S. stercoralis*. The management of patients with the pulmonary manifestations of these parasitic worms is non-specific and symptomatic. Reduction of exposure in areas in which transmission of ascariasis is seasonal decreases the prevalence and severity of clinical presentations. Specific antihelminthic therapy is ineffective during

Fishman.)*

Table 136-2

Therapies of Pulmonary Diseases Produced by Worms

Organisms	Common Therapies	Comments
Ascaris lumbricoides	Albendazole, mebendazole, pyrantel, ivermectin, piperazine	Infection may persist for 1–2 years
Ancylostoma duodenale		Infection for ~ 1 year
Necator americanus	Albendazole, mebendazole, levamisole, pyrantel	Infection may persist for 3–5 years
Strongyloides stercoralis	Ivermectin, albendazole, thiabendazole	Hyperinfection with *S. stercoralis* with meningitis or sepsis requires therapy for gram negative or mixed infection; infection may be latent for >30 years (lifetime)
Wuchereria bancrofti, Brugia malayi	None satisfactory; diethylcarbazine or ivermectin reduce worm burden but no effect on clinical course	Prevention by mosquito control; possible addition of albendazole to other therapies
Echinococcus granulosus	Albendazole, mebendazole	Space-occupying lesion may require surgical resection in toto; may risk dissemination without cysticidal therapy (hypertonic saline, 0.5% cetrimide, 70%–95% ethanol, iodine); PAIR procedure—percutaneous aspiration and cysticidal therapy
Paragonimus westermani	Praziquantel (bithionol not always available)	
Schistosoma mansoni, S. japonicum, S. haematobium	Praziquantel (oxamniquine for *S. mansoni* and metriphonate for *S. hematobium* not always available)	
Toxocara cania, T. catis	None proved (albendazole, thiabendazole, mebendazole, diethylcarbazine, others)	Anti-inflammatories for cough; corticosteroids for symptoms or with therapy

the pulmonary stage but can cure the infection once the parasites reach maturity in the small intestine.

Albendazole 400 mg po once or mebendazole 100 mg per day for 2 to 3 days (or 500 mg po once) are the drugs of choice for treating ascariasis and hookworms (Table 136-2). Ivermectin 200 μg/kg per day for 2 days or albendazole 400 mg po daily for 2 days (7 days for hyperinfection syndrome) are recommended for strongyloidiasis. In patients suspected of having the hyperinfection syndrome, early diagnosis, modification of the immunosuppressive therapy, and prompt anti-*Strongyloides* chemotherapy and antibacterial therapies are important elements in averting a fatal outcome. Thus, a high degree of suspicion that strongyloidosis is present is needed in dealing with pulmonary disease associated with bacteremia in immunosuppressed patients. Most instances of strongyloidiasis in these patients are diagnosed at autopsy or shortly before death. Aggressive efforts at demonstrating *S. stercoralis* larvae entail repeated examination of stools and duodenal aspirates. Sputum and bronchial washings are examined for parasite larvae. Serology may be of help. In these patients, therapy is started as early as possible and continued for at least 7 to 10 days. Serologically positive individuals for *Strongyloides* should be treated in advance of immune suppression for organ transplantation or cancer therapy, generally with empiric ivermectin.

Pulmonary Filariasis (Tropical Pulmonary Eosinophilia)

Persons living in areas endemic for *Wuchereria bancrofti* and *Brugia malayi* may present with an acute or chronic lung disease, usually referred to as *tropical pulmonary eosinophilia.*

This is still a poorly defined clinical entity. Its main features are a history of residence in filaria-endemic areas, particularly India, chronic nocturnal paroxysmal cough, marked eosinophilia, positive serologic evidence, and a therapeutic response to the administration of diethylcarbamazine.

Etiology

Human infection with the tissue nematodes *W. bancrofti* or *B. malayi* can cause several amicrofilaremic syndromes, including tropical pulmonary eosinophilia. Infection is transmitted by the bite of several species of mosquitoes, thereby introducing the infective third-stage larvae. These organisms undergo ill-defined maturational stages, culminating in the development of adult male and female worms that are usually situated in lymphatic vessels and lymph nodes. Mature worms deposit microfilariae that appear in peripheral circulation, often at maximum numbers at specific times of the day. However, some filariae show no periodicity with respect to the appearance of their microfilariae in peripheral blood. Microfilariae are taken up by mosquitoes during their bites, thereby completing the life cycle of the parasite.

The life span of adult filariae is not known. Nonetheless, serologic or histopathologic evidence of infection can be obtained in the syndrome known collectively as *amicrofilaremic states,* even though larvae cannot be found in the blood. For example, in tropical pulmonary eosinophilia, high concentrations of antifilarial IgG and IgE in serum have been demonstrated despite invariably negative blood examinations for parasites. Also, despite the negative blood examinations, microfilariae have been found in lung and lymph node biopsies, confirming the filarial origin of this syndrome.

Pathogenesis and Pathology

Patients with pulmonary filariasis *(tropical pulmonary eosinophilia)* show evidence of humoral hyperreactivity manifested as increased serum levels of total IgE and antifilarial IgG and IgE. The possibility has been raised that these antibodies play a causal role in producing the pulmonary symptoms by inducing clearance of microfilariae and acute IgE-mediated responses, which are manifested clinically as asthma and eosinophilic pulmonary infiltrates. Histopathologically, the earliest lesions are histiocytic infiltrates in the interstitium and alveolar spaces. In established cases, the cell infiltrate consists predominantly of eosinophils, lymphocytes, and histiocytes, and it assumes a nodular configuration.

Clinical Features

Young males are predominantly afflicted with tropical pulmonary eosinophilia. The syndrome is characterized by episodes of dry night cough, low-grade fever, and general fatigue. Examination of the chest may reveal coarse rales and rhonchi, along with wheezing. In many patients, pulmonary function tests disclose a restrictive pattern in which vital and total lung capacity and residual volumes are all decreased. Some patients with chronic disease have perfusion impairment. Radiographically, the syndrome may be associated with reticulonodular opacities and increased bronchovascular markings. The sera of these patients usually demonstrate high IgE levels and specific antibodies to the parasite. Eosinophil counts in peripheral blood generally exceed $3000/mm^3$.

Management

Diagnosis is based on the typical clinical, radiographic, functional, and immunologic findings in the setting of an appropriate epidemiology history—i.e., previous residence in a filaria-endemic area. A favorable response to doxycycline 100 mg po bid for 8 weeks has been documented, possibly by reducing bacteria available for nutrition. This agent appears active against both adult worms and filarial. Diethylcarbamazine therapy 6 mg per kg po once appears to be as effective as prolonged therapies (14 days) as an alternative. Recurrences of tropical pulmonary eosinophilia are rare. If they do occur, a second course of antihelminthic chemotherapy is indicated.

Dirofilariasis

Another filarial parasite, *Dirofilaria immitis* (dog heartworm), may accidentally be transmitted to humans by the bites of the mosquito intermediate vector (Fig. 136-3). Several cases of dirofilariasis have been reported in the United States. In most, the infection was discovered as a coin lesion on the chest radiograph after a worm lodges in the pulmonary arteries. In some, cough, chest pain, hemoptysis, and eosinophilia were manifested. Definitive diagnosis is usually obtained from microscopic examination of excised lesions.

Toxocariasis (Visceral Larva Migrans)

Toxocariasis is due to human infection with animal parasites (dog or cat ascarids). It is most commonly encountered in children. The invading parasite larvae migrate in human tissues, but cannot mature to adult worms. *Toxocara canis* and *T. cati* are the two recognized etiologic agents of human visceral larva migrans. They both are widely distributed, in both developing and developed countries.

Etiology

The eggs of *T. canis* and *T. cati* are passed in the stools of dogs and cats, respectively. Transmission to humans occurs by ingestion of embryonated eggs in the soil or contamination of food. Larvae hatch in the small intestine, penetrate the gut wall, migrate to the liver, and are then carried via systemic veins to the systemic arterial circulation for distribution throughout the body. Larval migration through the host tissues and the associated inflammatory responses are considered responsible for the manifestations of disease. Most of these manifestations relate to liver pathology, eosinophilia, and pulmonary invasion. The concentrations in serum of total and specific immunoglobulins are also increased.

Pulmonary Diseases and Disorders. New York, McGraw-Hill, 1980, pp 1182–1201.)*

Pathogenesis and Pathology

It is not clear whether tissue injury results from the invasion of different organs by the parasite larvae or from death and encapsulation of some organisms by an eosinophilic response of the host. The most commonly affected organ is the liver, in which granulomas surround parasite larvae. Similar lesions can be induced in experimental animals (Fig. 136-4). In the few fatal cases of toxocariasis, autopsy revealed that the major pathologic lesions were in the central nervous system.

Clinical Features

Toxocariasis is generally a disease of children 1 to 4 years of age, although it may be seen uncommonly in older individuals. It is particularly common in those with a history of pica. The two main presenting features relate to the chest and abdomen. Pulmonary complaints, such as cough and wheezing, and pulmonary infiltrates occur in more than one-third of symptomatic children. Peripheral eosinophilia is usually marked and may persist for years. In one study of serologically

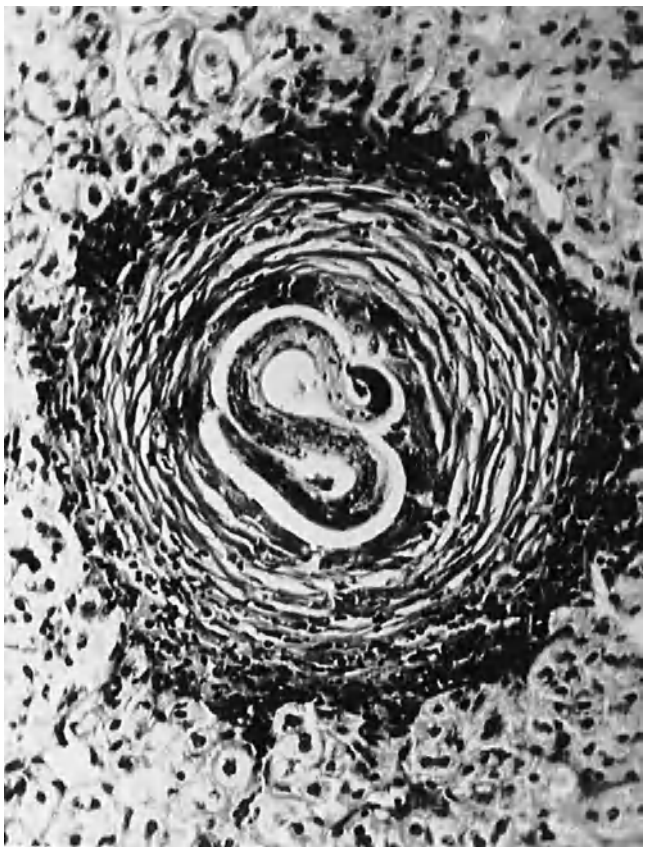

Figure 136-4 *Toxocara canis.* Granulomatous response to larvae in the liver. *(Courtesy of the American Society of Pathologists.)*

proven toxocariasis, hepatomegaly was present in 25 percent of patients.

Management

Toxocariasis is a cosmopolitan infection of children. Diagnosis is suspected because of the clinical presentation and serologic evidence of anti-*Toxocara* antibodies. Since the disease is usually benign and self-limiting and since the efficacy of most anti-helminthics against *Toxocara* infection is doubtful, no specific therapy is recommended. Corticosteroids may be necessary to limit the inflammatory response in patients with extensive disease of the lungs or central nervous system.

Rare Nematode Infections

In severe human *T. spiralis* infection, pneumonitis is accompanied by eosinophilia. The pulmonary syndrome follows the intestinal phase of infection and is usually associated with other allergic manifestations of trichinosis, including periorbital edema, muscle swelling, and weakness.

Anisakiasis in humans results from infection with the larval form of a nematode of marine mammals. The disease has been reported in Japan and Western Europe. Although it is usually manifested as an intestinal eosinophilic disorder, it has also been implicated as the probable cause of cough, eosinophilia, and pleural effusion.

DISEASES DUE TO CESTODES (SEGMENTED WORMS)

Echinococcosis

Human infection with the larval stage of the canine tapeworm *Echinococcus granulosus* is one of the most important helminthic pulmonary diseases. *E. granulosus* is worldwide in distribution; it occurs most commonly in sheep- and cattle-raising areas, particularly in Australia, South America, the Mediterranean, and some parts of Africa. The infection has also been reported in the United States.

Etiology

Adult *E. granulosus* worms are found in the intestines of dogs and wolves. They release eggs from their gravid segments that are passed in the feces. Humans acquire the infection by ingesting the eggs; embryos are then released and migrate to the liver, where most cysts in humans are found. Embryos may also migrate to the lungs or other tissues. Once the parasite has lodged in human tissues, it may develop in a space-occupying hydatid cyst. The inner lining of these cysts is a germinal layer capable of producing daughter cysts that may seed other organs upon spontaneous rupture or surgical manipulation of the original cyst (Fig. 136-5).

Pathogenesis and Pathology

Hydatid cysts are more frequently found in the lungs of children than of adults. In most instances, the slowly enlarging, space-occupying lesion is well tolerated. Cysts in the lungs are usually discovered early in the course of the disease because radiographic examinations of the chest are now so common. Pulmonary cysts are usually solitary, in 72 percent of cases affecting one lobe. The classic unilocular hydatid cyst is usually fertile: Cyst contents can seed other sites and start new cysts. The cyst is surrounded early in the course of infection by a granulomatous reaction on the part of the host; later, the inflammatory reaction is succeeded by fibrosis. Rupture of a fertile hydatid cyst may occur through a bronchus, leading to expectoration of scoleces in the sputum. Rupture into the mediastinum or pleural cavity can lead to secondary implantations. The fluid content of a hydatid cyst is believed to be immunogenic, and leakage of the cyst may evoke an anaphylactic response. Although eosinophilia has been reported to accompany hydatid disease of the lung, its frequency is not known.

Clinical Features

Hydatid cysts are usually asymptomatic; approximately half of the clinically diagnosed cysts are in the lungs. Most patients with pulmonary hydatid disease are children. In about three-fourths of patients, the cysts are in one lobe. Approximately half of the patients present with cough; smaller fractions present with dyspnea or chest pain. On chest radiography,

the lesions vary in diameter from 1 to 20 cm; sometimes the cyst is surrounded by an area of pneumonitis or atelectasis. Less often, a fluid level, "water lily sign" (Fig. 136-6), or calcification is seen. Other diagnostic procedures—e.g., serology and computed tomography—may be useful in improving characterization of the lesions.

Management

In most instances, diagnosis of the hydatid nature of a pulmonary cyst depends on immunologic procedures. Surgery is the treatment of choice for hydatid disease of the lungs. The Barrett procedure is currently recommended for small- or moderate-size cysts; the open method, in which the parasite cyst is removed but the cavity is left draining to the pleural space, is preferred for large cysts. More extensive procedures, such as lobectomy and segmental resection, may not be necessary for most pulmonary hydatid cysts. The use of the PAIR procedure with percutaneous aspiration, injection of cysticidal agent (hypertonic saline or absolute alcohol, although other agents have been used), and re-aspiration is common with radiographic guidance. This has proven successful in many cases. This is coupled with albendazole starting before

and continuing after drainage for 28 days (400 mg po bid for a greater than 60-kg individual; 15 mg/kg divided into two doses for those a less than 60-kg individual).

DISEASES DUE TO TREMATODES (FLAT WORMS)

Schistosomiasis

Schistosomal infections of humans represent one of the major endemic helminthiases in Southeast Asia, the Middle East, Africa, the Caribbean, and South America. Five species represent the most common and clinically significant infections: *Schistosoma haematobium, S. mansoni, S. japonicum, S. mekongi,* and *S. intercalatum.*

Etiology

The schistosomes are blood flukes; in humans, they inhabit the venous system around the urinary bladder or the small and large intestines. Human infection is initiated by penetration of intact skin by the free-living cercariae that are shed by specific freshwater snails. The cercariae change within a

few hours into schistosomula, which migrate from the subcutaneous tissues to the lungs and then the liver, where they mature into adult worms. Fecund adult parasites then migrate to their final habitat: the veins around the ureters and urinary bladder *(S. haematobium)* and the mesenteric veins (all other species). Adult worms deposit eggs that are intended to pass through the lumen of ureters or gut to the outside environment to complete the life cycle of the parasite. However, some of these ova may be trapped in the host tissues. Other ova may be carried by the venous circulation to the heart and then lungs. In *S. haematobium* infection, schistosome eggs reach the pulmonary circulation via the inferior vena cava. Eggs of the other species reach the systemic circulation after the development of portal hypertension and portosystemic anastomosis.

Pathogenesis and Pathology

Schistosome eggs reach the pulmonary circulation by routes that depend on the species of the parasite, their final habitat, and the stage of infection. Because *S. haematobium* worms parasitize the vesical plexus, which connects directly with the inferior vena cava, egg seeding to the lungs may occur at any phase of infection. By contrast, the anatomic location of adult worms of the other species in the mesenteric veins does not allow parasite ova to travel through the portal to the hepatic, and subsequently systemic, circulations. Eggs of these species are believed to reach the lungs only in the late stages of infection, after portal hypertension develops and anastomotic channels open between the portal and systemic circulations.

Upon reaching the pulmonary circulation, schistosome eggs usually gather in small arterioles, where they induce the formation of delayed-hypersensitivity granulomas, made up of eosinophils, lymphocytes, and macrophages (Fig. 136-7). In addition, deposition of fibrous tissue causes narrowing, thickening, and occlusion of pulmonary arterioles. In an autopsy study of 32 cases of *S. mansoni* cor pulmonale, two characteristic histopathologic lesions were identified: (1) focal changes related directly to the presence of schistosome eggs; these were located either within the alveolar tissue or within the pulmonary arteries or arterioles; and (2) plexiform or angiomatoid lesions consisting of several thin-walled and dilated vessels. The most prominent vascular lesions were associated with the focal changes surrounding mature schistosome eggs in the lumen of pulmonary arteries or arterioles. These were accompanied by fibrin deposition and remarkable proliferation of endothelial cells. Fibrosis surrounds most focal lesions. Because of the curtailment of the pulmonary vasculature and the decreased distensibility caused by the perivascular fibrosis, pulmonary hypertension and cor pulmonale ensue. Pulmonary function is predominantly restrictive and is accompanied by a decrease in the diffusing capacity.

Clinical Features

It is not clear whether schistosome infection during its early phases in humans is associated with appreciable pulmonary disease. Migration of schistosomula through human lungs is not known to cause detectable symptoms or signs. By contrast, after the onset of oviposition, some ova may reach the lungs, particularly in *S. haematobium* infection. Furthermore, chronic infection with the other schistosome species may be associated with sufficient deposition of eggs in the lungs to cause the development of cor pulmonale. The clinical features and radiographic findings in schistosomal pulmonary hypertension and cor pulmonale are not distinctive. The prevalence of the pulmonary hypertensive syndrome in schistosome-infected patients is not known. In Egypt, 7.5 percent of patients hospitalized with schistosomal hepatomegaly had cor pulmonale; in Brazil, 23 percent of similar patients had pulmonary hypertension (i.e., pulmonary arterial blood pressure higher than 20 mmHg).

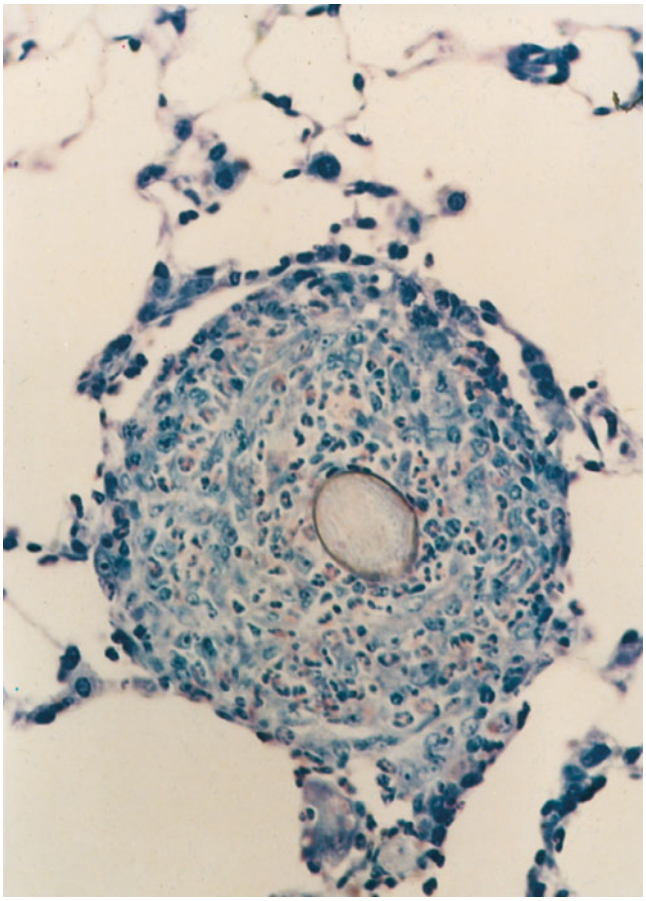

Figure 136-7 Schistosomal granuloma. *(Courtesy of Dr. Jay A. Fishman.)*

Management

Diagnosis of pulmonary disease due to schistosomiasis may be achieved by finding the parasite eggs in urine or stools of persons with suggestive clinical manifestations. However, pulmonary disease may occur several years after infection, and finding parasite ova may be difficult. Under these circumstances, demonstrating the characteristic pathologic

changes and ova in tissues or positive serology may settle the diagnosis.

Active schistosome infections are treated with praziquantel, which kills adult worms and stops further destruction of tissue by ova deposition. The drug is administered as 20 mg/kg body weight bid for 1 day (two doses) for *S. mansoni* and *S. haematobium* infection and three times a day (three total doses) for *S. japonicum* infection. However, reversal of pathologic lesions in the lungs after antischistosomal chemotherapy has not been documented.

Paragonimiasis

Human infection with species of the lung fluke *Paragonimus* is prevalent in the Far East, Africa, and South and Central America. Infection is maintained in endemic areas through contamination of water sources, with feces or sputum of infected individuals resulting in infection of the intermediate snail and crustacean hosts. Symptomatic paragonimiasis is initially characterized by cough and bloody sputum that may lead to bronchiectasis or lung abscesses.

Etiology

Human infection with *Paragonimus* is acquired from eating raw or pickled crustacea (freshwater crayfish and crabs) that harbor the infective parasite stage (metacercariae). These forms excyst in the duodenum, penetrate the intestinal wall, and migrate via the diaphragm and pleural cavity to the lungs, where they mature into adult worms (12 × 6 × 5 mm). Adult *Paragonimus* worms are hermaphroditic; they produce golden-brown eggs, which are coughed up and voided through either sputum or feces. The life cycle of the parasite outside the human host goes through a specific snail intermediate host; metacercariae then encyst on freshwater crustacea.

Pathogenesis and Pathology

The primary site of infection in humans is the lungs. The worm is also found in the brain in 25 percent of patients and less often in many other tissues. During invasion of the lungs by the maturing adult worms, parasite tunnels in the pulmonary parenchyma can usually be demonstrated, particularly in peripheral areas. The tunnels and parasites are surrounded by a granulocytic reaction made of eosinophils and neutrophils. Charcot-Leyden crystals are often seen. In patients with encysted worms, the parasites are enclosed with cystic lesions that may communicate with each other or with a bronchus. Death of the worms usually leads to collapse of the cyst, disintegration of the parasite, and fibrosis or calcification. The surrounding pulmonary tissue may show evidence of atelectasis, bronchiectasis, or compensatory emphysema. In some patients, secondary infection and lung abscess develop in the cystic lesions surrounding adult parasites. The radiographic changes correspond roughly to the three stages of parasite development within the lungs: (1) on arrival in the lungs, maturing worms are associated with the development of radiographic opacities; (2) these are succeeded by nodules that correspond to the parasite cysts; (3) fibrosis or calcification ensues.

Clinical Features

The incubation period between infection and the development of maturing adults in the lungs is 2 to 20 days. Few specific symptoms have been described during this stage. In persons with established infection, the worm load seems to determine the extent of clinical features. Light infection is invariably asymptomatic. In moderate to heavy worm loads, complaint of cough and respiratory discomfort (particularly upon rising in the morning) and rusty, blood-tinged sputum containing parasite eggs, necrotic material, and Charcot-Leyden crystals are common. Frank hemoptysis, sometimes severe, also occurs in patients with pulmonary paragonimiasis.

The chest radiograph is normal in 10 to 20 percent of infected persons. Radiographic signs in the others include infiltrate, cavitation, fibrosis, and pulmonary thickening. The characteristic ring shadow with a crescent corona occurs in some infected persons.

Management

The diagnosis of paragonimiasis is made from detection of the characteristic eggs in the sputum or stools of infected persons. Serologic testing may be helpful in egg-negative cases. The drug of choice for treating paragonimiasis is praziquantel. It is administered orally, 25 mg/kg three times per day for 2 days, or bithionol 30 to 50 mg/kg po alternate days for five doses. Chemotherapy usually leads to cessation of egg passage in sputum and stools, some clearing of the chest radiograph in almost two-thirds of treated patients, and a decrease in serum IgG antibodies against the parasite.

Zoonotic and Other Unusual Bacterial Pneumonias

Arnold N. Weinberg • Camille Nelson Kotton

Many different microorganisms can infect the lungs. Routes of spread are few, clinical presentations overlap, radiologic changes are often nonspecific, and pathophysiological mechanisms are limited. Making a clinical diagnosis of pneumonia is relatively easy; defining the causative agent can be difficult. The search for the specific agent is driven by a number of compelling issues, including the desire to use a specific therapy for a specific pathogen; the potential for progressive respiratory impairment when the wrong antibiotic is used; and epidemiological concerns in the family, the hospital community, and the general public for isolation and containment. An even more critical public health issue has emerged following the "mail room" anthrax attack in 2001 and concern for the aerosol use of anthrax spores and other zoonotic pathogens by terrorists.

In the three decades that have passed since the epidemic of acute respiratory disease erupted among delegates to the American Legion Convention in Philadelphia, physicians, microbiologists, and epidemiologists have become better prepared for the diagnostic challenges of patients with unusual pneumonias. The greater awareness of investigators and clinicians of the variety of infectious agents capable of causing respiratory disease is illustrated by the increased frequency of the *clinical* diagnosis of Q fever (due to *Coxiella brunetti*) in addition to retrospective serologic diagnoses. *Chlamydia pneumoniae,* the former "TWAR" agent, has been identified in military and school epidemics and as an important cause of pneumonia in isolated cases. The rapid identification of a Hantavirus in 1993 as the cause of a newly recognized respiratory syndrome is an example of the multidisciplinary approach toward recognition of emerging infectious diseases. The sudden appearance of severe acute respiratory syndrome (SARS) during the winter of 2002–2003 is a recent example of the emergence of a new respiratory disease. The response of the world community led to the rapid identification of a novel coronavirus as the causal agent of SARS and effective global efforts to understand the disease and contain its spread.

These infectious agents and diseases are covered in detail elsewhere in the text. They appear as part of the differential diagnosis in obscure pneumonia, and illustrate the range of pathogens associated with animals and their environments and acute respiratory disease in individuals and groups. The examples presented above include a number of viruses while the agents to be discussed in detail in this chapter are all bacterial pathogens and most are closely associated

with animals or animal products. Zoonotic infections may reflect an initiating event and then person-to-person spread, as exemplified by the SARS coronavirus. The avian influenza virus (H_5N_1) is another zoonotic microorganism that has spread to individuals within close contact with domestic chickens; fortunately, the jump to humans has led to very rare human-to-human spread. The potential for pandemic influenza as well as SARS are subjects dealt with in other chapters in this textbook.

A number of microorganisms, including many of the zoonotic bacteria discussed in this chapter, are recognized by the Centers for Disease Control and Prevention (CDC) and the National Institute of Allergy and Infectious Diseases (NIAID) as Category A Priority Pathogens. The global community has been developing rapid diagnostic technology and countermeasures to protect and treat people in the event of a bioterror attack. The "mail room" anthrax epidemic of September 2001 illustrated the potential for widespread inhalation disease, public panic, diagnostic and therapeutic challenges, significant costs in human life and infrastructure stability, and the expense involved in decontamination. Physicians need to become familiar with the typical and atypical spectrum of disease caused by these pathogens, including the impact and variable expression of a large inoculum aerosol release in a crowded urban area or building.

The general features of epidemiological and clinical data that should be helpful in evaluating typical and atypical features of disease in spontaneous and terrorist related events are described in Table 137-1. This discussion of *unusual bacterial pneumonias* focuses on a limited number of microorganisms and not on an exhaustive list of possible causative agents. The unique properties of these bacteria exemplify how bacteriology, ecology, epidemiology, and pathogenesis serve as helpful clues to earlier etiologic diagnosis and, therefore, specific therapy (Table 137-2).

Table 137-1

An Overview of Zoonotic and Other Unusual Pneumonias

Environmental Niche	Microorganism	Disease	Epidemiologic Associations	Distribution
Live animal contact or via arthropod	*Pasteurella multocida*	Tularemia	Contact with animals, birds, or arthropods	North America, Europe, Asia
	Yersinia pestis	Pasteurellosis	Feline and dog contact; chronic lung disease	Worldwide
	Francisella tularensis	*Rhodococcus* pneumonia	Airborne droplets; contact with soil contaminated with horse, cow, or swine excrement	Worldwide
	Rhodococcus equi	Plague	Contact with rodents, fleas; contact with plague pneumonia case	Worldwide, including Asia, southwest U.S.
Soil, stagnant water, and inert animal products	*Bacillus anthracis*	Inhalation anthrax or wool-sorter's disease	Industrial; use of animal products in hobbies	Worldwide in warmer regions
	Brucella species	Brucellosis	Ingestion or contact with infected animal products	Worldwide
	Burkholderia pseudomallei	Melioidosis	Direct penetrating contact with soil, water	Latitude 20°N to 20°S, especially rural Asia
	Yersinia enterocolitica	Yersiniosis	Ingestion of contaminated foods, water; cirrhosis	Worldwide
Obligate human commensal	*Neisseria meningitidis*	Meningococcal pneumonia	Airborne droplets, human to human; postviral, nosocomial	Humans worldwide
	Moraxella catarrhalis	*Moraxella* pneumonia	Aspiration, especially individuals with underlying lung disease	Humans worldwide

Table 137-2

Diagnostic Studies and Treatment Recommendations in Zoonotic Pneumonias

Disease	Gram's Stain Morphology	Culture Methods	Identifying Tests	Therapy Total Dose/Number of Doses Per Day*
Anthrax	Large gram-positive bacillus (rarely seen)	BAP, blood cultures	FA	CIP 800 mg/2 or D(200 mg/2) + CL (2.7 g/3) + RI (600mg/2) If PCN susceptible, PCN (24 mu/6)
Brucellosis	Small gram-negative coccobacillus (rarely seen)	Media enriched with serum, CO_2 + O_2	Rise in AA, Prozone	TMP-SMX (480 mg + 2.4 mg/3) + SM (1 g/2) D (200 mg/2) + RI (600 mg/1)
Melioidosis	Bipolar staining gram-negative bacillus	BAP, MAC	Morphology, FA, AA	TMP-SMX (640 mg + 3.2 g/4) and ceftazidime (6–9 g/3) or CL (4–6 g/4) + D (200 mg/2)
Pasteurellosis	Small bipolar staining gram-negative bacillus	BAP, CO_2	Inhibited by MAC, biochem. tests	PCN or A (6 mu or 8 g/4) or cefotaxime (6–8 g/4) or CL (3 g/4)
Plague	Enteric bipolar staining gram-negative bacillus	BAP, MAC, enteric media, blood cultures	Biochem. tests, FA, AA	SM (2 g/2) and D (200 mg/2) or CL (4–6 g/4)
Rhodococcus	Gram-positive coccobacilli (slightly acid-fast positive)	BAP	Biochem. tests	E (2 g/4) or CLA (1 g/2) or AZ (500 mg) and CIP (1.5 g/2) and RI (600 mg)
Tularemia	Small gram-negative coccobacillus	Enriched media with cysteine, serum	FA, AA, rarely cultured	SM or gentamicin (2 g/2 or 4.5 mg/kg/3) or CL (3–4 g/4) or D (200 mg/2)
Yersiniosis	Enteric gram-negative bacillus	BAP, MAC, enteric media, blood cultures	Biochem. tests, motility 25°C	A (8 g/4) or 2d or 3d gen. cephalosp. (4–6 g/4) or CL (3 g/4)

** Expressed as million units (mu), grams (g), or milligrams (mg) divided by number of doses in 24 h.*
NOTE: BAP = blood agar; MAC = MacConkey agar; FA = fluorescent antibody; AA = agglutinin antibody. Antibiotics include A = ampicillin; AZ = azithromycin; CIP = ciprofloxacin; CL = chloramphenicol; CLA = clarithromycin; D = doxycycline; E = erythromycin; PCN = penicillin; RI = rifampin; SM = streptomycin; TMP-SMX = trimethoprim-sulfamethoxazole.

ZOONOTIC BACTERIAL PNEUMONIAS

Pasteurella multocida

Pasteurella multocida is a common commensal of the oral cavity of most felines and many dogs and a frequent respiratory pathogen in animals and birds. The respiratory tract is the second most common site of *Pasteurella* infection following skin and supporting tissues. Respiratory infections are probably underreported and include tracheobronchitis, pneumonia, lung abscess, and empyema. Elderly people with structural lung diseases such as emphysema, bronchiectasis, or malignancy are at higher risk for pulmonary infection. Immunocompromised patients, including those with AIDS, may be prone to spontaneous infection without close contact or traumatic dog or cat exposures.

Bacteriology

P. multocida is a small gram-negative bipolar-staining coccobacillary organism that resembles *Haemophilus* spp. and

may form pairs and chains. Rapid growth on blood agar and inhibition by MacConkey medium separate this microorganism from other common components of the respiratory flora, including *Haemophilus* spp. Numerous virulence factors in *P. multocida* have been identified. These include the capsule in serogroups A and B (which interferes with phagocytosis), a toxin in strains causing atrophic rhinitis in pigs, lipopolysaccharide endotoxin, several iron acquisition proteins (e.g., TonB, ExbD, and ExbB), and the putative filamentous hemagglutinins PfhB1 and PfhB2.

Ecology and Epidemiology

In cats and other felines, the organism resides periodontally in the anterior regions of the mouth. Isolates from dogs are characteristically from the posterior pharynx. Many birds and domestic and wild animals worldwide harbor this organism as a commensal in oral or gastrointestinal areas. *P. multocida* is occasionally found in the secretions of persons with chronic lung disease, especially those with bronchiectasis and domestic animal contacts. Human-to-human transmission has been documented from mother to newborn infant, resulting in neonatal pneumonia. The organism can survive in soil and water for more than 3 weeks and in animal carcasses for approximately 2 months. In about half the cases of respiratory disease, no clue to airborne spread exists, but there are usually cats in the local environment.

Pathogenesis and Pathophysiology

Pathogenic strains have a polysaccharide capsule that inhibits phagocytosis, and they contain endotoxin in the cell envelope. Exotoxins and other pathogenicity-promoting factors have not been specifically identified (see Bacteriology). Almost all patients who develop respiratory infections have underlying chronic pulmonary disease. Aspiration probably initiates active infection. Necrosis and lung abscess, empyema, septicemia, and transbronchial spread to other lung segments have been described.

Clinical and Radiologic Features

The clinical features of *P. multocida* respiratory disease include worsening of the patient's baseline pulmonary function—especially when high fever, tenacious secretions, and pleural effusions develop. Radiologic changes include lobar, multilobar, or diffuse patchy infiltrates, usually sparing the upper lobes, superimposed on underlying chronic lung disease (Fig. 137-1). Effusions, including empyema, have been noted in approximately 20 percent of cases. Bacteremia has been reported in up to 55 percent of patients with pneumonia and endocarditis has occasionally complicated bloodstream invasion.

Diagnostic Features

Diagnosis depends on isolation of the organism from sputum, pleural fluid, or blood. Usually the pathogen can be identified with the routine methods of the diagnostic laboratory. The bipolar gram-negative staining bacilli resemble *Brucella*

Figure 137-1 Bilateral pneumonia due to *Pasteurella multocida* in a 69-year-old woman suffering from chronic obstructive pulmonary disease and a prior right lower lobectomy for carcinoma. Infiltrates disappeared with penicillin therapy.

spp., *Yersinia pestis, Francisella tularensis, Burkholderia* (formerly *Pseudomonas*) *pseudomallei,* and *Haemophilus* spp., but the clinical history of exposure to cats and/or dogs and bacteriologic characteristics can rapidly clarify the identification.

Treatment

Most strains are exquisitely susceptible to penicillin or ampicillin. The third-generation cephalosporins, cefotaxime and ceftriaxone, are as active as penicillin and more potent than earlier-generation relatives. Oral preparations of cephalosporins and penicillins are not recommended for treating pneumonias caused by *P. multocida* due to reduced bioavailability. The newer fluoroquinolones, including moxifloxacin, trovafloxacin, levofloxacin, and gatifloxacin, are very active in vitro against *P. multocida* and other *Pasteurella* spp., although there is limited published experience in humans. Tetracycline and chloramphenicol are effective alternatives when a history of allergic reactions precludes use of a β-lactam agent. (See Table 137-2 for further details.)

Yersinia pestis

This organism left an indelible mark on humanity long before its late–nineteenth-century isolation and characterization. The cause of three major pandemics from the sixth through the nineteenth centuries, pulmonary disease in a few victims led to aerosol spread to countless others, resulting in acute primary pneumonia and the "black death" of

epidemic plague. During the period from 1932 through the end of World War II (1945) the Japanese biological warfare program included the use of aerosol drops of *Y. pestis* as well as infected flea disseminations in occupied China and at the infamous experimental Unit 731. The effectiveness of the flea drops remains in question to this day but the aerosol disposal definitely led to clinical pneumonic plague. A contemporary global scare emanated from India's Maharashtra state in 1994, with reports of suspected pneumonic and bubonic plague. No exported cases were documented during rigorous quarantine and airplane surveillance measures, and no travelers to India became ill with a plague syndrome. In the United States, fewer than 20 cases of plague are reported yearly, of which one in five has lung involvement. Early recognition and specific therapy, combined with isolation procedures and appropriately directed prophylaxis of contacts, should help maintain the record of no human-to-human transmission in the United States since the 1920s. When plague is diagnosed outside an endemic area, bioterrorism should be considered. When *Yersinia* pneumonia occurred in a couple that recently became ill in New York City, the event was originally investigated as a potential bioterrorism event until their travel from an endemic area of plague was discovered. Although the bacteria are difficult to process, handle, and disperse in an aerosol form, person-to-person airborne spread is very efficient and laboratory accidents have occurred.

Bacteriology

Y. pestis is a bipolar-staining, gram-negative bacillus closely related to *Escherichia coli* and other *Enterobacteriaceae*. It grows well on blood or MacConkey agar and is identified definitively with differential biochemical tests, agglutination reactions, and direct fluorescent antibody staining. Concerns for laboratory safety have lead to routine of Biosafety Laboratory level 2 (BSL-2) procedures as well as better communication between clinicians and microbiology laboratory personnel.

Ecology and Epidemiology

In the United States, *Y. pestis* is endemic in rock squirrels, prairie dogs, rabbits, rats, and other small ground animals primarily in the Southwest. Spread among animals occurs via several species of rodent fleas, especially *Xenopsylla cheopis*. Domestic animals that wander outdoors, like cats, can become infected by direct contact with sick rodents or via rodent flea bites. In addition, cats and dogs can inadvertently carry fleas into the home. Occasionally rodent die-offs, called epizootics, occur, and many dead animals can be found with viable organisms in carcasses and in the soil surrounding ground dwellings.

In the United States, spread to humans occurs when an infected flea feeds on a susceptible person. Living or working in proximity to local enzootic "hot spots" places certain groups (such as Native Americans, geologists, hikers, veterinarians, and pet owners) at risk. Bubonic and cutaneous plague are usually acquired on exposed areas by contact with infected fleas, but aerosols from ill animals or carcasses can lead to primary pneumonia, pharyngitis, or conjunctivitis. Several cases of cat-to-human aerosol spread have been associated with respiratory infection or submandibular abscesses in pets. A great concern of physicians caring for patients with respiratory infection is the potential for rapid airborne dissemination, especially during coughing and face-to-face contacts.

Pathogenesis and Pathophysiology

After the organism gains access to human tissues at 37°C, massive multiplication occurs. The polysaccharide capsule imparts virulence properties that include resisting phagocytosis and persistence of bacteria within nonsensitized monocytes. Virulence factors include a potent endotoxin and V and W antigens of the cell envelope, which influence intracellular survival. Recent work with a mouse model has demonstrated a biphasic illness with an initial anti-inflammatory phase that rapidly progresses to a highly pro-inflammatory state by 48 hours and death by 3 days. Microarray analysis demonstrates a change in the expression of about 10 percent of the bacterium's genes after it infects a host.

Bacteremic spread usually follows initial multiplication in regional nodes (buboes) or at the local fleabite site (chancriforme lesion). Secondary pneumonia involving the well-perfused basilar segments can follow. When a person with plague pneumonia coughs, there may be aerosol spread to persons nearby, resulting in primary pneumonia and rapidly developing adult respiratory distress syndrome (ARDS).

Clinical and Radiologic Features

Clinical presentations include subclinical cases (positive serology without evidence of disease); a chancriform skin lesion (pestis minor abortive bubonic plague); pharyngitis; bubonic plague; septicemic plague; pneumonic plague; and meningitis. The clinical presentation of pneumonia depends on the mechanism of spread. In contemporary experience in the United States, cases have all been secondary to bubonic plague, primary septicemia without an overt skin lesion, or inhalation of droplets from an infected pet cat. The onset of respiratory disease follows after days to a week of a febrile illness, and is ushered in by the gradual onset of cough, dyspnea, and increasing toxicity. Pink to hemorrhagic frothy sputum, pleurisy, and increasing respiratory distress are additional symptoms. The unique feature in most cases of pneumonia is the epidemiological association with classic bubonic plague; i.e., in a person in or from an endemic area or who has had contact with a pet cat ill with respiratory symptoms or a facial abscess. From histories of primary inhalation pneumonia described previously, exposure to an index case may be followed by the rapid development of a fulminating respiratory illness, with dyspnea, cyanosis, and thin, watery sputum that rapidly becomes hemorrhagic. The clinical picture is not unlike that of overwhelming pneumococcal pneumonia, with marked toxicity and mental torpor associated with progressive cyanosis.

The radiologic features of secondary pneumonia include basal segment nodular to hazy airspace infiltrates, hilar and mediastinal node hypertrophy, and occasionally pleural effusions. In primary pneumonia, infiltrates may be minimal during the first 24 hours, followed by progressive airspace disease resembling ARDS or pulmonary edema.

Diagnosis and Differential Diagnosis

The presence of characteristic bipolar-staining gram-negative bacilli in sputum suggests the diagnosis when epidemiological clues are present. Cultures of blood, sputum, and lymph node aspirates often yield positive results. Direct fluorescent antibody staining can provide immediate etiologic confirmation. A passive hemagglutination test can be performed as a confirmatory study on acute and convalescent sera at selected reference laboratories such as CDC. Other acute respiratory infections caused by microorganisms that appear as gram-negative bacilli with bipolar staining must be considered, including *Francisella tularensis* and *P. multocida.* Rapid assays for diagnosis of plague are under active development, especially given the interest in its potential as a bioterror agent.

Treatment and Prevention

The combination of streptomycin and tetracycline has been the treatment of choice for serious plague infections. Gentamicin can be substituted for streptomycin if intravenous therapy is necessary or streptomycin is not available. Doxycycline and fluoroquinolones such as ciprofloxacin may also be effective in treating pneumonia; chloramphenicol is another option. (See Table 137-2 for further details.) Multi–drug resistant plague has been reported and clinicians should be aware of local trends as well as the potential for terrorist-instigated modifications in antibiotic susceptibility.

Persons suspected of having plague pneumonia should be rapidly isolated, and strict contact, respiratory, and conjunctival precautions instituted. Anyone exposed face to face with a coughing patient, including health care workers, should be given preventive tetracycline or ciprofloxacin (trimethoprim-sulfamethoxazole is used in pregnant women and children). Isolation procedures are continued until productive cough is no longer present or sputum cultures are negative for *Y. pestis.*

A vaccine is available for laboratory workers and others with frequent exposure to the microorganisms or hyperendemic areas, although it does not appear to protect against pneumonic plague. Careful surveillance of ground rodent populations, posting warnings in endemic regions, watching for die-offs that indicate epizootic spread, and spraying for local flea control may also be effective preventive measures along with public education.

Francisella tularensis

Tularemia is a common animal disease in the United States as well as many other regions of the temperate globe. The causative agent, *F. tularensis,* is ubiquitous, distributed among many species of wild and domestic animals and birds. Bloodsucking arthropods, especially ticks and deerflies, serve an important role in transmission to humans. As with plague, the major clinical manifestations include skin lesions and swollen or draining regional lymph nodes. Pulmonary impairment occurs secondary to bacteremia or as primary inhalation pneumonia. Approximately 150 human cases are reported in the United States yearly, but this is probably an underestimate. In the summer of 2000, an outbreak of pneumonic tularemia occurred on Martha's Vineyard, Massachusetts, and 11 of 15 patients were diagnosed as primary pneumonic tularemia; lawn mowing and brush cutting were found to be risk factors for infection. In addition to primary inhalation pneumonia, pulmonary invasion is seen following bacteremia in 10 to 15 percent of ulceroglandular cases and in more than 50 percent of patients with the typhoidal syndrome. An epidemic of tularemic pharyngitis from ingestion of contaminated well water and food occurred in war-torn Western Kosovo primarily among young children originally suspected of having group A Streptococcal pharyngitis. No secondary pneumonias were reported.

Bacteriology

F. tularensis is a fragile-appearing gram-negative coccobacillary organism that is quite fastidious and grows poorly on artificial media unless fortified with serum and cysteine (or sulfhydryl compounds). The potential for laboratory-acquired inhalation or ingestion-associated disease is great. Most routine laboratories will not attempt to culture the organism, leaving this to special reference centers. Identification is on the basis of morphologic and biochemical determinants, but direct fluorescent staining or agglutination reactions with specific antisera are also useful.

Ecology and Epidemiology

The organism is associated with more than 100 species of wild and domestic animals and birds, including aquatic mammals, but most clinical cases arise from contact with rabbits, squirrels, or arthropods. Of great concern is the recent fad for exotic pets; and tularemia in prairie dogs has led to spread in holding pens and to human transmission. In cold weather the organism can persist in water and mud environments for weeks to months. Bloodsucking arthropods, especially ticks and deerflies, act as reservoirs capable of harboring the pathogen for long periods and are responsible for dissemination among wildlife species as well as infecting people. Domestic cats represent a potentially increasing problem.

Less than half of human cases are acquired from contact with infected animals during hunting, trapping, and other outdoor pursuits, especially during colder months. In southern areas, or in the summer season in northern latitudes, gardening and lawn mowing without animal contact are becoming important methods of dissemination. Bloodsucking arthropods, constitute a significant and increasing mode of spread, especially in warmer seasons. Ingestion of contaminated food or water, animal bites, conjunctival contact, and

aerosol dissemination are also important mechanisms for acquiring the pathogen. In recent years, cases secondary to arthropods have been more frequent than those associated with direct animal contact, although domestic cat bites and airborne spread appear to be increasing. Human-to-human transmission is rare, in contrast to the significant theoretical potential for spread of pneumonic plague. If *F. tularensis* were to be used by terrorists, aerosol release would most likely be the mode of spread, with respiratory as well as other locations (skin, conjunctival, pharynx) occurring in the exposed population. Those criminally processing this organism would be at great risk for laboratory infection.

Pathogenesis and Pathophysiology

F. tularensis contains a number of protein and polysaccharide antigens in the cell envelope as well as an endotoxin component that is similar to endotoxins of other gram-negative microorganisms. Very little is known about other mechanisms of pathogenesis. The organism is capable of remaining viable in reticuloendothelial cells of nonimmune subjects and in macrophages that have not been activated by recent exposure to intracellular pathogens. As few as 10 to 50 organisms can initiate disease following cutaneous penetration or by inhalation, but a significant number are required when the challenge is through ingestion of contaminated water or foods. Local growth usually is followed by regional node suppuration and occasionally bacteremic dissemination to many organs, including the lungs. Rhabdomyolysis may accompany bacteremia and pneumonia. Ingestion may result in pharyngeal infection, involvement of the gastrointestinal tract, or subclinical disease followed by a typhoidal syndrome. Primary pneumonia follows inhalation of organisms, resulting in numerous areas of inflammation, necrosis, a tendency to granuloma formation, hilar and mediastinal adenopathy, and pleural inflammation and effusion.

Clinical and Radiologic Features

In appropriate epidemiological settings, respiratory disease is heralded by the onset of a nonproductive cough, usually in a febrile patient ill with the ulceroglandular form of tularemia. In the absence of a local chancriform lesion or tender swollen lymph node (bubo), the disease may be dominated by constitutional symptoms, with high fever, severe headache, prominent myalgias, and shaking chills (typhoidal tularemia). Pneumonia following an inhalation exposure results in cough, dyspnea, and occasionally pleurisy. Respiratory disease can be subtle, and the diagnosis may be apparent only if a chest radiograph is done. Pleural effusions may be serosanguineous or frankly bloody, an uncommon finding with other pulmonary infections except anthrax.

Radiologic changes include evidence of parenchymal and pleural disease, which is often out of proportion to the findings on examination. Diffuse areas of bronchopneumonia occur, with hilar node enlargement and occasionally mediastinal widening, similar to radiologic appearance of anthrax. Unilateral or bilateral pleural effusions are often noted

Figure 137-2 Patchy nodular and bronchopneumonia, hilar adenopathy, and left pleural effusion due to *Francisella tularensis* in a 38-year-old veterinarian exposed to a cat dying with a respiratory infection. All the findings resolved with tetracycline therapy.

(Fig. 137-2). Central oval infiltrates, described as characteristic in early reports, are seldom observed today. Lobar airspace disease, a miliary pattern, and lung abscess are unusual additional patterns that have been described.

Diagnosis and Differential Diagnosis

Any febrile patient with animal, arthropod, or landscaping exposure in an endemic region, especially presenting with a chancriforme skin lesion and/or a tender lymph node should be evaluated for tularemia. Cough, when present, is usually nonproductive, and blood cultures are seldom positive. Characteristic organisms are rarely seen in pleural fluid or aspirates of suppurating nodes. Direct fluorescent antibody staining of exudates can confirm the diagnosis, but this method is not widely available. Serologic testing remains the method of choice for confirming a diagnosis. ELISA and microagglutination methods may be more sensitive than tube agglutination testing. A single convalescent titer of 1:160 or greater is considered highly suspect for active disease, but a fourfold rise in titer between acute and convalescent (1 to 5 weeks) sera is more reliable, since antibodies can persist for many years after infection. Polymerase chain reaction and other molecular biological techniques have successfully diagnosed tularemia in human specimens. An elevated blood level of creatine phosphokinase may be a clue that tularemia-induced rhabdomyolysis is a response to the acute infection, especially in highly endemic areas. Skin testing can be helpful in diagnosis, but the antigen is currently not commercially available.

Perplexing diseases that are also associated with outdoor and animal exposures, such as psittacosis and Q fever, may be confused with tularemia. Legionnaires' disease and mycoplasmal pneumonia can present with similar clinical courses, without diagnostic sputum. Plague, tuberculosis,

and systemic fungal infections produce a spectrum of acute to chronic respiratory manifestations that can mimic pulmonary tularemia.

Treatment and Prevention

Streptomycin was the first effective antibiotic for treating all forms of tularemia, and it remains the agent of choice. Gentamicin appears to be equally potent and has the advantage of a broader spectrum of activity if one is initiating treatment when the etiologic diagnosis is less secure. Additionally, it can be given intravenously, and blood levels can be monitored. *Tobramycin, however, appears to be unreliable and therefore should not be substituted for other aminoglycosides.* Recent experience confirms that results of therapy are optimal when an aminoglycoside is chosen early in the clinical illness. Tetracycline/doxycycline, ciprofloxacin, and chloramphenicol may be useful alternatives when an aminoglycoside is contraindicated. Relapse rates are higher with the bacteriostatic tetracycline/doxycycline and chloramphenicol, especially when given for less than 2 weeks. β-Lactam antibiotics are not effective. The prognosis is excellent with appropriate antimicrobial therapy. (See Table 137-2 for further details.)

Cautious practices are required when one is dealing with animals and their carcasses. Using gloves, cooking wild animal meat thoroughly, and wearing protective clothing and repellants to avoid bloodsucking arthropods are helpful measures. An attenuated live vaccine strain (LVS) has been available for over 50 years, although it is not fully licensed (in part due to a lack of knowledge regarding the basis of attenuation), and does not offer a high level of protection against respiratory challenge. With the increase in concern in bioterrorism, numerous groups are working to develop an improved vaccine.

Rhodococcus equi

Rhodococcus equi, formerly known as *Corynebacterium equi,* was first isolated in 1923 by Magnussen when it was identified as a cause of suppurative pneumonia in foals. It was later shown to be a frequent pathogen in horses, cattle, and swine. First described as a pathogen in humans in 1967, the majority of recognized cases in recent years have been in immunocompromised patients, especially individuals receiving corticosteroids, those infected with the human immunodeficiency virus, or those who have undergone solid organ transplantation.

Bacteriology and Pathogenesis

Rhodococcus is a pleomorphic gram-positive bacillus in the order *Actinomycetales.* It grows well aerobically on most media, at 37°C, as mucoid pale-pink or salmon-pink colonies that are usually observed by 48 hours of incubation. *R. equi* has a high cell wall mycolic acid content and is acid-fast, similar to *Nocardia* spp. and *Mycobacteriaceae.* Some strains ferment glucose, but the majority will not ferment carbohydrates. Most produce catalase and hydrogen sulfide. β-Lactamase is present in some strains.

R. equi is a facultative intracellular pathogen that survives within macrophages. Prevention of phagosome–lysosome fusion is a major pathogenic mechanism. Humoral response as well as cell-mediated immunity has been demonstrated in animals, but it is unclear how much of a protective role each plays. In equine models, administration of antibody decreases the severity of pneumonia in foals challenged with aerosol inoculation. Protection was not seen in a murine model when the animals were infected intravenously. In murine models, depletion of both CD4+ and CD8+ T cells impairs the ability to clear the infection, although the CD8+ cells appear to play a more significant role.

Epidemiology

The majority of reported cases occurring in humans without HIV infection have been in patients who had significant contact either with livestock or soil and environments that were heavily contaminated with livestock waste. In contrast, HIV-related *Rhodococcus* disease appears to occur in patients who do not have any particular environmental exposure history—implying a wider distribution of the organism. There is no known geographic endemicity.

Pathogenesis and Pathophysiology

R. equi usually is inhaled, although soft-tissue infections after cutaneous inoculation can occur. As an intracellular pathogen it causes disease primarily in patients with impaired cell-mediated immunity and defects in phagocytic processing of organisms. Diseased tissues usually show a necrotizing

Table 137-3

Diagnosing *Rhodococcus equi* Respiratory Infection

History of exposure to horses, cattle, or their environment
Immunocompromised host: malignancy, steroids, HIV
Cavitary or nodular infiltrates on radiograph
Gram-positive pleomorphic bacilli
Modified acid fast
Pale-pink or salmon-pink mucoid colonies
Grows rapidly, aerobically on most media
Differential diagnosis includes, *Nocardia* species, mycobacteria

granulomatous reaction, with histiocytes and macrophages frequently containing bacteria. In contrast to lesions associated with *Mycobacterium tuberculosis* and systemic fungi, there is also a prominent infiltration of neutrophils in the affected areas, a characteristic shared with other *Actinomyces* spp.

Clinical and Radiologic Features

Patients frequently complain of indolent symptoms, such as fever, nonproductive cough, and mild dyspnea. Typically there is a paucity of findings on physical examination of the chest, but signs of consolidation and pleural friction rubs may be present. Patients with HIV infection generally present in a manner similar to patients without HIV infection, although pleuritic chest pain may be more common. In HIV-infected patients, *R. equi* disease tends to occur after there has been significant deterioration in their immune systems, with CD4 lymphocyte counts less than 200 cells/mm^3. It is often found associated with other pulmonary infections. Extrapulmonary dissemination occurs in HIV-infected and non–HIV-infected patients, but there appears to be a significantly greater rate of recovery of the organism from blood cultures in HIV patients. The central nervous system is a recognized site of metastatic infection, as it is for *Nocardia* spp.

The most common radiographic abnormalities are lobar infiltrates, which usually evolve into nodular or cavitating lesions within weeks or months. There is no predilection for involvement of any particular lobe. Pleural effusions are common, occurring in up to 40 percent of HIV patients with pulmonary *R. equi* infection. Significant hilar adenopathy is unusual.

Diagnosis and Differential Diagnosis

R. equi can readily be cultured from sputum, bronchial lavage, pleural fluid, or other infected tissue and often from blood. Since the organisms stain as pleomorphic gram-positive bacilli, grow readily on most media, and are usually catalase producers, they can be mistaken for "diphtheroid" or "Coryneform" contaminants unless further testing is done. Therefore it is important for the clinician to alert the microbiology laboratory staff if the possibility of *R. equi* is entertained. *R. equi* is slightly acid fast with modified Ziehl-Neelsen stain.

Rhodococci share many microbiologic features with *Mycobacteria* and *Nocardia,* and this may account for similarities in the subacute to chronic evolution of the disease. The high mycolic acid content of their cell walls results in their acid-fast staining properties and may also play a role in their similar clinical and pathological manifestations. *Nocardia* spp., *M. tuberculosis,* and nontuberculous mycobacteria also should be considered when acid-fast organisms are found in clinical specimens, especially in immunocompromised patients with nodular or cavitary pneumonia (Table 137-3).

Other considerations in the differential diagnosis of nodular or cavitating pulmonary lesions include malignancy, fungal infection such as *Cryptococcus neoformans,* anaerobic lung abscess, and necrotizing pneumonia caused by facultative bacteria such as *Staphylococcus aureus* or *Klebsiella pneumoniae.*

Treatment

Antibiotic therapy alone is usually adequate to achieve cure. As with mycobacterial infections, multidrug regimens and therapy of 2 to 6 months' duration may be needed, especially in immunocompromised patients. Erythromycin, rifampin, ciprofloxacin, and other fluoroquinolones, chloramphenicol, sulfonamides, and aminoglycosides are active against most isolates. *R. equi* is an intracellular pathogen that is capable of multiplying in phagocytes. Therefore, antibiotics that are capable of achieving high intracellular levels, such as rifampin or fluoroquinolones, but especially erythromycin and the expanded-spectrum macrolides, clarithromycin or azithromycin, are preferred. (See Table 137-2 for further details.) In some patients, surgical resection of a nodular or cavitating lesion may be necessary to achieve cure.

ENVIRONMENTAL AND ANIMAL PRODUCT PNEUMONIAS

This section focuses on four diseases that are spread to humans predominantly from contact with contaminated soil, water, foods, or animal structural elements. Epidemiological and ecologic characteristics are essential to understanding how humans become infected. The diagnosis usually depends on a careful history. Once alerted, the clinician can request studies that may reveal the cause of these often-obscure diseases. It should be apparent that this distinction—an association with environmental contamination and animal products—is somewhat arbitrary. For example, anthrax bacilli can spread directly from animals to humans, and *R. equi* contamination of soil could place it in this group rather than in the group infected via direct animal exposure.

Anthrax

Inhalation anthrax was a common enough disease in the nineteenth and early twentieth centuries to be referred to variously as Bradford's disease, after the English town, and woolsorter's disease for the epidemiological association with the sheep industry. Fortunately, inhalation anthrax has become a rare spontaneously acquired disease. An epidemic of anthrax following an accidental release at a bioweapons facility occurred in the area of Sverdlovsk (now renamed Ekaterinburg) in the former USSR in 1979, resulting in 42 deaths due to inhalational anthrax. In 2001 there were 18 confirmed cases of inhalational and cutaneous anthrax and an additional four suspected cases of cutaneous anthrax in the United States; of the 22 cases, $\geq$20 were definitively related to mail contaminated with the same strain of *B. anthracis.* The potential zoonotic as well as terrorist-induced exposure of susceptible

persons to *Bacillus anthracis* spores argues for including this devastating, often lethal, disease in this chapter.

Bacteriology

B. anthracis is a large (red blood cell diameter), square-ended bacillus that stains gram-positive and has a tendency to form chains. Growth on sheep blood agar results in dull, sticky, irregularly shaped colonies within 24 hours. The organism possesses a polyglutamic acid capsule, produces a complex potent trivalent exotoxin, and, under adverse conditions, forms highly refractile, centrally located spores that are very resistant to temperature and moisture extremes.

Ecology and Epidemiology

Anthrax is primarily a disease of herbivores. The resistant spores are present after animals dying of the disease contaminate the soil. Anthrax "hot spots" are found, for example, in milder regions in the United States, such as Oklahoma, Texas, and California. The optimal conditions for germination of spores and multiplication of bacilli include alkaline soils containing adequate calcium and low areas that are wet for prolonged periods, termed *incubator areas,* with thick vegetation that produces heat with decay. Periods of extreme drought after a rainy season favor spore formation. Animals grazing in these areas can inhale or ingest spores or pick them up on their fur. The cycle is completed when an animal develops the disease and dies, returning organisms to the soil, where they eventually sporulate under adverse conditions.

Inhalation anthrax rarely occurs from contact with live infected animals, and there is no human-to-human transmission. The animal hide industry, exposure to bone meal fertilizer, and use of imported goat skins and raw wool in home crafts can lead to inhalation of spores and clinical disease in susceptible persons. The unvaccinated individual who occasionally enters a goat wool or hide processing plant to do needed repairs is at greatest risk for an inhalation or contact exposure.

Pathogenesis and Pathophysiology

Inhalation results in activation of bronchial clearing mechanisms and entrapment of spores in hilar and mediastinal nodes, where reversion to vegetative bacilli can occur. The polyglutamic acid capsule is antiphagocytic, and the extracellular microorganisms produce a protein exotoxin that leads acutely to profound local edema, accompanied by hemorrhage in the mediastinal and hilar areas, with compromise of airflow. Recent studies have clarified the mechanisms involved in the pathogenesis of this tripartite toxin, which consists of a protective antigen, an edema factor and a lethal factor. The protective antigen fragment of the toxin serves as the binding domain, essential for cell penetration by both the edema factor and the lethal portions of the molecule. Edema factor is a potent adenylate cyclase; activation within mammalian cells stimulates production of cAMP, and the resultant flux of sodium, potassium, and water leads to abundant local edema. When this process takes place in hilar and mediastinal nodes and surrounding tissues, profound airway obstruction ensues, with pooling of secretions and if the patient survives, secondary bacterial pneumonia. Lethal factor is a potent protease that acts primarily in macrophages, activating intracellular mitogen-activated protein kinase kinase (MAPKK), leading to production of proinflammatory cytokines and reactive oxygen intermediates. The pathogen rarely invades lung tissue, as death from asphyxia occurs rapidly, usually associated with pleural effusions (secondary to lymphatic obstruction) and hemorrhagic septicemic lesions in many organs, including the central nervous system. Typical thoracic pathological findings include hemorrhagic mediastinitis with hemorrhagic mediastinal lymphadenopathy. In a large inoculum exposure, as occurred in the 2001 "mail room" criminal outbreak, patients developed disease within the pulmonary parenchyma and the gastrointestinal tract.

Clinical and Radiologic Features

In spontaneously occurring disease, the onset is insidious, usually resembling a nonspecific febrile influenza–like illness. Malaise and muscle aches, mild headache, coryza, pharyngitis, and chest pains have been described as early symptoms. Cough, if present, is usually mild and nonproductive, and fever is low grade. At this stage, it is hardly possible for the physician to entertain a presumptive or possible diagnosis of anthrax unless a history of industrial or craft-related exposure to imported animal hair or hides or to animal products such as bone meal is obtained. A number of the nonspecific features described above may be relevant. Watery nasal discharge can be indicative of nasal or paranasal sinus involvement. Cough may represent hilar and mediastinal node swelling, and careful auscultation may reveal prolonged expiration wheezes or evidence of a pleural effusion. Chest pain may be the first clue that hilar and mediastinal inflammation is present.

Within hours to a few days, the mild complaints abruptly worsen and acute airway obstructive features dominate the clinical picture. Any activity precipitates severe dyspnea, stridor, and wheezing. Impairment of the nervous system (hemorrhagic meningitis) and hypoxemia result in decreasing levels of consciousness. Edema of the pharynx, neck, and anterior chest may develop. Chest pain, fever, and cyanosis are progressive changes. Worsening airway obstruction can lead to intercostal space retraction, and pleural effusions are noted on examination. Death usually occurs within hours to a day once acute respiratory symptoms are present.

Inhalation anthrax is primarily a mediastinitis, and the radiologic features mostly reflect the pathological findings. Widening of the mediastinum or prominence of hilar nodes is the earliest radiologic finding, sometimes accompanied by pleural effusion. In advanced cases, the mediastinal shadow is greater than 9 cm in width and sharply demarcated from surrounding lung tissue because of absence of airspace consolidation. There may be perihilar and peribronchial streaking associated with edema and hemorrhage. In the 2001 exposure to a significant spore burden some patients had a biphasic

illness with early upper respiratory and gastrointestinal symptoms, followed by respiratory distress days later.

Diagnostic Features

A physician alerted to the possibility of inhalation anthrax has few laboratory studies to rely on. Nasal secretions and sputum rarely reveal the characteristic bulky gram-positive bacilli. Half of the reported cases of inhalation disease are complicated by meningitis, and hemorrhagic cerebrospinal fluid with observable organisms can confirm the diagnosis. There are no available data on examination of buffy-coat smears, and therapy must be instituted before blood culture results become available. Microscopic examination of pleural fluid may reveal the characteristic organisms. The most commonly recognized form of anthrax, the cutaneous chancriform necrotic lesion, does not usually accompany inhalation cases in naturally occurring disease.

Differential diagnosis includes other causes of acute mediastinitis, such as esophageal perforation. Tuberculosis, histoplasmosis, and tularemia rarely produce acute respiratory failure as part of hilar and mediastinal node involvement. Hantavirus pulmonary syndrome is associated with similar central pulmonary changes, including edema, but should be separable from anthrax by epidemiological data, the presence of air space disease and absence of mediastinal involvement. Lymphoproliferative diseases, like nodular sclerosing Hodgkin's disease, evolve at a slower pace. Chest wall and neck edema, associated with acute breathing difficulties, can accompany diphtheria or *Streptococcus pyogenes* pneumonia, with bilateral pleural effusions an early manifestation of streptococcal pneumonia. Acute epiglottitis, caused by *Haemophilus influenzae,* was an occasional disease of preteen children prior to vaccine development and can mimic some of the manifestations of inhalation anthrax. A large epiglottis seen by direct examination or a lateral radiograph or computed tomographic scan of the neck in a person not immunized for *H. influenzae* type B can alert the physician to this possibility.

Treatment and Prophylaxis

Combination therapy is currently recommended based upon the "mail room" epidemic of 2001. Regimens with ciprofloxacin or doxycycline, plus clindamycin (to block toxin production) and rifampin (which penetrate CSF and intracellular sites) are favored. Monotherapy with penicillin should not be used in inhalation disease since the strain in the 2001 "mail room" outbreak, as well as multiple historical strains, produce an inducible β-lactamase. There is concern that the bacteria could be weaponized and highly antibiotic resistant. Treatment is recommended for 60 days to avoid activation of persistent spore forms. (See Table 137-2 for specific recommendations.) Corticosteroids should be considered for treatment of significant mediastinal edema or meningitis and early thoracentesis appears to be beneficial. Unfortunately, the airway obstructive manifestations are not reversible once acute respiratory manifestations have progressed. Assisted ventilation and use of diuretics are all reasonable support efforts, but they are generally not successful due to the continued effects of tissue bound toxin. Historically, before 2001 mortality in inhalation anthrax approached 100 percent of cases, compared with the rarity of death from cutaneous disease. In the 2001 experience mortality was 45 percent (5 of 13 respiratory cases) and knowledge gained from that experience may prove helpful in future cases.

In the animal hide industry, vaccination is the cornerstone of preventing anthrax. Plant workers and others in contact with potentially infected animal products should be immunized with the currently available vaccine. Numerous new vaccines are under development, many based upon the protective antigen segment of the toxin. Animal products imported from endemic regions of the world (e.g., Africa, the Near East and the Indian subcontinent) are steam sterilized, and there is modern ventilation in the workplace. At-risk subjects, then, are people who service these plants, such as ventilation specialists and other transients who are unlikely to be vaccinated. Bone meal is another vehicle for carrying inert spores. It should be treated by heat sterilization before packaging for use by commercial and home gardeners. Those who import yarn from endemic areas are at special risk unless the rules for commercial hide sterilization are also imposed on casual animal hair imports. A recent case of inhalation anthrax in a drum maker who carried goatskins into the United States emphasizes the need for appropriate education and importation controls.

Brucella spp.

In the approximately 200 cases of brucellosis that are reported yearly in the United States, acute respiratory manifestations are usually insignificant. Lung involvement is an uncommon presentation of brucellosis. Brucellosis is often a prolonged and perplexing illness however, and in chronic cases pleurisy, hilar adenopathy, and nodular lung lesions can be encountered. Exposure to animals or animal foods, or residence in an endemic region is usually present when sought.

Bacteriology

Brucellae are small coccobacillary, gram-negative, nonmotile, aerobic, nonencapsulated organisms that are now classified with the alpha-Proteobacteria, closely related to *Rochalimaea* and *Bartonella* spp. Carbon dioxide is essential for growth of *Brucella abortus,* and all four pathogenic species require growth medium enriched with vitamins and serum. With the aid of a battery of biochemical, metabolic, and immunologic criteria, *Brucellae* pathogenic for humans can be classified as *B. abortus, B. suis, B. melitensis,* and *B. canis.* In general, the species designation corresponds to the animal usually colonized or diseased.

Ecology and Epidemiology

Brucellae spp. are distributed worldwide. Infection and disease occur primarily in domestic animals in geographic

regions such as the Mediterranean littoral (*B. melitensis*), worldwide except areas of Europe and Japan (*B. abortus*), the midwestern United States (*B. suis*), and North and Latin America (*B. canis*). Spread from one region to another occurs with live animal movements or when infected animal products are commercially or privately shipped. Rigorous control measures such as herd inspections and vaccination procedures have dramatically reduced enzootic and epizootic disease in many regions.

The epidemiology of brucellosis is intimately related to the association of susceptible persons with infected animals and animal products. Abattoir workers (especially slaughterers) and others in the meat-processing industry, farmers, dairy workers, veterinarians, and bacteriology laboratory technicians account for most cases in the United States, with a general preponderance of male patients. An eightfold increase in incidence in California, Texas, and the other borderlands between the United States and Mexico has been noted when compared with the national rate. Also at risk are military personnel and travelers to endemic regions who eat local foods and people who consume imported goat cheese, sausage, and other unpasteurized edibles from endemic areas. The organisms are usually acquired by ingestion, through skin abrasions and lacerations, or via conjunctival inoculation. Evidence indicates that aerosol spread can be a route in abattoir workers. No human-to-human transmission has been reported.

Pathogenesis and Pathophysiology

Organisms invade the local reticuloendothelial system and lymph nodes, followed by bacteremic spread to many organs during the following weeks. There is increasing evidence that the aerosol route may be especially efficient as a portal of entry. The distribution of nodular lesions in lung tissue is primarily in basal segments, however, which argues for bacteremia rather than primarily an inhalation mechanism for most cases of pulmonary disease.

A race between bacterial growth and the development of cell-mediated immunity ensues, primarily in lymph nodes and the reticuloendothelial system. As with tuberculosis, the end result is often containment within granulomas that eventually become fibrotic or calcify. Species and strain differences account for the wide variety of tissue reactions encountered, including granulomas, necrosis, and abscess formation. Smooth variants appear to be more virulent than rough forms, and many contain polysaccharide polymers in their superficial envelope that, like true capsules, inhibit phagocytosis and intracellular destruction. Lipopolysaccharide endotoxin is present in the cell envelope and may be responsible for profound metabolic and cardiovascular effects initially and as organisms are killed during therapy. *Brucella* spp. are able to survive within nonstimulated macrophages and can destroy these cells while escaping host antibodies and physician-directed antibiotic therapy. As macrophages become activated, they develop the capacity to rapidly kill phagocytosed *Brucella* organisms. The development of host immunity appears to be primarily cell mediated, just as in *M. tuberculosis* disease. Impairment of cell-mediated immunity can lead to reactivation of latent *Brucella* or greater susceptibility and severity of a primary infection.

Clinical and Radiologic Features

The clinical expression of brucellosis is dominated by nonspecific flu-like constitutional manifestations, including fever and headache. Nonproductive cough has been described in 10 to 33 percent of cases, but other indicators of respiratory involvement are rarely or poorly described. In one review of 59 cases, dyspnea and pleuritic chest pain were present in 10 percent of the patients. Hoarseness, bronchitis, and, rarely, mucopurulent, purulent, or hemorrhagic sputum have been noted. Only one patient with verified pulmonary invasion was described in a review of 160 acute and subacute cases of brucellosis reported in 1974. In a recent review of 37 patients with *Brucella* respiratory disease, 32 percent had typical lobar pneumonia, 41 percent had an interstitial pattern on chest x-ray, and a honeycomb pattern was seen in 11 percent, with pleural effusion(s) in the same number. Extrapulmonary disease was found in 76 percent of patients, with 22 percent having greater than one extrapulmonary complication. Direct comparison of the clinical manifestations of *B. abortus* with *B. melitensis* reveal that the latter presents more acutely as fevers of unknown origin with statistically significant higher rates of abdominal tenderness, hepatomegaly, splenomegaly, thrombocytopenia, pancytopenia, and hepatic dysfunction. Unilateral hilar adenopathy and granulomas occur occasionally.

Diagnostic Features

During the acute illness or in relapse, blood cultures may be positive—especially if kept for a minimum of 14 days. In the presence of an infiltrate or pleural effusion, material for gram stain and culture should be obtained, even though the yield from these studies is small. A positive culture may be obtained from a lymph node or pulmonary granuloma biopsy. In most cases the diagnosis is made from a fourfold rise or a single value of at least 1:160 in the agglutination titer. Occasionally "inhibitory" or blocking antibodies are present in the serum, and a positive titer is discovered only if the serum is further diluted (so-called prozone phenomenon). The standard tube agglutination test utilizes *B. abortus* as the antigen and will detect antibodies to *B. suis* and *B. melitensis,* but not to *B. canis.* Diagnostic confusion and numerous alternative diagnoses are the rule in cases of brucellosis. Acute disease can be confused with miliary tuberculosis, endocarditis, tularemia, disseminated histoplasmosis, and lymphoproliferative diseases. Subacute and chronic cases must be differentiated from subacute bacterial endocarditis, tuberculosis, histoplasmosis, other systemic fungal infections and sarcoidosis.

Treatment and Prevention

The combination of doxycycline with rifampin for 4 to 6 weeks is one of the most effective and easiest oral antibiotic

regimens. Doxycycline combined with streptomycin or gentamicin, or trimethoprim-sulfamethoxazole are also effective alternative regimens. Fluoroquinolones are active in vitro, but they are associated with an unacceptably high relapse rate as monotherapy (see Table 137-2).

Preventive measures for cattle have been successful utilizing vaccination programs and destruction of diseased animals. Quarantine and inspection activities have diminished the risk of importing infected animals into the United States, and this reduction of disease in cattle has resulted in a decline in human cases. The program for *B. suis* eradication has been ineffective, and human cases of *B. suis* now outnumber those due to *B. abortus.* The efficacy of human vaccines is marginal. Education programs for workers in abattoirs have been aimed at protecting and preventing skin lacerations and eye contamination.

Burkholderia (pseudomonas) pseudomallei

Melioidosis is primarily an acute necrotizing or, in the later stage, a chronic fibronodular cavitating process indistinguishable from tuberculosis. It is a disease of tropical latitudes, and most cases have been seen in Southeast Asia, associated with rural settings. A number of cases were noted in survivors of the 2004 tsunami. Infection with *Burkholderia pseudomallei* has been seen in the United States almost exclusively after a latent period of months to years in military personnel returning from regions such as Vietnam and in refugees from endemic areas, although case reports from areas such as the Caribbean, Africa, the Middle East, and Brazil have also been reported.

Bacteriology

The organism is an aerobic, bipolar-staining gram-negative bacillus that is motile and lacks a well-defined capsule. Similar to the pseudomonads, *B. pseudomallei* grows well on minimal as well as enriched media, including blood and MacConkey agar, used in most routine laboratories. Typical colonies are distinctive in appearance, rough or wrinkled, and cream to orange in color; they may resemble a flower with folds radiating from a central core. Colonies have the typical musty, fruity odor of the pseudomonads but lack pyocyanin and other pigments that characteristically color the surrounding medium. Identification rests on a battery of biochemical reactions, and confirmation is based on agglutination or fluorescent antibody studies.

Ecology and Epidemiology

B. pseudomallei occupies an environmental niche that includes moist soils, rice paddies, and other stagnant water in tropical and subtropical regions, approximately subtended by latitude 20 degrees north to 20 degrees south. Evidence of subclinical and clinical disease occurs in wild and domestic animal populations, as well as in humans living permanently or transiently in rural endemic areas, especially in southeast Asia and northeast Australia. As many as 10 to 30 percent of native populations have evidence of prior infection based on serologic data. Approximately 1 to 2 percent of healthy American military personnel who served in Southeast Asia have antibodies, and almost 9 percent of soldiers wounded in Vietnam have titers for *B. pseudomallei.* A significant number of the approximately 3 million U.S. soldiers who fought in the region constitute a reservoir of latent disease that, like tuberculosis, can become active even decades later, far removed from an endemic area. Refugees from Southeast Asia represent another important group of carriers.

Transmission is mainly by direct contact with contaminated soil or water through minor abrasions or major wounds. Ingestion and inhalation are probably less frequent modes of spread, but common source outbreaks occur in animals and humans. Animal-to-human disease is very rare, with only three cases reported from Australia, and human-to-human spread has also been exceptional, associated with breastfeeding, urinary catheter contamination, or between siblings with cystic fibrosis. In endemic regions, lack of previous exposure and debilitating circumstances, including malnutrition and uncontrolled diabetes, may increase susceptibility to infection and disease. In a survey of 524 patients with melioidosis in northeast Thailand, coinfection with HIV was detected in only 8 of 524 adults (1.5 percent); clinical presentation and acute outcome were similar in HIV-positive and -negative patients. Melioidosis in a diabetic renal transplant patient has been reported from India, although it is not clear if solid organ transplant alters the risk for melioidosis.

Pathogenesis and Pathophysiology

The presence of potent endotoxin and the absence of an antiphagocytic capsule have been noted. Acute infections are associated with necrotic lesions containing polymorphonuclear neutrophils (PMNs) in lung and other tissues. Chronic infections, especially in the respiratory tract, resemble tuberculosis with granuloma formation, Langhans or foreign-body giant cells, central caseating necrosis, and occasionally a PMN response in the necrotic area. Activation of latent infection after a period of months to even decades occurs. This "awakening" can be in the wake of influenza and other acute infections, acute stress (trauma, thermal burn, surgery, etc.), and immunosuppressing illnesses or therapies, but spontaneous activation also occurs. The location of dormant microorganisms and the specific molecular events that stimulate recurrent disease are unknown but remain an area of active investigation.

An antecedent local infection in an area of broken skin can be followed by acute septicemia in nonimmune subjects. Initial pulmonary lesions occur predominantly in the better-vascularized basal segments consistent with bacteremic spread to the lungs. Eventually other areas of the lungs and other tissues are affected. Subacute and chronic disease may result from a subclinical primary focus, often localized in an apical segment, resembling tuberculosis in location

and propensity for granuloma formation and cavitation. Subpleural invasion can result in empyema or sympathetic sterile effusions.

Clinical and Radiologic Features

Primary melioidosis occurs within a few days to 3 weeks of exposure, usually in persons present in or recently from an endemic area. Military personnel with outdoor injuries constitute a potential group for delayed active disease. Although the acute phase of melioidosis is the most common manifestation in endemic areas, it is very rarely seen in the United States. The portal of entry may be present as a small necrotic skin lesion in an area of known trauma, with accompanying cellulitis or lymphangitis. In addition to marked toxicity and high fevers, the respiratory complaints include cough, dyspnea, pleuritic pain, and purulent sputum. Bibasilar rales may be heard, but objective physical findings are often minimal in the face of severe toxicity.

Milder types of subacute and chronic pneumonia are often seen. In addition to fever, productive cough, and pleuritic pain, many patients experience marked weight loss and a clinical picture resembling tuberculosis or fungal disease. Secondary skin manifestations are rarely seen unless bacteremia ensues. Physical changes are often subtle but can include localized rales, a pleural friction rub, signs of an effusion, and manifestations of disease localized to soft tissues, lymph nodes, bones, or joints.

Radiologic findings reflect the stage of disease present. In acute fulminant infections, airspace disease can be absent or miliary to larger nodular densities seen in basal segments. In subacute and chronic cases, fibronodular or cavitary apical lesions are found, similar to reactivation tuberculosis.

Diagnostic Features

Melioidosis should be seriously entertained in any febrile patient with a history of residence in a major endemic region such as Southeast Asia or northeast Australia. If sputum is available, the gram-negative bipolar staining bacilli may be seen, and the organisms can be readily cultured and identified in the routine laboratory. Blood and urine cultures are frequently positive in acute cases. In more indolent infections, biopsy may be necessary. Molecular biology techniques such as polymerase chain reaction are being developed for diagnostic use. Serologic studies can be helpful in active and recrudescent disease, especially in patients residing in nonendemic areas. A specific IgM immunofluorescence test is often positive in recent infections and recrudescent disease. Complement fixation and indirect hemagglutination tests are available and require testing of paired sera over several weeks to confirm active disease.

Differential Diagnosis

In patients from Southeast Asia, acute fulminating infections with pneumonia may be due to traditional bacteria and viruses, but may also be caused by infection with *Y. pestis* (plague) and *F. tularensis* (tularemia) (see above). Chronic forms of melioidosis resemble tuberculosis and fungal infections such as histoplasmosis and blastomycosis. Occupation, travel, and history of respiratory illness should help to clarify the cause. Confirmation usually requires appropriate cultures and sometimes biopsy or serologic data.

Treatment and Prevention

Recommendations for therapy of acute septicemic melioidosis must be couched in cautious statements. During the Vietnam War, mortality greater than 50 percent occurred, even with use of three-drug regimens in massive doses. In subacute and chronic pneumonias and recrudescent disease cure rates approach 100 percent. Treatment must be prolonged and surgical intervention for drainage or removal of cavitary lesions is sometimes necessary to prevent relapse.

Imipenem/meropenem or the third-generation cephalosporin ceftazidime in high doses are considered first-line therapy. Once a good clinical response is seen, oral therapy may be initiated. Combination therapy for several months results in a lower relapse rate; regimens are varied and include such agents as doxycycline, chloramphenicol, trimethoprim-sulfamethoxazole, azithromycin, and ciprofloxacin. Amoxicillin-clavulanic acid may be used in children. A study of clinical isolates from Thailand demonstrated an 81 percent trimethoprim-sulfamethoxazole resistance rate among 200 isolates tested. With the exception of kanamycin, other aminoglycosides are ineffective.

No prophylactic antimicrobial studies are available, nor has a vaccine been developed. People traveling, living, or working in endemic regions should be advised of this soil- and water-dwelling organism. Care and caution should be used to avoid traumatic injuries, and any wounds contaminated with soil or stagnant water should be assiduously cleaned.

Yersinia enterocolitica

Most infections caused by *Y. enterocolitica* are gastrointestinal, resulting in a self-limited gastroenteritis or appendicitis-mimicking mesenteric and terminal ileum adenitis. Septicemias and involvement of the lungs and other viscera are extremely rare, usually occurring in persons suffering from cirrhosis or who are immunocompromised.

Yersinieae belong to the family *Enterobacteriaceae. Y. enterocolitica* is a gram-negative, facultative bacillus that resembles many other enteric microbes. Identification procedures include the ability to grow and exhibit motility at room temperature plus a battery of biochemical and serologic tests. Although occasionally overlooked in stool because it is confused with many other members of the fecal flora, the organism is readily identified in blood and respiratory specimens. Most strains are non-lactose or slow lactose fermenters, causing confusion with *Y. pestis, Salmonella, Shigella,* and several other members of the Enterobacteriaceae family. Cold enrichment techniques and highly selective media, extensively used to identify this organism in feces, are not

necessary in other specimens. Various serotypes and biotypes, with distribution in geographically distinct regions, have been described.

Y. enterocolitica has been isolated from a variety of rodents and other wild species, and from cats, dogs, and other domestic animals. There is little evidence for direct transmission or for spread among people other than by the fecal–oral route. Most cases occur singly, but epidemics involving families and hundreds of people have been described. Disease is initiated by ingestion of contaminated milk or other food. Most cases of respiratory disease have been reported in immunocompromised hosts, alcoholics, and cirrhotics.

Direct aspiration may be the mechanism for initiation of pulmonary disease, following an initial pharyngitis focus. Bacteremia can complicate pharyngeal disease, although the most likely mechanism entails ulceration of Peyer's patches in the terminal ileum, mesenteric adenitis, and portal bacteremia. Systemic shunting to the lungs can follow, especially in cirrhotics, the group that most frequently develops septicemia. Strains virulent for animals and causing human disease have plasmid-mediated V and W envelope antigens, temperature-sensitive calcium dependency (as with *Y. pestis*), a factor that enhances cell penetration, and endotoxin. An enterotoxin, similar to stable toxin of *E. coli,* is also produced, but an extra-gastrointestinal role has not been established for this protein. The development of immune complex manifestations such as erythema nodosum and nonsuppurative polyarthritis may contribute to pathogenicity and same as clues to etiology.

In the past three decades, approximately 15 cases of pneumonia have been described in the literature. Respiratory infections occur in association with an acute febrile septicemic illness or as a primary respiratory process, with cough, dyspnea, and signs of consolidation. The history is usually vague for gastrointestinal symptoms, animal exposure, or unusual food intake. There may be signs of increasing hepatic failure with ascites or peritonitis in patients with underlying cirrhosis. Radiologic findings include nodular basilar densities consistent with septicemic spread, dependent segment infiltrates suggesting an aspiration mechanism, occasionally with cavitation, and fluffy widespread densities consistent with septic emboli. Immunocompromised patients may be especially prone to severe necrotizing pulmonary infections.

The diagnosis often depends on information obtained from blood or sputum cultures. Enteric gram-negative bacilli can be seen in sputum. Pharyngeal cultures should be done if signs of local inflammation are present. Suppurating nodes and peritoneal or joint fluids are other sources of material that may contribute to the diagnosis.

Cases of respiratory infection have responded well to a variety of antibiotics, including ampicillin or second-generation cephalosporins. Third-generation cephalosporins, chloramphenicol, aminoglycosides, fluoroquinolones and trimethoprim-sulfamethoxazole may also be effective. Treatment should be based on antibiotic susceptibility testing. Underlying diseases influence the outcome, but when pneumonia is the major problem, prognosis is excellent. Treatment is usually continued for a total of 3 to 6 weeks. (See Table 137-2 for further details.)

Preventive measures include avoiding rodent or domestic animal contamination of food and water supplies. Opportunities for susceptible individuals to come in contact with this zoonotic microorganism may be increasing as well, as healthy and immunocompromised people turn to oraganically grown foods and mountain streams for improved health but with potential contamination with pathogens from animal droppings.

PNEUMONIAS CAUSED BY OBLIGATE HUMAN COMMENSALS

Most bacterial pneumonias are caused by encapsulated obligate human commensals that are easy to isolate, such as *Streptococcus pneumoniae.* Among the less common causes of pneumonia due to human commensals, *Neisseria meningitidis* (the meningococcus) and *Moraxella* (formerly *Branhamella*) *catarrhalis* stand out as pathogens or opportunists that may escape bacteriologic identification and therefore present problems in diagnosis and therapy.

Neisseria meningitides (Fig. 137-3)

During the influenza viral pandemic of 1918–1919, *N. meningitidis* was an important respiratory pathogen. Afterward, few references to the meningococcus appeared in the medical literature on bacterial pneumonias, as reports of meningococcal disease focused on its role in causing meningitis and septicemia. With the advent of improved bacteriologic techniques, an increasing number of cases of *N. meningitidis* pneumonia have been diagnosed.

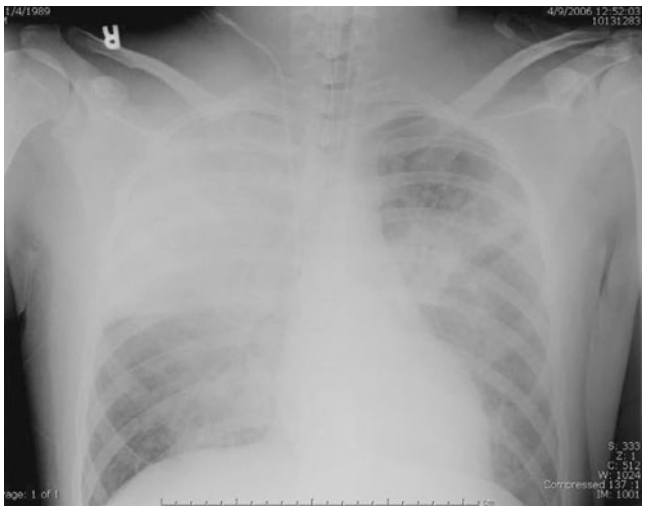

Figure 137-3 Patchy bronchopneumonia, predominantly in the right upper lobe, in 16-year-old boy with *Neisseria meningitidis* pneumonia and bacteremia. *(Image courtesy of Holly Rawizza, MD.)*

Bacteriology and Immunology

Neisseria are oxygen-requiring, gram-negative cocci recognized by their characteristic pairing as kidney-shaped diplococci. They are fastidious, succumbing rapidly to the external environment and extremes of temperature or humidity. Although *Neisseria* can grow on blood agar, optimal conditions include enriched media, such as chocolate agar, and incubation in an atmosphere of 6 percent CO_2 at 35 to 37°C with 50 percent humidity. *N. meningitidis* is distinguishable from other *Neisseria* spp. that are residents of the oral-respiratory region by sugar fermentation reactions and serologic identification, which depends on specific capsular polysaccharides. Isolation and identification of *N. meningitidis* in sputum are facilitated by the use of a selective medium, such as modified Thayer-Martin agar (MTM), which contains antibiotics that suppress more rapidly growing microorganisms. The presence of *Neisseria*-like diplococci in a Gram's stain of sputum should provide the impetus to culture the specimen on MTM media as well as on less selective media, such as blood and chocolate agar (Fig. 137-4).

Figure 137-4 Gram stain of expectorated sputum from a patient with proven *Moraxella* pneumonia. In this black-and-white photomicrograph, the distinguishing features include the presence of morphologic kidney-shaped diplococci (gram-negative) associated with polymorphonuclear neutrophils. This appearance suggests *Neisseria* or *Moraxella* infection.

N. meningitidis is a typical gram-negative organism containing a potent lipopolysaccharide endotoxin in the outer membrane layer of the cell envelope. Exterior to this layer is a polysaccharide capsule, by which *N. meningitidis* can be separated into at least 13 chemically defined serogroups. Groups A, B, C, Y, and W-135 are currently the most important clinically. The less frequently observed serogroup Y meningococci accounted for 44 percent of isolates in one series of 58 cases of meningococcal pneumonia.

Immunity to meningococci is complex. Bactericidal antibody, present in the newborn, disappears by approximately 6 months of age. During childhood and adolescence, overt disease and subclinical encounters with various capsular strains of *N. meningitidis,* as well as with nonpathogenic *Neisseria* spp., lead to stimulation of bacterial antibody. Immune lysis of organisms is facilitated by the terminal complement components C5 through C8. Congenital absence of one or more of these terminal complement components has been associated with recurrent acute meningococcal disease. Antibodies to certain outer membrane proteins and a variety of envelope antigens of *E. coli* and other commensals cross-react with antigens from *N. meningitides* and may import nonspecific immunity. Persons lacking bactericidal or capsular antibody to a specific serogroup are susceptible to colonization and disease caused by that serogroup. With increasing age, acquisition of protective antibodies is associated with less likelihood of developing clinical disease.

Epidemiology

Nasopharyngeal carriage of various serogroups of meningococci occurs in approximately 5 to 25 percent of subjects. Convening and crowding large numbers of young persons from widely separated geographic areas, as occurs in the military, in boarding schools and universities can result in significant and rapid spread of an individual serogroup from a few asymptomatic carriers to many susceptible individuals. A case of meningococcal disease in a family is often associated with an increased prevalence of meningococcal isolation from relatives with symptoms of upper respiratory infection. In the prior experience military carrier rates could rapidly approach 100 percent, followed by many cases of meningitis if prophylactic antibiotics and other prevention measures were not undertaken. Today, protective immunization has markedly altered this concern.

Respiratory disease due to meningococci was recognized early in the twentieth century, especially during the influenza pandemic of 1918–1919. In the mid-1970s, outbreaks of serogroup Y meningococcal pneumonia occurred in military installations. Over the past 25 years, isolated respiratory disease, primarily due to serogroups Y and W-135, has been detected in civilian populations and nosocomially in persons in contact with an index case. Spread is probably by aerosol droplets during close contact, since drying rapidly kills meningococci. People ill with influenza or adenoviral respiratory infections appear to be more susceptible—as occurs with other respiratory pathogens, including *S. pneumoniae* and *Staphylococcus aureus.*

Pathogenesis and Pathophysiology

Initiation of infection begins when an encapsulated strain colonizes the nasopharynx of a person lacking immunity to that serogroup. Attachment to mucosal cells is facilitated by filamentous pili and outer membrane proteins such as Opa and Opc, and perhaps by the action of bacterial IgA1 protease. The capsule helps evade complement fixation and subsequent phagocytosis. Lipopolysaccharide (endotoxin) stimulates release of inflammatory mediators, including TNF-α, IL-1β, IL-6, and IL-8, and thus has a crucial role in the pathogenesis of meningococcal septic shock. The lower respiratory tract is invaded by aspiration or inhalation of droplet particles. A preceding viral infection can stimulate excessive airway secretions, damage surface epithelial structures, and interfere with clearance of microorganisms. Meningitis, petechial eruptions diffuse intravascular coagulation, and ARDS seldom accompany pneumonia, supporting a postulated aspiration mechanism. Bronchopneumonia, lobar extension, and necrosis and abscess formation are seen. Modern pathological correlations are lacking, since there are no animal models of meningococcal pneumonia and histopathological material is essentially nonexistent due to favorable outcome of this primary respiratory infection.

Clinical and Radiologic Features

The clinical presentation of meningococcal pneumonia resembles that of pneumococcal infection (Table 137-4). Productive cough, pleuritic pain, chills, and fever are associated with physical changes of rales with consolidation. Unlike pneumococcal disease, pleural rubs, and hemoptysis are unusual. Suspicion of meningococcal disease is enhanced if many cases of bacterial pneumonia erupt in closed populations such as military or school groups or among hospital patients. The spectrum of respiratory disease includes pharyngitis, common in outbreaks, and purulent tracheobronchitis. Invasive meningococcal respiratory disease carries a mortality rate of 5 to 10 percent.

Table 137-4

Diagnosing Meningococcal Pneumonia

Antecedent viral respiratory infection
Multiple community or hospital respiratory cases
Purulent or frothy sputum
Kidney-shaped gram-negative diplococci on smear (Fig. 137-4)
Culture sputum on modified Thayer-Martin medium
Incubation with CO_2 enrichment

Radiologic features are nonspecific and include patchy bronchopneumonia and lobar airspace infiltrates. The air space disease is usually located in the right lung (56 percent, the majority with findings in the right lower lobe) or left lung (24 percent). Bilateral involvement occurs in 20 percent of cases and an effusion is noted in about 13 percent of cases. Occasionally, as occurs in pneumococcal pneumonia the radiologic appearance resembles diffuse pulmonary edema or an antecedent viral infection.

Diagnostic Features

Diagnosis depends on isolation of predominantly *N. meningitidis* from a carefully collected sputum specimen that has characteristic gram-negative diplococci and PMNs on the stained smear (Fig. 137-4). Attention to these criteria is essential, since pathogenic and nonpathogenic *Neisseria* and *Moraxella* spp. are part of the normal respiratory flora. Invasive procedures such as bronchoscopy are not necessary if valid sputum is available, and the gram stain appearance prompts culturing the specimen on MTM media. Alternative methods of identification include the capsular swelling technique (to rule out pneumococcal infection), latex bead coagglutination, and fluorescent antibody staining. Recent purification of all of the major group-specific capsular polysaccharides should lead to expansion of these rapid diagnostic methods. Blood cultures were positive in a significant number of recent cases.

Differential Diagnosis

Respiratory infections due to other causes, especially when there are clusters of cases, must be considered in the differential diagnosis. Viral agents such as influenza A or B or adenoviruses can cause acute respiratory infections affecting a number of people, especially under institutional or crowded circumstances. A viral diagnosis is usually confirmed by the epidemiological and clinical circumstances; a nonspecific sputum examination, positive laboratory test, absent or interstitial infiltrates radiologically, and paired serologic titers.

Mycoplasmal pneumonia is frequently biphasic, with upper respiratory inflammation and headache prominent early symptoms and, occasionally, bullous tympanitis producing severe ear pain. The sputum is often purulent, with a mixture of PMNs and mononuclear cells, but no dominant microorganism is observed with gram stain. Diagnosis is usually confirmed by a cold agglutinin titer of 1:32 or greater, a rising titer of complement-fixing antibody, or PCR of sputum. When many cases occur in a family or closed community, they usually erupt sporadically over many weeks rather than days to a week. Other atypical pneumonias to consider include *Legionellae*, *Chlamydia psittaci,* and *Chlamydia pneumoniae.*

Acute bacterial pneumonias often follow in the wake of viral respiratory infections. *S. pneumonia* and *S. aureus* infections are differentiated with microscopic examination, culture of sputum, and the results of blood cultures. In hospitals, especially among immunocompromised patients or patients

attached to respirators, a variety of gram-negative microorganisms can produce pneumonia. *H. influenzae* infections can usually be suspected, but *M. catarrhalis* resembles *Neisseria* morphologically and may not respond to penicillin treatment (see below).

Acute respiratory failure secondary to small-vessel endothelial cell damage or ARDS can complicate Rocky Mountain spotted fever. A petechial or morbilliform eruption is usually seen on the extremities. With meningococcal respiratory disease, a rash is rarely seen and the seasonal appearance and tick exposure help to separate the two diseases. Any large cluster of respiratory cases must also raise the specter of a terrorist-mediated pathogenic exposure.

Treatment and Prevention

Although penicillin was first-line therapy until 1991, the majority of patients since then have received cephalosporins. Low-dose penicillin is effective for most cases of susceptible *N. meningitides* pneumonia, although those complicated by cavitation or empyema should be treated with a minimum of 6 million units daily. Patients allergic to β-lactams can be given chloramphenicol. In contrast to meningitis or meningococcemia, respiratory infections appear to respond uniformly well to treatment.

Meningococci spread via droplet aerosols, so isolation of suspected cases is essential, especially during the first 24 hours of treatment. Chemoprophylaxis and immunoprophylaxis are effective in epidemics of meningitis, but no data are available for respiratory disease protection. Penicillin, the drug of choice for treating active disease, does not reliably eradicate the carrier state or protect intimately exposed contacts. Rifampin is an effective prophylactic agent probably due to its transport into oral and respiratory tract secretions in high concentrations. Fluoroquinolones such as ciprofloxacin are also effective. Minocycline diffuses into upper respiratory secretions in high concentrations and is a useful alternative to rifampin.

Immunoprophylaxis has been safe and effective when given systematically to large at-risk groups in military installations, schools, day care centers, or defined communities. Both a polysaccharide as well as a protein conjugate quadrivalent vaccine is commercially available, containing serogroups A, C, Y, and W-135. Vaccines for serogroup B are in development or available presently in other countries. There are no contemporary data for efficacy of the vaccine for respiratory infections. Immunizing persons with influenza viral vaccines should eliminate some cases of secondary bacterial infections, including those caused by *N. meningitidis.*

Moraxella (Branhamella) catarrhalis

Formerly considered a nonpathogenic respiratory commensal, *M. catarrhalis* has aroused renewed interest as an opportunist and primary pathogen. Resemblance to *Neisseria* on gram stain encourages its inclusion in this section.

Bacteriology

Moraxella are gram-negative cocci that pair as kidney-shaped diplococci; hence, they cannot be distinguished morphologically from *Neisseria.* The organisms grow well on nonselective media such as sheep blood agar and enriched chocolate agar, especially when supplemented with added CO_2. Growth of *Moraxella* is variable on selective media such as MTM—in contrast to pathogenic *Neisseria,* which thrive on that medium. They fail to utilize a variety of sugars. These and other biochemical tests help to distinguish them from *Neisseria.* Many clinical isolates produce β-lactamase and, therefore, are resistant to penicillin.

Epidemiology

A member of the resident microflora of the nasopharynx and pharynx, *M. catarrhalis* can also colonize the mucosa of the genital tract. Among persons with chronic lung disease it can be found, along with other bacteria, in respiratory secretions. The extent of colonization of mucous surfaces in healthy or diseased subjects is not known. There is no evidence for human-to-human transmission, although infections in the hospital occur and are probably related to nosocomial spread and the selective pressures from the various antimicrobials used. In normal children and adults, otitis media, sinusitis, and laryngotracheobronchitis probably result from direct invasion from colonized mucosal surfaces. This view is supported by the finding of mixed infections with other commensals, such as *H. influenzae* and mouth anaerobes.

Pathogenesis and Pathophysiology

In contrast to pathogenic *Neisseria, Moraxella* lack antiphagocytic capsules and IgA proteases. They have outer-envelope lipopolysaccharide endotoxin, characteristic of all gram-negative microbes. Neutrophils as well as humoral immunity have been reported as significant factors in natural host defense of this member of the normal flora.

The mechanism of initiation of respiratory disease appears to be primarily related to underlying obstruction and chronic inflammation. Aspiration of nasopharyngeal secretions, stimulated by an acute viral upper respiratory infection, is the most common predisposing pathophysiological event. Contributing immunocompromising conditions—such as steroid therapy, malignancy, hypogammaglobulinemia, and neutropenia—are present in a large number of patients. Paranasal sinus and ear infections occur predominantly in children, probably because of compromised drainage ducts in anatomically crowded areas. Rarely, *Moraxella* produce primary invasive diseases outside the respiratory tract, including meningitis, endocarditis, septic arthritis, and, in immunocompromised patients, septicemia.

Clinical and Radiologic Features

Most people who develop respiratory infections are adults with chronic lung disease associated with smoking, industrial exposures, or bronchitis and bronchiectasis. Purulent bronchitis or bronchopneumonia can follow an intercurrent viral

infection. Respiratory distress, if present, may be related to the acute process, with bronchospasm and fever superimposed on the chronic underlying disease. Signs of consolidation or pleural fluid may be present, along with persistent obstructive changes. Evidence has been accumulating that normal adults may develop primary laryngitis and children a nonproductive cough as other manifestations of clinical respiratory tract disease, but primary pneumonia is very uncommon at any age in subjects with healthy lungs.

The underlying chronic lung disease influences the radiologic appearance. No acute changes may be observed, but usually increased markings are seen superimposed on the findings of obstructive lung disease and fibrosis. Patchy consolidation is often noted. Lobar infiltrates, cavitation, and pleural effusions are distinctly unusual findings and suggest mixed infections or other complications of the underlying disease.

Diagnostic Features

The unique challenge in cases of *M. catarrhalis* respiratory infections is identifying this organism when gram-negative kidney-shaped diplococci associated with a PMN exudate are noted and suggest a meningococcal infection (Fig. 137-4). Diagnosis depends on careful examination of an adequate expectorated sputum sample and culturing the specimen on nonselective blood and enriched chocolate agar as well as on selective MTM. The use of several media assures that these fastidious organisms will be identified in a crowd of other commensals. Serologic methods are not available to help verify a pathogenic role for *Moraxella* in mixed infections (Table 137-5).

Differential Diagnosis

The major diagnostic confusion results from the presence in sputum of *Neisseria* spp. and other potential pathogens, such as *S. pneumoniae* and *H. influenzae*. In patients with chronic lung disease, mixed infections make it impossible to ascribe pathogenicity to a single organism. Coccobacillary microorganisms, or gram-negative bacilli that demonstrate bipolar staining (e.g., *Brucella, Pasteurella*) can also be confused with *M. catarrhalis*.

Treatment

As the pathogenic role for *M. catarrhalis* was recognized, it became apparent that many isolates produced β-lactamase and were resistant to penicillin and ampicillin. Numerous treatment failures with penicillins have been described, often with dramatic improvement once an alternative antibiotic was administered. Therefore, therapy should be initiated with either a second- or third-generation cephalosporin such as cefuroxime, or trimethoprim-sulfamethoxazole. Alternatives include the expanded-spectrum macrolides clarithromycin or azithromycin, amoxicillin–clavulanic acid (Augmentin), or a fluoroquinolone until β-lactamase activity is determined. In vitro testing may appear to deceptively demonstrate susceptibility to penicillin, amoxicillin-clavulanic acid, or first-generation cephalosporins if β-lactamase production is at a low level. Clinical failures may occur if these drugs are used. Supportive therapy with adequate hydration, bronchodilators, and other measures directed at treating the underlying respiratory disease is essential for a successful outcome.

CHAPTER

The Epidemiology, Prevention, and Control of Tuberculosis in the United States

Philip A. LoBue • Michael F. Iademarco • Kenneth G. Castro

Tuberculosis is a contagious disease that progresses from a systemic infection caused by bacteria of the *Mycobacterium tuberculosis* complex. Most commonly, *M. tuberculosis* is spread from person to person by airborne transmission of droplet nuclei. Despite a relatively low transmission rate compared with other contagious diseases and the existence of effective chemotherapy for five decades, tuberculosis remains a major global public health problem. Approximately one-third of the world's population is infected with tuberculosis. Each year there are 9 million new cases and nearly 2 million deaths attributed to this disease. The continuing spread of human immunodeficiency virus (HIV) infection has dramatically altered tuberculosis epidemiology and is driving much of the global tuberculosis epidemic, especially in Africa and Asia. Another million deaths attributed to HIV infection also have tuberculosis as a contributing cause of death. The current epidemic has been accompanied by a rise in multidrug-resistant (MDR, defined as resistance to at least isoniazid and rifampin) tuberculosis cases, highlighting the impact of failure to adequately invest in public health programs in many parts of the globe.

In the 1980s, factors, such as HIV infection, MDR, increased immigration from high-incidence countries, and deteriorating public health infrastructure eroded the capacity

to control tuberculosis in the United States. The resulting unprecedented resurgence (for an industrialized country) translated into an estimated excess of 52,000 cases by 1992. Several outbreaks of drug-resistant tuberculosis greatly strained the existing public health infrastructure, created public concern, and brought significant attention to the national tuberculosis epidemic. A decision to address the problem and a comprehensive strengthening of tuberculosis control activities, including the allocation of large, sustained increases in tuberculosis-specific federal, state, and local support, are credited with reversing the rising tuberculosis case rate. Since that time, the United States has experienced a steady decline in tuberculosis cases and case rates, although the decline in cases has primarily been limited to U.S.-born persons. The number of cases among foreign-born persons has not changed substantially. As a consequence, recent surveillance data suggest the overall number of tuberculosis cases in the United States may be starting to plateau. Thus, without control of the global tuberculosis epidemic, the goal of elimination of tuberculosis in the United States is likely to remain elusive in the near future.

SURVEILLANCE

Tuberculosis is a reportable disease in all U.S. health jurisdictions. The Centers for Disease Control and Prevention (CDC) began collecting aggregate tuberculosis surveillance data from reporting jurisdictions in 1953. Since 1985, individual tuberculosis case reports, without identifying information, have been relayed to CDC from 60 reporting areas (50 states, the District of Columbia, New York City, Puerto Rico, and seven other jurisdictions in the Pacific and Caribbean). For surveillance purposes, a case of tuberculosis must meet either laboratory criteria or the clinical case definition (Table 138-1). The laboratory criteria for case confirmation are: (1) isolation of *M. tuberculosis* from a clinical specimen; (2) demonstration of *M. tuberculosis* from a clinical specimen by nucleic acid amplification test; or (3) demonstration of acid-fast bacilli (AFB) in a clinical specimen when a culture has not been or cannot be obtained. A clinical case is defined by satisfying all of the following four criteria: (1) a positive tuberculin skin test; (2) symptoms and signs consistent with tuberculosis, such as worsening or improving chest radiograph or clinical evidence of disease; (3) treatment with two or more antituberculosis drugs; and (4) a completed diagnostic evaluation.

EPIDEMIOLOGY

Overall Incidence and Trends

From 1953, when CDC began systematic national tuberculosis surveillance, until 1985, reported cases decreased at about 5 percent per year from 84,304 (case rate 52.6*) to 22,201 (case rate 9.3). This steady decline was interrupted, however, by a resurgence of tuberculosis beginning in 1985 and peaking in 1992 (Fig. 138-1) during which time the number of reported cases increased to 26,673 (case rate 10.5). This increase was concentrated in young (predominantly aged 25 to 44 years), urban (especially New York, New Jersey, and California), racial and ethnic minority populations. Tuberculosis was also found to be prevalent among the homeless, injection and non-injection drug users, and inmates of correctional facilities. In many of these groups, the rise in tuberculosis was linked to high rates of HIV infection. A second epidemiologic trend emerged with increased immigration to the United States of persons from countries in which tuberculosis is prevalent (especially Latin America, South and

*All case rates are per 100,000 population.

Table 138-1

CDC Tuberculosis Case Definition for Public Health Surveillance*

Clinical description

A chronic bacterial infection caused by *Mycobacterium tuberculosis*, characterized pathologically by the formation of granulomas. The most common site of infection is the lung, but other organs may be involved.

Clinical case definition

A case that meets all of the following criteria:
- A positive tuberculin skin test result
- Other signs and symptoms compatible with tuberculosis, such as an abnormal, unstable (i.e., worsening or improving) chest radiograph, or clinical evidence of current disease
- Treatment with two or more antituberculosis medications
- A completed diagnostic evaluation

Laboratory criteria for diagnosis

- Isolation of *M. tuberculosis* from a clinical specimen,† or
- Demonstration of *M. tuberculosis* from a clinical specimen by nucleic acid amplification test,‡
- Demonstration of acid-fast bacilli in a clinical specimen when a culture has not been or cannot be obtained

Case classification

Confirmed: a case that meets the clinical case definition or is laboratory confirmed

** CDC: Case definitions for infectious conditions under public health surveillance. MMWR 46(RR-10):40, 1997.*
† Use of rapid identification techniques for M. tuberculosis (e.g., DNA probes and mycolic acid high-pressure liquid chromatography performed on a culture from a clinical specimen) are acceptable under this criterion.
‡ Nucleic acid amplification (NAA) tests must be accompanied by culture for mycobacteria species. However, for surveillance purposes, CDC will accept results obtained from NAA tests approved by the Food and Drug Administration (FDA) and used according to the approved product labeling on the package insert.

Figure 138-1 Reported tuberculosis cases in the United States, 1982–2004. (Adapted from Centers for Disease Control and Prevention: *Reported Tuberculosis in the United States, 2004*. Atlanta, GA, U.S. Department of Health and Human Services, CDC, 2005.)

Southeast Asia, Africa, and Eastern Europe). Because of extensive national, state, and local control efforts, the annual incidence of tuberculosis has been on the decline again since 1992, falling 46 percent between 1992 and 2004 (Fig. 138-1). During 2004, 14,517 (case rate 4.9) tuberculosis cases were reported to CDC, the lowest annual incidence. Despite this welcome decline, the associations of this disease with conditions such as HIV infection, homelessness, injection drug use, and foreign birth remain. Of perhaps even greater concern, the decreases in reported cases from 2002 to 2003 (1.4 percent) and 2003 to 2004 (2.3 percent) represent the smallest and third smallest yearly declines, respectively, since 1992.

Age, Race, and Ethnicity

In older adults, tuberculosis usually results from activation of infection acquired some time in the past. There is an intervening period of latency lasting years or decades between initial infection and activation of disease, which has also been called post-primary tuberculosis.[†] In contrast, tuberculosis in infants and young children is due to progression of recent infection and termed primary tuberculosis. Primary tuberculosis may develop in more than 40 percent of untreated infected children less than 1 year of age. As tuberculosis incidence declines, there is less transmission to uninfected persons, especially children and younger adults. Consequently, it is not surprising that as tuberculosis incidence decreased in the United States, the median age of persons with tuberculosis increased, rising to 49 years in 1985. With cases increasing starting in 1985, the median age of persons with tuberculosis fell to 43 years, and there were more cases of tuberculosis in younger persons, especially among racial and ethnic minorities. With the number of tuberculosis cases declining again in recent years, the case rate in children (defined as under 15 years of age) has decreased sharply (from 2.9 1993 to 1.6 in 2004). Case rates in adults have also fallen by 25 to 50 percent, depending on the age group (adults aged 15 to 24 years from 5.0 to 3.8, 25 to 44 years from 11.5 to 5.9, 45 to 64 years from 12.4 to 5.9, and 65 years and older from 17.7 to 7.8).

Along with many other conditions, tuberculosis reflects a health disparity in the United States because it disproportionately affects racial and ethnic minorities. Differences in case rates between white and nonwhite populations have been associated with socioeconomic status (tuberculosis is essentially a disease of the poor) and country of birth. When tuberculosis was decreasing prior to 1985, the rate of decline was less for nonwhite persons than for white persons. During the period of resurgence from 1985 through 1992, tuberculosis cases in minorities rose while those in whites continued to decrease. Cases among non-Hispanic blacks and Hispanics increased 26.8 and 74.5 percent, respectively. As total cases declined again after 1992, minority tuberculosis cases also decreased. In 2004, Asian and Pacific Islanders had the highest TB rate, 27.2, which was down from 44.1 in 1993. Rates declined about 50 percent over the past decade in other racial/ethnic minority groups: among non-Hispanic blacks from 28.5 in 1993 to 11.3 in 2004, among Hispanics from 19.9 to 10.1, and among American Indians and Alaska Natives from 14.0 to 7.3. In 2004, for the first time, Hispanics (29 percent) exceeded blacks (28 percent) as the racial/ethnic group with the largest percentage of cases.

Country of Birth

Over the past decade, one of the most notable trends in tuberculosis epidemiology in the United States is the increase in the proportion of cases that has occurred in persons born outside the United States (Fig. 138-2). In 1993, 69 percent of reported cases were among U.S.-born persons (case rate 7.4), whereas 29 percent were in foreign-born persons (case rate 33.6). In comparison, by 2004, 54 percent of reported cases occurred among foreign-born persons, and the respective case

[†]The term "reactivation" has also been used; historically, in the pre-chemotherapeutic era, this term referred to patients who developed tuberculosis, experienced self-cure, and then subsequently progressed to disease for a second time (in the absence of exogenous reinfection). Although this term has been applied in the post-chemotherapeutic era to patients who are latently infected and then progress to disease, this usage may be seen as inaccurate because patients have only experienced one episode of disease, and have not "reactivated."

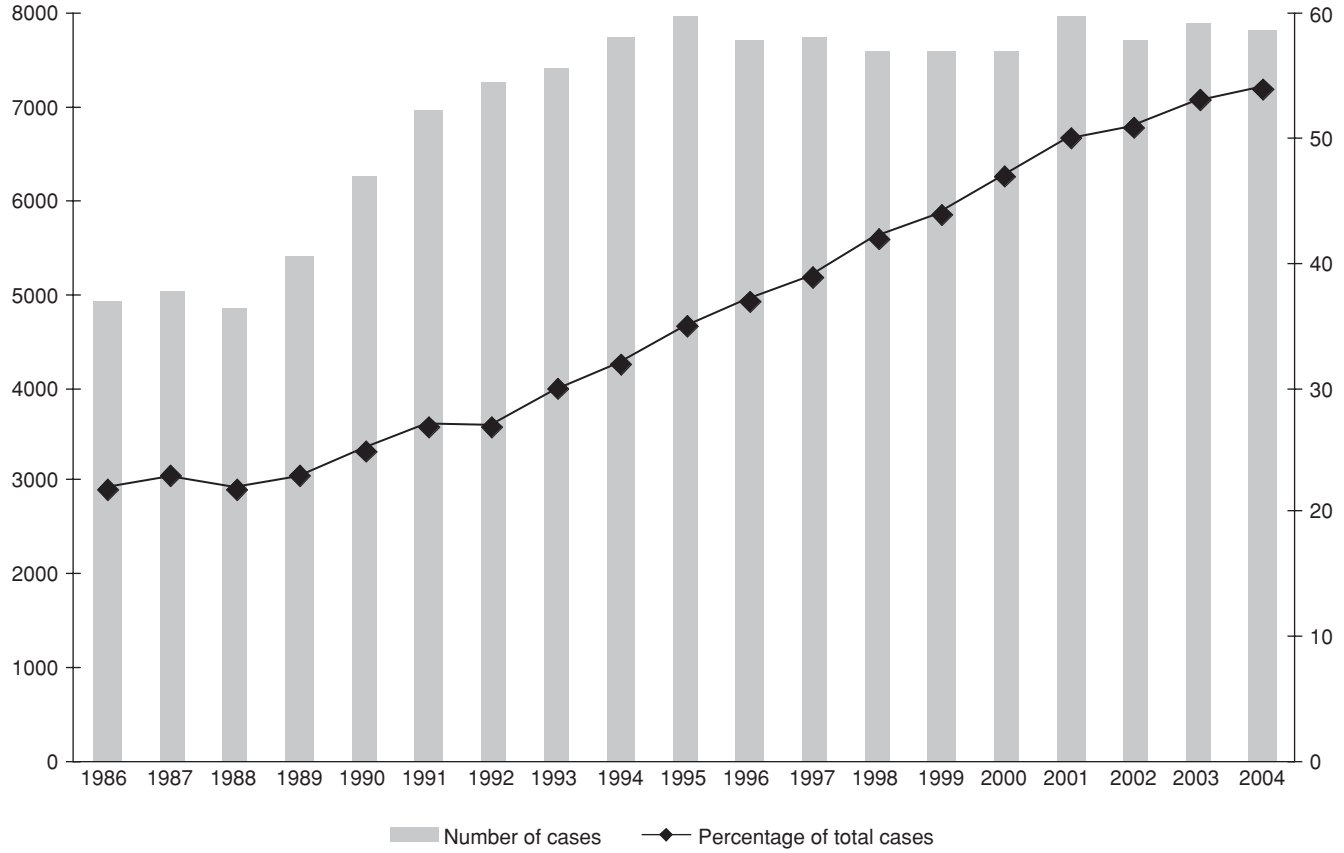

Figure 138-2 Trends in tuberculosis cases in foreign-born persons, United States, 1986–2004. (Centers for Disease Control and Prevention: *Reported Tuberculosis in the United States, 2004*. Atlanta, GA, U.S. Department of Health and Human Services, CDC, 2005.)

rates were 2.6 for U.S.-born persons and 22.8 for foreign-born persons. The number of states reporting more than 50 percent TB cases among foreign-born persons increased from five in 1993 to 22 in 2004. Of these 22 states, six (California, Hawaii, Massachusetts, Minnesota, Nebraska, and New Hampshire) had more than 70 percent of their cases among foreign-born persons. In 2004, the top five countries of origin of foreign-born persons with tuberculosis (by percentage of cases) were Mexico (25 percent), the Philippines (11 percent), Vietnam (8 percent), India (7 percent), and China (5 percent). Although these national trends are informative, local epidemiological profiles vary and should be developed by state and county health departments to respond to local public health needs.

Anatomic Site of Disease

The lung is the most common disease site for persons reported with tuberculosis (about 80 percent of cases), and pulmonary tuberculosis poses the greatest public health concern because of its contagiousness. In 2004, 71.2 percent of reported cases involved the lung only and 8.3 percent involved the lung and an extrapulmonary site. For extrapulmonary tuberculosis, the most common types were lymphatic (43.8 percent), pleural (19.0 percent), bone and joint (11.2 percent), meningeal (5.8 percent), peritoneal (5.5 percent), and genitourinary (3.8 percent). Two severe forms of disease, meningeal and miliary tuberculosis, are more common in children and comprise approximately 20 percent of cases reported in newborns to 4 year olds.

HIV Infection

Beginning in the 1980s, untreated HIV infection came to be recognized as the greatest risk factor for progression from latent tuberculosis infection (LTBI) to tuberculosis disease. In the absence of antiretroviral therapy, seven to ten percent of HIV-infected persons with LTBI will progress to tuberculosis disease *per year*; this is comparable to the *lifetime* risk of progression of five to ten percent in otherwise healthy people. Because of the high likelihood of progression from infection to disease, which often occurs rapidly, numerous outbreaks among HIV-infected persons have been reported, including outbreaks of MDR tuberculosis. Chest radiograph findings in HIV-infected tuberculosis patients, especially in those with CD4+ T-lymphocyte counts below 200/μl, are frequently atypical: Cavities are less common, whereas hilar adenopathy and lack of pulmonary infiltrates are seen more frequently than in immunocompetent patients. Extrapulmonary tuberculosis is more common in HIV-infected patients, occurring in as many as 40 to 60 percent of patients in some studies.

Incomplete reporting has limited the analysis of national tuberculosis surveillance data by HIV status. Reporting

of HIV status has improved slowly since 1993, the year such information was first included on tuberculosis case reports submitted to the CDC. In 2004, 64 percent of tuberculosis case reports for persons aged 25 to 44 years (highest risk age group) included information about HIV status. Thirty-four states, New York City, and the District of Columbia reported this information for at least 75 percent of cases among persons in this age group. Of these states and cities that also reported HIV results on at least 10 cases, the percentage of tuberculosis cases aged 25 to 44 years with HIV co-infection varied from 3.7 to 41.9 percent (Nevada and District of Columbia, respectively). To help estimate the proportion of reported tuberculosis cases with HIV co-infection, state health departments have compared tuberculosis and acquired immunodeficiency syndrome (AIDS) registries. Using registry matched data to supplement HIV test results reported on the individual tuberculosis case report, minimum estimates of the proportion with HIV co-infection ranged from 15 percent in 1993 to 1994 to 10 percent in 1998 to 1999 for persons of all ages reported with tuberculosis and from 29 percent in 1993 to 1994 to 19 percent in 1998 to 1999 for persons aged 25 to 44.

Homelessness, Incarceration, and Substance Abuse

Other conditions associated with poverty are also risk factors for tuberculosis. Prominent among these are homelessness, incarceration, and substance abuse. In 2004, 5.8 percent of cases were reported as being homeless within the past 12 months of diagnosis, whereas 3.4 percent were residing in a correctional facility at the time of diagnosis. In addition, injection drug use, non-injection drug use and excess alcohol use were reported in 1.8, 7.4, and 14.2 percent, respectively, of tuberculosis cases reported in 2004. In tuberculosis patients, these conditions frequently overlap with HIV infection.

Drug Resistance

In individual mycobacteria, drug resistance begins with spontaneous genetic mutations that confer resistance to specific drugs. Even though the rate of spontaneous mutations is low (on the order of one mutation per 10^{10} organisms to one mutation per 10^6 organisms), patients with advanced tuberculosis disease have a very large burden of organisms (one cavity may have 10^9 organisms). Therefore, thousands of mutants resistant to an individual drug may be present. With prolonged exposure to a single drug, the subpopulation of organisms resistant to that drug will be selected, expand, and become dominant. This phenomenon is termed acquired drug resistance. Consequently, from a bacteriological perspective, tuberculosis disease must be treated with at least two drugs to which the organism is susceptible. Drug-resistant tuberculosis may also be transmitted directly from a contagious patient to another person. Persons who contract drug-resistant tuberculosis in this manner have what is called primary or initial drug resistance.

Resistance to isoniazid is fairly common in the United States, ranging from 7.0 to 8.4 percent in the years 1993 to 2004. Isoniazid resistance is more frequent in foreign-born tuberculosis cases than U.S.-born tuberculosis cases (10.4 versus 4.5 percent in 2004) and more frequent in cases with a previous history of tuberculosis (in 2004, 11.4 percent versus 7.8 percent in those without previous tuberculosis).

MDR tuberculosis is defined as tuberculosis caused by an organism resistant to at least isoniazid and rifampin. MDR tuberculosis is difficult to treat and generally requires a minimum of 18 to 24 months of therapy with second-line medications (generally less effective, more toxic, and more costly); surgery is also indicated in some patients. The greatest risk factor for the presence of MDR-tuberculosis is a history of prior treatment for tuberculosis. Patients with tuberculosis from U.S. communities or foreign countries with high MDR tuberculosis rates are also at increased risk.

Since 1993 (when the case report was expanded to include drug-susceptibility results) the proportion of patients with primary MDR tuberculosis decreased from 2.5 percent to 0.9 to 1.2 percent each year during 1998 to 2004. The number of overall primary MDR tuberculosis cases in 2004 was 101, and only 27 of those cases were in U.S.-born persons. Decreases in the percentage of cases with primary MDR tuberculosis have been documented in both the U.S. born and foreign born, although the decline in the U.S. born is more pronounced. Since 1999, the percentage of U.S.-born persons with MDR tuberculosis has remained at approximately 0.6 percent. However, of the total number of reported primary MDR tuberculosis cases, the proportion occurring in foreign-born persons increased from 26 percent (105 of 410) in 1993 to 73 percent (74 of 101) in 2004.

TRANSMISSION

Determining Factors

M. tuberculosis is transmitted from person to person via the airborne route. Infection may occur after an uninfected person inhales respiratory droplets containing *M. tuberculosis*, most commonly produced when a patient with pulmonary tuberculosis coughs. As water evaporates, residual particles, known as droplet nuclei, remain suspended in the air. When inhaled, these particles are small enough (1 to 5 μm in size) to evade upper airway defenses and settle in the alveoli of the lung, causing infection in susceptible hosts.

Several factors determine the probability of tuberculosis transmission: (1) infectiousness of the source patient—a positive sputum smear for acid fast bacilli or a cavity on chest radiograph being strongly associated with infectiousness; (2) host susceptibility of the contact; (3) duration of exposure of the contact to the source patient; and (4) the environment in which the exposure takes place—a small, poorly ventilated space providing the highest risk. Even among household contacts of active tuberculosis patients, the risk of infection is surprisingly low; the United States Public Health Service (USPHS) reported an approximate 30 percent incidence of infection in household contacts. In addition, animal and human studies have demonstrated that *M. tuberculosis*

transmission may dramatically decrease within days to weeks of instituting effective treatment.

Medical procedures that generate aerosols of respiratory secretions, such as sputum induction and bronchoscopy, entail significant risk for *M. tuberculosis* transmission unless proper precautions are taken. In addition, transmission has occurred with aerosol generation in association with irrigation of draining wounds and performance of autopsies.

Molecular Epidemiology

Over the past decade, genotyping of *M. tuberculosis* strains has become an increasingly valuable tool in tuberculosis control. Molecular epidemiology has helped to identify unsuspected transmission, determine likely locations of transmission, and measure the extent of transmission. Often traditional contact investigations focus on persons in the household and workplace. Numerous reports describe tuberculosis cases linked through genotyping of *M. tuberculosis* isolates, where detection of transmission was initially missed by conventional contact investigation because the setting was non-traditional. Frequently this type of transmission occurs among members of a "social network" that is centered around a specific activity, including illicit drug use, excess alcohol use, or gambling, or location, such as a homeless shelter, adult entertainment club, or HIV residential care facility. When genotyping detects previously unrecognized transmission in a non-conventional setting, public health interventions to contain and subsequently end the outbreak can be redirected to focus on the social network or location associated with transmission.

PREVENTION AND CONTROL

Prevention and Control Strategies

There are three ordered priority strategies for tuberculosis prevention and control in the United States: (1) identifying and treating persons who have tuberculosis disease; (2) contact investigation—finding persons exposed to infectious tuberculosis patients, evaluating them for *M. tuberculosis* infection and disease, and providing subsequent treatment, if appropriate; and (3) targeted testing—screening populations at high risk for LTBI and progression to tuberculosis disease to detect infected persons and provide treatment to prevent progression to disease.

The first priority of tuberculosis control in the United States is detection and treatment of patients with tuberculosis disease. Diagnosing and reporting a patient with suspected or confirmed tuberculosis triggers several interventions that interrupt transmission. These include placing the patient in respiratory isolation if contagious, starting the patient on tuberculosis treatment, and conducting a contact investigation. Health departments seek to be notified of persons with suspected or confirmed tuberculosis as early as possible and use active and passive methods of case finding to achieve this goal. Details of the diagnosis and treatment of tuberculosis disease are discussed in Chapter 140.

Investigation of contacts of persons with infectious tuberculosis is an essential function of tuberculosis control in the United States and has been identified as the second priority. Among close contacts, approximately 1 to 2 percent will have tuberculosis disease and 31 to 36 percent will have LTBI. Approximately 3 to 5 percent of contacts with newly acquired LTBI will develop tuberculosis within 2 years of infection. Therefore, contact investigations are an effective method for active case finding and identifying persons with LTBI who are also at a high risk of developing tuberculosis disease. State and local public health agencies are responsible for ensuring that contact investigations are conducted effectively and that all exposed contacts are identified, evaluated for tuberculosis infection and disease, and appropriately treated. Consequently, 90 percent of contact investigations in the United States are performed by public health departments.

The third priority for tuberculosis control in the United States is targeted tuberculin testing and treatment of persons with LTBI. The number of persons in the United States with LTBI is estimated at 9.5 to 14.7 million. To continue progress toward the elimination of tuberculosis in the United States, public health programs must devise effective strategies to address the challenge of preventing tuberculosis in this population of infected persons. Guidelines on targeted testing and treatment of LTBI have been published and revised. Those guidelines include recommendations for diagnosis and treatment of LTBI, as well as recommendations for identifying persons and groups to target for testing.

Although prevention and control of tuberculosis in the United States is primarily the responsibility of state and local tuberculosis control programs, rarely are these activities implemented solely by the health department. Patients with tuberculosis disease are usually diagnosed and often treated by private providers. Contacts to infectious cases may also be evaluated and treated by their private physicians or other community providers. Private providers, as well as non-health department community or governmental entities, also screen and treat individuals at high risk for LTBI. However, the health department is responsible for coordination and oversight of these activities to ensure that objectives related to tuberculosis prevention and control are achieved.

Diagnosing Tuberculosis Infection

The Tuberculin Skin Test

The tuberculin skin test (TST) is a major tool for investigating tuberculosis infection. It can be used diagnostically in the individual patient and epidemiologically in the general population. The recommended method for the TST, the Mantoux method, is performed by the intradermal injection of a standardized, stabilized dose of 5 tuberculin units of purified protein derivative (PPD). The extent of induration is measured 48 to 72 hours later. Multiple puncture techniques (e.g., tine test or Heaf test) are not recommended. The interpretation of the TST is based on an individual's epidemiological risk factors

Table 138-2

Criteria for a Positive Tuberculin Skin Test by Risk Group*

Reaction 5 mm of Induration	Reaction 10 mm of Induration	Reaction 15 mm of Induration
Human immunodeficiency virus (HIV)–positive persons	Recent immigrants (i.e., within the last 5 y) from high-prevalence countries	Persons with no risk factors for tuberculosis
Recent contacts of tuberculosis patients	Injection drug users	
Fibrotic changes on chest radiograph consistent with prior tuberculosis	Residents and employees‡ of the following high-risk congregate settings: prisons and jails, nursing homes and other long-term facilities for the elderly, hospitals and other health care facilities, residential facilities for patients with HIV, and homeless shelters	
Patients with organ transplants and other immunosuppressed patients (receiving the equivalent of 15 mg/d of prednisone for 1 mo or more), including those receiving TNF-α antagonists†	Mycobacteriology laboratory personnel	
	Persons with the following clinical conditions that place them at high risk: silicosis, diabetes mellitus, chronic renal failure, some hematologic disorders (e.g., leukemias and lymphomas), other specific malignancies (e.g., carcinoma of the head or neck and lung), weight loss of 10% of ideal body weight, gastrectomy, and jejunoileal bypass	
	Children younger than 4 y of age or infants, children, and adolescents exposed to adults at high risk	

** Modified from American Thoracic Society and Centers for Disease Control and Prevention: Targeted tuberculin testing and treatment of latent tuberculosis infection. MMWR 49(RR-6): 1, 2000.*

† Risk of TB in patients treated with corticosteroids increases with higher dose and longer duration.

‡ For persons who are otherwise at low risk and are tested at the start of employment, a reaction of 15 mm induration is considered positive.

for tuberculosis infection. The 2000 American Thoracic Society (ATS)/CDC guidelines for interpretation of TST results are as follows (Table 138-2): (1) 5 mm induration is considered a positive result for (a) individuals with HIV infection or other comparable immunosuppression (equivalent to receiving 15 mg or greater of prednisone for one month or more), including patients receiving tumor necrosis alpha [TNF-α] antagonists, (b) close contacts to an active tuberculosis case, or (c) patients with a chest radiograph suggestive of prior tuberculosis (e.g., fibronodular) disease (also termed inactive disease)); (2) 10 mm induration is considered a positive result for (a) recent immigrants (within the last 5 years) from high-incidence countries, (b) injection drug users, (c) residents and employees of high-risk congregate facilities such as nursing homes, homeless shelters, or prisons, (e) mycobacterial laboratory personnel, (f) persons with underlying medical conditions such as diabetes, silicosis, end-stage renal disease, certain malignancies, and low body weight (loss of at least 10 percent of ideal body weight), or (g) children younger than 4 years of age and infants, children, or adolescents exposed to adults at high risk; and (3) 15 mm induration is considered a positive result for all others.

In general, a positive TST result is considered to indicate the presence of infection with *M. tuberculosis*. A targeted testing strategy prioritizes those at highest risk for progression to tuberculosis disease if infected and those, who if

they get disease, will experience greater morbidity and mortality. Consequently, testing should be reserved for persons at high risk for LTBI or at high risk to progress to disease based on their epidemiological profile. In the United States it is recommended that persons with positive results receive treatment for LTBI to prevent progression to disease. Thus, an intent to test for LTBI (based on a proper assessment of risk) should indicate an intent to treat (assuming exclusion of medical contraindications to drug therapy) for LTBI when found.

In a number of situations, the TST is neither sensitive nor specific for *M. tuberculosis* infection. A positive TST result is a manifestation of type IV delayed hypersensitivity. Certain biologic conditions, such as viral illnesses, including HIV infection, vaccination, malignancies and other debilitating illness (including advanced tuberculosis disease), and certain medications (e.g., TNF-α antagonists, corticosteroids, and other immunosuppressive drugs), will suppress the type IV response and T-lymphocyte function. In addition, proper application of the TST requires careful attention to technique and interpretation. TST should be performed by well-trained, experienced operators. False-positive test findings can occur for a number of reasons, including cross-reactions caused by non-tuberculous (atypical) mycobacterial infection and bacille Calmette-Guérin (BCG) vaccination.

Interferon-Gamma Release Assays

The QuantiFERON-TB Gold (QFT-G, Cellestis Ltd., Carnegie, Victoria, Australia) test is a blood assay for *M. tuberculosis* (BAMT). This in vitro test detects the release of interferon-gamma (IFN-γ) from lymphocytes of sensitized persons when their blood is incubated with peptide mixtures simulating two *M. tuberculosis* proteins called ESAT-6 and CFP-10. QFT-G has been approved by the U.S. Food and Drug Administration (FDA) for use as an in vitro aid in diagnosing *M. tuberculosis* infection, including both LTBI and tuberculosis disease. It replaces an earlier version of the test, QuantiFERON-TB (QFT), which used PPD and was indicated solely for the diagnosis of LTBI. Current data indicate that ESAT-6 and CFP-10 are secreted by all *M. tuberculosis* and pathogenic *M. bovis* strains, but are absent from all BCG vaccine strains. These proteins are also absent from commonly encountered non-tuberculous mycobacteria, with the exception of *M. kansasii*, *M. szulgai*, and *M. marinum*. Thus, QFT-G offers the possibility of detecting *M. tuberculosis* infection with greater specificity than has been possible previously with tests that used tuberculin PPD as the tuberculosis antigen.

Although the performance of QFT-G has not been sufficiently evaluated in select populations of interest (e.g., the HIV infected), available data indicate that QFT-G is as sensitive as TST for detection of tuberculosis disease and more specific than TST for detection of LTBI. CDC guidelines for QFT-G recommend that QFT-G can be used in place of TST in all circumstances in which TST is currently used. This includes initial and periodic screening of individuals at risk for *M. tuberculosis* infection and screening of exposed persons in contact investigations.

The performance of QFT-G, in particular its sensitivity and its rate of indeterminate results, has not been determined in persons who, because of impaired immune function, are at increased risk for infection progressing to disease. Conditions or treatments known or suspected to decrease responsiveness to the TST (see the tuberculin skin test above) also might decrease production of IFN-γ in the QFT-G assay. Consequently, as with a negative TST result, negative QFT-G results alone might not be sufficient to exclude *M. tuberculosis* infection in these persons. In addition, only limited data document the performance of QFT-G in children aged less than 17 years; a subset of this population, children younger than 5 years old, is also at high risk for rapid progression from infection to disease, including meningitis and miliary tuberculosis. With TST or BAMT, persons who have a negative test result can still have LTBI. Those who have a negative result, but who are likely to have LTBI and are at greater risk for severe illness or poor outcomes if TB disease occurs, such as persons with HIV infection, should be considered for LTBI treatment and close monitoring for disease.

QFT-G represents one type of IGRA. The other type of assay, called Elispot, enumerates individual lymphocytes producing IFN-γ after peripheral blood mononuclear cells are incubated with similar antigens. Although a commercial Elispot test for the diagnosis of tuberculosis infection exists (T-SPOT, Oxford Immunotech, Oxford, UK), it has not been reviewed or approved by the FDA for use in the United States.

BCG Vaccination

Two methods have been used for tuberculosis prevention: BCG vaccination and isoniazid therapy for LTBI. BCG is a live, attenuated bacterial vaccine that has been evaluated extensively. In 1974 BCG was incorporated into the WHO's Expanded Program of Immunization and BCG is thought to be one of the most commonly administered vaccines in the world. The World Health Organization recommends administering BCG once at birth in endemic countries. There has been some concern about vaccinating congenitally HIV-infected infants, and symptomatic infants with AIDS should not be vaccinated. In immunocompetent persons, however, except for occasional local reactions, BCG's toxicity is minimal.

In controlled trials, the efficacy of BCG vaccination as measured by case reduction has varied from 0 percent to greater than 80 percent. In most trials, the incidence of miliary and meningeal tuberculosis in children has been greatly reduced. There are many hypotheses for variations in the efficacy of case reduction. These include flaws in study design, differences in vaccine potency based on the BCG strain used, heterogeneity in virulence of *M. tuberculosis* strains encountered in various geographic regions, differences in nutritional status and host (genetic) susceptibility of the population vaccinated, and geographic variability in environmental mycobacterial strains that may mask vaccine effect. In a

recent study, the vaccine's protective effect against tuberculosis disease has been shown to be persistent, up to 60 years in duration.

The vaccine generally converts an individual's TST result to positive, at least in the short term; however, the TST response has been somewhat variable with different vaccines and in different individuals and it correlates poorly with vaccine effectiveness. BCG may therefore limit the diagnostic value of the TST in certain circumstances. BCG has not been used in the United States because the original studies did not demonstrate efficacy and its use is not justified because of the low incidence of tuberculosis. BCG has been most useful in areas of the world where the case rate and new infection rate remain high.

Treatment of LTBI

The principal preventive tool in the United States has been treatment of LTBI with isoniazid. In the 1950s, when isoniazid became available as an inexpensive, bactericidal, and relatively nontoxic drug for the treatment of tuberculosis disease, controlled trials were instituted to determine its efficacy for the treatment of LTBI. In more than 70,000 patients, the USPHS and others consistently demonstrated a 60 to 70 percent case reduction rate attributable to isoniazid therapy. Follow-up for as long as 15 years confirmed the long-term protection isoniazid provides against progression to disease.

Concern regarding toxicity, especially hepatotoxicity, and the need for adherence to a prolonged course of therapy have limited isoniazid therapy's effectiveness as a public health intervention. Older studies revealed that isoniazid-associated liver injury occurred in almost 1 percent of patients, and deaths secondary to isoniazid-induced liver injury were reported. More recently, however, public health clinics in Seattle and San Diego reported incidences of hepatotoxicity of 0.1 and 0.3 percent, respectively, among over 14,000 patients treated. There were no deaths reported and only one hospitalization. Despite the low incidence of liver injury, completion rates for 6 months of therapy were below 65 percent in both reports.

The preferred isoniazid regimen is 9 months of daily therapy for all groups of patients, including those with HIV infection, those with a chest radiograph suggestive of prior tuberculosis disease (inactive tuberculosis), and children. Six months of treatment is considered an acceptable alternative for immunocompetent adults without evidence of prior tuberculosis on chest radiograph, but this shorter duration is felt to be less effective based on existing data (Table 138-3). Clinical monitoring, on a monthly basis at minimum, is recommended for all patient receiving isoniazid. Routine transaminase monitoring should be reserved for individuals at particular risk for hepatotoxicity including those who are pregnant or in the immediate postpartum period (first 3 months) or those with HIV infection, a history of liver disease, a history of excess alcohol use, or other risks for liver disease.

Initial studies done in HIV-infected patients suggested that the combination of daily rifampin and pyrazinamide for 2 months (called 2RZ) was equally efficacious and safe for the treatment of LTBI when compared with 6 or 12 months of isoniazid. Subsequently, as this regimen came in to general use, multiple hospitalizations and deaths resulting from hepatoxicity were reported. A follow-up study determined that the rate of severe toxicity, defined as hospitalization or death, due to the combination of rifampin and pyrazinamide for 2 months was on the order of 1 per 1000. ATS and CDC now recommend that the combination of rifampin and pyrazinamide should generally not be offered to persons with LTBI.

Table 138-3

Drug Regimens for Treatment of Latent Tuberculosis Infection (LTBI)*

Drugs	Months of Duration	Interval	Minimum Doses	Rating (Evidence)†	
				HIV−‡	HIV+
Isoniazid	9	Daily	270	A (II)	A (II)
		Twice weekly	76	B (II)	B (II)
Isoniazid	6	Daily	180	B (I)	C (I)
		Twice weekly	52	B (II)	C (I)
Rifampin	4	Daily	120	B (II)	B (III)

** The combination of rifampin and pyrazinamide had been recommended for the treatment of latent tuberculosis infection in the publication Targeted Tuberculin Testing and Treatment of Latent Tuberculosis Infection (*MMWR *49(RR-6):1, 2000.), but this regimen is generally not recommended for use based on subsequent reports of severe hepatotoxicity (Update: adverse event data and revised American Thoracic Society/CDC recommendations against the use of rifampin and pyrazinamide for treatment of latent tuberculosis infection—United States, 2003. MMWR 52:735, 2003).*

† Ratings are based on modification of US Public Health Service rating system as described in Targeted Tuberculin Testing and Treatment of Latent Tuberculosis Infection (MMWR 49(RR-6): 1, 2000.). A = preferred, should generally be offered; B = alternative, acceptable to offer; C = offer when preferred or alternative regimens cannot be given; I = at least one randomized trial with clinical end points; II = clinical trials that either are not randomized or were conducted in other populations; III = expert opinion.

‡ HIV− = human immunodeficiency virus negative; HIV + = human immunodeficiency virus infected.

For contacts exposed to isoniazid-resistant, rifampin-susceptible tuberculosis patients, rifampin (4 months duration) can be used. It is important to note that rifampin and a closely related medication, rifabutin, interact with protease inhibitors and non-nucleoside reverse transcriptase inhibitors that are used to treat HIV. Consultation with an expert familiar with both HIV infection and tuberculosis treatment is recommended in this situation.

For MDR tuberculosis exposures, the selection of medication should be based on the drug susceptibility test results of the source patient and the likelihood of disease progression. If the source isolate is susceptible, some experts have recommended the use of pyrazinamide and ethambutol or pyrazinamide in combination with a fluoroquinolone. Subsequent reports have described toxicity and poor tolerance of these recommended regimens. If the exposed contact cannot tolerate a combination of medications, treatment with a fluoroquinolone alone may be considered. Data on the efficacy of these regimens are not available, however.

ACKNOWLEDGMENTS

The authors would like to thank the CDC Division of Tuberculosis Elimination Surveillance Team for providing their analysis of the 2004 national surveillance data, and the staff of local and state health departments throughout the United States who collect and report the national surveillance data. The authors also acknowledge Drs. Ida Onorato and Renee Ridzon, who co-authored the previous edition's version of this chapter, which was used as a foundation for the current chapter. Some original contributions from these authors have been retained in the current chapter.

The Microbiology, Virulence, and Immunology of Mycobacteria

Jennifer A. Philips • Eric J. Rubin

Tuberculosis (TB) remains a leading killer, in part because it is still a diagnostic and treatment challenge. Although molecular details underlying bacterial pathogenesis and host response are emerging, the picture remains incomplete. Newer culturing systems and molecular techniques have the potential to improve the speed and certainty with which a diagnosis can be made, but they have not yet replaced conventional tuberculin skin testing, smear, culture, or antibiotic sensitivity testing, all of which remain imperfect diagnostic tools. Furthermore, development of a much-needed vaccine is still a formidable task. Thus, for the clinician in low- prevalence areas, TB often presents a challenge both diagnostically and therapeutically, while the vast burden of disease exists in settings where resources are lacking and access to emerging technology is limited.

TUBERCULOUS AND NONTUBERCULOUS MYCOBACTERIA

The genus *Mycobacterium* contains a large number of species which span the spectrum from pathogen to commensal. The group of closely related species that constitute the *Mycobacterium tuberculosis* complex (*M. tuberculosis, M. bovis*, *M. africanum*, *M. microti*, and *M. canetti*) is composed of obligate pathogens. Nontuberculous mycobacteria (NTM) can be distinguished based upon their pigment production, growth rates, and biochemical properties (Table 150-1). Clinically, species identification helps to determine the likelihood that an organism is a true pathogen. For example, rapidly growing mycobacteria (e.g., *M. chelonae*) are associated with acute infections such as abscesses, more slowly growing organisms (e.g., *M. kansasii*) generally cause lung disease, and other commensals (e.g., *M. gordonae*) rarely cause disease but can contaminate clinical specimens. Infection with NTM, in particular members of the *M. avium* complex (MAC), is associated with immune-compromised states. For example, MAC often causes systemic infection in the setting of profound defects in cell-mediated immunity as seen in advanced acquired immunodeficiency virus (AIDS). In contrast to *M. tuberculosis*, there is little evidence of person-to-person spread of NTM, and instead, NTM are likely acquired from environmental sources. For example, rapidly growing mycobacteria have been associated with nosocomial transmission via infected instruments or solutions. Because NTM have different antibiotic susceptibility than *M. tuberculosis*, the identification of the organism helps

Table 139-1

Classification of the Nontuberculous Mycobacteria Recovered from Humans

Clinical Disease	Common Etiologic Species	Features of the Common Species		Unusual Etiologic Species
		Geography	Morphologic Features*	
Pulmonary disease	1. *M. avium* complex	Worldwide	Usually not pigmented; slow growth (> 7 d)	1. *M. simiae* 2. *M. szulgai*
	2. *M. kansasii*	USA, coal mining regions, Europe	Pigmented; often large and beaded on acid-fast stain	3. *M. fortuitum* 4. *M. celatum*
	3. *M. abscessus*	Worldwide but mostly USA	Rapid growth (<7 d); not pigmented	5. *M. asiaticum* 6. *M. shimodii*
	4. *M. xenopi*	Europe, Canada	Slow growth, pigmented	7. *M. haemophilum*
	5. *M. malmoense*	UK, northern Europe	Slow growth, not pigmented	8. *M. smegmatis*
Lymphadenitis	1. *M. avium* complex	Worldwide	Usually not pigmented	1. *M. fortuitum*
	2. *M. scrofulaceum*	Worldwide	Pigmented	2. *M. chelonae*
	3. *M. malmoense*	UK, northern Europe (especially Scandinavia)	Slow growth	3. *M. abscessus* 4. *M. kansasii* 5. *M. haemophilum*
Cutaneous disease	1. *M. marinum*	Worldwide	Photochromogen; requires low temperatures (28–30° C) for isolation	1. *M. avium* complex 2. *M. kansasii* 3. *M. nonchromogenicum*
	2. *M. fortuitum* 3. *M. chelonae* 4. *M. abscessus*	Worldwide, mostly USA	Rapid growth, not pigmented	4. *M. smegmatis* 5. *M. haemophilum*
	5. *M. ulcerans*	Australia, tropics, Africa, SE Asia	Grows slowly, pigmented	
Disseminated disease	1. *M. avium* complex	Worldwide	Isolates from patients with AIDS unusually pigmented (80%)	1. *M. abscessus* 2. *M. xenopi* 3. *M. malmoense*
	2. *M. kansasii*	USA	Photochromogen	4. *M. genavense*
	3. *M. chelonae*	USA	Not pigmented	5. *M. simiae*
	4. *M. haemophilum*	USA, Australia	Not pigmented; requires hemin, often low temperatures, and CO_2 to grow	6. *M. conspicuum* 7. *M. marinum* 8. *M. fortuitum*

** Photochromogen: isolate is buff-colored in the dark turns yellow with brief exposure to light.*

guide antibiotic choices while awaiting drug susceptibility testing.

In addition to species distinctions, there are also differences among *M. tuberculosis* strains. Strains can be differentiated by methods that rely on highly variable genomic sequences or the distribution of mobile genetic elements (insertion sequences). Some strains, such as the W/Beijing strain, appear to be spreading more widely, suggesting that they have characteristics mediating increased transmission.

HOST DETERMINANTS OF DISEASE

The most striking feature of TB is the ability of disease to remain latent for as long as decades. While approximately 95 percent of patients infected with *M. tuberculosis* do not develop acute disease upon infection, most (perhaps all) patients are unable to eradicate infection even in the presence of a normal immune system. Because organisms are inaccessible during the latency period, our understanding of this state is

necessarily limited, but it is clear that the immune response is intimately involved in maintaining latency. For example, patients with human immunodeficiency virus (HIV) and other compromised states are highly susceptible to both primary infection and reactivation of latent TB.

While the determinants of the immune response remain poorly understood, the macrophage is unquestionably important in controlling infection, although ultimately inadequate at eradicating it. The initial interaction between bacteria and macrophages likely occurs through innate "pattern recognition receptors" such as Toll-like receptors, DC-SIGN, complement receptors, and mannose receptors. Bacteria are taken up into the macrophage phagosome, a compartment that ordinarily becomes acidified and fuses with lysosomes. However, the phagosome containing mycobacteria do not acquire the proton pump required for acidification, and the internalized bacteria are not exposed to mature lysosomal enzymes. Therefore, mycobacteria persist and grow within this specialized structure, an environment that may limit antigen presentation and protect them against immune-mediated killing mechanisms.

Additional effectors play an important role in controlling infection. Animal models of TB have shown that both CD4+ and CD8+ Tcells are required for protection against disease, an observation borne out clinically in patients who lack adequate T-cell function. At least in part, T cells function to activate infected macrophages, making them more potently bactericidal. Several cytokines that mediate the interaction between T cells and macrophage are important. Chief among these is interferon-γ (IFN-γ). Mice lacking this signaling molecule die rapidly of *M. tuberculosis* infection, while children who lack the IFN-γ receptor develop serious infections with mycobacteria that rarely cause disease in normal hosts. Similarly, defects in interleukin (IL)-12, its receptor, or the downstream intracellular signaling mediator STAT1 lead to abnormal susceptibility to mycobacterial infection. Tumor necrosis factor-α (TNF-α) is also crucial in host immunity as patients who receive infliximab are uniquely susceptible to reactivation of TB. Other TNF-α inhibitors may also increase risk but appear to do so to a lesser degree. These cytokines result in the production of nitric oxide and the induction of apoptosis in infected macrophages, both of which help control mycobacterial growth. However, additional pathways and effectors are also likely to play a role.

It remains unclear how the immune system recognizes mycobacteria. Although several potent T-cell antigens and immunogenic mycobacterial lipids have been described, none are individually protective in model systems. Therefore, we currently lack good markers of a protective immune response, and, likewise, have a limited understanding of the determinants that define host susceptibility. Aside from the rare genetic diseases described above, several common allelic variants may influence the risk of developing active infection. For example, genes involved in antigen presentation or modulating macrophage function may have some effect in human populations. Likewise, genetic studies in mice suggest that Ipr1 and LRG-47 are strong modulators of disease, but this is yet to be confirmed in human studies. Currently none of these markers appear to have strong enough predictive power to be clinically useful.

BACTERIAL DETERMINANTS OF DISEASE

Mycobacteria are quite distantly related to most other pathogens. Members of this genus have an unusual lipid-rich cell wall that seems vital for bacterial survival. These bacteria synthesize distinctive long chain fatty acids (mycolic acids). The presence of these and other associated lipids has important implications for disease and its treatment. The cell wall represents a barrier to diffusion and is likely responsible for the observation that few routinely used antibiotics have significant activity against mycobacteria. In addition, cell wall lipids play an integral role in interaction with the host. For example, a complex lipid (phthiocerol dimycoserate) is required for bacterial growth in the lungs of mice. Likewise, modification of mycolic acids and production of specific glycopeptolipids modulate mycobacterial virulence, although the molecular mechanisms by which these lipids exert their effects are unknown.

Lipids, of course, are not the only determinants of mycobacterial virulence. In fact, sequencing of the complete mycobacterial genome has provided an entire catalogue of potential virulence factors. Unfortunately, as with all complete genomes to date, the function of many of the potential genes is unknown and thus their contribution to virulence mechanisms remains obscure. The genome sequence has, however, served as a starting point for many experimental investigations. For example, it has provided a direct genomic comparison between the avirulent vaccine strain, bacille Calmette-Guérin (BCG), and *M. tuberculosis*. Although there is considerable sequence identity between these strains, several genomic regions are deleted in *M. bovis*-BCG. Among these is a region that encodes two secreted proteins (ESAT-6 and CFP-10) and several associated proteins that appear required for their secretion. Deletion of this region in an otherwise wild type strain results in marked attenuation. At this point, several other bacterial factors have been identified that may play an important role in pathogenesis, but details regarding how they function to coordinate bacterial survival remains poorly understood.

DIAGNOSIS OF TUBERCULOSIS

Indirect Methods

Infection with *M. tuberculosis* can be detected by direct or indirect methods. Indirect methods rely on measuring host responses to infection and, at least as currently implemented, cannot distinguish between active and latent infection. Direct

methods, which are insensitive, are only useful to detect active infection.

There is no gold standard to detect latent infection. Evidence of infection can be obtained by detecting a delayed type hypersensitivity response to protein derivative (PPD). However, PPD is a crude mix of *M. tuberculosis* antigens that can also elicit responses due to prior vaccination with *M. bovis*-BCG or exposure to NTM, thus limiting its specificity. Unfortunately, the test also cannot rule out active infection, as only 75 to 90 percent of patients with active TB are positive, and the sensitivity drops in patients with underlying immunosuppression.

Newer diagnostic tests, such as QuantiFeron-TB Gold or T Spot-TB, measure release of IFN-γ from sensitized lymphocytes *in vitro*. These tests have enhanced specificity because they selectively detect responses to CFP-10 and ESAT-6, antigens secreted by *M. tuberculosis* that are not present in BCG, hence diminishing false positives due to prior BCG vaccination. In addition, most NTM do not have antigens that generate cross-reactivity, with the possible exceptions of *M. kansasii*, *M. szulgai*, and *M. marinum*, perhaps making the test more specific in low-prevalence areas as well. Both tests are promising in their ability to discriminate latent TB infection from prior BCG vaccination and may also be more sensitive in detecting active TB. Therefore, in countries with adequate resources, QuantiFeron-TB Gold or T Spot-TB may ultimately replace skin testing in the diagnosis of latent TB infection while also serving as an adjunct in the diagnosis of active TB.

Direct Microscopic Examination

Direct examination of specimens by means of an acid-fast stain such as Ziehl-Neelsen or Kinyoun provides supportive evidence of mycobacterial disease weeks before the culture and identification may be available. In addition, the presence of sufficient numbers of bacteria to be seen on direct smear correlates with infectivity. The term *acid fast* refers to the fact that dilute acids fail to remove basic dyes such as carbolfuchsin from the mycobacterial cell wall, owing to its lipid-rich complex structure. Although microscopic examination is rapid, simple, and economical, it is relatively insensitive, requiring more than 10,000 bacilli per milliliter to detect acid-fast bacilli (AFB). The sensitivity can be improved with a fluorescent (auramine) stain and sputum concentration. Nonetheless, smear still has a low sensitivity, failing to detect up to 30 percent of pulmonary TB when compared to culture.

Conventional Culture Techniques

Although culture remains the gold standard, it is also imperfect. It is generally able to detect 100 bacilli/ml of sputum, but results take weeks and approximately 20 percent of clinically suspected pulmonary *M. tuberculosis* infections remain culture-negative. The false-negative rate is likely to be even higher in extrapulmonary disease, though lack of a gold standard makes this difficult to estimate. Growth on solid media (such as Lowenstein-Jensen or Middlebrook agar) takes 3 to 6 weeks. Broth detection systems are designed to detect early changes in the media due to growth of bacteria, such as consumption of oxygen, reduction of tetrazolium salts, production of carbon dioxide, or changes in pressure. These systems can provide a more rapid turnaround time, often becoming positive after 1 to 2 weeks.

Since solid and liquid media will support growth of most NTM as well, once an isolate is recovered further testing is required for species identification. Molecular approaches have significantly speeded this process. For example, AccuProbe (Gen-Probe) is able to make species identification within a day by hybridizing a single-stranded, chemiluminescent DNA probe to ribosomal RNA, which differs between species. Commercially available probes can identify *M. tuberculosis* complex, *M. avium* complex, *M. gordonae*, and *M. kansasii*.

Certain NTM exhibit specific growth characteristics that aid in their identification. For example, specimens obtained from skin and soft-tissue infections are incubated at 28 to 32°C, in addition to the standard temperature of 35 to 37°C, because common soft-tissue pathogen, such as *M. ulcerans*, *M. marinum*, and *M. chelonae*, may only grow at lower temperatures. If an AFB culture becomes positive in several days, the species is invariably a rapid grower, which is most commonly *M. fortuitum*, *M. abscesses*, or *M. chelonae*.

Techniques for the Rapid Diagnosis of Tuberculosis

Nucleic acid amplification (NAA) tests have improved the identification of *M. tuberculosis*, but have not obviated the need for smears or cultures. These tests detect mycobacterial nucleic acids directly from clinical respiratory specimens and can be processed within several hours. In other words, NAA tests can quickly determine whether the AFB seen on smear is a member of the *M. tuberculosis* complex prior to culture. Unfortunately, these tests have been relatively insensitive on smear negative samples, so that, currently, the main advantage afforded by NAA testing is enhanced diagnostic certainty and the ability to confirm *M. tuberculosis* infection weeks before cultures are available.

Given the low sensitivity of smear, it would be advantageous to be able to detect *M. tuberculosis* in smear-negative samples as well. Modified direct amplification tests with enhanced sensitivity may be able to do this. An alternative approach involves detecting the presence of mycobacteria in sputum samples by infecting them with mycobacteriophages. The number of phages produced reflects the number of mycobacteria in the original specimen. Phage technology, commercially available as FAST Plaque TB, used in combination with smears, may confirm the presence of *M. tuberculosis* in 80 to 90 percent of culture-positive specimens, although it has also been reported to have variable results. Although NAA and phage technology have the potential to improve detection of mycobacteria in smears, neither can replace conventional smear and culture, which provide information on infectivity, response to therapy, and antibiotic susceptibility.

DRUG SUSCEPTIBILITY TESTING

Drug susceptibility testing has become increasingly important with the emergence of multidrug-resistant TB (MDR-TB), in which isolates exhibit resistance to at least isoniazid and rifampin, two of the first-line antimycobacterials. Unfortunately, conventional drug susceptibility testing takes months, as the bacteria have to grow initially in culture and then be subjected to subculturing in the presence of antibiotics. This period can be reduced by the liquid medium–based methods, but these are also costly and require sophisticated equipment and trained personnel. Therefore, more rapid methods to detect antibiotic susceptibility, particularly those that could be employed in resource-limited settings, are needed.

A number of molecular strategies have been developed that are designed to detect mutations that are commonly associated with antibiotic resistance. In the case of rifampin, approximately 95 percent of all resistant strains contain mutations within the core region of the *rpoB* gene, so detecting the common mutations can identify most resistant isolates. Moreover, since rifampin resistance is often a marker of other drug resistance, this allows a rapid method to detect suspected MDR cases. A variety of molecular strategies are feasible, but a limitation of this approach is that only the most common mutations are sought, so there is a failure to detect rare or unknown mutations, making conventional phenotypic testing a necessary adjunct. Nonetheless, in the future such genotypic tests may be helpful in providing rapid antibiotic sensitivity information in cases where MDR-TB is suspected. Unfortunately, most MDR cases occur in parts of the world least able to afford such tests.

There are several emerging strategies to rapidly determine drug susceptibility that are more amenable to implementation in resource-poor settings. In all cases, the goal is to detect viable bacteria in the presence of antibiotics by some means other than growth. This can be achieved by assessing a change in the color of the medium due to bacterial metabolism as indicated by colorimetric redox indicators. Alternatively, phage technology can determine the presence of viable bacteria based upon their ability to support infection by mycobacteriophages. These are potentially affordable assays that do not require highly skilled personnel or expensive reagents. Although the experience with these tests remains limited, phage-based assays appear sensitive and specific for detecting rifampin resistance in low-resource reference laboratories.

PREVENTION

The widely used vaccine, BCG, is an attenuated strain of *M. bovis* that was derived fortuitously during serial passage in the laboratory. Although the vaccine may have some efficacy in preventing severe disease in children (particularly tuberculous meningitis), it does little if anything to diminish pulmonary disease in adults. Development of an improved vaccine, however, remains a formidable challenge. First, the vaccine needs to generate long-lived protective immunity, but the determinants of such immunity are poorly understood. In fact, infection with *M. tuberculosis* itself may fail to generate protective immunity, as at least some individuals are susceptible to reinfection. Similarly, in mice treated for an episode of TB, immunity is inadequate to prevent subsequent reinfection and disease. Thus, there is reason to think that a vaccine will have to do a better job in eliciting immunity than natural infection. Ideally, a vaccine should also generate protective immunity in patients co-infected with HIV and must be safe in populations of immunocompromised individuals. In addition, as the vaccine will be used in areas with a high rate of existing latent TB infection, it should not generate an overly exuberant inflammatory response that could worsen underlying disease.

Several features of BCG may explain why it is a suboptimal vaccine against *M. tuberculosis*: it is derived from a different species, has numerous changes from the parent strain, and fails to make certain T-cell antigens. Hence, one strategy has been to genetically engineer a new attenuated strain from *M. tuberculosis*, while attempting to maintain its antigenicity. Directed mutations have been made that render the strain defective for growth in the absence of certain nutrients, such as leucine, which make it attenuated for growth in animals. The hope is that this will prove more effective than the "overly attenuated" BCG. Alternatively, it may be possible to improve BCG, for example, by restoring secretion of known antigens such ESAT-6. The complication of this approach is that, at least for ESAT-6, this is also a virulence factor, so immunity may be improved but potentially at the cost of safety.

There are reasons to think that *M. tuberculosis* has active mechanisms that undermine the establishment of adequate immunity, for instance by blunting cytokine signaling and inhibiting antigen presentation. Thus, an alternative approach has been to deliver immunodominant antigens, for instance a fusion of ESAT-6 and Ag85B, using a DNA delivery system such as adenovirus, either as a priming vaccine or to boost immunity from prior BCG vaccination. It might also be possible to improve the visibility of antigens present in BCG to the host immune system. Because the bacteria are generally sequestered in the phagosomal compartment and do not induce significant amounts of apoptosis of host cells, there may be relatively poor presentation of antigens via major histocompatibility complex (MHC) class I. A clever strategy has been to modify BCG such that it lyses the phagosomal membrane and generates enhanced cellular apoptosis. This appears to generate a more robust protective immune response without compromising safety. Although our improved molecular understanding has provided several avenues to explore for improved vaccines, the logistical barriers are still substantial. In particular, since we lack good markers of protection and only a fraction of infected people develop active disease over decades, efficacy studies will require following large numbers of patients for many years.

TREATMENT

Current treatment guidelines for TB require multiple antibiotics for a minimum of 6 months. The standard regimen of INH, rifampin, pyrazinamide, and ethambutol is long and complex, often complicated by side effects or drug interactions, resulting in a substantial rate of treatment failure. These drugs each function by distinct mechanisms—INH inhibits mycolic acid synthesis in the cell wall, rifampin inhibits RNA synthesis, while pyrazinamide targets the cell membrane. All of the drugs are most active against replicating bacteria. With the exception of rifampin, they have limited activity against non-growing bacilli which makes them ineffective at eliminating dormant bacteria.

Despite the limitation of current therapy, no medication with a new mechanism of action has been brought to market for TB therapy in over 40 years. However, a number of antibiotics, developed against other bacteria, have activity against *M. tuberculosis*, and there is a concerted effort to identify novel therapeutics, some of which are entering clinical trials. Among already available antibiotics, fluoroquinolones, in particular moxifloxacin and gatifloxacin, have potent anti-TB activity. The bactericidal and sterilizing activity of moxifloxacin suggest that it may have a role as a first-line drug with the potential to shorten treatment. However, given the widespread use of fluoroquinolones for other infections, there is concern that emerging antibiotic resistance may limit their use. Linezolid also has antituberculous activity and has been used in combination therapy for the treatment of MDR-TB, although the poor tolerability with prolonged use limits its utility in this context.

There are two strategies for identifying new drugs. The first involves the identification of potential drug targets—for example, molecules that are essential for bacterial growth. If the activity of these molecules can be assayed *in vitro*, then it is possible to screen for small molecules that inhibit the activity. The advantage of this approach is that the drug target is known, greatly aiding modifications of lead compounds. The limitation, however, is that although the compound may inhibit the desired activity *in vitro*, it does not guarantee that it will be able to cross the microbial cell wall or bypass bacterial defenses such as degradative enzymes or efflux pumps. Moreover, it is impossible to identify pro-drugs, which require activation by the bacterial cell.

The alternative approach involves identifying compounds that inhibit microbial growth. This straightforward approach identifies molecules with antimicrobial activity, but in the past, it has been difficult to subsequently determine the drug target. The ability to make structure-based modifications, which is usually necessary to improve activity and minimize toxicity, is then limited. However, a promising new anti-TB agent was identified using this strategy, and the putative target was quickly found by use of modern genomics. In this case, a library of diarylquinolone compounds was screened, identifying a bactericidal agent (R207910) with broad activity against mycobacterial species. Whole genome sequencing of resistant isolates quickly established the molecular lesion responsible for resistance, thus identifying the putative target. This drug appears to be effective in animals and well tolerated in humans.

Other drugs reported to be in development include PA-824, a nitroimidazopyran that inhibits protein and cell wall lipid synthesis. It exhibits activity against both replicating and static *M. tuberculosis*, and has sterilizing effects similar to the combination of INH and rifampin. A compound from Otsuka Pharmaceutical Group and LL-3858 of Lupin Laboratories are also under investigation, although there is little publicly available information. Although the clinical efficacy and safety of newer agents awaits further trials, the identification of novel drugs highlights the promise of functional genomics, structure-based drug design, and combinatorial chemistry for improved TB therapeutics.

Clinical Presentation and Treatment of Tuberculosis

Mary Elizabeth Kreider • Milton D. Rossman

Tuberculosis is a disease that has afflicted humankind throughout recorded history. Spinal lesions that are highly suggestive of tuberculosis have been observed in a skeleton recovered from a grave near Heidelberg that dates from 5000 B.C.; a skeleton excavated from the Arene Candide Cave in Liguria, Italy that dates from 4000 B.C.; and similarly ancient graves in Denmark and the Jordan Valley. Mycobacterium tuberculosis DNA has been recovered from a pre-Columbian mummy from Peru. The earliest records that are consistent with tuberculosis are Egyptian wall paintings that depict typical hunchback deformities and correlate with the findings of spinal tuberculosis in mummies. Hippocrates not only described the condition, but also named it "phthisis," which means to melt or waste away. Aristotle noted its contagious nature, but it was not until Koch discovered the tubercle bacillus in 1882 that the etiologic agent was identified. Today tuberculosis describes an infection in humans that is caused by either *Mycobacterium tuberculosis* or *Mycobacterium bovis*. Infections caused by other mycobacteria should be referred to as diseases caused by each specific mycobacterium. Despite the discovery of the cause of tuberculosis and the development of effective chemotherapy in the 1950s, tuberculosis continues to be a major pulmonary pathogen and is a leading cause of infectious death in adults worldwide.

The pathogenesis of tuberculosis is reviewed in detail elsewhere in this volume and is only briefly summarized here. The lung is the site of entry in the overwhelming majority of cases of tuberculosis. After inhalation, the tubercle bacillus sets up a localized infection in the periphery of the lung where it is deposited. The first stage of infection typically results in few or no clinical signs or symptoms. In 4 to 6 weeks the host immune system develops a hypersensitivity response to the bacillus and at this time mild fever and malaise may develop, and occasionally other hypersensitivity manifestations are noted.

In the preponderance of patients, the process is contained by local and systemic defenses and no further evidence of disease develops. The subpleural location of the initial infection occasionally leads to a rupture into the pleural space leading to tuberculous pleurisy with effusion. Commonly, the infection can also spread locally to hilar lymph nodes, and from there to other areas of the body. This hematogenous dissemination results in both the pulmonary and extrapulmonary foci that are responsible for the major clinical manifestations of tuberculosis. On chest radiographs this spread is manifested by enlargement of the lymph nodes, with later calcification of both the lymph nodes and parenchymal lesion (the Ghon's complex). Progressive (or reactivation) tuberculosis usually develops after a variable period of dormancy and arises from the sites of hematogenous distribution.

Accordingly, the first infection with tuberculosis frequently is clinically silent or unrecognized. In the majority of patients, the disease remains latent either indefinitely or for many years, and when a breakdown occurs it may be secondary to a decrease in immunity (e.g., the development of cancer, immunosuppressive therapy, etc.).

CLINICAL PRESENTATION

Pulmonary Tuberculosis

The lung is the most commonly affected organ in tuberculosis. In the 2004 CDC surveillance reports, 79.5 percent of the newly diagnosed cases of tuberculosis had lung involvement. Similar rates of pulmonary involvement are found in both immunocompetent and immunocompromised hosts, such as those with human immunodeficiency virus (HIV) infection. Studies from the 1980s to the 1990s suggested that the rates of pulmonary involvement in HIV were 70 to 92 percent. However, these individuals are also more likely to have extrapulmonary disease.

Symptoms and Signs

Given the wide spectrum of lung involvement seen in tuberculosis, ranging from skin positivity with clear x-rays to far advanced disease, a wide range of signs and symptoms can also be seen. Frequently there are minimal symptoms that are fairly non-specific until the disease is far advanced, and these may be attributed to other causes. Symptoms are often divided into two categories: constitutional and pulmonary. The most frequently reported symptoms in studies of active pulmonary tuberculosis include cough (23 to 47 percent), fever (18 to 79 percent), weight loss (7 to 24 percent), and hemoptysis (8 to 9 percent). The frequency of these symptoms differs according to whether the patient has primary tuberculosis or reactivation tuberculosis, with lower frequencies of all symptoms in the primary tuberculosis groups. A classic fever pattern has been described, with a fever that develops in the late afternoon and may not be accompanied by pronounced symptoms. With defervescence (typically at night) sweating occurs—the classic "night sweats." As the infection progresses and the caseation necrosis and liquefaction occur, patients can develop a productive cough often associated with mild hemoptysis. Chest pain may be localized and pleuritic. Shortness of breath typically is due to extensive parenchymal lung disease and is therefore a late manifestation of the infection.

Laboratory Examination

Routine laboratory examinations are rarely helpful in establishing or suggesting the diagnosis. A mild normochromic normocytic anemia may be present in chronic tuberculosis. The WBC count is often normal, and counts over 20,000/μL may suggest another infectious process; however, a leukemoid reaction occasionally may occur in miliary tuberculosis. Other nonspecific tests that may be elevated in active tuberculosis include the sedimentation rate, α_2-globulins, and γ-globulin. On rare occasions, the serum sodium may be depressed owing to inappropriate secretion of antidiuretic hormone. This only occurs in advanced pulmonary tuberculosis.

Radiography

Primary

The most common radiographic appearance of primary tuberculosis is a normal radiograph. Primary tuberculosis parenchymal involvement can happen in any segment of the lung. In the primary infection there is only a slight predilection for the upper lobes. The airspace consolidation (Fig. 140-1) appears as a uniform density with ill-defined

Figure 140-1 Primary tuberculosis: A 31-year-old woman from Taiwan with mild cough and fever. There is an infiltrate in the right lower lobe. PPD was positive. Primary TB must be considered in the differential of this radiograph. *(Courtesy of Wallace Miller, Jr., M.D.)*

borders, and cavitation is rare except in malnourished or other immunocompromised patients. Typically these infiltrates are small and subpleural in location. Hilar or paratracheal lymph node enlargement is a characteristic finding in primary tuberculosis. However, it is most commonly seen in children. Usually, the adenopathy is unilateral. In contrast to lymphadenopathy, infiltrates are seen more commonly in adults with primary TB. Miliary involvement (seen as multiple small nodules) at the onset of disease is seen in less than 3 percent of cases, most commonly in children under 2 to 3 years of age, but can also be seen in adults. Finally, an isolated pleural effusion of mild-to-moderate degree may be the only manifestation of primary tuberculosis.

Reactivation Tuberculosis

Although reactivation tuberculosis may involve any lung segment, the characteristic distribution usually suggests the disease. In 95 percent of localized pulmonary tuberculosis, the lesions are present in the apical or posterior segment of the upper lobes (Fig. 140-2) or the superior segment of the lower lobes. The typical parenchymal pattern of reactivation tuberculosis is of an airspace consolidation in a patchy or confluent nature. Frequently there are increased linear densities to the ipsilateral hilum. As the lesions become more chronic, they become more sharply circumscribed and irregular in contour. Lymph node enlargement is rarely seen. Cavitation can occur in up to 40 percent of cases. These cavities typically have moderately thickened walls, but fewer than 10 percent of cases have air-fluid levels. Cavities are associated with endobronchial spread of the disease. Fibrosis leads to volume loss in the involved lung. The combination of patchy pneumonitis, fibrosis, and calcification is suggestive of chronic granulomatous disease, often tuberculosis.

Computed tomographic images demonstrate small nodules and a cavitary lesion. Sputum cultures were positive for *M. tuberculosis*. *(Courtesy of Wallace Miller, Jr. M.D.)*

Chest Computed Tomography

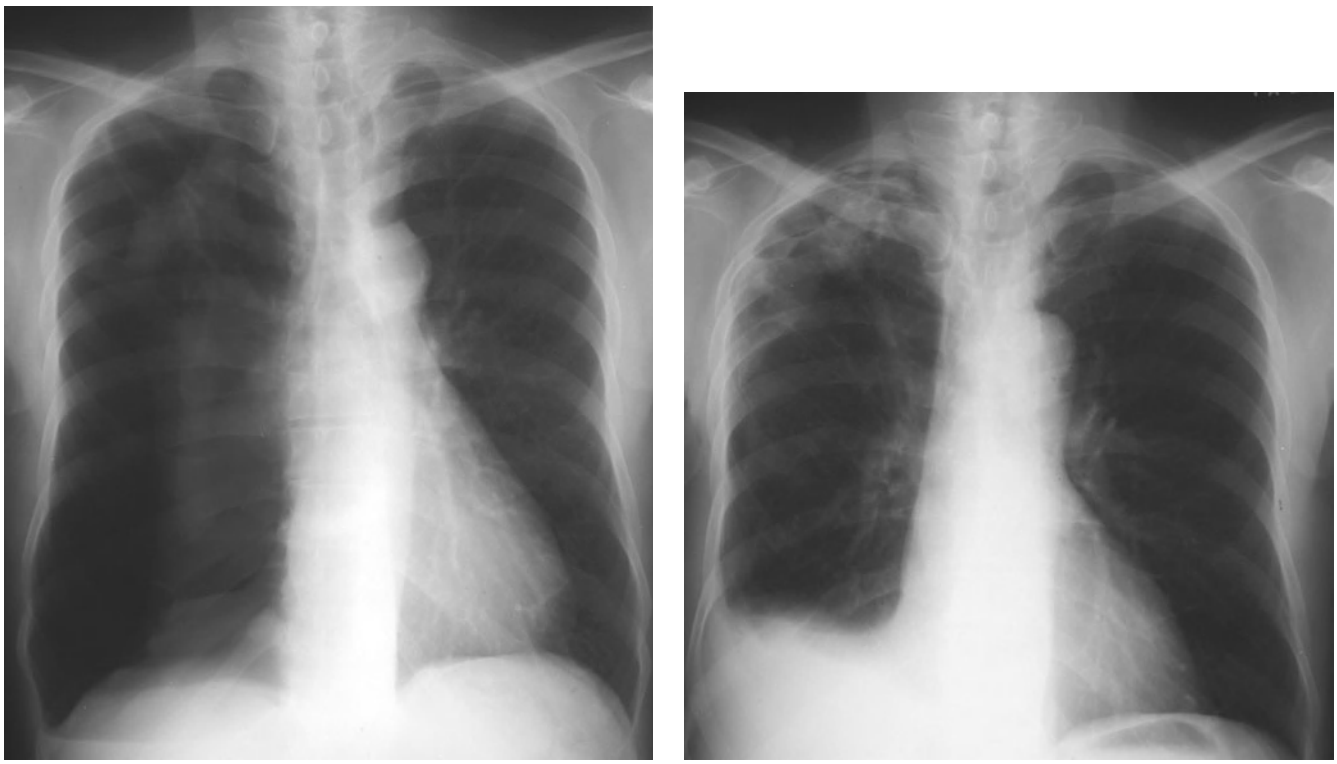
Computed tomography (CT) scans offer a more detailed examination of the parenchyma and the lymph nodes than can be done with plain chest x-ray alone. The chest CT in patients with primary tuberculosis typically demonstrates lobar consolidation in association with mediastinal or hilar adenopathy. The consolidation is usually well defined, dense, homogenous, and confined to a segment or lobe. CT may allow the visualization of tiny cavities that were not recognized on the plain chest x-ray. Reactivation tuberculosis may be characterized by the presence of centrilobular nodules or branching linear structures (tree in bud) with or without bronchial wall thickening, lobular consolidation, cavity formation, bronchiectasis, and/or fibrotic changes. Debate exists over whether CT scans can dependably discriminate active tuberculosis from latent infection. Some authors argue that findings such as the tree in bud and/or areas of centrilobular nodules are more consistent with active disease.

Complications of Pulmonary Tuberculosis

Minor endobronchial disease of the distal bronchi is a frequent occurrence in tuberculosis. Resected lung specimens frequently show either ulceration or stenosis of the draining bronchioles or bronchi. However, significant bronchial stenosis of major bronchi is rare. The same endobronchial processes may result in bronchiectasis due to destruction of the bronchial wall. Bronchiectasis also usually involves the distal airways and has a predilection for the upper lobes. Often this bronchiectasis is associated with little sputum production (dry bronchiectasis) and may manifest itself predominantly as low-grade hemoptysis.

Pneumothorax (Fig. 140-3) is a rare but serious complication of tuberculosis that requires immediate attention. A pneumothorax is believed to occur from subpleural infection rupturing into the pleural space. This may lead to the spread of infection into the pleural space and, if left untreated, can lead to the development of an empyema with subsequent fibrothorax and associated trapped lung. A bronchopleural fistula may persist after a pneumothorax and, especially if untreated, may result in major problems from secondary or superimposed bacterial infection (mixed empyema).

Even if tuberculosis is treated and cured, the destruction of lung parenchyma that occurs during active infection



A *B*

Figure 140-3 Tuberculosis pneumothorax: A 69-year-old patient admitted with spontaneous pneumothorax (*A*). After chest tube was placed and lung re-expanded, new RUL infiltrate was seen (*B*). Bronchoscopy specimens grew out *M. tuberculosis. (Courtesy of Wallace Miller, Jr., M.D.)*

can lead to later complications. Colonization of cavities and areas of bronchiectasis may occur with a variety of infectious agents. Infection with typical respiratory flora can convert "dry" to "wet" bronchiectasis, with frequent exacerbations of purulent sputum production. *Aspergillus* species may commonly colonize and/or infect areas of badly damaged lung. One prospective study in England revealed that 25 percent of clinically healed tuberculosis patients who had residual cavities developed positive precipitins to *Aspergillus* species and 11 percent had demonstrable cavitary "balls," presumed to be aspergillomas. Three years later, these numbers had risen to 34 and 17 percent, respectively.

Hemoptysis can occur in early and late infection. Mild hemoptysis is very frequent in acute infection and may be the first symptom that leads patients to present. Larger volume hemoptysis can occur later in the disease and may be due to rupture of a Rasmussen's aneurysm (a mycotic aneurysm of a branch of the pulmonary). These bleeds are still typically fatal. Even after infection, hemoptysis can occur due to the secondary development of an aspergilloma or exacerbations of bronchiectasis.

Hyponatremia can develop during active tuberculosis due to two processes; the syndrome of inappropriate antidiuretic hormone excretion (SIADH) and a reset osmostat. The SIADH of tuberculosis is similar to all other causes of SIADH and can cause clinical symptoms with renal salt wasting. A reset osmostat, on the other hand, is characterized by decreased serum osmolality without clinical symptoms or salt wasting. Both conditions disappear with control of the infection; however, they should be differentiated from each other since SIADH requires metabolic control.

DIAGNOSIS

Tuberculin skin testing with purified protein derivative (PPD) is the current standard diagnostic test for latent tuberculous infection. In 1891 Robert Koch described a broth culture filtrate of tubercle bacilli. Although it was not the cure for tuberculosis that he first described, he did note that a subcutaneous inoculation of it led to a febrile reaction in patients with tuberculosis that did not occur in healthy individuals. Over time the technique was refined to create a intradermal reaction with a PPD. It cannot distinguish, however, between latent and active infection. False-positive skin reaction can occur with infection with non-tuberculous mycobacterial (NTM) infection or from vaccination with *M. bovis* BCG. False-negatives can occur with anergy due to immunocompromised states or recent or active infection, since it can take up to 10 weeks to develop a typical skin reaction. In 2000 the Centers for Disease Control (CDC), the American Thoracic Society, and the Infectious Disease Society of America issued guidelines for the use of PPD testing as a screening test for latent tuberculous

Table 140-1

Guidelines for the Interpretations of PPD Skin Tests

Induration >5 mm
HIV-positive patients
Recent contracts of active tuberculosis cases
Fibrotic changes on chest x-ray consistent with prior tuberculosis infection
Patients with organ transplants or other chemically immunosuppressed patients (equivalent of >15 mg/day of prednisone for 1 month or more)
Induration >10 mm
Recent immigrants from high prevalence countries
Injection drug users
Residents and employees of prisons, nursing homes, long-Term care facilities, hospitals, and shelters
Mycobacteriology laboratory personnel
Persons with silicosis, diabetes, chronic renal failure, hematological disorder, and specific malignancies (i.e., head and neck cancer), malnourished individuals, and subjects after gastrectomy and jejunoileal bypass
Children younger that 4 or those exposed to adults at high risk
Induration >15 mm
Persons with no risk factors for TB

infection. The guidelines suggest that risk for infection should affect the cutoff used to determine a positive result. Table 140-1 illustrates the suggested cutoff values for patients with different risk factors for the presence of tuberculous infection. Newer techniques for the diagnosis of latent infection are being developed including the QuantiFERON-TB and QuantiFERON-TB Gold tests (Cellestis Limited, St. Kilda, Australia) and the T SPOT-TB test (Oxford Immunotec, Oxford, UK). These tests are based on detection of either interferon gamma by T cells exposed to *M. tuberculosis* antigens or detection of the T cells themselves. The advantages of these tests may include greater specificity (no cross reactivity with BCG and NTM) and improved sensitivity in immunosuppressed patients, and the lack of the need for follow-up in 48 to 72 hours. However, these tests are still expensive and require some laboratory expertise, which may limit their usefulness, especially in the developing world. The utility of these tests is still being evaluated in studies and they are already being widely used in the European Union.

The diagnosis of active tuberculosis often can be very difficult. A confident diagnosis of tuberculosis requires bacteriologic confirmation. It is important to remember that a positive acid-fast smear is not specific for *M. tuberculosis*. Other mycobacteria, both saprophytes and potential pathogens, are usually acid-fast, and can cause similar patterns of pulmonary disease. Thus, culture of *M. tuberculosis* is the only absolute way of confirming the diagnosis.

Freshly expectorated sputum is the best sample to stain and culture for *M. tuberculosis*. Sputum samples 24 hours old are frequently overgrown with mouth flora and are much less useful. The sensitivity of expectorated sputum (by smear, and/or culture) ranges from 34 to 80 percent in studies, and is highest in cavitary disease. If the patient is not spontaneously producing sputum, induced sputum is the next best specimen for study. It can be obtained by having the patient breathe an aerosol of isotonic or hypertonic saline for 5 to 15 minutes. A single induced sputum may have a yield of 64 percent for the diagnosis of tuberculosis by smear and 70 percent by culture. Increasing the number of induced sputum samples obtained to three increases the yield to 91 percent for smear and 99 percent for culture.

In some cases, bronchoscopy may be considered to obtain a sputum sample when none are expectorated or inducible. In 41 patients with proven tuberculosis, cultures of specimens taken during fiberoptic bronchoscopy were positive in 39 (95 percent) cases. Mycobacteria were seen on initial smear in 14 (34 percent) cases, and in eight (20 percent) cases granulomas were seen on biopsy. Similar results have been obtained in another study of 22 patients with proven mycobacterial disease and negative smears prior to bronchoscopy. The local anesthetics used during fiberoptic bronchoscopy may be lethal to *M. tuberculosis*, so specimens for culture should be obtained using a minimal amount of anesthesia. However, irritation of the bronchial tree during the fiberoptic bronchoscopy procedure frequently leaves the patient with a productive cough. Thus, collection of the postbronchoscopy sputum can be another valuable source of diagnostic material. In nine (13 percent) of the preceding cases, the postbronchoscopy sputum was the only source of positive material.

Nucleic acid amplification (NAA) assays have become a useful adjunct in the diagnosis of tuberculosis. These assays amplify *M. tuberculosis* specific amino acid sequences using a probe. The advantage of these assays is that they require a much lower bacillus load to detect the presence of tuberculosis (10 bacillus vs. 5000 to 10,000 bacilli needed for smear positivity and 10 to 100 organisms for positive culture). They are also very specific for MTB. There are new assays that may not only detect *M. tuberculosis,* but also amplify sequences specific for INH and rifampin resistance and thus may provide information on drug sensitivity as well. These sensitivity assays are not yet widely available for clinical practice and their performance in general clinical situations has not been tested. All of these assays are very expensive and require a sophisticated laboratory. Therefore, the exact role of the NAA assays remains in debate. Most authorities agree that they are useful when attempting to confirm that a positive smear is indeed due to *Mycobacterium tuberculosis*. They may also be useful in cases with negative smears but a high clinical

suspicion to suggest the diagnosis while awaiting the culture results.

In 2004, as reported to the CDC, 45 percent of pulmonary cases of tuberculosis were smear positive, 42 percent were negative, and 13 percent were not done or unknown. Sputum culture was positive in 69 percent, negative in 17 percent and unknown in 14 percent of cases. Thus, in a significant number of cases, the diagnosis of tuberculosis had been made in the absence of bacteriologic confirmation. In these cases, the diagnosis was made by a combination of a positive skin test, a compatible chest radiograph, and a therapeutic trial.

Extrapulmonary Tuberculosis

Tuberculosis can spread to almost any organ in the body and is associated with several common extrapulmonary syndromes. In the most recent CDC report of new infection in the United States, the most commonly affected sites outside the lung included lymph nodes (44 percent), pleural space (19 percent), bone and joint infection (11 percent), meninges (6 percent), peritoneal (5.5 percent), genitourinary track (4 percent), miliary (1.8 percent), and other (11 percent). Older studies in the United States show different patterns with a recent decrease in the frequency of genitourinary disease, bone and joint infection, and miliary disease. Other countries display different frequencies largely due to the prevalence of other immune-modulating diseases such as HIV.

Lymphadenitis

Mycobacterial infection involving the cervical lymph nodes, or scrofula, is the most common extrapulmonary manifestation of tuberculosis. Seventy percent of patients with nodal disease have cervical node involvement alone, 7 percent have inguinal involvement, 7 percent have axillary involvement, and 16 percent have multiple nodes involved simultaneously. Only 5 to 10 percent of patients have active pulmonary tuberculosis concomitantly. Therefore, constitutional symptoms such as weight loss, night sweats, or hemoptysis are unusual. There may be an enlarged single node or several nodes matted together. Infrequently these nodes are flocculent or have draining sinuses. Patients with tuberculous lymphadenitis are PPD positive in 74 to 96 percent of cases at the time of presentation. Fine-needle aspiration of the involved node can diagnose tuberculosis as the causative agent by cytology in 83 percent of cases and another 25 percent of those with negative cytology subsequently grow *M. tuberculous* on culture. In negative fine-needle aspirates, excisional biopsy may be necessary to make the diagnosis and rule out other possibilities, including lymphoma. Lymphadenitis is treated medically with antituberculous therapy, as described later in this chapter. Surgical intervention is reserved for situations in which excision is necessary for diagnosis or to remove nodes that remain enlarged after therapy. Medical therapy even for sinus tracks and/or flocculent nodes is undertaken first because of the propensity for the development of further sinuses if surgery occurs while the infection is still active.

Pleural Disease

Pleural disease accounted for 19 percent of cases of extrapulmonary tuberculosis reported to the CDC in 2004. Tuberculous pleural effusions (Fig. 140-4) are usually due to the rupture of subpleural foci of tuberculosis and an accompanying delayed hypersensitivity reaction to a small number of bacilli within the space. The effusions in tuberculosis are typically unilateral and mild to moderate in size. Miliary spread may lead to the development of bilateral effusions. The natural course of a tuberculous pleural effusion is to gradually resorb without treatment and usually resolves with minimal changes on the chest radiograph. However, these patients are at significant risk of reactivation within subsequent years.

The diagnosis of pleural effusions due to tuberculosis can be accomplished by appropriate studies of the pleura and/or pleural fluid in approximately 80 percent of cases. These studies involve evaluation of the character of the fluid, which is an exudate (pleural fluid protein greater than 4 g/dL) with a prominent lymphocytosis and few mesothelial cells. Smears of the fluid usually are negative for tubercle bacilli, but positive cultures are found in more than half of the cases. Repeated thoracenteses with culture of large quantities of fluid combined with centrifugation may also increase bacteriological yield. When one combines the histological examination and culture of the pleural biopsy specimen with study of the fluid, one has the highest rate of diagnosis (80 percent). For each undiagnosed pleural effusion, in addition to the studies for tuberculosis, studies for malignant cells, fungi, and bacteria should be performed on the aspirated fluid and any biopsy material. Elevated adenosine deaminase (ADA) is frequently found in tuberculous effusions but the utility of this test depends on the pre-test probability of tuberculosis in the individual patient. When a patient has a positive 5-TU tuberculin test (greater than 10-mm induration), his or her effusions should be presumed to be tuberculous until proved otherwise. If a patient has an undiagnosed exudative effusion and a negative tuberculin test, the tuberculin test should be repeated within 2 weeks, since it is not uncommon for patients with tuberculous effusions to have an initially negative tuberculin test. At times, a video assisted or standard thoracotomy with pathological examination of the pleura for tuberculosis, fungi, malignant cells, and bacteria may be necessary to establish the cause of a pleural effusion.

In the absence of a diagnosis and the presence of a compatible pleural effusion, consideration should be given to a trial of antituberculous therapy on the basis of a presumptive diagnosis of tuberculosis. Many patients with an undiagnosed pleural effusion later develop progressive parenchymal tuberculosis if they are not treated. However, a therapeutic trial in pleural tuberculosis is not as helpful diagnostically as one in pulmonary tuberculosis, since the natural course of pleural tuberculosis is toward resolution.

Figure 140-4 Tuberculosis effusion. *A*. A 23-year-old patient with persistent shortness of breath postpartum whose chest radiograph demonstrated a large right pleural effusion. Thoracentesis to obtain pleural fluid was nondiagnostic. *B*. Two months later, chest radiograph revealed miliary nodules in addition to right pleural effusion and culture of bronchoscopy washing grew out *M. tuberculosis. (Courtesy of Wallace Miller, Jr., M.D.)*

Tuberculosis empyema is a rare condition due to purulent infection of the pleural space with a large bacillus burden; thus, typically AFB cultures of the fluid are positive. However, in contrast to tuberculous pleurisy, which does not require surgery, tuberculous empyema is usually accompanied by a thick pleural peel and requires surgical drainage or decortication (see complications) in addition to antituberculosis therapy.

Bone/Joint Infection

The classic description of spinal tuberculosis was written by Percival Pott in 1779. However, mummified remains from Egypt dated to 3400 B.C. show evidence of its existence. It remains the most common site of tuberculosis involvement of the bone with approximately 50 percent of bone infections with tuberculosis in the United States occurring in the spine. Pain at the site of the infection is the most common symptom. Chronic constitutional symptoms are also frequent. Neurological involvement occurs in 10 to 61 percent of patients and late presentation and cervical involvement may predispose to higher rates of disability. MRI with gadolinium has become the radiographic test of choice with bone scans and gallium scans being frequently unreliable. However, there are no pathognomic findings of Pott's disease on x-ray, so biopsy and culture remain the gold standards for diagnosis. Medical therapy is required. Surgery is restricted to those who need biopsy, unstable spinal lesions, and those with progressive neurological symptoms while on appropriate therapy. This disease, like other extrapulmonary and paucibacillary types of TB, is not only more difficult to diagnose by culture, but likely to be associated with a longer time to culture positivity than pulmonary TB. High clinical suspicion of TB in the spine should prompt consideration for empiric antituberculous therapy while cultures are pending, especially if a biopsy shows granulomatous inflammation.

Tuberculosis has been reported in all bones in the body. However, large bones/joints are more commonly affected than smaller bones/joints. Multiple simultaneously involved joints are rare. Joint infection can present as worsening arthritis with effusions and infrequently with draining sinuses. Often systemic symptoms are absent. Aspiration of the joint rarely yields the diagnosis and a biopsy of the synovial tissue is typically required. Like spinal infection, medical therapy is first line and surgery is reserved for complicated cases.

Gastrointestinal/Peritoneal

Tuberculosis can involve any part of the gastrointestinal tract. However, the most commonly affected area is the ileocecal

region. Peritoneal involvement may occur due to spread from abdominal lesions or associated lymph nodes. Most patients have fever (40 to 70 percent), pain (80 to 95 percent), diarrhea (11 to 20 percent), constipation, weight loss (40 to 90 percent), anorexia, and malaise. Despite these constitutional symptoms, pulmonary involvement is present in less than half of the affected patients. In peritoneal involvement, ascitic fluid may provide diagnostic information. The fluid typically has elevated fluid protein, elevated white count with lymphocyte predominance, and low glucose. Unfortunately, the yield of fluid culture is low (less than 20 percent). This is a volume-dependent test and if one wants to send a culture of this fluid, one should consider sending several liters to the laboratory, which can be spun down and concentrated prior to culture. Several studies have found that adenosine deaminase levels may be elevated in the ascitic fluid. However, HIV status and malignancy can alter these levels. Similar, to pleural disease, biopsy of the affected surface is necessary in most cases to confirm the diagnosis. Usually direct visualization by laparoscopy or laparotomy reveals studding of the peritoneum or mesentery, and directed biopsies of the lesions usually demonstrate granulomas instead of tumor, which is sufficient to prompt treatment.

Meningitis/Central Nervous System Involvement

Tuberculous meningitis is the most common form of central nervous system (CNS) involvement with the infection. Seeding of meninges is believed to occur from hematogenous spread of the bacilli. After the meninges are seeded, the disease can remain quiescent for a period of time until reactivation. After reactivation cell-mediated immunity leads to the formation of a thick, gelatinous exudate along the basal surface of the cerebrum. These exudates can obstruct cerebrospinal fluid (CSF), leading to hydrocephalus and encase cranial nerves, leading to further dysfunction. Additionally, the granulomas formed during the infection can coalesce to form a tuberculoma that can lead to focal neurological defects depending on their location. Finally, the infection can also lead to a vasculitis leading to infarction and stroke symptoms.

Clinical signs and symptoms of tuberculous meningitis include headache (50 to 80 percent), fever (60 to 95 percent), vomiting (30 to 60 percent), photophobia (5 to 10 percent), anorexia (60 to 80 percent), neck stiffness (40 to 80 percent), confusion (10 to 30 percent), coma (30 to 60 percent), cranial nerve palsy (30 to 50 percent), hemiparesis (10 to 20 percent), paraparesis (5 to 10 percent), and seizures (children: 50 percent; adults: 5 percent). There are no pathognomonic findings on neurological imaging, but common findings include basal meningeal enhancement, hydrocephalus, and infarction in the supratentorial brain parenchyma and brain stem. Lumbar puncture classically shows an elevated white count with a lymphocyte predominance, elevated protein, and very low glucose levels. Initial reports of yields from AFB smears and cultures from CSF were quite low. The yield can be increased by extremely careful microscopy and large volume (greater than 6 mL) analysis. In one study, increasing the volume of CSF from 2 mL to 6 mL examined increased the percentage of positive AFB cultures from 40 to 80 percent.

Genitourinary

Genitourinary (GU) tuberculosis occurs after hematogenous spread of the bacilli to the glomerulus. The infection can then spread down the GU system into the renal pelvis, ureters, bladder, epididymis, and testes. It frequently takes years to develop. The symptoms depend on the location of the burden of infection and range from symptoms of recurrent pyelonephritis, including flank pain, frequency, and dysuria, to chronic testicular pain with micturition that does not respond to typical antibacterials. The GU disease is more common in men. Untreated disease can lead to stenosis and/or stricture over time. Sterile pyuria is a classic finding. Diagnosis is made by culture of the urine, usually collected first thing in the morning on three consecutive days. Culture of ejaculate may also be positive in many cases, but does not seem to add to the yield from urine. GU tuberculosis is a significant cause of infertility in areas of the world where tuberculosis is endemic (e.g., 5 to 16 percent of cases of infertility in Indian women).

Miliary Tuberculosis

Miliary tuberculosis (Fig. 140-5) occurs when there is hematogenous spread of bacilli to multiple organs leading to the formation of small (less than 2 mm in diameter) granulomatous nodules. This widespread dissemination can occur at the time of primary infection or years later when the immune response is suppressed. Because multiple organs are involved, the symptoms are often protean, including fever, weight loss, malaise, and cough. Tuberculous meningitis occurs in 10 to 30 percent of patients with miliary disease and one-third of patients with TB meningitis have underlying miliary disease.

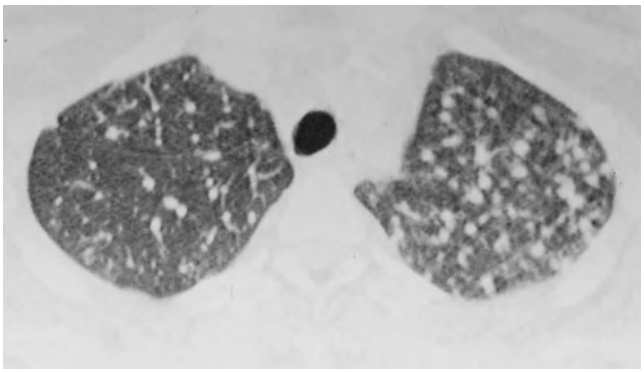

Figure 140-5 Miliary tuberculosis: A 30-year-old patient undergoing treatment for Hodgkin's disease with right neck lymphadenopathy and shortness of breath. Chest computed tomography demonstrated multiple military nodules, and sputum cultures grew out *M. tuberculosis. (Courtesy of Wallace Miller, Jr., M.D.)*

Within the lung, miliary lesions can lead to restriction and diffusion abnormalities, and in an extreme form is a cause of the adult respiratory distress syndrome (ARDS). Additionally, severe infection can lead to multiple organ dysfunction syndrome (MODS). Laboratory abnormalities can include anemia, hyponatremia, and liver function test elevation. Renal insufficiency can occur as part of MODS or because of direct parenchymal infection. Miliary tuberculosis is more common in patients with advanced HIV infection and in the elderly. Mortality is typically 25 to 30 percent in adults and 15 to 20 percent in children. Tuberculin skin tests may be negative in up to 50 percent of patients with miliary tuberculosis. Diagnosis can be difficult due to a typically low bacillus burden, and more invasive sampling techniques including BAL, bone marrow biopsy, or liver biopsy may be necessary.

TUBERCULOSIS IN SPECIAL HOSTS

Tuberculosis and Human Immunodeficiency Virus

Authorities agree that human immunodeficiency virus (HIV) infection is part of the explanation for the resurgence of tuberculosis in the United States since 1984. Prior to 1984, there had been a consistent decline in the numbers of newly reported active cases of tuberculosis. Since 1984, there has been a slight increase in the number of newly reported active cases. Several important differences have emerged regarding the clinical presentations of tuberculosis in patients with or without HIV infection. Patients with HIV infection are more likely to present with disseminated disease. Approximately 50 percent of people with HIV have extrapulmonary disease as compared to 20 percent of the general population. Additionally, they tend to have an increased number and severity of symptoms and have a more rapid progression to death unless treatment is begun.

Radiographic findings of TB in HIV correlate with the degree of immunosuppression due to the CD4 cell depletion. Hilar and mediastinal lymphadenopathy are usually associated with lower CD4 counts (i.e., less than 200/mm^3), while cavitation is seen more commonly is patients with higher CD4 counts. Additionally, HIV subjects may be more likely to have non-apical infiltrates, pleural effusions, and miliary infiltrates.

In patients with HIV infection but without the manifestations of AIDS, the tuberculin skin test is positive in 50 to 80 percent of patients with tuberculosis. Once an individual has developed AIDS, the tuberculin skin test is less likely to be positive, but reactivity may be seen in as many as 30 to 50 percent of patients. As noted, active tuberculosis should be considered in any HIV-infected patient with a tuberculin skin test that has greater than 5 mm of induration. The proportion of positive sputum smears and cultures is similar for HIV-infected and -uninfected patients. Therefore, the diagnostic algorithm of spontaneous or induced sputum followed by bronchoscopy with BAL as noted above for immunocompetent individuals should be followed. However, given the risk of rapid progression, the assumption must be that an acid-fast organism present in the sputum of a patient with HIV and pulmonary disease is *M. tuberculosis,* and treatment should be initiated pending definitive identification of the organism.

Tuberculosis in Children

In contrast to adults, tuberculosis in children often represents primary infection rather than the result of reactivation. Additionally, pediatric TB occurs more frequently in the very young, with greater than 60 percent of cases in children less than 5 years old and 26 percent in children less than 2 years old. When compared with adults, children (less than 15 years of age) have more lymphatic (15.5 vs. 6.8 percent) and meningeal involvement (2.1 vs, 0.9 percent). They are also less likely to have cavitary disease (4.9 vs. 27 percent in adults). HIV co-infection was lower in children and the proportion of multi-drug–resistant organisms was similar. Death rates were significantly lower in children (11.2 vs. 0.7 percent). Additionally there are two forms of TB unique to pediatrics. Congenital TB is rare and due to transmission in utero of the bacillus from mother to fetus. These children typically present within the first weeks of life with nonspecific symptoms, including cough and increased work of breathing, fever, hepatosplenomegaly, poor feeding, lethargy, and skin lesions. Mortality for congenital tuberculosis is high at around 40 percent. Neonatal tuberculosis occurs with transmission after birth and more frequently has CNS and miliary involvement.

Tuberculosis in the Elderly

Recent studies have begun to suggest that not only is increasing age a risk factor for the development of active tuberculosis, but the disease itself may present differently in the elderly, making it harder to recognize and diagnose. One study in South Africa prospectively examined 93 consecutive patients over the age of 60 admitted with pulmonary tuberculosis. Among these patients, "atypical" radiographic findings were the norm rather than the exception. For instance, only 7 percent had purely apical infiltrates, while 48 percent had mid and lower lung zones only, and 46 percent had mixed infiltrates between upper and lower lung fields. A pleural reaction was common (46 percent) and cavities were not (33 percent), with half of those seen in the lower and mid-lung fields. In addition the investigators found that systemic abnormalities of routine blood work were common, including anemia (66 percent), elevated erythrocyte sedimentation rates (90 percent), hyponatremia (60 percent), and hypoalbuminemia (83 percent). However, not all studies have confirmed these differences. One recent meta-analysis of 12 studies of tuberculosis found that the elderly were less likely to have symptoms such as fever, sweating, hemoptysis, and cavitary lung disease. They were more likely to have dyspnea and significant co-morbidities. In this study, the only differences seen in radiographic patterns between young adults and the elderly

was an increased incidence of miliary disease in the older population.

TREATMENT OF TUBERCULOSIS

History of the Treatment of Tuberculosis

In the late 1800s, before chemotherapeutic agents had been discovered, patients with TB were isolated in sanitariums for nutrition and rest. Lung collapse therapy was performed by pneumothorax or various surgical techniques that frequently left patients disfigured for life. In 1946, streptomycin was introduced as an effective antituberculosis drug and initially was used in TB patients by Feldman and Henshaw. However, it quickly became evident that streptomycin monotherapy resulted in relapse and the emergence of drug resistance. PAS, which was also used initially as monotherapy, could reduce the emergence of resistance to streptomycin; thus, two-drug therapy was born. In 1953, isoniazid (INH) and pyrazinamide (PZA) were released for therapy, and an era of truly effective chemotherapy began. Following the development of ethambutol (EMB) in 1964, INH and EMB became the cornerstone of an 18-month treatment regimen. Rifampin (RMP) was developed in 1965 and released for use in 1971. In the early 1980s, it was found that RMP and INH reduced the duration of therapy to 9 months. Addition of PZA to this regimen shortened the period of treatment to 6 months. Thus, in the 60 years since the introduction of the first effective drugs for the treatment of TB, the care of these patients has been transformed from long hospitalizations and a lifetime of fear of relapse to a relatively short outpatient treatment regimen and cure. The challenge today is not so much how to treat TB as how to ensure that patients receive the proper treatment. Failure to deliver proper care is the major cause for the development of drug-resistant strains and the fear for the recrudescence of this dreaded malady. Thus, directly observed therapy (DOT) has been adopted as the preferred method for insuring completion of effective therapy.

Theoretical Basis for Effective Treatment Strategies

Effective chemotherapy for tuberculosis is based on the observation that only actively replicating organisms can be killed. In addition, the environment in which the organism lives can affect not only its growth rate but also its susceptibility to different antibiotics. Mycobacteria that are living extracellularly in pulmonary cavities are metabolically very active and are rapidly growing in a hyperoxic and neutral pH environment. There organisms are highly susceptible to Streptomycin, INH, and ethambutol. Mycobacteria that live extracellularly in closed caseous lesions are less active metabolically and grow slowly in a hypoxic and neutral pH environment. These organisms are susceptible to rifampin and INH. Mycobacteria that live in the acidic, hypoxic environment of macrophages have a slow or intermittent growth, and PZA and rifampin are effective antibiotics. Finally, some mycobacteria may be trapped in fibrosis and encapsulated and may be completely dormant. These organisms are unaffected by antibiotics and the cellular immune system.

A second major consideration for effective chemotherapy is the presence of drug-resistant mutants. These mutants develop spontaneously at a rate of 10^{-7} to 10^{-10} mutations per bacterium per generation. Since cavitary lesions can contain 10^8 to 10^9 bacilli, it is likely that in cavitary lesions, some bacilli are resistant to any single drug. In addition, the probability of resistance to one drug is independent of the development of resistance to any other drug. Therefore, the probability of spontaneous resistance to two drugs is extremely low. Thus, antituberculosis chemotherapy should always consist of at least two effective drugs to prevent the emergence of drug-resistant mycobacteria.

Finally, because tuberculosis is an infectious disease and a public health threat, all providers, public and private, must ensure that patients complete effective chemotherapy. This is important because failure to complete effective chemotherapy is the most likely cause for the emergence of drug-resistant organisms. Thus, DOT has become the standard method of insuring completion of adequate chemotherapy. Adding individual incentives and enablers to DOT has resulted in greater than 90 percent of patients completing chemotherapy for pulmonary tuberculosis.

Specific Antituberculosis Drugs

First-Line Drugs

Isoniazid

Because of its bactericidal effect and low cost, INH is the most important drug used for the treatment of TB. INH should be included in all regimens except when a high proportion of INH-resistant organisms are present. INH is the hydrazide of isonicotinic acid, which most probably acts by inhibiting mycolic acid synthesis by mycobacteria. For INH to be effective, three things must occur. First, the drug has to be taken up by the organisms. Second, INH needs to be activated by a catalase-peroxidase enzyme within mycobacteria. Third, this activated form of INH then interferes with mycolic acid synthesis. Mutations that result in resistance of mycobacteria to INH have been reported in at least four different genetic loci. The most important is the katG gene, which encodes a catalase-peroxidase enzyme. Mutations at codon 315 have been associated with high levels of resistance and virulent organisms. Other genes associated with resistance to IHN are the inhA which codes for a protein involved in fatty acid elongation, the ahpC gene, which encodes a protein for alkyl hydroperoxidase reductase, and the oxyR gene, which encodes a protein involved in the regulation of oxidative stress. Thus, multiple molecular tests are necessary to identify all INH-resistant mycobacteria even though the katG gene seems to be the most important.

INH has a bactericidal effect for both intra- and extracellular organisms and is well absorbed from the

gastrointestinal tract, reaching serum levels equal to those following parenteral administration. The peak serum concentration of 3 to 5 μg/ml occurs 1 to 2 hours after a dose of 5 mg/kg. The small molecular size of INH allows widespread distribution. The drug can be detected in serous membranes, caseous foci, cavities, and macrophages. INH is metabolized in the liver by both acetylation and oxidation via the cytochrome P-450 system. The serum half-life is around 3 hours in slow acetylators and 1 hour in rapid acetylators. The inactive metabolites are excreted in the urine, accounting for 75 to 95 percent of a dose within 24 hours. If the serum creatinine levels are higher than 12 mg/dl, these metabolites accumulate in the body. In renal failure, INH should be administered after dialysis. The drug can be given by nasogastric tube, intramuscular injection, or intravenously if the patient is unconscious.

When INH and phenytoin are administered together, an increase in serum concentration of phenytoin will be observed since INH is a noncompetitive inhibitor of diphenylhydantoin (DPH). In such patients, the serum levels of phenytoin should be monitored and a dose reduction may be necessary. In cases of DPH intoxication, the drug should be discontinued for at least a week and then therapy restarted with low doses (100 to 200 mg/day). INH may also decrease the threshold for acetaminophen hepatotoxicity.

A major toxic manifestation of INH is peripheral neuritis. Susceptibility is highest in chronic alcoholics, persons with malnutrition, and slow acetylators. Major manifestations are sensory dysfunctions and numbness of the lower extremities. The syndrome is dose related (in 40 percent of patients at doses of 20 mg/kg per day, in 20 percent at 10 mg/kg per day, and in 1 to 2 percent at 5 mg/kg per day). Owing to its pyridoxine-like structure, INH competitively inhibits pyridoxine-requiring reactions. INH-induced depletion of pyridoxine stores can be prevented with pyridoxine 50 mg/day. Unless there is an obvious muscle weakness (i.e., atrophy or fasciculations), the symptoms of peripheral neuritis are reversible within a few weeks after withdrawal of INH and treatment with pyridoxine 100 to 200 mg/day. Autonomic dysfunctions, ataxia, muscle twitching, CNS irritability, depression, acute psychosis, and encephalopathy are other neurological symptoms that may occur after INH therapy or overdose. Pyridoxine may terminate all these adverse effects.

The other major side effect of INH is toxic hepatitis. This is related to toxic drug metabolites. After acetylation, INH converts to hydrazine, which may be changed to a toxic agent, acetyl hydrazine. In addition, as RMP inducts the enzymatic conversion of INH to acetyl hydrazine, the hepatotoxic effect is potentiated when these drugs are used together. In the first months of therapy, a mild elevation of transaminase levels may occur in 10 to 20 percent of patients receiving INH. If the enzyme levels rise above three times normal values, the drug should be discontinued. Monthly monitoring of liver enzymes is recommended for all patients on INH therapy. The frequency of tests should be increased in patients who have elevated enzyme levels. INH causes a hepatocellular type of hypersensitivity reaction and histology is indistinguishable from that of viral hepatitis. INH-induced hepatitis is age dependent, occurring in 2 to 3 percent of patients over 50 years of age but less than 1 percent of children. Fatal liver damage may occur in 1 to 2 percent of patients with INH hepatitis. This may be asymptomatic until jaundice develops. Before onset of jaundice, patients may suffer from weakness, fatigue, and generalized malaise. Therefore, patients may unknowingly continue taking INH after the onset of drug-induced hepatitis. Patients given INH should be warned about such symptoms and instructed to promptly inform their physician if such symptoms occur.

INH and RMP together produce hepatotoxicity more frequently then either drug alone. Risk factors for hepatitis are age greater than 35, slow acetylators, history of cholelithiasis, alcohol use, and preexisting liver disease. Liver transplantation has been successful in patients who develop hepatic failure from either INH alone or INH and RMP therapy. Thus, liver transplantation may be a lifesaving therapy.

Rifampin

Rifampin (RMP) is bactericidal against intracellular and extracellular bacterial populations. It is a semisynthetic antibiotic that inhibits RNA synthesis by inhibiting DNA-dependent RNA polymerase enzyme, encoded by the rpoB gene. Most strains of *M. tuberculosis* are inhibited with 0.20 μg/ml. RMP is considered to be a "sterilizing" agent. A standard oral dose of 600 mg/day may produce serum concentrations of 7 to 10 μg/ml in 1 to 2 hours. RMP is metabolized in the liver and excreted in bile. As only 30 percent of the drug is excreted in the urine, dose reduction is not necessary in renal failure. RMP is able to penetrate into caseous foci, serous membranes, and macrophages. RMP does not pass the blood-brain barrier under normal conditions, but inflammation of the meninges causes an increase in penetration. Rifampin penetrates well into tissues and can be detected in urine, tears, sweat, and other body fluids, coloring then to red-orange. Patients should be advised of this harmless discoloration. RMP can be given to unconscious patients by nasogastric tube or intravenous injection.

In nearly all isolates of *M. tuberculosis* resistant to RMP, a short region of 27 codons in the center of the rpoB gene was mutated.

Major side effects of RMP are gastrointestinal upset, skin eruptions, and fever. Twenty percent of patients receiving high-dose intermittent RMP (600 to 1200 mg/day) develop an immunologically mediated influenza-like reaction, hemolytic anemia, acute renal failure, and thrombocytopenia. When these syndromes occur, RMP should be discontinued.

Another important adverse effect of RMP is its hepatic toxicity. An elevation in serum hepatic enzyme levels occurs in 5 to 10 percent of patients. Usually this resolves spontaneously, and therapy does not need to be altered or interrupted. The clinical presentation of hepatotoxicity varies from transaminase elevations to fatal hepatic necrosis. RMP is also a potent inducer of hepatic microsomal enzymes, resulting in an increased rate of metabolism of a number of drugs and, thus, a rapid elimination and diminished effects

of these drugs, which include methadone, Coumadin derivatives, glucocorticoids, estrogens, oral hypoglycemic agents, and antiarrhythmic agents. Bidirectional interactions can occur between RMP and antiretroviral agents, which complicates the treatment of TB patients on retroviral therapy.

Several studies have shown that the incidence of hepatitis in regimens containing both INH and RMP may be two to four times that of INH alone. Hepatic toxicity due to INH usually occurs after 2 months of therapy. In contrast, in INH and RMP combined therapies, jaundice may occur within the first 2 weeks of therapy and may be fulminate. The reason for this toxic effect was the accelerated production of toxic metabolites of INH due to the stimulation of hepatic microsomal P-450 system by RMP.

Rifabutin

Rifabutin (RIF) is a semisynthetic antibiotic similar to rifampin in structure and activity. RIF has a relatively low oral bioavailability of about 20 percent after single dose administration. After long-term administration RIF induces its own metabolism. The half-life for elimination of RIF is long (45 hours). As a result of a very large volume of distribution (greater than 9 L/kg), average plasma concentrations remain relatively low even after repeated administration of standard doses.

Because RIF has fewer interactions with antiretroviral agents, it is more frequently used in the treatment of TB patients on retroviral therapy. Careful monitoring of drug levels is essential in these cases. Neutropenia may necessitate stopping the drug in 2 percent of AIDS patients. Neutropenia has not been associated with RIF in non-AIDS patients. Uveitis is rare at the standard doses, but can occur in 8 percent when given at higher doses. Drugs (i.e., macrolide antibiotics, protease inhibitors, and azole antifungal agents) that reduce RIF clearance may also be associated with increased incidence of uveitis.

Gastrointestinal symptoms and polyarthralgias were reported to occur in less than 3 percent of subjects, but have not been reported in more recent literature.

Similar to RMP, RIF can cause hepatitis and causes orange discoloration of body fluids. No adjustment for renal failure is necessary. Similar to RMP, RIF penetrates inflamed meninges.

Rifapentine

Rifapentine (RPT) is a long-acting cyclopentyl-derivative of rifampin. The mean half-life for RPT elimination is over 16 hours. RPT is only used in the continuation phase of TB treatment in non-HIV patients as a once or biweekly drug. Its side effects are similar to RIF.

Pyrazinamide

Pyrazinamide (PZA) is a nicotinic acid derivative similar to INH, but it has no cross-resistance with INH. Its bacteriocidal activity at acid pH makes PZA particularly effective against slowly metabolizing intracellular bacilli. This "sterilizing" property has made PZA an essential component of short-course therapy. Regimens not including PZA require at least 9 months to succeed. This beneficial effect is limited to the first 2 to 3 months of treatment. PZA is absorbed from the gastrointestinal tract and distributed throughout the body, including the CNS. PZA is excreted from the kidneys. Serum levels of 30 to 50 μg/ml are achieved with doses of 20 to 25 mg/kg of PZA. It has a minimum inhibitory concentration of 15 to 20 μg/ml.

PZA is thought to be converted to pyrazine acid by a mycobacterial enzyme pyrazinamide. Pyrazine acid is thought to kill mycobacteria by lowering the intracellular pH. Resistance to PZA may be due to failure of the drug to be taken up by mycobacteria due to a lack of a PZA transport system in addition to mutations in the PZase gene.

The most adverse reaction of PZA is hepatotoxicity. After 2 months of therapy, 15 percent of patients who receive PZA at a dose of 3000 mg/day (40 to 50 mg/kg) develop liver dysfunctions and 2 to 3 percent develop jaundice. Liver function should be monitored closely, and the treatment should be discontinued if elevations of SGOT levels occur. Another common side effect of PZA is hyperuricemia. Occasionally, mild non-gouty polyarthralgias occur as a result of inhibition of urate excretion. This complication usually responds to nonsteroidal anti-inflammatory drugs. Clinical gout is rarely seen, and allopurinol therapy is usually indicated. Therapy is not necessary for patients who have only elevated urate levels without symptoms. Other side effects, such as skin rash and gastrointestinal intolerance are rare.

Ethambutol

Ethambutol (EMB) is a bacteriostatic agent. It has no activity on bacilli in the stationary growth phase. It is a unique butanol derivative that may block a step of cell wall synthesis. Following a 5 mg/kg oral dose, the peak serum level is approximately 4 μg/ml after 2 to 4 hours. Serum half-life is approximately 4 hours and is prolonged in renal failure. EMB may be bacteriocidal at 25 mg/kg doses, whereas it is bacteriostatic at 15 mg/kg doses. EMB is active against both intracellular and extracellular bacilli. Most strains of M. tuberculosis are inhibited in vitro by 1 to 5 μg/ml of EMB. Cerebrospinal fluid concentrations are low (1 to 2 μg/ml), even in the presence of meningeal inflammation.

The main toxicity of EMB is optic neuritis. This is manifested by central scotoma, decreased red-green color vision, decreased visual acuity, and rarely, concentric concentration of visual fields, leading to gun-barrel vision. This side effect is dose dependent and largely reversible. Optic neuritis occurs in 3 percent of patients taking 25 mg/kg but in less than 1 percent of patients taking 15 mg/kg. Patients should be questioned concerning visual symptoms, and tests of visual acuity and color vision should be performed. In cases of optic neuritis, the visual function returns after withdrawal of the drug. Like PZA, EMB may cause hyperuricemia and rarely, gout. Skin rash, drug fever, and gastrointestinal disturbance are other rarely seen side effects.

Second-Line Drugs

Second-line drugs have increased toxicity and decreased effectiveness and should only be used by physicians experienced with their use. Second-line drugs include cycloserine, ethionamide, streptomycin, amikacin, kanamycin, capreomycin, p-aminosalicylic acid, and the fluoroquinolones. Because of the concern about the emergence of drug-resistant organisms, whenever new drugs are introduced into a patient's regimen, care should be taken that the patient is always on at least two drugs to which the mycobacteria is sensitive.

Cycloserine

Cycloserine is a bacteriostatic drug. It is an analog of D-alanine and competes with it for incorporation into the cell wall. It is rapidly absorbed from the gut and is distributed to all compartments. Urine excretion accounts for 70 percent of the active form of the drug, as only 30 percent is metabolized. Common side effects include neurological and psychiatric disturbances ranging from headache, tremor, memory problems, and somnolence to psychosis (paranoid, depressive, or catatonic reactions) and seizure. Some patients with depression or anxiety have committed suicide. The usual dose is 15 to 20 mg/kg, with a maximal dosage of 1 g/day. Most of the adverse CNS effects are dose related and disappear when the medication is discontinued. To prevent serious psychic problems, periodic monitoring of mental status and serum drug levels is necessary. To diminish the potential for seizures and convulsions, pyridoxine at doses of 100 to 150 mg/day is helpful. Cycloserine may affect the elimination of phenytoin especially when taken with INH. Dose reduction of phenytoin is necessary in these cases. In the presence of renal failure, the daily dose of the drug must be reduced.

Ethionamide

Ethionamide has a structure similar to INH but cross-resistance with INH is very rare. A dose of 2.5 μg/kg has a bacteriostatic effect. Ethionamide is well absorbed from the gut and metabolized in the liver. Peak serum levels are 15 to 20 mg/ml. The optimum dosage is usually 1 g. It is almost completely and widely distributed in the body compartments. Nausea, vomiting, loss of appetite, and abdominal pain are the most common adverse effects. Serious neurological reactions include headache, restlessness, diplopia, tremors, and convulsions. It is necessary to increase the dose to the full amount gradually. As it is very irritating to the gastrointestinal tract, a bedtime dose is recommended with an anti-emetic and a hypnotic drug. Hepatitis may develop in 1 percent of patients. To monitor hepatotoxicity, monthly hepatic enzyme determination is necessary. In the presence of a fivefold elevation of liver enzyme levels, the drug should be stopped. If well tolerated, ethionamide can be a lifesaving agent in patients with drug-resistant TB.

Streptomycin

Streptomycin (SM) was the first major antituberculosis drug release. SM acts through inhibition of protein synthesis. It is effective only against extracellular bacterial populations in cavities, where the pH is neutral. SM must be administered parenterally, as it is not absorbed from the gut. Peak serum concentration of 40 μg/ml occurs approximately 1 hour after a 15 mg/kg intramuscular dose. Most strain of *M. tuberculosis* are inhibited in vitro at a concentration of 8 μg/ml. SM's half-life is 5 hours in blood.

Several mechanisms are responsible for resistance to SM. One of them is a mutation in the rpsL gene, encoding the S12 protein. This has been associated with a high level of resistance. Mutations in the rrs gene are usually associated with a low level of resistance; however, many isolates with a low level of resistance do not carry mutations in these genes. The frequency of resistance to SM in high-incidence countries limits the usefulness of SM.

Although SN has good tissue penetration, it can enter the CSF only in the presence of meningeal inflammation. Its major toxicity is irreversible eighth nerve damage, leading to vestibular dysfunction and, less frequently, deafness. It is a nephrotoxic drug like other aminoglycosides, and the frequency of renal toxicity is increased in patients with preexisting renal diseases or with simultaneous use of other nephrotoxic drugs. Renal and eighth-nerve toxicity increases in patients more than 50 years of age, and SM should be used very cautiously in these patients. Patients should be questioned regarding balance and asked to perform simple tests of vestibular function. In TB treatment, its use is usually limited to 2 months.

Amikacin and Kanamycin

Amikacin and kanamycin are closely related aminoglycoside antibiotics that act on ribosomes, inhibition protein synthesis. Both have eighth nerve and renal toxicity. Monthly audiograms should be used to monitor both drugs. Amikacin can be given intramuscularly or intravenously. Average peak serum concentration is 21 μg/ml and the MIC is 4 to 8 μg/ml. Kanamycin is usually given intramuscularly and serum concentrations should be in a range of 15 to 20 μg/kg. There is cross resistance among amikacin, kanamycin, and streptomycin.

Capreomycin

Capreomycin is chemically distinct from aminoglycosides, but it is likely to have cross-resistance with SM, amikacin, and kanamycin. It has the same therapeutic activity, pharmacology, and toxicity.

Para-amino Salicylic Acid

Para-amino salicylic acid (PAS) was the first oral antituberculosis drug that had strong bacteriostatic effect. This effect is potentiated when it is used in conjunction with SM or INH. Ass the drug is excreted rapidly, high doses are necessary to maintain bacteriostatic activity. The usual oral daily therapeutic dose is approximately 150 mg/kg, and the total dose should not exceed 10 to 12 g/day. The 10- to 12-g/day dosage causes a high rate of adverse gastrointestinal effects, including nausea, vomiting, diarrhea, and epigastric

pain. The half-life of PAS is about 1 hour and is markedly prolonged in renal failure. PAS is well absorbed orally but does not cross the blood-brain barrier. In 5 to 10 percent of patients, PAS may also cause hypersensitivity reactions and rarely, hepatitis, hypothyroidism, or hemolytic anemia. Adverse effects may be diminished by beginning therapy with a low dose and gradually increasing to a full dose over 7 to 10 days. To avoid gastrointestinal effects, PAS should be taken after eating. Antacids may also be helpful to reduce these side effects.

Fluoroquinolones

Fluoroquinolones are broad-spectrum antibacterial agents that act by inhibiting DNA gyrase enzyme. They are the preferred oral agent for treating drug-susceptible organisms that are sensitive to these agents. There is no cross-resistance with other antituberculosis drugs. Levofloxacin is the preferred agent. Cross-resistance is present among the fluoroquinolones and is presumably a class effect. Administration of quinolones with theophylline increases serum theophylline levels and the risk of adverse effects from theophylline. Both ferrous sulfate and antacids with magnesium and aluminum may affect the absorption of the fluoroquinolones. Side effects include nausea, bloating, dizziness, insomnia, tremulousness, headache, rash, pruritus, and photosensitivity.

Deciding to Initiate Treatment

Frequently, the decision to initiate treatment for tuberculosis is made before there is culture confirmation. This is a clinical decision based on the patient presenting signs and symptoms, laboratory tests, radiological findings, microscopic examination of sputum or other specimen smears, and histological examination of any tissue specimens. When a decision is made about initiating antituberculosis therapy, physicians should consider the following issues and try to avoid common mistakes (Table 140-2).

1. Tuberculosis should be viewed not only as a disease affecting personal health requiring treatment to cure the patient, but also as a disease of public health concerns because of community transmission.
2. A positive PPD, while helpful, is not necessary for the initiation of treatment as a negative PPD is not uncommon in active tuberculosis.
3. Before starting therapy, one should attempt to confirm the diagnosis by sending material to the laboratory for culture.
4. In newly diagnosed TB patients, at least three sputum samples should be sent for culture and drug susceptibility testing before starting therapy.
5. In smear-negative cases, five or six sputum samples and, if necessary, bronchoalveolar lavage material should be sent for mycobacterial culture.
6. If no other cause can be found in a severely ill, smear-negative, presumed TB patient, antituberculosis therapy should be started immediately.

Table 140-2

Common Errors in the Management of Tuberculosis

Addition of a single drug to a falling regimen
Failure to identify preexisting or acquired drug resistance
Chest radiographs findings absent or misinterpreted
Inadequate primary regimen
Failure to identify and address noncompliance
Inappropriate isoniazid preventive therapy

7. The emergence of drug resistance is usually due to noncompliance and failure to take all of the drugs. Resistance is usually to the omitted drug. Directly observed therapy is the preferred method in all patients.
8. Therapy should never be stopped unless one is certain that the cultures are negative.

Initiation of Treatment

Currently accepted drug regimens are summarized in Table 140-3 and suggested doses are given in Table 140-4. During treatment for pulmonary tuberculosis all patients should have monthly sputum examined by smear and culture. Patients who have cavitation on the initial chest radiograph or have positive cultures after 2 months are at increased risk for relapse. In these individuals, the continuation phase of treatment should be prolonged to 7 months, making the total duration of treatment 9 months. Repeat susceptibility testing should be done if cultures remain positive after 3 months of treatment.

Monitoring for Adverse Reactions

For evaluation of standard regimens, baseline measurement of a complete blood count, hepatic enzymes, serum bilirubin, and creatinine levels should be obtained. If PZA is used, serum uric acid levels should be monitored. Patients receiving EMB should have both visual acuity measurement and a red-green color perception testing. The baseline tests have two major goals: first, to detect abnormalities that could complicate the regimen and, if necessary, make rearrangements; and second, to monitor the adverse reactions of drugs by means of comparing the baseline measurements with the follow-up results. The same tests should be repeated at monthly examinations. The patients with abnormalities detected on the baseline tests should be evaluated for the cause of the result. If symptoms suggesting drug toxicity occur, appropriate laboratory testing

Table 140-3

Drug Regimens for Pulmonary Tuberculosis Caused by Drug Susceptible Organisms

Initial Phase (8 wk)			Continuation Phase (18 wk Except Regimen 4)			Rating	
Regimen	**Drugs**	**Interval and Doses**	**Regimen**	**Drugs**	**Interval and Doses**	**HIV−**	**HIV+**
1	INH RIF PZA EMB	7 d/wk for 56 doses or 5 d/wk for 40 doses	1a	INH/RIF	7 d/wk for 126 doses or 5 d/wk for 90 doses	A	A
			1b	INH/RIF	2 ×/wk for 36 doses	A	A†
			1c*	INH/RPT	1 ×/wk for 18 doses	B	E
2	INH RIB PZA EMB	7 d/wk for 14 doses (2 wk) or 5 d/wk for 10 doses (2 wk), then 2 ×/wk for 12 doses 6 wk)	2a	INH/RIF	2 ×/wk for 36 doses	A	B†
			2b*	INH/RPT	1 ×/wk for 18 doses	B	E
3	INH RIF PZA EMB	3 ×/wk for 24 doses	3a	INH/RIF	3 ×/wk for 54 doses	B	B
4	INH RIF EMB	7 d/wk for 56 doses or 5 d/wk for 40 doses	4a	INH/RIF	7 d/wk for 217 doses (31 wk) or 5 d/wk for 155 doses (31 wk)	C	C
			4b	INH/RIF	2 ×/wk for 62 doses (31 wk)	C	C

Note: Abbreviations: EMB = ethambutol; INH = isoniazid; PZA = pyrazinamide; RIF = rifamppin; RPT = rifapentine.
Ratings: A = preferred; B = acceptable alternative; C = offer when A and B cannot be given; E = should never be given.
**Not recommended for HIV-infected patients with CD4+ cell counts <100 cells/μl.*
DOT is the preferred method for giving drugs on an intermittent basis.
† Options 1c and 2b should be used only in HIV-negative patients who have negative sputum smears at the time of completion of 2 months of therapy and who do not have cavitation on initial chest radiograph. For patients started on this regimen and found to have a positive culture from the 2-month specimen, treatement should be extended an extra 3 months.
SOURCE: *Adapted from Treatment of tuberculosis,* MMWR *52:3, 2003.*

should be performed. Patients should always be informed about the common adverse effects of drugs before starting therapy (Table 140-5).

Duration of Observation and Evaluation of Response to Treatment

Patients with Positive Pretreatment Sputum

To monitor conversion and detect the possible emergence of drug resistance, sputum smear and cultures should be obtained monthly or at least after 2, 4, and 6 months of therapy. With INH- and RMP-containing regimens, sputum should convert to negative within 2 months. If smear and culture results continue to be positive after 2 months of therapy, emerging drug resistance and noncompliance should be major concerns. A new drug susceptibility test should be performed immediately. Unless drug resistance is demonstrated, the regimen in use should be continued carefully under direct observation. If drug resistance occurs, at least two new drugs to which the organism is sensitive should be added to the therapy and administered under direct observation. Addition of a single drug to therapy should never be done since it increases the risk of the rapid development of resistance to the new drug. Bacteriologic culture and susceptibility tests should be performed at monthly intervals until the cultures become negative. Relapse of drug-sensitive infections after adequate INH- and RMP-containing treatment is very infrequent. For patients who have completed a standard regimen and have had a satisfactory bacteriologic response, follow-up after completion of therapy is not necessary. In contrast, the patient with extensive disease, immunosuppressed patients, the persistence of radiologic findings after therapy, or suspicion of poor patient compliance, are indications for prolonged follow-up.

A chest radiograph before the start of therapy is necessary to compare with one taken after the completion of therapy. Monthly chest radiographs during therapy are helpful, but not as essential as sputum examinations. A chest

Table 140-4

Doses* of Antituberculosis Drugs for Adults and Children†

Drug	Adults/Children	Daily Dose	Intermittent Dose (2 ×/wk)
First-line drugs			
Isoniazid	Adults (max.)	5 mg/kg (300 mg)	15 mg/kg (900 mg)
	Children (max.)	10–15 mg/kg (300 mg)	20–30 mg/kg (900 mg)
Rifampin	Adults‡ (max.)	10 mg/kg (600 mg)	10 mg/kg (600 mg)
	Children (max.)	10–20 mg/kg (600 mg)	10–20 mg/kg (600 mg)
Rifabutin	Adults‡ (max.)	5 mg/kg (300 mg)	5 mg/kg (300 mg)
	Children	Unknown for children	Unknown for children
Rifapentine	Adults (max.)	—	10 mg/kg (600 mg) continuation phase (once weekly)
	Children (not approved)		
Pyrazinamide	Adults (max.)	20–25 mg/kg (2.0 g)	50 mg/kg (4.0 g)
	Children (max.)	15–30 mg/kg (2.0 g)	50 mg/kg (2.0 g)
Ethambutol	Adults (max.)	15–20 mg/kg (1.6 g)	50 mg/kg (4.0 g)
	Children§ (max.)	15–20 mg/kg (1.0 g)	50 mg/kg (2.5 g)
Second-line drugs			
Cycloserine	Adults (max.)	10–15 mg/kg divided into two doses (1.0 g)¶	No data
	Children (max.)		
Ethionamide	Adults (max.)	15–20 mg/kg (1.0 g) may be divided into two doses#	No data
	Children (max.)		
Streptomycin	Adults (max.)	**	**
	Children (max.)	20–40 mg/kg (1.0 g)	20 mg/kg
Amikacin/kanamycin	Adults (max.)	**	**
	Children (max.)	15–30 mg/kg (1.0 g)	15–30 mg/kg
Capreomycin	Adults (max.)	**	**
	Children (max.)	15–30 mg/kg (1.0 g)	15–30 mg/kg
p-Aminosalicyclic acid (PAS)	Adults	8–12 g	No data
	Children (max.)	200–300 mg/kg (10 g)	
Levofloxacin	Adults	500–1000 mg	No data
	Children	††	††
Moxifloxacn	Adults	400 mg	No data
	Children	‡‡	‡‡
Gatifloxacin	Adults	400 mg	No data
	Children	§§	§§

* *Dose per weight is based on ideal body weight. Children weighing more than 40 kg should be dosed as adults.*

† *For purposes of this document adult dosing beigns at age 15 years.*

‡ *Dose may need to be adjusted when there is concomitant use of protease inhibitors or nonnucleoside reverse transcriptase inhibitors.*

§ *The drug can likely be used safely in older children but should be used with caution in children less than 5 years of age, in whom visual acuity cannot be monitored. In younger children EMB at the dose of 15 mg/kg per day can be used if there is suspected or proven resistance to INH or RIF.*

¶ *It should be noted that although this is the dose recommended generally, most clinicians with experience using cycloserine indicate that it is unusual for patients to be able to tolerate this amount. Serum concentration measurements are often useful in determining the optimal dose for a given patient.*

The single daily dose can be given at bedtime or with the main meal.

** *Dose: 15 mg/kg per day (1 g), and 10 mg/kg in persons more than 59 years of age (750 mg). Usual dose: 750–1000 mg administered intramuscularly or intravenously, given as a single dose 5–7 days/week and reduced to two or three times per week after the first 2–4 months or after culture conversion, depending on the efficacy of the other drugs in the regimen.*

†† *The long-term (more than several weeks) use of levofloxacin in children and adolescents has not been approved because of concerns about effects on bone and cartilage growth. However, most experts agree that the drug should be considered for children with tuberculosis caused by organisms resistant to both INH and RIF. The optimal dose is not known.*

‡‡ *The long-term (more than several weeks) use of moxifloxacin in children and adolescents has not been approved because of concerns about effects on bone and cartilage growth. The optimal dose is not known.*

Table 140-5

Side Effects of Antituberculosis Drug

Drugs	Most Common Side Effects	Tests to Detect Side Effects	Remarks
Isoniazid	Peripheral neuritis, hepatotoxicity, hypersensitivity	SGOT, SGPT	Pyridoxine 50 mg as prophylaxis for neuritis, 100–200 mg as treatment
Rifampin	Hepatitis, GI upset (skin eruptions, fever)	SGOT, SGPT	Orange urine and other body secretions
Pyrazinamide	Hyperuricemia, hepatotoxicity, (skin rash, GI irritation)	Serum uric acid level, SGOT, SGPT	NSAIDS for nongouty polyarthralgias: allopurinol for frank gout
Streptomycin	8th nerve damage, nephrotoxicity	Vestibular function, audiograms, BUN/creatinine	Use in caution in older patients or those with renal disease
Ethambutol	Optic neuritis (reversible), (hyperuricemia, gout, skin rash, drug fever, GI iritation)	Red-green color discrimination and visual acuity	Use with caution when eye test is not feasible
Ethionamide	GI intolerance, endocrine disturbances, hepatitis, hypersensitivity	SGOT, SGPT	Consider antiemetics or bedtime dosing
Cycloserine	Neurological and psychiatric distubances	Serum levels of drug, regular evaluation of mental status	Pyridoxine
Capreomycin, kanamycin, amikacin, viomycin	Hearing loss, vestibular damage, renal toxicity, electrolye disturbances	Audiogram, vestibular examinations, BUN/creatinine	Use with caution in older patients or those with renal disease
p-amino-salicylic acid (PAS)	GI intolerance, hepatitis, hypersenstivity	SGOT, SGPT	Consider antacids or dosing at meal time
Ciprofloxacin, ofloxacin	GI intolerance, headache, restlessness, hypersensitivity, drug interactions	Monitoring for drug interactions	Avoid antacids, iron, zinc, and sucralfate, which decrease absorption
Clofazimine	Abdominal pain, skin discolorations (both dose related), photosensitivity		Consider dosing at mealtime, avoid sunlight

radiograph taken at the end of therapy will also help for comparison with any future films.

Patients with Negative Sputum

In patients with radiographic abnormalities and clinical findings consistent with TB, diagnostic tests should be performed to isolate *M. tuberculosis.* If an alternative diagnosis cannot be established, treatment against TB should be started while culture results are awaited. For this group of patients, clinical evaluation and chest radiographs are the major indicators of response to therapy. If cultures are negative and radiographic changes have not occurred after 3 months of an INH- and RMP-containing regimen, the abnormality is probably due to another disease or a TB fibrotic scar if the patient is PPD positive.

Retreatment of Patients Who Have Relapsed

Patients whose sputum is persistently positive after 5 to 6 months of therapy are considered treatment failures. A current sputum specimen should be obtained for the susceptibility testing. While susceptibility results are pending, the original therapy may be continued, or at least three new drugs added to the therapy. DOT should be done if that has not already been done. When the new susceptibility test results are received, a new regimen should be adopted in accordance with the results of the susceptibility tests. Patients who relapse after completing a regimen containing both INH and RMP, and whose organisms were susceptible to the drugs at the onset of treatment, may be restarted on their original therapy, since the organisms are still usually susceptible. In contrast, patients who relapse after taking a regimen that did not contain both INH and RMP should be assumed to be infected with an organism that is resistant to all previous drugs and managed accordingly.

Adherence and Directly Observed Therapy

Nonadherence to therapy is a major reason for failure of antituberculosis treatment. To overcome this problem, therapy should be given under DOT, if possible. A medical or other responsible person should observe as the patient ingests antituberculosis drugs. A health care worker may observe the patient in the "field" (patient's home, place of work, school, etc.) or the clinic. Following the initial therapy of daily treatments for the first 2 weeks, DOT may be administered. While DOT is especially useful in alcoholic, drug addictive or homeless patients, as their risk of nonadherence is very high, DOT increases successful completion of treatment in all groups. The cost of DOT is insignificant compared with the cost of hospitalization for advanced TB or multi-drug–resistant TB.

Treatment of Drug-Resistant Tuberculosis

Patients can become infected with *Mycobacteria* resistant to drugs in two ways. The first is to become infected with resistant organisms. This is called primary resistance. The second is that the resistant organism develops in TB patients during therapy. This is called secondary resistance. Multi-drug–resistant TB (MDT-TB) is defined as organisms that are resistant to both INH and RMP and requires the use of second-line drugs. Extensively or extremely resistant TB (XDR-TB) is not only resistant to INH and RMP but also resistant to three or more of the six classes of second-line drugs. MDR-TB has been reported to be higher than 20 percent in South Africa and XDR-TB as high as 2 percent.

During the initial phase of treatment with a single drug, most of the susceptible bacilli are destroyed, but the small number of resistant mutants continues to grow and, after 2 weeks to several months, the resistant bacilli outgrow the susceptible bacilli; this is known as the "fall and rise" phenomenon. This is most likely to occur when the bacillary population is very large (i.e., cavitary TB). Mutants with multiple mutations may be selected out, resulting in organisms with resistance to multiple drugs. Basically, nonadherence to prescribed therapy and the use of inadequate therapy regimens cause the development of drug resistance. The best treatment for drug-resistant TB is to make sure the patient receives adequate treatment initially and prevent the emergence of drug resistance.

Treatment of drug resistant TB should only be done in close consultation with experts in the management of drug-resistant TB. The initial course of treatment for drug-resistant TB represents the patient's best hope for cure. Inappropriate therapy can lead to serious morbidity and mortality.

Surgery

Surgery is rarely used for the treatment of TB. Before the chemotherapeutic era, surgery was used as an adjunct to "resting" of the lungs. Operations such as artificial pneumothorax, artificial pneumoperitoneum, plombage, artificial phrenic nerve paralysis, thoracoplasty, pulmonary resection, cavity drainage, and decortication were performed as important adjunctive treatment for managing cavity lesions, progressive focal disease, empyemas, and fibrothorax. Today, surgery has a role for treatment failure, such as multi-drug resistant TB with localized disease, chronic empyema, bronchopleural fistula, life-threatening hemoptysis unresponsive to arteriographic embolization, and closed pleural evacuation.

Adjunctive Corticosteroid Therapy

Corticosteroids do not play a major role in treatment of TB, but they are useful in some types of diseases. In fulminant military disease, ARDS, and obstructive lymphadenopathy, 20 to 30 mg/day of prednisone is helpful to relieve symptoms, improve oxygenation, and abolish fever. Patients with tuberculous meningitis at stages 2 and 3 (uncomplicated cases) seem to benefit from corticosteroid therapy. Prednisone should be begun at 60 to 80 mg/day and gradually decreased after 1 to 2 weeks. Corticosteroid therapy has been recommended in treatment of pericardial TB to prevent constriction.

Special Treatment Situations

Tuberculosis in HIV-infected individuals is associated with a high mortality. This is usually in patients with advanced HIV and may be due to stimulation of HIV replication secondary to tuberculosis. However, the effective use of antiretroviral therapy may change this. The treatment of persons with HIV infection is essentially the same as the treatment of patients without HIV infection with two exceptions. First, once-weekly INH-rifapentine should not be used in the continuation phase; and second, twice-weekly INH-RIF should not be used in patients with a CD4+ lymphocyte count less than 100/μl. A major concern about the treatment of tuberculosis in patients who are HIV+ is the interaction of rifampin with the anti-retroviral agents (see above).

Mycobacterial Infections and HIV Infection

Petros C. Karakousis • Richard E. Chaisson

Mycobacterial infections are important complications of human immunodeficiency virus (HIV) disease. During the past two decades, the emerging HIV pandemic has resulted in dramatic increases in illness caused by mycobacteria. In particular, the spread of HIV has caused sharp increases in tuberculosis rates in endemic countries, as well as in those with previously declining rates. Although the incidence of *Mycobacterium avium*-complex infection among HIV-infected persons has decreased significantly since the introduction of highly active antiretroviral therapy, *M. avium* complex remains an important pathogen for those who are not receiving or are unable to tolerate such therapy. By lowering cell-mediated immune responses, HIV infection increases the susceptibility to new mycobacterial infections, as well as the risk of progression from latent tuberculosis infection to active disease. Infections with other nontuberculous mycobacteria, such as *M. kansasii*, *M. genavense*, and *M. haemophilum*, are also associated with HIV infection.

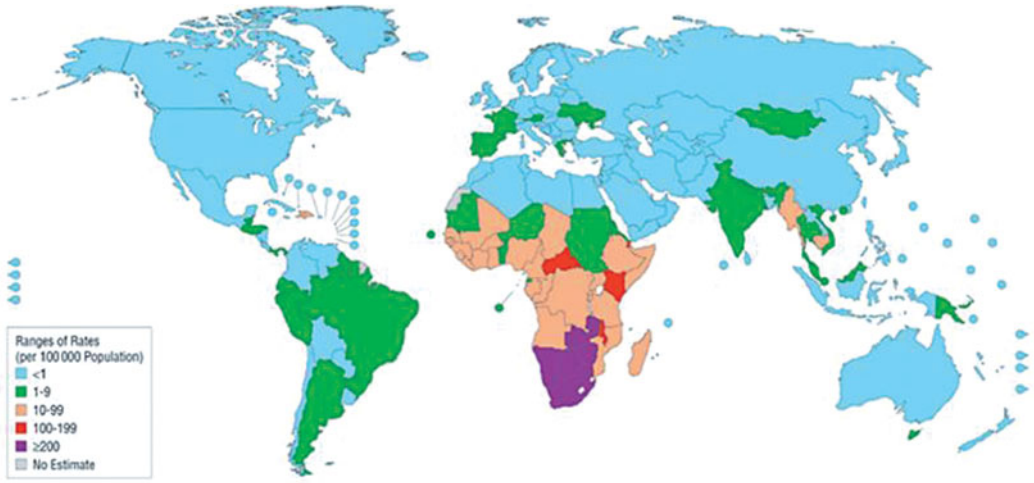
In developing countries, tuberculosis is exceedingly common in patients with HIV infection, while *M. avium* complex is more unusual. Figure 141-1 shows the worldwide prevalence of co-infection with HIV and *M. tuberculosis*. The World Health Organization estimates that at least 11 million adults are infected with both agents. Throughout the world, mycobacterial infections are common complications of HIV-associated immunodeficiency. This chapter will review the clinical and therapeutic aspects of HIV-related mycobacterial infections.

MYCOBACTERIUM TUBERCULOSIS

Epidemiology

HIV infection is increasingly common in populations with a high prevalence of *M. tuberculosis* infection. In the United States, for example, HIV is prevalent in injection drug users, people from racial and ethnic minority groups, and residents of inner cities—populations with historically high rates of tuberculosis. Recent data suggest an exceedingly high prevalence of HIV (80 percent) among injection drug users with tuberculosis in New York City. The increased susceptibility of these co-infected persons to developing active tuberculosis has contributed to a significant rise in tuberculosis rates in the United States. Prior to the HIV epidemic, new cases of tuberculosis were stably decreasing between 1953 and 1984 at a rate of 5 percent per year. With the spread of HIV, new cases of tuberculosis began to rise, peaking in 1992 at 26,673 new cases that year.

The risk of tuberculosis among HIV-infected individuals is dependent on the prevalence of tuberculosis in the community, the degree of immune suppression from HIV, and the



Corbett, E. L. et al. Arch Intern Med 2003;163:1009-1021.

accessibility to treatment for latent tuberculosis infection. In developing countries, where the prevalence of tuberculosis infection in adults may exceed 50 percent, the spread of HIV has caused sharp increases in tuberculosis case rates. Substantial increases in tuberculosis morbidity related to HIV infection have occurred in sub-Saharan African countries, Thailand, and Latin American countries. A recent analysis of global tuberculosis trends estimates that approximately one-tenth of all cases worldwide are attributable to HIV, ranging from 1 percent in the Western Pacific, to one-third of all cases in Africa. Despite a low overall prevalence of tuberculosis, one-fourth of tuberculosis cases in the United States are attributable to HIV, reflecting the vulnerability of certain subpopulations to co-infection with HIV and *M. tuberculosis*. As case rates of tuberculosis have increased due to the HIV epidemic, additional problems have emerged, including outbreaks of tuberculosis in HIV-infected persons in hospitals or other congregate living facilities, and the rise of multidrug-resistant tuberculosis.

Pathogenesis

HIV is the strongest known risk factor for development of tuberculosis. In patients with latent tuberculosis infection the acquisition of HIV infection results in progressive impairment of cell-mediated immunity, which is required for the successful containment of tubercle bacilli. A number of immunologic defects have been noted in patients with *M. tuberculosis* and HIV infections, including reductions in CD4 cell levels, impaired T-cell proliferation, decreased cytolytic T-cell responses, deranged intracellular killing, and reduced cytokine elaboration in response to mycobacterial antigen challenge. The risk of reactivation of latent tuberculosis infection increases dramatically in patients with HIV co-infection, from 5 to 10 percent per lifetime in immunocompetent hosts to 5 to 10 percent per year in co-infected patients. The risk of reactivation rises as CD4 cell levels decline.

The early natural history of *M. tuberculosis* infection is also greatly affected by HIV disease. Although it is not clear if HIV-infected persons are more likely to acquire *M. tuberculosis* infection after exposure to infectious cases, it has been definitively shown that there can be rapid progression to clinical disease following initial tuberculosis infection in HIV-infected individuals. For example, in a residential care facility for HIV-infected persons in San Francisco, 38 percent of susceptible residents developed active pulmonary tuberculosis with an identical strain of *M. tuberculosis* (identified with restriction fragment length polymorphism analysis) within 120 days of exposure to the index case. The rapid progression of tuberculosis infection to tuberculosis disease in persons with HIV infection has resulted in numerous outbreaks of tuberculosis in institutions such as hospitals, nursing homes, and prisons, as well as in community settings. Molecular epidemiological studies have shown that approximately 40 percent of tuberculosis cases in urban areas of the United States are epidemiologically clustered, indicating recent transmission and primary disease. In these settings, HIV infection is significantly associated with clustering of tuberculosis cases.

Because *M. tuberculosis* is a virulent pathogen even in the normal host, tuberculosis tends to occur relatively early in the course of HIV infection. In general, HIV-seropositive patients tend to have higher CD4 counts than patients with opportunistic infections such as *Pneumocystis jiroveci* pneumonia. A recent retrospective cohort analysis of over 20,000

mineworkers in South Africa showed that the risk of tuberculosis doubled within the first year of HIV infection, prior to any significant reduction in CD4 cell counts. HIV-infected patients also appear to be at higher risk for re-infection, probably because of an impaired capacity to mount long-lasting protective immune responses. Using DNA fingerprinting, a study of South African HIV-infected mineworkers who had completed treatment for pulmonary tuberculosis showed that recurrence of tuberculosis was a consequence of re-infection rather than relapse. Interestingly, several cross-sectional studies and a prospective cohort study have shown that HIV-infected individuals with pulmonary tuberculosis are less likely than HIV-uninfected patients to transmit *M. tuberculosis* to close contacts. Possible explanations for the decreased contagiousness of HIV-infected individuals may include a lower sputum bacillary burden, decreased duration of smear-positivity due to rapid progression and earlier presentation to medical care, weakened cough with more severe disease, or greater social isolation.

While HIV has a major effect on the natural history of tuberculosis, there is also evidence that tuberculosis may affect the course of HIV disease. Experimental evidence indicates that *M. tuberculosis* increases HIV replication and enhances susceptibility to viral infection at the cellular level. A number of retrospective studies have shown worsened survival in HIV-infected persons with tuberculosis. The largest prospective cohort study to evaluate the impact of tuberculosis on survival of HIV-infected individuals demonstrated a threefold increased risk of death in patients with CD4 counts greater than 200 cells/mm^3, but no significant effect on individuals with more advanced immunosuppression. However, other studies have shown that a high viral load and low CD4 cell count precede the onset of tuberculosis, implying that the latter is a marker of advanced HIV disease, rather than the cause of accelerated immunosuppression. Furthermore, another study showed that there was no significant difference in viral load or CD4 cell counts in 111 HIV-infected patients during the treatment of active tuberculosis. Therefore, although treatment of tuberculosis may have a modest effect on the course of HIV infection, clearly the most important intervention in controlling HIV progression is institution of highly active antiretroviral therapy.

Clinical Manifestations

Depending on the degree of immune suppression, the clinical features of tuberculosis in HIV infection may differ significantly from those seen in patients without HIV infection. Patients with higher CD4 counts (greater than 300 cells/mm^3) tend to have more typical presentations, involving the lungs predominantly with upper-lobe infiltrates, with or without cavitation. As CD4 cell levels decline, tuberculosis is more likely to present atypically, including extrapulmonary involvement and disseminated disease, with low rates of tuberculin skin test reactivity. Unusual findings on chest radiographs in these patients are common, including lower

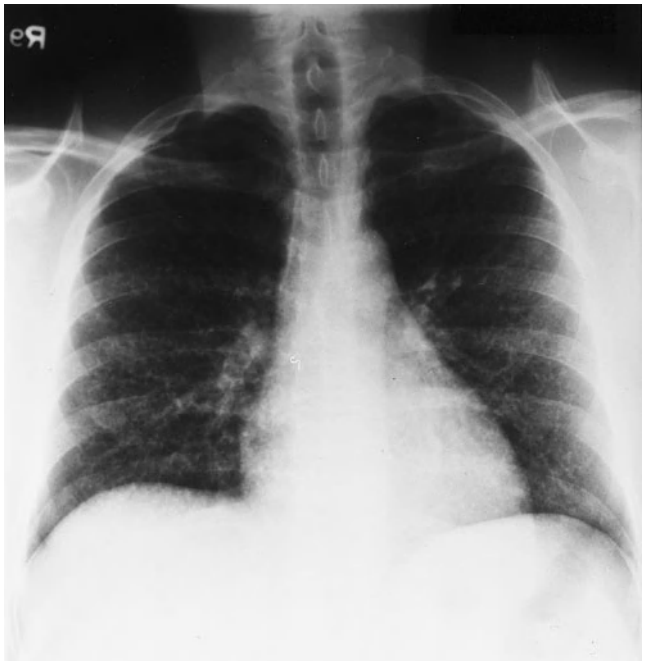

Figure 141-2 Chest radiograph from a 40-year-old HIV-infected man with HIV and miliary tuberculosis.

lung zone involvement and diffuse interstitial or alveolar infiltrates, which may mimic *P. jiroveci* pneumonia (Fig. 141-2). Hilar adenopathy is seen more frequently in patients with HIV infection, but cavitation and pleural effusions are uncommon, especially with advanced HIV disease. The most frequent sites of extrapulmonary involvement include lymph nodes, the urinary tract, meninges, and bone marrow. Mycobacteremia is not unusual, particularly in patients with low CD4 cell counts. One study found that mycobacterial blood cultures were positive in 49 percent of HIV-infected tuberculosis patients with CD4 counts less than or equal to 100 cells/mm^3, as opposed to 11 percent for patients with CD4 counts greater than 100/mm^3. However, despite the increased frequency of atypical manifestations of tuberculosis among HIV-infected patients, pulmonary disease tends to predominate in most series.

The diagnosis of tuberculosis in the HIV-infected patient requires a high index of suspicion and the use of appropriate diagnostic tests. The presence of acid-fast bacilli on sputum or tissue sample smears has a high positive predictive value for the diagnosis of tuberculosis, even in populations where *M. avium* complex is more common. However, only two-thirds to three-fourths of HIV-infected patients with pulmonary tuberculosis will have a positive acid-fast smear on a sputum sample. Since the diagnostic yield of sputum smears depends to some extent on cavitation, the sensitivity of this test may be lower in patients with advanced immunosuppression who are less likely to develop cavitary lesions. The number of bacilli in the sputum of HIV-infected patients may be lower than in the sputum of HIV-uninfected

patients, but sputum concentration through centrifugation may improve detection of acid-fast bacilli in these samples. Bronchoalveolar lavage and transbronchial biopsy are useful in diagnosing HIV-related pulmonary tuberculosis, as well as in evaluating for the presence of other pathogens, such as *P. jiroveci*. Biopsy is particularly useful in patients with pulmonary nodules or intrathoracic lymphadenopathy, since identification of granulomas or caseous necrosis is strongly suggestive of tuberculosis. Given the moderate sensitivity of acid-fast smears, presumptive therapy should be initiated in patients suspected of having tuberculosis after diagnostic tests have been performed and cultures are pending.

Tuberculin skin testing using protein purified derivative (PPD) has lower sensitivity in diagnosing tuberculosis in patients with HIV infection than in other populations. Because the tuberculin skin test loses sensitivity with progressive immune suppression, induration of greater than or equal to 5 mm is considered positive in HIV-infected individuals. In one study, only 14 percent of HIV-infected drug users had a reaction of at least 5 mm induration to PPD, whereas 25 percent of HIV-seronegative drug users had a reaction of at least 10 mm induration. In addition, the sensitivity of the tuberculin skin test declines as CD4 cell levels fall. However, even in the setting of advanced HIV disease, almost half of patients with active tuberculosis have a positive PPD, and the test maintains a high positive predictive value for the diagnosis of tuberculosis.

Nucleic acid amplification tests have good sensitivity and specificity for the diagnosis of tuberculosis in respiratory specimens that are smear-positive for acid-fast bacilli, but the sensitivity declines significantly in smear-negative samples. Although these tests have not been extensively validated in HIV-infected individuals, they appear to maintain the same specificity with slightly lower sensitivity as compared to HIV-uninfected individuals. The Quantiferon assay, an enzyme-linked immunosorbent assay (ELISA)-based test quantifying interferon-γ in plasma after stimulation of whole blood with PPD, was shown to have a relatively high agreement with the tuberculin skin test in HIV-negative persons in areas with a relatively low prevalence of tuberculosis. However, concordance between these two tests is relatively low in HIV-infected patients. T-cell–based assays using *M. tuberculosis*-specific antigens, including ESAT-6 and CFP-10, may be useful in the diagnosis of active and latent tuberculosis infection in HIV-infected persons. These assays appear to have increased specificity as compared to the tuberculin skin test, particularly in bacille Calmette-Guérin (BCG)–vaccinated individuals, but they are relatively expensive and require laboratory-based expertise, thus limiting their potential use in areas of the world with the highest prevalence of tuberculosis and HIV co-infection.

Treatment and Prevention

As in HIV-uninfected individuals, the successful treatment of tuberculosis in patients with HIV infection relies heavily on directly observed therapy involving a four-drug induction phase followed by a two-drug continuation phase. Despite similar responses to therapy, patients with HIV infection have a higher overall mortality and are at higher risk for tuberculosis reinfection than HIV-uninfected patients. Concurrent opportunistic infections, drug interactions, and immune reconstitution may complicate the therapy of patients with tuberculosis and HIV infection.

Retrospective and prospective studies have shown that treatment regimens which include isoniazid and rifampin supplemented by pyrazinamide and ethambutol (or streptomycin) for the first 2 months are effective in treating HIV-infected patients with active tuberculosis. Sputum conversion, time to defervescence, and resolution of radiographic abnormalities occurs as rapidly in HIV-infected patients as those without HIV infection. After successful completion of therapy for tuberculosis, relapse rates are similar for HIV-infected and HIV-uninfected persons (i.e., between 2 and 5 percent), although HIV-infected persons remain at increased risk for exogenous reinfection. In addition, mortality rates are higher for patients with HIV and tuberculosis co-infection, since these patients are at increased risk for infection with opportunistic pathogens.

Patients with HIV infection are generally more likely to experience adverse reactions from first-line antituberculosis medications. For example, dermatologic reactions are common in HIV-infected individuals receiving isoniazid and rifampin. The use of thiacetazone in developing countries has been linked with severe mucocutaneous hypersensitivity and toxic epidermal necrolysis in HIV-infected patients, and should be avoided in this population. Adverse reactions are especially common in patients treated concomitantly with antituberculosis medications and antiretroviral therapy. Peripheral neuropathy is common in patients receiving isoniazid and the antiretrovirals stavudine and didanosine. In addition, concurrent therapy for HIV and tuberculosis infections leads to many potential drug interactions. Use of rifampin, which is a potent inducer of cytochromes P450, can result in subtherapeutic levels of protease inhibitors or non-nucleoside reverse transcription inhibitors, leading to antiretroviral treatment failure. Rifabutin, the rifamycin with the least potential for induction of cytochromes P450, is recommended for use in patients receiving protease inhibitors. However, protease inhibitors, especially ritonavir, cause a marked reduction in the metabolism of rifabutin, resulting in supratherapeutic rifabutin levels and increased toxicity. Therefore, rifabutin doses must be decreased when used together with protease inhibitors (except saquinavir). In contrast, rifabutin doses must be increased when this drug is used with efavirenz. Rifampin may be used with efavirenz, but some experts recommend increasing the efavirenz dose to 800 mg daily. None of the rifamycins should be used with delavirdine because they may reduce delavirdine concentrations by up to 90 percent. Despite the numerous potential interactions, rifamycins should be included in the treatment of tuberculosis in HIV-infected patients, since non-rifamycin–based

regimens are generally more complicated to administer and are associated with higher rates of relapse.

One concern in treating patients with tuberculosis and HIV infection is paradoxical worsening associated with immune reconstitution upon initiation of highly active antiretroviral therapy, which may occur in up to one-third of cases. The immune reconstitution inflammatory syndrome usually occurs within 6 weeks of antiretroviral initiation in patients with very low initial CD4 counts who experience a rapid rise in CD4 cells or decline in HIV viral load over a short period of time. The syndrome is consistent with an enhanced inflammatory response to *M. tuberculosis* with the rapid improvement of immune function, manifesting as high fevers, lymphadenopathy, and respiratory compromise. Although data from randomized trials are lacking, nonsteroidal anti-inflammatory agents are often used for mild cases, and corticosteroids at doses of approximately 1 mg/kg per day may be used for more severe presentations. Steroids should be tapered very slowly over the course of weeks to months, depending on the clinical response. Although some authorities have advocated delaying the initiation of antiretroviral therapy until the completion of 2 months of therapy for active tuberculosis, it appears that the risks of AIDS-defining illnesses and mortality outweigh any benefits associated with delaying HIV therapy. Therefore, antiretroviral therapy should not be delayed in individuals with CD4 counts below 100 cells/mm^3.

Given the high rate of reactivation of latent tuberculosis infection in patients with HIV infection, treatment of latent tuberculosis infection in these patients is paramount. Two meta-analyses of randomized clinical trials performed in the United States, Africa, and Latin America prior to 1998 showed that treatment of latent tuberculosis infection in HIV-infected persons with isoniazid for 6 to 12 months reduces the risk of tuberculosis by over 40 percent but does not affect mortality. Because subgroup analyses of prospective, randomized trials in HIV-uninfected persons indicate that the maximal beneficial effect of isoniazid is achieved by 9 months of therapy, the same duration of therapy for latent tuberculosis infection is recommended for HIV-infected persons. Short-course regimens for the treatment of latent tuberculosis infection have been investigated in HIV-uninfected and HIV-infected patients. Four months of therapy with rifampin appears to have equivalent efficacy to 9 months of isoniazid, but special attention is required to the multiple potential drug interactions with antiretroviral agents, particularly with protease inhibitors. The combination of rifampin and pyrazinamide for 2 months appears to have similar efficacy and safety as isoniazid for 12 months in the treatment of latent tuberculosis infection in HIV-seropositive persons, and the former regimen is associated with greater medical adherence. However, several studies have reported a significantly increased risk of hepatotoxicity associated with rifampin and pyrazinamide in HIV-seronegative persons, occurring in as many as 10 percent of cases. Interestingly, this regimen is not associated with hepatotoxicity in HIV-infected patients. This discrepancy has led to speculation that the hepatotoxicity associated with this regimen is immune-mediated or that there is reduced bioavailability of the medications in HIV infection. Because of these concerns, the Centers for Disease Control has issued a recommendation against the use of rifampin and pyrazinamide in HIV-seronegative individuals and a warning for HIV-seropositive persons.

MYCOBACTERIUM AVIUM COMPLEX

Epidemiology

Disseminated *Mycobacterium avium* complex is the most common bacterial opportunistic infection in HIV-1-infected adults in the developed world, with an annual frequency of 10 to 20 percent in patients with AIDS who are not receiving antiretroviral therapy. The rate of *M. avium*-complex infection among HIV-infected persons has decreased significantly since the introduction of highly active antiretroviral therapy. In the Johns Hopkins HIV cohort, the incidence of disseminated *M. avium* complex fell steeply from 9 cases per 100 person years in 1993 to 0.5 cases per 100 person years in 2003 (Fig. 141-3). A multivariate Cox proportional hazards analysis showed that predictors for developing disseminated *M. avium* complex in this cohort of patients with CD4 counts less than 200 cells/mm^3 were enrollment between 1990 and 1995, younger age, and no use of highly active antiretroviral therapy. However, persons with HIV infection and advanced immunosuppression who are not receiving or are unable to tolerate highly active antiretroviral therapy continue to be at risk for disseminated *M. avium* complex. In addition to causing substantial morbidity in advanced HIV disease, disseminated *M. avium* complex is an independent predictor of mortality, even after adjustment for CD4

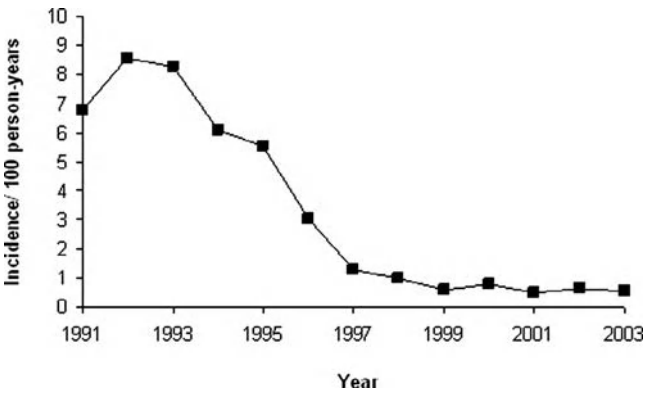

Figure 141-3 Incidence of *M. avium*-complex infection inpatients with a CD4 count less than 200 cells/mm^3 in the Johns Hopkins HIV clinic cohort, 1991–2003. (*Methods are described in Moore RD, Chaisson RE: Natural history of opportunistic disease in an HIV-infected urban clinical cohort. Ann Intern Med 124:633–642, 1996.*)

lymphocyte count. Because of the frequency, severity, and effect on survival of *M. avium*-complex infections, physicians caring for patients with HIV infection should be familiar with the treatment and prevention of this important complication of AIDS.

M. avium complex is acquired from the environment and is not spread from person to person. The organism is a common environmental mycobacterium, which is concentrated in soil and water and is also found in a number of animal reservoirs throughout the world. Although the organism is found widely in the environment, there is marked geographic variability in the incidence of *M. avium*-complex disease among HIV-infected individuals. For example, disseminated *M. avium* complex is frequently seen in AIDS patients in the United States, but the disease is unusual in African AIDS patients. In addition, *M. avium*-complex bacteremia is more prevalent among HIV-infected patients in the southern United States, as compared with those in the northern states and Canada. There are several potential explanations for the observed differences in worldwide distribution of *M. avium*-complex infection. Environmental concentrations of *M. avium* complex may be higher in areas of increased prevalence of disease, such as in the acidic swamps of the southeastern United States, although most environmental *M. avium* complex isolates are not linked to human disease. A possible explanation for the lower prevalence of *M. avium*-complex disease in African countries is that HIV-infected persons living in these countries may succumb to tuberculosis or other pyogenic infections at CD4 cell levels sufficient to protect against *M. avium* complex. Alternatively, prior exposure of these populations to other mycobacterial infections, including tuberculosis or BCG vaccination, may result in protection against disseminated *M. avium*-complex disease. However, African HIV-infected persons who migrate to Europe have rates of *M. avium*-complex disease similar to those of European HIV-infected patients, suggesting that differences in environmental concentrations of this organism may be responsible for observed geographic disparities in prevalence of *M. avium*-complex disease. It is also possible that *M. avium* complex is isolated and reported less frequently in African countries as a result of inadequate diagnostic capabilities or clinical evaluation.

The environmental sources responsible for most human *M. avium*-complex infections are not known. Studies using molecular epidemiological techniques have shown that some patients with AIDS and disseminated *M. avium* complex may acquire infection from hospital hot-water supplies or community potable water sources. Other possible epidemiological risk factors have been identified, including history of gastrointestinal endoscopy or bronchoscopy, consumption of raw seafood or hard cheese, and tobacco use. However, no study has convincingly established any connection between environmental exposures and subsequent *M. avium*-complex disease. Therefore, specific recommendations for avoiding particular exposures in HIV-infected patients cannot be made with confidence.

Pathogenesis

The *M. avium*-complex family comprises numerous organisms of varying serotypes from the species *M. avium* and *M. intracellulare*. In HIV-infected persons, *M. avium*-complex infection most commonly presents as disseminated disease and isolated pulmonary involvement is rare. This may reflect differences in organism tropism and virulence, as the majority of bacteremic strains in patients with AIDS are *M. avium*, whereas *M. intracellulare* is more commonly associated with pulmonary infection in HIV-seronegative persons with underlying structural lung disease.

M. avium complex is acquired from environmental sources either by inhalation or ingestion of organisms, leading to pulmonary and gastrointestinal infection, respectively. In healthy hosts, infection is usually self-limited or may not be recognized clinically, and is apparent only by reactivity to delayed-hypersensitivity skin testing. In HIV-infected persons, colonization of the respiratory and gastrointestinal tracts increases the risk of disseminated *M. avium*-complex significantly, although most patients with *M. avium*-complex bacteremia do not have evidence of prior colonization. Chin et al reported that for HIV-infected patients with CD4 less than or equal to 50/mm^3 who were colonized with *M. avium* complex, the risk of *M. avium*-complex bacteremia was 60 percent within 1 year. Specifically, colonization of the stool increased the risk of disseminated *M. avium*-complex sixfold and colonization of the sputum increased the risk more than twofold. However, two-thirds of patients who ultimately developed *M. avium*-complex bacteremia had no evidence of prior colonization. Thus, culture of these sites to detect colonization has limited use as a screening test.

The most important predictor of disseminated *M. avium*-complex is low CD4 lymphocyte count. Prospective studies have shown that as CD4 counts decline to below 100 cells/mm^3 the annual incidence of *M. avium*-complex bacteremia rises substantially. The annual risk of *M. avium*-complex bacteremia is between 10 and 20 percent for patients with CD4 counts below 50 cells/mm^3, and most patients with *M. avium*-complex bacteremia have CD4 lymphocyte counts below 20 cells/mm^3. On the other hand, patients with CD4 counts of at least 100 cells/mm^3 are very unlikely to develop *M. avium*-complex bacteremia in the subsequent year. Several other immunologic abnormalities contribute to the development of disseminated *M. avium* complex in HIV-infected patients. Although the ability of macrophages to phagocytose *M. avium* complex in patients with advanced AIDS is not impaired, intracellular killing is reduced and the organisms multiply within macrophages. This intracellular killing defect may result from diminished cytokine production (especially interferon-γ and interleukin-12), leading to reduced activation of macrophages. The important role of interferon- γ in control of *M. avium*-complex infection has been clearly demonstrated, as patients who have genetic defects in the interferon- γ regulatory pathway are predisposed to disseminated infection with *M. avium* complex and other

nontuberculous mycobacteria. In addition, cell-mediated killing of infected macrophages and granuloma formation, which are important mechanisms of control of *M. avium*-complex infection, are also substantially impaired in patients with AIDS.

After initial infection is established, the infection spreads via local lymphatics. Eventually, as cell-mediated immunity wanes because of progressive HIV infection, *M. avium* complex disseminates hematogenously. *M. avium*-complex bacteremia is associated with elevations of serum tumor necrosis factor-α and interleukin-6 levels, which may account for the common constitutional symptoms of fever, night sweats, and cachexia. The organisms are taken up by mononuclear phagocytic cells throughout the body, and reticuloendothelial organs such as the liver, spleen, and bone marrow are the most frequently affected sites.

Clinical Manifestations

Common symptoms of disseminated *M. avium* complex include fever, weight loss, night sweats, fatigue, and diarrhea. The pace of the illness is usually insidious, and symptoms are often present for many weeks before the diagnosis is established. Clinical signs and laboratory abnormalities frequently include cachexia, lymphadenopathy, hepatosplenomegaly, anemia, neutropenia, and elevated liver-associated enzymes. However, these clinical and laboratory features are relatively nonspecific and are frequently observed in other opportunistic infections and malignancies associated with advanced HIV infection. Case-control studies have shown that patients with AIDS and disseminated *M. avium* complex are significantly more likely than matched controls to have fever, night sweats, weight loss, and respiratory and gastrointestinal symptoms, as well as abnormal laboratory values, including raised serum alkaline phosphatase and lactate dehydrogenase, and reduced hemoglobin levels.

M. avium-complex infection may be limited to the lymph nodes, gastrointestinal tract, or lungs in some patients. In particular, pulmonary *M. avium*-complex infection, including focal pneumonia and endobronchial lesions, may occur with or without bacteremia. However, isolated *M. avium*-complex infection involving the lungs without evidence of dissemination is extremely unusual in patients with AIDS, and most cases occur in the setting of immune reconstitution syndrome. Figure 141-4 shows the radiographic findings of chronic *M. avium*-complex pulmonary disease in a patient with long-standing bacteremia. Cavitary disease with extensive infiltrates is common in this setting and pulmonary impairment may be acute or chronic. Disseminated *M. avium* complex may be difficult to distinguish clinically from disseminated tuberculosis, especially in the presence of pulmonary involvement. Clinical features that favor the diagnosis of disseminated tuberculosis include an absence of previous AIDS-defining illnesses, the presence of acid-fast bacilli in sputum smears, and chest radiographic findings of hilar enlargement; clinical features that favor the diagnosis of disseminated *M. avium* complex include hepatosplenomegaly, elevated serum alkaline phosphatase, and leukopenia.

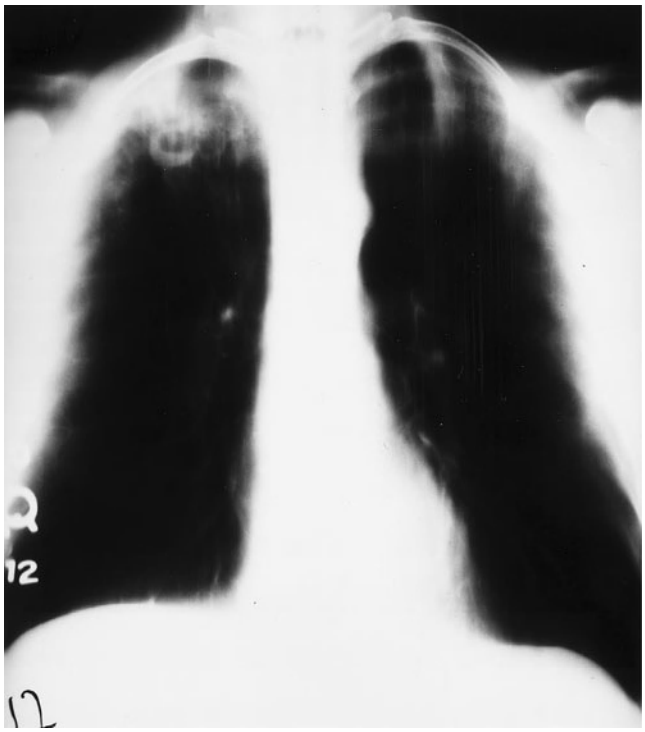

Figure 141-4 Radiographic presentation of *M. avium*-complex pulmonary disease in a patient with HIV infection. Chest radiograph showing cavitary infiltrates in a 37-year-old man with AIDS and long-standing *M. avium*-complex bacteremia.

The diagnosis of disseminated *M. avium* complex is usually made by isolation of organisms from blood or bone marrow cultures. Patients in whom *M. avium* complex is identified in other tissues should also have blood cultures performed to detect disseminated disease. Culture results may be obtained expeditiously with the use of Bactec and other rapid culture assays. DNA-RNA hybridization probes allow for speciation within 1 to 2 days after growth in liquid media. Isolation of *M. avium* complex in sputum or stool specimens does not necessarily indicate systemic disease, although, as noted above, colonization increases the risk for disseminated *M. avium* complex significantly. Presumptive therapy may be initiated in patients with CD4 counts below 50 cells/mm^3 and compatible symptoms while cultures are pending, but long-term treatment should be based on isolation of the organism in culture. If blood cultures are negative in patients with suspected disseminated *M. avium* complex, a bone marrow aspirate and biopsy may confirm the diagnosis.

Treatment and Prevention

Treatment outcomes of patients with AIDS and disseminated *M. avium* complex have improved substantially since the introduction of the extended-spectrum macrolides, which are now considered the cornerstone of any potent regimen. Clarithromycin and azithromycin given alone significantly

reduce levels of bacteremia and are associated with clinical improvement. Although both drugs are clearly effective against disseminated *M. avium* complex, several studies directly comparing these two drugs when used in combination with ethambutol suggest trends toward more rapid clearance of bacteremia with clarithromycin. Lower doses of clarithromycin (less than or equal to 1 g/day total) are associated with fewer gastrointestinal side effects and improved survival as compared to higher doses. The mechanism of increased mortality with higher doses (1000 mg twice daily) of clarithromycin is not known, and there is no evidence of any specific organ system–related toxicity. Macrolide monotherapy for disseminated *M. avium* complex is associated with clinical relapses secondary to selection of preexisting, innately macrolide-resistant *M. avium*-complex clones during therapy. Drug-resistant organisms usually begin to emerge after 2 to 3 months of therapy, and the majority of patients will experience recrudescence of symptoms after 4 or more months of therapy.

Combination therapy for disseminated *M. avium* complex is necessary to prevent the emergence of macrolide resistance. Treatment regimens should consist of clarithromycin or azithromycin with at least one other antimycobacterial agent (Table 141-1). The combination regimen of clarithromycin and ethambutol, which is the standard treatment regimen, is clinically active and prevents relapses with drug-resistant organisms in a large proportion of patients. The addition of clofazimine to this regimen does not improve efficacy and is associated with increased mortality. Recent data suggest that the addition of rifabutin to clarithromycin and ethambutol may be associated with a reduction in clarithromycin-resistance, and possibly improved survival. The aminoglycosides and fluoroquinolones have in vitro and in vivo activity against *M. avium* complex, but are generally reserved for patients who are failing first-line therapy.

A major limitation to the treatment of *M. avium*-complex disease is the occurrence of adverse drug reactions. Clarithromycin and azithromycin are associated with dose-related gastrointestinal side effects, which occur in up to one-half of patients. Common complaints include abdominal pain, nausea, vomiting, and diarrhea. Dose reduction or drug holiday may alleviate symptoms and permit further treatment. Taste and smell perversion occurs in 5 to 15 percent of macrolide-treated patients. Hepatotoxicity and rash are less common. Ethambutol is generally well tolerated, although gastrointestinal intolerance may occur. When dosed at less than 20 mg/kg daily, optic neuritis is rare. Rifabutin is associated with orange discoloration of urine, tears, and sweat in one-third to one-half of patients. Other adverse reactions include nausea, rash, and neutropenia. Uveitis is frequent with high doses (450 to 600 mg daily) of rifabutin, particularly when clarithromycin and fluconazole are coadministered. These drugs inhibit clearance of rifabutin by cytochromes P450, resulting in higher serum concentrations of rifabutin.

Routine testing of all *M. avium*-complex isolates for drug susceptibility is not currently recommended. Patients who develop systemic symptoms consistent with disseminated *M. avium* complex following apparent initial clinical response should also undergo testing for other opportunistic infections. Testing for relapse of *M. avium* complex involves obtaining blood cultures, which should be held in the laboratory for 4 to 6 weeks, since drug therapy may delay growth. If the organism is isolated on blood cultures, clarithromycin susceptibility should be performed. For patients who are known or suspected to be failing therapy, at least two new agents from different classes should be added or substituted. Azithromycin should not be substituted for clarithromycin, since cross-resistance to these agents is expected. Although no formal studies have been performed, suggested treatment for patients with clarithromycin-resistant *M. avium*-complex infection includes a fluoroquinolone (moxifloxacin or levofloxacin) in combination with ethambutol and rifabutin. Amikacin may be given initially, but extended treatment is challenging because of toxicity and the need for parenteral administration. Therapy with interferon-γ appears to be effective against disseminated *M. avium* complex in patients without HIV, but its efficacy in patients with AIDS has not been studied.

As with underlying tuberculosis infection (discussed above), HIV-infected patients with previously treated or subclinical *M. avium*-complex infection may develop immune reconstitution inflammatory syndrome soon after initiation of highly active antiretroviral therapy. This pathological inflammatory response may be seen in up to one-third of cases with HIV and *M. avium*-complex co-infection, usually manifesting as fever, abdominal pain, and lymphadenopathy. Although there are scarce data regarding the proper

Table 141-1

Regimens for the Treatment of Disseminated *M. avium* complex in Patients with HIV Infection

Preferred Regimens	Additional Drugs for Macrolide-Resistant Infections
Clarithromycin 500 mg twice daily or 1000 mg extended release once daily + ethambutol 15 mg/kg daily (± rifabutin 300 mg once daily) *or* Azithromycin 600 mg once daily + ethambutol 15 mg/kg daily (± rifabutin 300 mg once daily)	Moxifloxacin 400 mg daily *or* Levofloxacin 500–750 mg once daily + ethambutol 15 mg/kg daily + rifabutin 300 mg once daily ± amikacin 10–15 mg/kg IV daily

Table 141-2

Indications for Starting and Stopping Prophylaxis and Treatment for *M. avium*-Complex Infection in HIV-Infected Patients

Indication	When to Start	When to Stop
Prophylaxis	CD4 <50/mm^3	Increase in CD4 count to >100/mm^3 after at least 3 months of HAART
Treatment of disseminated infection	Positive blood culture	Negative blood cultures for 1 year + increase in CD4 count to >100/mm^3 after at least 3 months of HAART

HAART, highly active antiretroviral therapy.

Table 141-3

Regimens for the Prevention of *M. avium*-Complex Infection in Patients with Advanced HIV Infection

Preferred Regimens	Alternative Regimens
Clarithromycin 500 mg twice daily (or 1000 mg extended release once daily)	Rifabutin 300 mg once daily
Azithromycin 1200 mg once weekly	Azithromycin 500–600 mg once daily

management of this condition, most authorities recommend the use of nonsteroidal anti-inflammatory agents for mild cases, and systemic steroids for more severe presentations. Corticosteroids should be tapered over weeks to months, depending on the clinical response.

Although data on the discontinuation of chronic maintenance treatment for *M. avium*-complex infection are scarce, clinical evidence from other opportunistic infections support the safe discontinuation of treatment for *M. avium*-complex infection after completion of a greater than 12-month course, assuming there are no *M. avium*-complex–specific signs and symptoms, and there is a sustained rise (greater than 6 months) in CD4 cell count to greater than or equal to 100 cells/mL after highly active antiretroviral therapy.

Because disseminated *M. avium* complex is a predictable late complication of HIV infection that occurs in a large proportion of patients, chemoprophylaxis to prevent disease is desirable. In particular, patients who have a CD4 count less than or equal to 50 cells/mm^3 are at increased risk for *M. avium*-complex infection and should receive chemoprophylaxis (Table 141-2). Although official guidelines do not include criteria for initiation of prophylaxis on the basis of HIV plasma RNA (viral load) measurements, high viral loads (greater than or equal to 100,000 copies/mL) appear to be independently associated with *M. avium*-complex infection. Once-weekly azithromycin and twice-daily clarithromycin are both very effective in preventing *M. avium*-complex bacteremia in persons with low CD4 cell counts. Moreover, azithromycin prophylaxis reduces the risk of *Pneumocystis carinii* pneumonia and bacterial infections, and clarithromycin prophylaxis reduces the risk of bacterial respiratory tract and soft-tissue infections by 44 percent, and also significantly reduces mortality. Although azithromycin achieves low serum levels, the drug is concentrated in macrophages, the primary cells infected by *M. avium* complex. Therefore, the drug has a long half-life in tissue, permitting once weekly dosing.

Rifabutin is somewhat effective in preventing *M. avium*-complex bacteremia, but it is not currently recommended as first-line prophylaxis because of its modest efficacy, numerous potential drug interactions, high cost, lack of widespread availability, and potential for development of rifampicin cross-resistance in tuberculosis patients. The addition of rifabutin to either of the macrolide regimens does not appear to be significantly more effective in preventing *M. avium*-complex bacteremia, selection of macrolide-resistant organisms, or death, but is associated with increased medication-related toxicities. Therefore, current guidelines recommend clarithromycin 500 mg twice daily or azithromycin 1200 mg once weekly as first-line agents for the prevention of disseminated *M. avium* complex in HIV-infected patients with a CD4 count less than 50 cells/ mm^3 (Table 141-3). Alternative doses of clarithromycin and azithromycin are possible, although they have not been studied in human clinical trials for *M. avium*-complex prophylaxis. There have been no studies directly comparing the two drugs, and the choice of agent is based on perceptions of relative convenience, cost, tolerability, and effectiveness.

Primary prophylaxis for *M. avium* complex may be safely withheld in HIV-infected patients whose CD4 cell counts have risen to greater than or equal to 100/ mm^3 for more than 3 months in response to antiretroviral therapy (Table 141-2). Continuation of *M. avium*-complex prophylaxis in the setting of immune reconstitution after initiation of antiretroviral therapy confers no clinical benefit, and increases pill burden, costs, and the potential for drug toxicity and selection of drug-resistant organisms. A recent cohort study of over 46,000 HIV-infected persons showed that implementation of these discontinuation guidelines significantly increased the proportion of eligible patients who discontinued primary

prophylaxis from 17 percent in 1996 to 85 percent in 2002, and there was no increased risk of disseminated *M. avium* complex observed. Primary prophylaxis should be reintroduced if the CD4 count falls to less than or equal to 50 to 100 cells/mm^3.

Other Mycobacteria

Patients with HIV infection are susceptible to a number of other mycobacterial infections, although these are less common than tuberculosis or *M. avium* complex. *Mycobacterium kansasii* is generally considered to be one of the most pathogenic nontuberculous mycobacteria, and isolation of this organism on sputum cultures is associated with clinical disease in approximately 50 percent of patients. *M. kansasii* infections may closely mimic tuberculosis, causing cavitary lung lesions or diffuse pulmonary infiltrates in severely immunocompromised patients. Before the onset of the HIV epidemic, *M. kansasii* infections were extremely unusual. *M. kansasii* infections are more frequently seen with advanced HIV infection, often in the setting of concomitant opportunistic infections, than is disease caused by *M. tuberculosis*. Bacteremia, osteomyelitis, septic arthritis, pericarditis, and soft-tissue infections are also seen. Without treatment, the disease is generally progressive. Although recent American Thoracic Society (ATS) guidelines do not distinguish between HIV-positive and HIV-negative patients and recommend treating pulmonary *M. kansasii* infection only in the presence of multiple positive cultures and clinical and radiographic abnormalities, some experts advocate initiation of therapy after a single positive culture in HIV-infected patients. In HIV-infected patients with pulmonary *M. kansasii* infection, predictors of survival include higher CD4 counts, antiretroviral therapy, negative smear microscopy, and adequate treatment for *M. kansasii* infection, but not ATS diagnostic criteria. Treatment with isoniazid, rifampin, and ethambutol for 18 months is recommended, and until sputum cultures remain culture-negative for at least 12 months. All isolates are resistant to pyrazinamide, but sulfamethoxazole and clarithromycin are active against this organism. *M. genavense* may cause disseminated disease in patients with advanced immunodeficiency, including bacteremia and involvement of lymph nodes, liver, spleen, and gastrointestinal tract. The diagnosis is suggested in HIV-infected patients with an *M. avium*-complex–like illness who have weakly positive (low-growth index) cultures that cannot be speciated or who have negative cultures despite the presence of acid-fast bacilli in tissue samples. Isolation of *M. genavense* may be facilitated by use of acidic liquid media and prolonged incubation of cultures (mean growth in blood cultures is approximately 6 weeks). Although formal studies are lacking, disseminated *M. genavense* is usually treated with two or more of the following drugs: ethambutol, rifampin, rifabutin, clofazimine, and clarithromycin. *M. haemophilum* may cause skin and soft-tissue infections in AIDS patients, and infections with *M. fortuitum*, *M. chelonei*, *M. xenopi*, and *M. sherrisii* have been reported in HIV-infected patients.

Diseases due to Non-Tuberculous Mycobacteria

Jay A. Fishman

Mycobacterium tuberculosis and *M. leprae* are among the most important mycobacterial species causing disease in humans. However, many other species of non-tuberculous mycobacteria (NTM) are common as environmental inhabitants and are increasingly recognized in infections of the lungs and systemically, generally in patients with immune compromise. The non-tuberculous mycobacteria are not obligate human parasites, as are *M. tuberculosis* and *M. leprae*. Prior to the AIDS epidemic, most cases presented as indolent, cavitating pulmonary infections in persons with other underlying lung diseases such as chronic obstructive pulmonary disease (COPD) or previous tuberculosis. During the 1980s pulmonary and disseminated infections due to the more common NTM (*Mycobacterium avium, M. intracellulare*, some *M. scrofulaceum*, some unclassified) emerged as complications of acquired immunodeficiency syndrome (AIDS) and were termed *M. avium* complex or MAC infections (described by Chaisson in Chapter 141). Subsequently, a syndrome of predominantly mid-lung zone bronchiectasis with MAC pulmonary infection was described in otherwise healthy middle-aged women. Mycobacterial infections after solid organ and hematopoietic transplantation have increased in frequency, reflecting both increased exposure and/or improved diagnostic methods. In the absence of mandatory infection reporting, the true incidence of NTM disease in the general population and transplant recipients can only be estimated. In the United States, the rate of NTM isolation based on laboratory surveillance is estimated to be 7.5 to 8.2 per 100,000 population. However, in the absence of clinical information, the incidence of disease due to NTM cannot be determined. In recipients of hematopoietic stem cell transplants (HSCT) the incidence of NTM infection ranges from 0.4 percent to 4.9, 50 to 600 times greater than the general population. Among renal transplant recipients, the incidence of NTM infection is between 0.16 and 0.38 percent. Slightly higher rates are reported in recipients of heart (0.24 to 2.8 percent), and lung (0.46 to 2.3 percent) transplants. The one systematic study of mycobacterial infection in liver transplant recipients reported an incidence of 0.04 percent, which may reflect local epidemiology, underdiagnosis, or a true, low incidence of infection. Newer guidelines of the American Thoracic Society (2007) can be used to guide therapy in most hosts.

ORGANISM AND DISEASE

Microbiology

Over 125 NTM species have now been identified and speciated. Many of these have been implicated in human disease.

A comprehensive list of all validated NTM species is available online at www.bacterio.cict.fr/m/mycobacterium.html. The increased number of species reflects improved microbiologic techniques for isolating NTM from clinical specimens and to the use of 16S rRNA gene sequencing as a standard for defining new species. To simplify understanding of these organisms, particularly as applied to clinical circumstances, they often are grouped into complexes of closely related species. The *M. avium* complex, for example, consists of many serotypes, including *M. avium, M. intracellulare,* and *M. scrofulaceum.* Certain species are associated with human disease more often than others and are presumed to be more virulent.

Key aspects of laboratory evaluation include:

1. Be aware that these organisms may be present, and request mycobacterial cultures in appropriate specimens. The gram stain will not detect mycobacteria. The preferred staining procedure is the fluorochrome method, although the Ziehl-Neelsen method and Kinyoun stain are less sensitive alternatives. NTM are often more sensitive to the acid-fast decolorization procedure.
2. Specimens should be cultured on both liquid and solid media. Species that are often associated with cutaneous and lymph node disease may require special growth conditions and/or lower incubation temperatures, including *M. haemophilum*, *M. genavense*, and *M. conspicuum.* Methods for the isolation of NTM in clinical laboratories have been approved by the Clinical and Laboratory Standards Institute (CLSI), formerly known as the National Committee for Clinical Laboratory Standards (NCCLS).
3. Molecular testing is used primarily (initially) to distinguish *M. tuberculosis* from NTM species. DNA probes exist for some common NTM species (*M. avium* complex or MAC, *M. kansasii*, and *M. gordonae*).
4. NTM should be identified to the species level.
5. ATS guidelines suggest that routine susceptibility testing be limited for MAC isolates (clarithromycin) and for *M. kansasii* isolates (rifampin). However, many centers perform more extensive testing due to the frequency of resistance, drug intolerance, and in HIV infection and transplant recipients, drug interactions.
6. For "rapid growers" in particular (*M. fortuitum*, *M abscessus*, *M. chelonae*), isolates should used for extended antibiotic in vitro susceptibility testing. Testing should include amikacin, imipenem, meropenem, moxifloxacin and gatifloxacin (*M. fortuitum* only), doxycycline, a sulfonamide or trimethoprim-sulfamethoxazole, cefoxitin, clarithromycin, linezolid, and amikacin, and tobramycin (*M. chelonae* only).

Some specific guidelines have been adopted to avoid potential sources of contamination, especially tap water, in specimen collection. Specimens should be submitted without fixatives. Refrigeration of samples at 4°C should be used if transportation to the laboratory is delayed for over 1 hour.

Respiratory Specimens

To establish the diagnosis of NTM lung disease, sputum is often induced or collected via bronchoscopy (Table 142-1). Alternatively, three early-morning specimens may be collected on different days. Respiratory specimens can be shipped to the laboratory on ice. Recent treatment with macrolides or fluoroquinolones often affects the yield of NTM recovery and should be avoided. Lung or other tissue (lymph node) biopsy specimens can be used for cultures also. Individuals with NTM lung disease may also have bacteremia. Blood cultures should be obtained specifically for NTM, although rapid growers normally grow in standard blood culture bottles.

Epidemiology and Pathogenesis

NTM are ubiquitous in the environment, often isolated from soil and water, including treated water sources (*M. kansasii*, *M. xenopi*, and *M. simiae*). There has been no documentation of animal-to-human or human-to-human transmission of NTM, including that in highly susceptible hosts (e.g., those with cystic fibrosis). In general, the environmental source of human disease is unidentified. NTM may cause both asymptomatic infection and symptomatic disease in humans. NTM disease is often detected in asymptomatic patients awaiting organ transplantation with diffuse nodular or interstitial lung disease. Skin test studies in adults indicate that a substantial proportion have had prior infection with NTM, notably in the southeastern United States. While disease is often asymptomatic (and often in individuals with other underlying lung disease), in the immunologically normal host, NTM has not been shown to lead to latent infection. However, disease may be exacerbated by immune suppression.

The most common clinical manifestation of NTM disease is probably lung disease, but lymphatic, skin/soft tissue, and disseminated disease are underdiagnosed. CDC reports that of NTM isolates reported to the Public Health Laboratory System (PHLIS) database between 1993 and 1996, 75 percent were pulmonary, 5 percent were from blood, 2 percent from skin/soft tissue, and 0.4 percent from lymph nodes. Disseminated NTM infections occurs in HIV-infected patients with CD4+ T-lymphocyte counts below 50/cc. In individuals with congenital immune deficiencies such as chronic granulomatous disease, there may be defects in production of interferon (IFN)-γ or interleukin (IL)-12, or defects in receptors or pathways controlling responses to IFN-γ. These IFN-γ pathway defects include receptor and signaling mutations in the nuclear factor-κB essential modulator, IFN-γ receptor 1 and receptor 2, IL-12 receptor 1 subunit, IL-12 subunit p40, and the signal transducer and activator of transcription 1 (STAT1). These defects are important given the role of macrophages in the innate immune response to NTM

Table 142-1

Bacteriologic Criteria for Diagnosis of NTM Pulmonary Disease

Normal Host or Local Immunosuppression*	Systemic Immunosuppression†
At least three available sputum/bronchial wash samples within 1 yr • Three positive cultures with negative AFB smears **OR** • Two positive cultures and one positive AFB smear	Same
OR	**OR**
Single available bronchial wash and inability to obtain sputum samples • Positive culture with 2+, 3+, or 4+ growth **OR** • Positive culture with a 2+, 3+, or 4+ AFB smear	Single available bronchial wash and inability to obtain sputum samples • Positive culture with 1+ growth **OR** • Positive culture with a 2+, 3+, or 4+ AFB smear
OR	**OR**
Tissue biopsy • Any growth bronchopulmonary tissue biopsy • Granuloma and/or AFB on lung biopsy with one or more positive cultures from sputum/bronchial wash • Any growth from usually sterile extrapulmonary site	Same

**Alcoholism, bronchiectasis, cyanotic heart disease, cystic fibrosis, prior mycobacterial disease, pulmonary fibrosis, smoking/COPD.*
†Leukemia, lymphoma, SOT, HIV, other systemic immunosuppression.

with IL-12 and IFN-γ essential for intracellular killing of mycobacteria.

Recent experience with inhibitors of tumor necrosis factor (TNF-α) suggests that TNF also is essential in the prevention of disease activation. These agents have been used in a variety of chronic inflammatory conditions, including inflammatory bowel disease and rheumatoid arthritis. The effect of these agents may persist for months to years after administration. In addition to NTM infection, such agents have been associated with activation of *Aspergillus species*, histoplasmosis, coccidioidomycosis listeriosis, and *M. tuberculosis.*

Pulmonary Disease

Older physicians are well aware that disease due to NTM in immunologically normal hosts tends to occur in the setting of structural lung disease, such as bronchiectasis, chronic obstructive pulmonary disease (COPD), old cavitary TB, mesothelioma and pneumoconioses, and with pulmonary alveolar proteinosis (Fig. 142-1). Bronchiectasis and NTM infection may coexist. As noted, some women without obvious immune defects have developed pulmonary NTM disease and tend to have characteristics that include scoliosis, pectus excavatum, mitral valve prolapse, and joint hypermobility. The relationship between these physical traits and NTM infection is unknown.

The histology of disease is indistinguishable from that caused by *M. tuberculosis*, although classical granulomata are often less "tight" in NTM infections. The general pattern is that of bronchiectasis, bronchiolar and peribronchiolar inflammation, and granuloma formation. Disease should be treated as caused by *M. tuberculosis* until identification

Figure 142-1 PA chest radiograph showing exudative infiltrate and probable cavitation in left upper lung.

of the organism proves otherwise. The granulomatous response may not occur in patients with overwhelming infection or severe underlying innate or cellular immune deficiency.

CLINICAL PRESENTATION AND RADIOGRAPHY

Most patients have preexisting structural lung disease (Figs. 142-2 and 142-3) and present with chronic cough or sputum production, often with nonspecific signs, including dyspnea, fatigue, malaise, low-grade fevers, and weight loss. Cavitary disease may be associated with hemoptysis and chest pain. Physical examination is generally unrewarding, with diffuse rhonchi and wheezes on auscultation. As noted, some women have a characteristic morphotype and are often thin, with scoliosis, pectus excavatum, and mitral valve prolapse.

Three forms of disease merit comment: hypersensitivity pneumonitis with NTM infection, infection in cystic fibrosis, and infection in transplant recipients. The hypersensitivity lung disease has been termed "hot tub lung." It is unknown whether the hot tub itself plays a role in the pathogenesis of this syndrome, but a unique form of hypersensitivity pneumonitis may be seen after exposure to NTM and hot tubs, undrained spas, and occasionally contaminated showers, with aerosolization devices. A similar syndrome is seen in metal workers associated with exposures to metalworking fluids (paraffins, pine oils, and polycyclic aromatic hydrocarbons) containing mycobacteria. This syndrome is associated almost exclusively with *M. immunogenum*, a rapidly growing mycobacterium. Onset of symptoms is subacute and is generally in non-smokers without a clear disposition to infection. Chest radiographs and chest CT scans have diffuse small nodules with ground-glass infiltrates. Lung biopsy generally reveals centrilobular and bronchocentric non-necrotizing granulomata, although some cases may have necrotizing granulomas, bronchiolitis and organizing pneumonia, or interstitial inflammation.

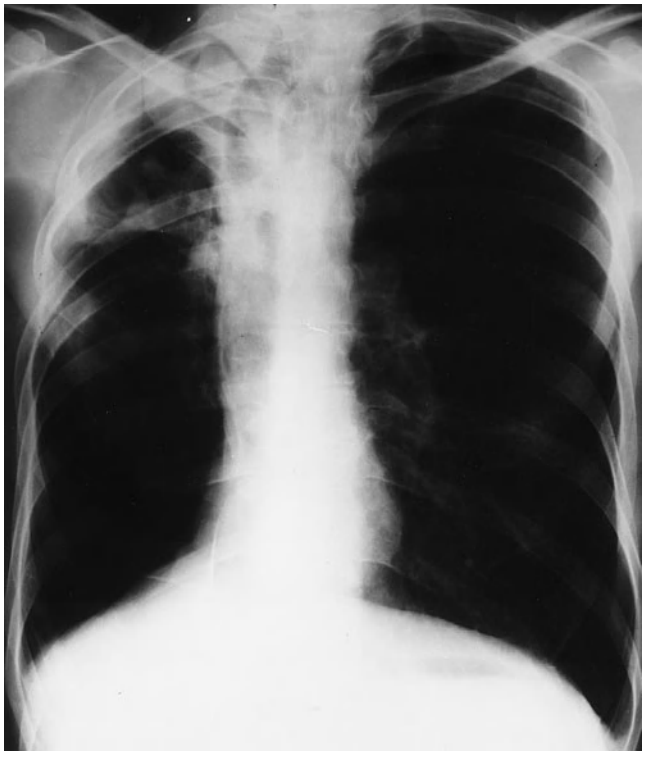

Figure 142-2 PA radiograph view of the chest showing extensive bilateral emphysema with cavitary destruction of right upper lobe.

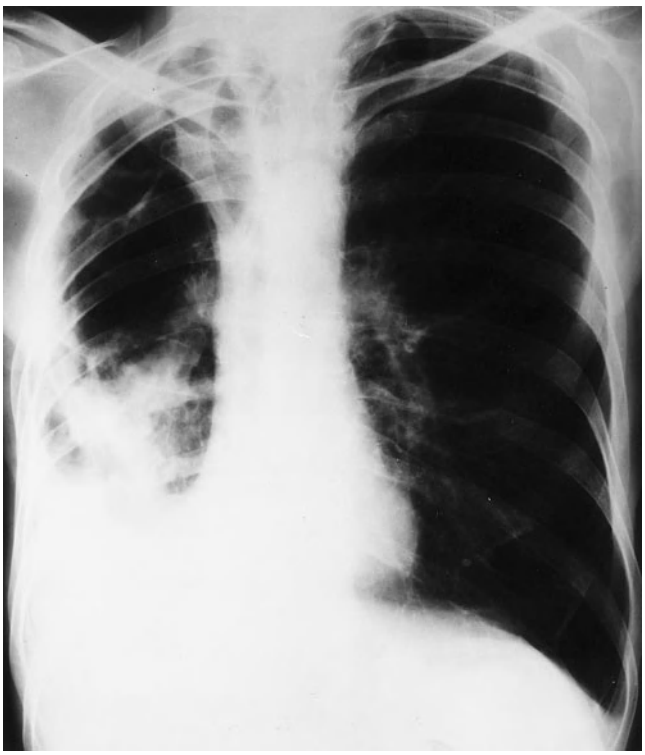

Figure 142-3 PA chest radiograph $2^1/_2$ years later showing pleural involvement and further marked progression of disease and destruction of the right lung.

In cystic fibrosis, NTM are increasingly isolated, often with uncertain clinical significance. As a result, such patients should have episodic sputum cultures for NTM, notably in advance of macrolide therapy.

In solid organ transplant recipients, the most common manifestations of NTM infection include cutaneous and pleuropulmonary disease. Catheter-related infection is the most commonly reported manifestation of NTM disease in hematopoietic stem cell transplant recipients. In such hosts, skin and pulmonary lesions should be biopsied for histology, special staining, and microbiologic cultures, including bacteria, *Nocardia* species, fungi, and mycobacteria. Mycobacterial infections associated with catheters may be documented by tunnel or blood (isolator) cultures. The pattern of NTM infection in transplantation differs from that of HIV-infection

Table 142-2

Interactions Between Drugs Used to Treat NTM and Immunosuppressive Medications

NTM Medication	Immunosuppresive Agent	Anticipated Reaction
Rifamycins (rifampin > rifabutin)	Calcineurin Inhibitors (CNI) (cyclosporin, tacrolimus) Sirolimus Steroids	Decreased level of CNI Loss of sirolimus efficacy Decreased steroid effectiveness
Macrolides (clarithromycin, azithromycin)	Calcineurin Inhibitors (CNI) (cyclosporin, tacrolimus)	Increased CNI level and risk of toxixcity
Ethambutol	NS*	N/A†
Aminoglycosides (streptomycin, amikacin)	Calcineurin Inhibitors (CNI) (cyclosporin, tacrolimus)	Possible additive or synergistic risk of renal impairment
Clofazamine	NS*	N/A†
Fluoroquinolones	NS*	N/A†
Isoniazid	NS*	N/A†
Doxycycline	NS*	N/A†
Cefoxitin	NS*	N/A†
Imipenem	Cyclosporin	May result in neurotoxicity (mental confusion, agitation, tremor)

**NS = no significant inteaction.*
†N/A = not applicable.

(less commonly *Mycobacterium avium* complex), which limits extrapolation of therapeutic data from HIV-infected individuals to this population. Drug interactions are common and outlined in Table 142-2.

Radiographic patterns are non-specific also, with fibrosis, small or large cavities, and predominantly interstitial disease, or with classical nodules (less than 5 mm by CT scans) and bronchiectasis. In general, the diffuseness of the disease is out of proportion to clinical illness. Radiographs often have multiple thin-walled cavities and significant pleural involvement, in addition to tree-and-bud appearance. Apical pleural disease is less common than with tuberculosis (Figs. 142-1, 142-4, 142-5). Most abnormalities are found in the lower and mid-lung fields.

TREATMENT

The approach to treatment varies with the species (Table 142-3). Many patients respond to regimens of several drugs, but toxicity and drug interactions are common (Table 142-2). Therapy should be based on antimicrobial susceptibility testing. During therapy, monitoring for toxicity of drugs is essential. Such testing should include visual acuity (ethambutol and rifabutin), liver enzymes (clarithromycin, azithromycin, rifabutin, rifampin, isoniazid, and ethionamide), auditory and vestibular function (streptomycin, amikacin, clarithromycin, and azithromycin), renal function (streptomycin and amikacin), and leukocyte and platelet counts (rifabutin). Red-green color discrimination (ethambutol) and drug interactions are also common. Clarithromycin enhances rifabutin toxicity (especially uveitis), whereas the rifamycin (rifampin more than rifabutin) lowers clarithromycin serum drug levels.

Some patients (e.g., those with localized pulmonary disease or hemorrhage) merit consideration for lung resection. This may be beneficial in patients with developing drug resistance.

Pulmonary *M. avium* Complex

Therapy is covered in detail by Chaisson in Chapter 141. In general, this is a syndrome of HIV infection and presents

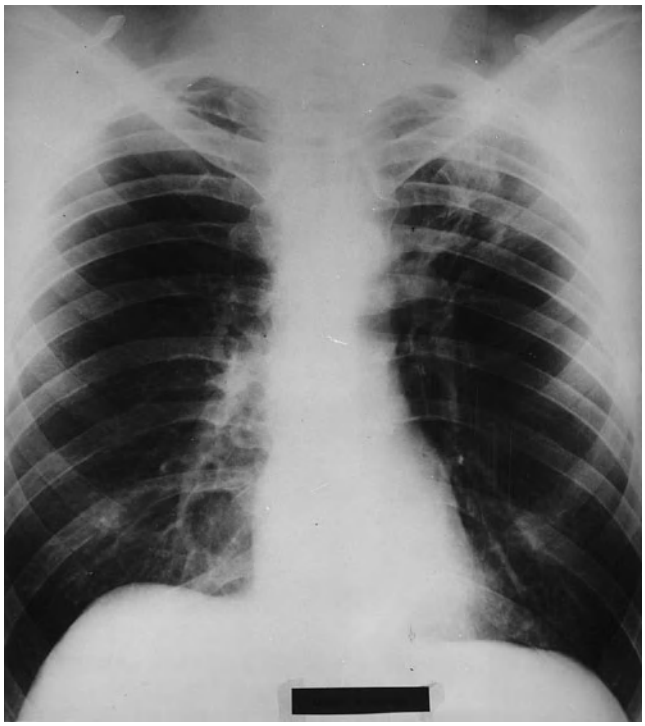

Figure 142-4 PA chest radiograph 2 months later showing decreased infiltration.

Figure 142-5 PA chest radiograph 7 years later showing a stable scar in left upper lung.

Table 142-3

Dosages of Drugs Used in Treating Adults with NTM Infection

Rifampin	600–900 mg per day in a single dose
Isoniazid	300–600 mg per day in a single dose
Ethambutol	25 mg/kg daily in a single dose until cultures are negative for 6 months, then 15 mg/kg daily thereafter
Streptomycin, capreomycin, kanamycin, amikacin	15 mg/kg up to 1 gm, once daily 5 days a week–when cultures are negative or significant toxicity occurs, dosages can be reduced and/or the drug given less frequently
Azithromycin	500–1000 mg per day in a single dose
Clarithromycin	500–750 mg twice daily
Ciprofloxacin	500–750 mg twice daily
Ofloxacin	800 mg per day in a single dose
Clofazimine	100–200 mg per day in a single dose
Rifabutin	300–600 mg per day in a single dose
Ethionamide	500–1000 mg per day usually in divided dose; give highest tolerated dose
Cycloserine	500–1000 mg per day usually in divided doses; give highest tolerated dose

with nodular and bronchiectatic lung disease. Intermittent therapy and monotherapy are not recommended due to the emergence of resistance. It should also be noted that patients respond best to the first course of MAC treatment; therefore, adherence and use of a multi-drug regimen are essential. Treatment is with three times weekly dosing of clarithromycin 1000 mg or azithromycin 500 mg, ethambutol 15 to 25 mg/kg, and rifampin 600 mg. For fibrocavitary or severe nodular/bronchiectatic disease, a daily regimen is used that includes clarithromycin 500 to 1000 mg/day or azithromycin 250 mg/day, ethambutol 15 mg/kg per day, and rifampin 10 mg/kg per day (maximum 600 mg). For prolonged therapy, visual acuity and color vision testing are recommended. The primary microbiologic goal of therapy is 12 months of negative sputum cultures while on therapy. A macrolide with a single companion drug, ethambutol, may be adequate for nodular/bronchiectatic MAC disease. Patients are considered treatment failures if they have not had response (microbiologic, clinical, or radiographic) after 6 months of appropriate therapy or achieved culture negativity of sputum after 12 months of therapy. Common factors in such patients include medication nonadherence and emergence of a macrolide-resistant MAC isolates.

M. kansasii

This organism is susceptible to anti-tuberculous agents, including rifampin and rifabutin. Response to a three-drug regimen of isoniazid, rifampin, and ethambutol plus pyridoxine (50 mg/d) is excellent. Isoniazid is sometimes given at doses higher than those recommended by guidelines (5 mg/kg per day to a maximum of 300 mg/d) because of the relative resistance of *M. kansasii* to this drug. Doses of 400 to 600 mg daily have been used in resistant cases. The rifampin dose is 10 mg/kg per day to a maximum of 600 mg daily, and ethambutol is given at 15 mg/kg per day. An initial 2 months of ethambutol at 25 mg/kg per day is no longer recommended. The total duration of treatment is 18 to 24 months, although good results with 12 months of therapy have been reported. Other drugs usually given in three-drug combinations are effective for retreatment of disease that has become resistant to rifampin; they include ethionamide, cycloserine, streptomycin, capreomycin, and kanamycin. Relapse after treatment with rifampin-containing regimens is uncommon.

M. marinum

This organism usually causes superficial skin infections following trauma and exposure to infected water (swimming pool granuloma). The disease often disappears with topical care. When the disease is more prolonged or extensive, treatment with isoniazid and rifampin is often successful. Minocycline or a trimethoprim-sulfa drug is sometimes useful when this approach fails.

M. abscessus

Soft-tissue abscesses related to trauma or surgery are the most common form of disease, but pulmonary disease is no longer rare. *M. abscessus* is the third most frequently recovered NTM pulmonary pathogen in the United States. These patients are generally women, non-smokers, without previously recognized lung disease, presenting with symptoms of bronchiectasis. Our patients have had a mixed radiographic picture with patchy interstitial-alveolar disease with upper lobe predominance. CT scanning reveals small nodules with bronchiectasis. Some have had cavity formation or scant hemoptysis. Dual infection with MAC is common. Disease is slowly progressive. *M. abscessus* has complicated lung transplant surgery causing sternal osteomyelitis.

M. abscessus isolates are uniformly resistant to standard antituberculous agents. Resistance to clarithromycin (23S rRNA gene) and amikacin (16S rRNA gene) can occur during therapy because *M. abscessus has* only a single gene copy. Drugs that may be useful include clarithromycin, amikacin, and cefoxitin. Some isolates respond to imipenem or linezolid. Combination therapy is mandatory for significant disease, usually for a minimum of 4 to 6 months.

No antibiotic regimens based on in vitro susceptibilities have been shown to produce long-term sputum conversion for patients with *M. abscessus* lung disease. For macrolide-resistant *M. abscessus* isolates or macrolide intolerance, a combination of parenteral drugs should be used based on in vitro susceptibilities. We have recently had some success with newer classes of drugs, the oxazolidinones (linezolid), the glycylcyclines (tigecycline), and the ketolides (telithromycin). Long-term therapy with linezolid has resulted in some peripheral neuropathy and marrow suppression. Tigecycline therapy has a problem with gastrointestinal intolerance and must be given intravenously. Telithromycin has not been well studied in vitro against NTM isolates.

M. chelonae and *M. fortuitum*

M. chelonae is a rapid grower that causes pulmonary disease similar to that of *M. abscessus. M. chelonae* isolates are susceptible to doxycycline, ciprofloxacin, tobramycin (more often than amikacin), clarithromycin, imipenem, clofazimine, and linezolid. *M. chelonae* are resistant to cefoxitin. Pulmonary disease due to *M. fortuitum* is also similar to that of *M. abscessus* but is most common in patients with gastroesophageal reflux disorders with recurrent aspirational lung disease. *M. abscessus may also be seen in such patients.* Dual therapy with an active agent should be given for 12 months or until clinical resolution of disease. *M. fortuitum* isolates are usually susceptible to clarithromycin and azithromycin, fluoroquinolones, doxycycline and minocycline, sulfonamides, amikacin, imipenem, and in about half to cefoxitin. Acquired resistance to macrolides is common.

143
CHAPTER

Respiratory Failure: An Overview

Michael A. Grippi

Respiratory failure is a condition in which the respiratory system fails in one or both of its gas-exchanging functions—i.e., oxygenation of, and carbon dioxide elimination from, mixed venous (pulmonary arterial) blood. Hence, respiratory failure is a syndrome rather than a disease. Many diseases result in respiratory failure, as discussed elsewhere in this text.

Respiratory failure may be acute or chronic. The clinical presentations of patients with acute and chronic respiratory failure usually are quite different. While acute respiratory failure is characterized by life-threatening derangements in arterial blood gases and acid-base status, the manifestations of chronic respiratory failure are more indolent and may be clinically inapparent.

Although the causes of respiratory failure are diverse, common underlying pathophysiological mechanisms and management strategies merit a general discussion. This chapter begins with a focus on the definition of respiratory failure and underscores distinctions between acute and chronic varieties. Hypoxemic and hypercapnic respiratory failure are described, and the pathophysiological underpinnings of each type are reviewed. The concepts of ventilatory supply and demand are considered before an overview of the many categories of disease that result in respiratory failure. Finally, an approach to clinical evaluation and management is outlined, followed by a summary of complications and comments on prognosis.

CLASSIFICATION OF RESPIRATORY FAILURE

As noted previously, respiratory failure is characterized by inadequate blood oxygenation or carbon dioxide removal. "Adequacy" is defined by tissue requirements for oxygen uptake and carbon dioxide elimination. In the absence of bedside techniques for direct measurement of these metabolic parameters, clinicians must rely on arterial blood gas values.

Respiratory failure may be classified as *hypercapnic* or *hypoxemic* (Fig. 143-1). *Hypercapnic respiratory failure* is defined as an arterial P_{CO_2} (Pa_{CO_2}) greater than 45 mmHg. *Hypoxemic respiratory failure* is defined as an arterial P_{O_2} (Pa_{O_2}) less than 55 mmHg when the fraction of oxygen in inspired air (F_{IO_2}) is 0.60 or greater. In many cases, hypercapnic and hypoxemic respiratory failure coexist. Disorders that initially cause hypoxemia may be complicated by respiratory pump failure (see below) and hypercapnia. Conversely, diseases that produce respiratory pump failure are frequently complicated by hypoxemia due to secondary pulmonary parenchymal processes (e.g., pneumonia or atelectasis) or vascular disorders (e.g., pulmonary embolism).

Distinctions between *acute* and *chronic* respiratory failure are summarized in Table 143-1. In general, acute hypercapnic respiratory failure is defined as a Pa_{CO_2} greater than 45 mmHg with accompanying acidemia (pH less than 7.30). The physiological effect of a sudden increment in Pa_{CO_2} depends on the prevailing level of serum bicarbonate anion. In patients with chronic hypercapnic respiratory failure—e.g., due to chronic obstructive pulmonary disease (COPD)—a long-standing increase in Pa_{CO_2} results in renal "compensation" and an increased serum bicarbonate concentration. A superimposed acute increase in Pa_{CO_2} has a less dramatic effect than does a comparable increase in a patient with a normal bicarbonate level.

Table 143-1

Distinctions between Acute and Chronic Respiratory Failure

Category	Characteristic
Hypercapnic respiratory failure	Pa_{CO_2} >45 mmHg
Acute	Develops in min to h
Chronic	Develops over several days or longer
Hypoxemic respiratory failure	Pa_{O_2} <55 mmHg when F_{IO_2} ≥0.60
Acute	Develops in min to h
Chronic	Develops over several days or longer

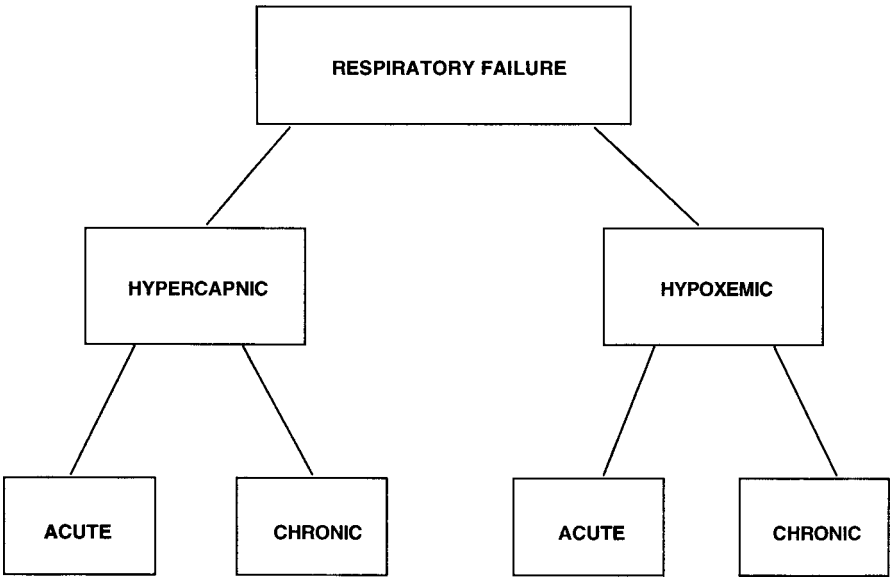

Figure 143-1 Classification of respiratory failure. Although depicted as distinct entities, hypercapnic and hypoxemic respiratory failure frequently coexist. Either may be acute or chronic.

Distinction between acute and chronic hypoxemic respiratory failure may not be readily made on the basis of arterial blood gas values. The presence of markers of chronic hypoxemia (e.g., polycythemia or cor pulmonale) provides clues to a long-standing disorder, whereas abrupt changes in mental status suggest an acute event.

It is important to bear in mind that even though the definition of hypoxemic respiratory failure rests on measurement of Pa_{O_2}, the major threat of arterial hypoxemia is inadequate tissue oxygenation, reflected in tissue *oxygen delivery*. Tissue oxygen delivery is determined by the product of cardiac output and blood *oxygen content* (see Chapter 13); the latter, in turn, depends on hemoglobin concentration and oxygen saturation. Therefore, factors that lower cardiac output or hemoglobin concentration, or inhibit dissociation of oxygen from hemoglobin at the tissue level, may promote tissue hypoxia without technically producing respiratory failure.

PATHOPHYSIOLOGY

Respiratory failure can arise from an abnormality in any of the "effector" components of the respiratory system—central nervous system, peripheral nervous system, respiratory muscles and chest wall, airways, or alveoli (Fig. 143-2). A defect in any of the first four components, which constitute the "respiratory pump," may cause coexistent hypercapnia and hypoxemia; at least initially, disorders of the alveoli are more apt to result in hypoxemia.

Hypoxemic Respiratory Failure

As described in Chapters 10, 11, and 12, four pathophysiological mechanisms account for the hypoxemia seen in a wide variety of diseases: alveolar hypoventilation, ventilation-perfusion mismatch, shunt, and diffusion limitation. Alveolar hypoventilation occurs in neuromuscular disorders that affect the respiratory system. In the absence of underlying pulmonary disease, the hypoxemia accompanying alveolar hypoventilation is characterized by a normal alveolar-arterial oxygen gradient, as defined by Eq. (1):

$$P_{A_{O_2}} - Pa_{O_2} = [P_{I_{O_2}} - Pa_{CO_2}/R] - Pa_{O_2} \qquad (1)$$

where

$P_{A_{O_2}}$ = alveolar P_{O_2}
Pa_{O_2} = arterial P_{O_2}
$P_{I_{O_2}}$ = inspired P_{O_2}
Pa_{CO_2} = arterial P_{CO_2}
R = respiratory exchange ratio

In contradistinction, disorders in which any of the other three mechanisms are operative are characterized by widening of the alveolar-arterial oxygen gradient, which is normally less than 20 mmHg. With ventilation-perfusion mismatching, areas of low ventilation relative to perfusion contribute to the hypoxemia. Similarly, with shunt, either intrapulmonary or intracardiac, deoxygenated mixed venous blood bypasses ventilated alveoli, resulting in "venous admixture." Finally, diseases that increase the diffusion pathway for oxygen from the alveolar space to pulmonary capillary impair oxygen transport across the alveolar-capillary membrane.

Although changes in minute and alveolar ventilation can change Pa_{CO_2} considerably, this is not so for Pa_{O_2}. Increases in minute ventilation and, secondarily, in alveolar ventilation, modestly increase Pa_{O_2}. Indeed, at a Pa_{O_2} above 55 to 60 mmHg, the effect of increasing ventilation on oxygen content is minimal, since the oxyhemoglobin dissociation curve is flat in this range.

Hypercapnic Respiratory Failure

At a constant rate of CO_2 production ($\dot{V}_{CO_2}$), Pa_{CO_2} is determined by the level of alveolar ventilation. The relationship

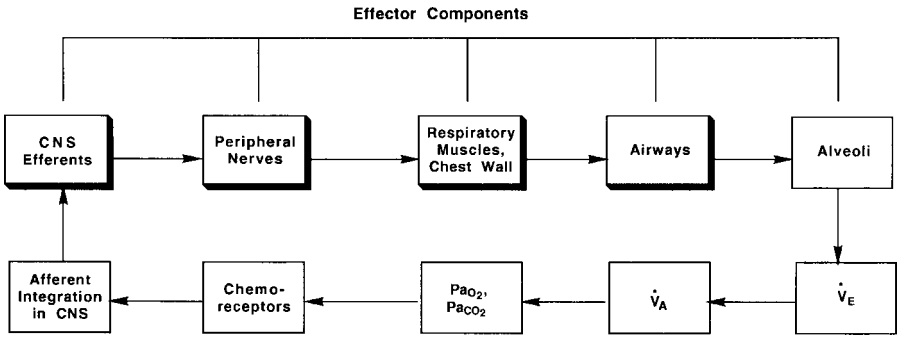

Figure 143-2 Functional components of the respiratory system and its controller. Abnormalities in any of the effector components can result in respiratory failure. The central and peripheral nervous systems, respiratory muscles and chest wall, and airways constitute the "respiratory pump" (shaded boxes). Hypercapnia is the hallmark of respiratory pump failure, while hypoxemia constitutes the primary disturbance in alveolar disorders producing respiratory failure. *(From Lanken PN: Respiratory failure: An overview, in Carlson RW, Geheb MA (eds),* Principles and Practice of Medical Intensive Care. *Philadelphia, WB Saunders, 1993, pp 754–763.)*

between alveolar ventilation, rate of CO_2 production, and Pa_{CO_2} is described by Eq. (2):

$$\dot{V}_A = K \cdot \dot{V}_{CO_2}/Pa_{CO_2} \qquad (2)$$

where

$\dot{V}_A$ = minute alveolar ventilation
K = a constant
$\dot{V}_{CO_2}$ = rate of CO_2 production

When $\dot{V}CO_2$ is constant, Pa_{CO_2} is determined by $\dot{V}_A$, which, in turn, is dictated by two factors: minute ventilation ($\dot{V}_E$) and the relationship between $\dot{V}_E$ and $\dot{V}_A$. The latter is determined by the proportion of $\dot{V}_E$ that constitutes dead space ventilation—i.e., the dead space to tidal volume ratio (V_D/V_T):

$$\dot{V}_E = K \cdot (\dot{V}_{O_2} \cdot RQ)/(Pa_{CO_2}/[1 - V_D/V_T]) \qquad (3)$$

where

$\dot{V}_{O_2}$ = rate of O_2 consumption
RQ = respiratory quotient (the respiratory exchange ratio in the steady state)
V_D = dead space volume
V_T = tidal volume

Inspection of Eq. (3) indicates that disorders reducing $\dot{V}_E$ or increasing the proportion of dead space ventilation may result in hypercapnia.

Ventilatory Supply vs. Demand

A useful theoretical construct for understanding the pathophysiological basis for hypercapnic respiratory failure is the relationship between ventilatory supply and ventilatory demand (Fig. 143-3).

Ventilatory supply is the maximal spontaneous ventilation that can be maintained without development of respiratory muscle fatigue; ventilatory supply is also known as *maximal sustainable ventilation* (MSV).

Ventilatory demand is the spontaneous minute ventilation, which, when maintained constant, results in a stable Pa_{CO_2} (assuming a fixed rate of CO_2 production).

Normally, ventilatory supply greatly exceeds ventilatory demand. Hence, major changes in minute ventilatory requirements (e.g., during exercise) may occur without hypercapnia. In lung disease, significant abnormalities may be present before ventilatory demand encroaches on MSV. Consequently, hypercapnia is a late finding. When ventilatory demand exceeds MSV, Pa_{CO_2} increases.

As a general rule, MSV is approximated as one-half the *maximal voluntary ventilation,* or MVV (see Chapter 34). A 70-kg adult has an MVV of about 160 L/min, an MSV of 80 L/min, and, under basal conditions, a $\dot{V}_E$ of approximately 6 to 7 L/min (90 ml/kg/min). Normally, therefore, there is a 10- to 15-fold difference between resting $\dot{V}_E$ and MSV. In disease states, the $\dot{V}_E$ requirement may approach a markedly

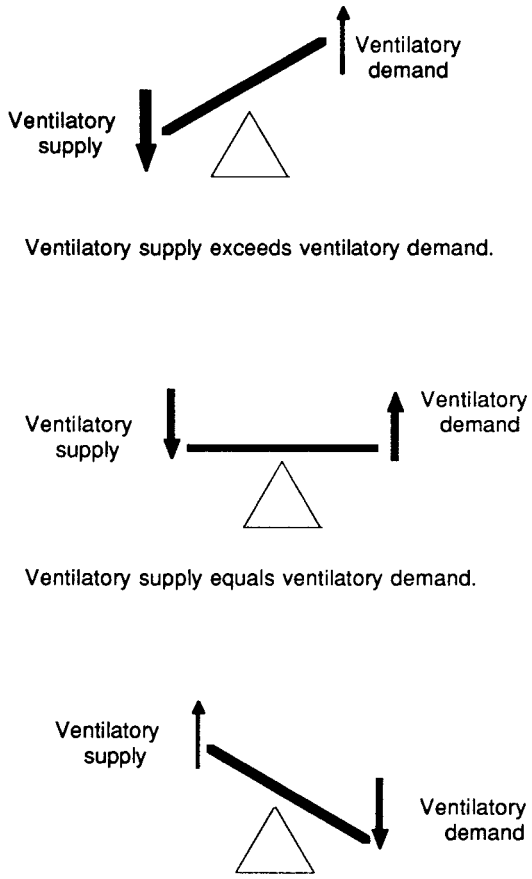

Figure 143-3 Relationship between ventilatory supply (maximal sustainable ventilation) and ventilatory demand (overall level of ventilation specified by the central nervous system controller). Relative size of the arrows indicates levels of supply and demand in each of the three circumstances illustrated. *A*. Normal. Ventilatory supply greatly exceeds ventilatory demand. Physiological "reserve" is maintained. *B* .Ventilatory supply is decreased and ventilatory demand increased (e.g., acute asthma attack). "Borderline" respiratory failure exists. *C* . Ventilatory demand exceeds ventilatory supply (e.g., sepsis in a patient with chronic obstructive pulmonary disease). Respiratory muscle fatigue develops, and hypercapnic respiratory failure ensues. See text for details. *(From Lanken PN: Pathophysiology of respiratory failure, in Grippi MA (ed), Pulmonary Pathophysiology. Philadelphia, JB Lippincott, 1995, pp 267–280.)*

reduced MSV. Further reductions in MSV result in ventilatory demand exceeding supply, and hypercapnia occurs.

Factors that Reduce Ventilatory Supply or Increase Ventilatory Demand

Disruption of any component of the efferent arm of the respiratory control system may diminish ventilatory supply (Table 143-2). While a variety of diseases produce specific abnormalities along the efferent pathway (e.g., phrenic nerve and respiratory muscle disorders), some result in respiratory

Table 143-2

Factors That Diminish Ventilatory Supply

Factor	Examples
Decreased respiratory muscle strength	
Muscle fatigue	Recovery from acute respiratory failure, high respiratory rates, increased inspiratory time
Disuse atrophy	Prolonged mechanical ventilation, following phrenic nerve injury
Malnutrition	Protein-calorie starvation
Electrolyte abnormalities	Low serum phosphate or potassium concentrations
Arterial blood gas abnormalities	Low pH, low Pa_{O_2} high Pa_{CO_2}
Fatty infiltration of diaphragm	Obesity
Unfavorable alteration in diaphragm length–tension relationship	Flattened domes of diaphragm caused by hyperinflation
Increased muscle energy requirement or decreased substrate supply	
High elastic work of breathing	Low lung or chest wall compliance, high respiratory rate
High resistive work of breathing	Airway obstruction
Reduced diaphragm perfusion	Shock, anemia
Decreased motor neuron function	
Decreased phrenic nerve output	Polyneuropathy, Guillain-Barré syndrome, phrenic nerve transection or injury, poliomyelitis
Decreased neuromuscular transmission	Myasthenia gravis, use of paralyzing agents
Abnormal respiratory mechanics	
Airflow limitation	Bronchospasm, upper-airway obstruction, excessive airway secretions
Loss of lung volume	After lung resection, large pleural effusion
Other restrictive defects	Pain-limited inspiration; tense abdominal distention due to ileus, peritoneal dialysis fluid, or ascites

muscle fatigue—the biochemical, cellular, and molecular mechanisms of which remain poorly understood.

As described previously, ventilatory demand can be assessed according to Eq. (3):

$$\dot{V}_E = K \cdot (\dot{V}_{O_2} \cdot RQ)/(Pa_{CO_2}/[1 - V_D/V_T]) \qquad (3)$$

Any factor that affects terms on the right-hand side of the equation may result in ventilatory demand exceeding supply. Selected clinical examples are given in Table 143-3.

CATEGORIES OF RESPIRATORY FAILURE

Although many different diseases cause respiratory failure, they may be grouped conveniently according to primary abnormalities in the individual effector components of the respiratory system.

Abnormalities of the Central Nervous System

A variety of pharmacologic, structural, and metabolic disorders of the central nervous system (CNS) are characterized by suppression of the neural drive to breathe. The resultant hypoventilation and hypercapnia may be acute or chronic.

An overdose of a narcotic or other drug with sedative properties is a common cause of respiratory failure. While the most striking clinical picture occurs with an acute overdose, long-standing use of some agents (e.g., methadone) may result in chronic hypercapnia.

"Structural" CNS abnormalities producing hypercapnic respiratory failure include meningoencephalitis, localized tumors or vascular abnormalities of the medulla, and strokes affecting medullary control centers. Usually, respiratory failure is observed in the context of other neurological findings.

Table 143-3

Factors That Increase Ventilatory Demand

Factor	Clinical Examples
Increased V_D/V_T	Acute asthma, emphysema, late phase of acute respiratory distress syndrome, pulmonary emboli
Increased V_{O_2}	Fever, sepsis, trauma, shivering, increased work of breathing, massive obesity
Increased RQ	Excessive carbohydrate feeding
Decreased Pa_{CO_2}	Hypoxemia, metabolic acidosis, anxiety, sepsis, renal failure, hepatic failure

Source: Data from Lanken PN: Pathophysiology of respiratory failure, in Grippi MA (ed), Pulmonary Pathophysiology. *Philadelphia, JB Lippincott, 1995, pp. 267–280.*

A variety of metabolic derangements may produce hypercapnia through depression of respiratory control centers. Examples include severe myxedema, hepatic failure, and advanced uremia. In addition, elevation of P_{CO_2} in the CNS results in neural depression, further enhancing CO_2 retention. A common clinical setting in which elevation of Pa_{CO_2} is observed is chronic metabolic alkalosis (e.g., due to diuretic use), as detailed in Chapter 14.

Finally, obesity-hypoventilation syndrome is characterized by hypercapnia due to hypoventilation on a central basis. The underlying mechanisms have not yet been elucidated.

Abnormalities of the Peripheral Nervous System or Chest Wall

A wide variety of disorders of the peripheral nerves, neuromuscular junction, and chest wall may be associated with hypercapnic and hypoxemic respiratory failure. While the hallmark is an inability to maintain a level of $\dot{V}_E$ appropriate for the rate of CO_2 production, many of these disorders are complicated by impaired expiratory muscle strength, atelectasis, and aspiration. Through mechanisms outlined previously, hypoxemia develops in conjunction with the hypercapnia.

Among the most common neuromuscular causes of hypercapnic respiratory failure are Guillain-Barré syndrome, myasthenia gravis, polymyositis, the muscular dystrophies, and a large number of metabolic muscle disorders. In addition, acute poliomyelitis and traumatic spinal cord injury are associated with hypercapnia. Development of respiratory muscle fatigue during prolonged weaning from mechanical ventilation may cause recurrent hypercapnia in the critical care setting.

Pharmacologic causes of hypercapnia in the intensive care unit are frequently encountered. Use of depolarizing and nondepolarizing paralyzing agents, particularly in conjunction with systemic corticosteroids (e.g., in management of status asthmaticus), cholinergic crisis during therapy of myasthenia gravis, and administration of aminoglycosides to patients with myasthenia are examples.

Primary disorders of the chest wall constitute another important category of neuromuscular respiratory failure. The prototype is severe kyphoscoliosis. Additional examples include flail chest (see Chapter 100), extensive thoracoplasty, morbid obesity, and massive abdominal distention due to ascites or distended loops of bowel.

In each of these disorders, a common pathophysiological sequence develops. Because of inadequate activation of inspiratory muscles or limited thoracic excursion, tidal volume falls. While an increase in respiratory rate compensates initially for the fall in $\dot{V}_E$ (and in $\dot{V}_A$), $\dot{V}_E$ eventually declines. In addition, the sigh mechanism is impaired, which, in conjunction with the low tidal volume, results in atelectasis and reduced lung compliance. Reduced lung compliance produces a further fall in tidal volume and an increase in the elastic work of breathing (see Chapter 9). Hence, ventilatory supply becomes limited, while ventilatory demand increases due to a rise in V_D/V_T (as a result of atelectasis and other factors noted below). An imbalance between ventilatory supply and demand arises, and hypercapnia ensues. Furthermore, an impaired gag reflex in the setting of bulbar weakness, coupled with impaired cough due to respiratory muscle involvement, may result in aspiration pneumonia and secondary hypoxemia.

In addition to the pathophysiology described, structural abnormalities of the thoracic cage (e.g., severe kyphoscoliosis) are characterized by an increase in the elastic component of the work of breathing. This results in a higher $\dot{V}_{O_2}$ and a higher proportion of total O_2 consumption by the respiratory muscles (normally, less than 5 percent of $\dot{V}_{O_2}$).

Abnormalities of the Airways

Obstructive diseases of the airways—either upper or lower—are common causes of acute and chronic hypercapnia. Examples in the upper airways include acute epiglottitis, aspirated foreign body, tracheal tumor, and narrowing of the trachea or glottis by fibrotic tissue. Disorders of the lower airways include COPD, asthma, and advanced cystic fibrosis. The underlying mechanisms are multifaceted and variable. However, several common pathophysiological pathways are operative.

Airway narrowing results in a greater transthoracic pressure gradient requirement for inspiratory airflow. The resistive component of the work of breathing is increased, and the increase is associated with an elevation in $\dot{V}_{O_2}$. In addition, tidal volume falls and dead space ventilation increases. Respiratory muscle fatigue may develop; the consequences of a shallow breathing pattern ensue.

Finally, in some disorders (e.g., acute asthma or an exacerbation of COPD), air trapping and lung hyperinflation occur, resulting in diaphragm flattening and worsening diaphragm mechanics (see Chapters 9, 41 and 42). The overall effect is a growing imbalance between ventilatory supply and demand.

Abnormalities of the Alveoli

Although diseases characterized by diffuse alveolar filling frequently result in hypoxemic respiratory failure, hypercapnia may complicate the picture. Common clinical examples in this category include cardiogenic and noncardiogenic pulmonary edema, diffuse pneumonia, extensive pulmonary hemorrhage, aspiration of stomach contents, and near-drowning.

Diffuse alveolar filling creates a large right-to-left shunt as pulmonary blood flows through nonventilated or poorly ventilated regions of the lung. In addition, coexisting interstitial edema may impair diffusion across the alveolar-capillary membrane, further impairing oxygenation of mixed venous blood.

In extensive, acute pulmonary disease characterized by alveolar filling, ventilatory demand is high because of hypoxemia and increases in V_D/V_T, the elastic work of breathing (due to reduced lung compliance), the resistive work of breathing (due to airway narrowing and increased airway reactivity), and the neural drive to breathe (mediated by pulmonary parenchymal vagal fibers). In conjunction with heightened ventilatory demand, ventilatory supply is reduced because of alveolar flooding, reduced lung elasticity, respiratory muscle fatigue, and, possibly, reduced blood supply to the diaphragm secondary to shock. Once again, the imbalance between ventilatory supply and demand results in hypercapnia.

APPROACH TO THE PATIENT

The diagnosis of acute or chronic respiratory failure begins with clinical suspicion of its presence. Confirmation of the diagnosis is based on arterial blood gas analysis (Table 143-1). Evaluation for an underlying cause must be initiated early, frequently in the presence of concurrent treatment for acute respiratory failure. While the diagnosis of chronic respiratory failure is usually easily established with clinical findings of chronic hypoxemia (with or without findings of hypercapnia), the diagnosis of acute respiratory failure requires more careful analysis.

Signs and symptoms in acute respiratory failure reflect the underlying disease process and associated hypoxemia or acidemia due to hypercapnia. Localized pulmonary findings reflecting the acute causes of hypoxemia (e.g., pneumonia, pulmonary edema, asthma, or COPD) may be readily apparent. Alternatively, the predominant findings may be systemic (e.g., hypotension due to sepsis). The principal manifestations may even be remote from the thorax—e.g., abdominal pain in acute pancreatitis or leg pain due to a long bone fracture—each associated with acute (adult) respiratory distress syndrome (ARDS) (see Chapter 145). Frequently, neurological or cardiovascular symptoms and signs predominate. Neurological manifestations include restlessness, anxiety, confusion, seizures, or coma. Asterixis may be seen with severe hypercapnia. Common cardiovascular findings include tachycardia and a variety of arrhythmias. Finally, there may be few or no findings other than a complaint of dyspnea, as in some patients with hypoxemia due to pulmonary embolism.

Once respiratory failure is suspected on clinical grounds, arterial blood gas analysis is performed to confirm the diagnosis, to assist in the distinction between acute and chronic forms, to assess the magnitude and metabolic impact, and to help guide management (Table 143-4).

PRINCIPLES OF MANAGEMENT

The principles of management of patients in acute respiratory failure include those that are cause-specific and those that are more general. Triage of the patient to the proper clinical setting, airway maintenance, correction of hypoxemia and hypercapnia, and management of the underlying cause are of paramount importance.

Triage Decisions

The first step in management is to determine the appropriate setting for care—admission to a standard inpatient facility or to an intensive or intermediate care unit. Factors that constitute the basis for this decision include the acuity of the respiratory failure; the degree of hypoxemia, hypercapnia, and acidemia; the presence of co-morbid conditions (e.g., cardiac disease or renal insufficiency); and the clinical direction that the patient takes over the first few minutes or hours of observation. At one end of the spectrum is the patient with fulminant hypoxemic respiratory failure, metabolic acidosis, and imminent cardiovascular collapse, who needs emergent intubation, mechanical ventilation, and admission to a critical care unit. At the other end of the spectrum is the patient with COPD and chronic, compensated hypercapnic respiratory failure, who requires observation in an intermediate care unit. Notably, in recent years, a number of studies have indicated that use of noninvasive mechanical ventilation may obviate the need for endotracheal intubation in selected patients with hypercapnic or acute, hypoxemic respiratory failure (other than ARDS-related). Although studies also point to the potential role of noninvasive mechanical ventilation in recurrent respiratory failure following extubation, a multicenter, randomized trial found no reduction in mortality or in the need for reintubation with its use.

Airway Management

Assurance of an adequate airway is key in the patient with acute respiratory distress. Whether emergency intubation is

Table 143-4

Changes in Arterial Blood Gases, $P_{A_{O_2}}$–Pa_{O_2}, and Ventilation in Acute Respiratory Failure

Failed Respiratory System Component	pH	Pa_{CO_2}	Pa_{O_2}	$P_{A_{O_2}}$–Pa_{O_2}	$\dot{V}_E$	$\dot{V}_A$

required depends on the clinical circumstances described previously. For patients with chronic respiratory insufficiency, the need for intubation depends on critical arterial blood gas values and the patient's early acute course. When progressive hypoxemia or hypercapnia is observed over the first few minutes or hours of care, intubation and mechanical ventilation are warranted.

Correction of Hypoxemia and Hypercapnia

Once the airway is secured, the clinician must turn attention to the treatment of hypoxemia—the most life-threatening aspect of acute respiratory insufficiency. The goal is to assure adequate oxygen delivery to tissues, generally achieved with a Pa_{O_2} of about 60 mmHg (assuming an adequate hematocrit and cardiac output). In patients who have coronary or cerebrovascular disease, a slightly higher level of arterial oxygenation may be desirable in order to provide a "buffer" for any sudden, unpredictable changes in gas exchange.

The means by which supplemental oxygen is administered is determined by the clinical circumstances. While some patients may simply require nasal prongs or a face mask to achieve an adequate Pa_{O_2}, others are best treated with controlled-flow oxygen delivered via a Venturi mask—e.g.,

the patient with COPD and chronic hypercapnia (see Chapters 42 and 149). Generally, if an acceptable level of oxygenation, as judged by arterial blood gases, cannot be attained using a face mask, or if administration of supplemental O_2 causes hypercapnia to worsen significantly (e.g., in some patients with COPD), either noninvasive mechanical ventilation or endotracheal intubation and mechanical ventilation will be required.

While correcting hypoxemia, the clinician must also address any coexisting hypercapnia and respiratory acidosis. Once again, the immediacy of correction depends on the magnitude of the acidosis and its attendant effects (e.g., elevation of serum potassium). A partly compensated respiratory acidosis in a patient with COPD usually constitutes a less urgent clinical circumstance than does profound respiratory acidosis in a patient with a drug overdose.

Search for an Underlying Cause

Finally, as therapy is initiated to correct the hypoxemia, hypercapnia, and acidosis of respiratory failure, a search for the cause of the problem and its management must be undertaken. In some cases, the cause and management are straightforward (e.g., administration of a narcotic antagonist to the patient with a narcotic overdose). In others, a more protracted course may be in store (e.g., long-term ventilator management of fulminant ARDS due to sepsis).

In both brief and prolonged cases of respiratory failure, attention to details of management is important in order to minimize the risks of complications of therapy, as discussed below.

MONITORING PATIENTS WITH ACUTE RESPIRATORY FAILURE

Repeated assessment of the patient with incipient or resolving respiratory failure, as well as the patient with frank hypoxemic or hypercapnic failure, is critical in formulating decisions about therapy. Monitoring methods range from routine bedside observations to use of invasive techniques.

For many patients with acute respiratory failure, simple observation of respiratory rate, tidal volume, use of accessory muscles, and presence of paradoxical breathing movements provides evidence of worsening respiratory failure and the need for mechanical ventilation. The patient with asthma or an acute exacerbation of COPD will frequently manifest rapid, shallow breathing and paradoxical thoracoabdominal breathing movements as respiratory mechanics deteriorate.

Once placed on mechanical ventilation, the patient must be monitored carefully for ventilator-associated complications (see below). In addition, placement of indwelling arterial and venous catheters, patient immobilization, and use of a broad range of pharmacologic agents present additional potential threats to the acutely ill patient.

While many monitoring techniques are routine and may be universally applicable to patients in a critical care setting (e.g., pulse oximetry), others may be of particular importance in selected clinical circumstances. For example, routine assessment of static respiratory system compliance in a mechanically ventilated patient with ARDS or pulmonary fibrosis may provide an early warning of barotrauma. In the patient with status asthmaticus requiring mechanical ventilation, development of hypotension due to intrinsic positive end-expiratory pressure (PEEP) or "auto-PEEP," as discussed in Chapters 152 and 153, may signal the need to alter ventilator settings or implement sedation or pharmacologic paralysis.

COMPLICATIONS OF ACUTE RESPIRATORY FAILURE

The respiratory patient in a critical care unit must navigate not only the obstacles presented by the underlying pulmonary process, but also the hazards associated with use of mechanical devices and pharmacologic agents. Complications of acute respiratory failure may be broadly categorized as pulmonary, cardiovascular, gastrointestinal, renal, infectious, nutritional, and other (Table 143-5). For details in each of these areas, the reader is referred to other chapters in this text.

Pulmonary

Common pulmonary complications of acute respiratory failure include pneumonia (discussed in detail elsewhere), pulmonary emboli, pulmonary barotrauma, pulmonary fibrosis, and complications directly related to use of mechanical devices.

Pulmonary emboli have been reported in up to one-fourth of patients with respiratory failure in intensive care units. The diagnosis is difficult in this setting, since patients typically have diffuse underlying lung disease, abnormal gas exchange, and many coexisting potential causes for the clinical, radiographic, and physiological consequences of pulmonary emboli.

Pulmonary barotrauma, identified as the presence of extra-alveolar air in structures that do not normally contain air, may occur in patients receiving mechanical ventilation for a variety of indications. It is particularly common in patients with ARDS. Manifestations of barotrauma include pulmonary interstitial emphysema, pneumothorax, pneumomediastinum, pneumoperitoneum, subcutaneous emphysema, tension lung cysts, and subpleural air cysts.

Pulmonary fibrosis may follow acute lung injury associated with ARDS. In addition, use of high inspired concentrations of oxygen may enhance development of fibrosis in the presence of acute lung injury.

Based on recent studies, a strategy of "low stretch" ventilation has emerged for managing patients with acute lung injury or ARDS and is aimed at minimizing the risks of ventilator-induced pulmonary damage, as discussed in

Table 143-5

Complications of Acute Respiratory Failure

Pulmonary
Pulmonary emboli
Pulmonary barotrauma (interstitial emphysema, pneumothorax, subcutaneous emphysema, pneumoperitoneum, tension lung cyst, subpleural air cyst)
Pulmonary fibrosis
Related to Use of Mechanical Devices
Complications of mechanical ventilation (infection, arterial desaturation, hypotension, barotrauma, others)
Complications of insertion and maintenance of pulmonary artery catheter (pneumothorax, air embolism, arrhythmias, infection, thrombosis, pulmonary artery rupture)
Complications of tracheal intubation
Related to prolonged intubation attempt (hypoxemic brain injury, cardiac arrest, seizures, others)
Related to right main bronchus intubation (hypoventilation, pneumothorax, atelectasis)
Self- or inadvertent extubation
Endotracheal tube dislodgment
Endotracheal tube cuff leak
Injury to pharynx, larynx, trachea
Complications of tracheotomy (pneumothorax, bleeding, tube dislodgment, tracheoinnominate fistula, tracheoesophageal fistula, tracheal stenosis)
Gastrointestinal
Hemorrhage (including "stress" ulceration)
Ileus
Diarrhea
Cardiovascular
Hypotension
Arrhythmias
Decreased cardiac output
Myocardial infarction
Pulmonary hypertension
Renal
Acute renal failure
Fluid retention
Infectious
Nosocomial pneumonia
Bacteremia
Sepsis
Paranasal sinusitis
Nutritional
Complications of underlying malnutrition (decreased respiratory muscle strength, immune suppression, others)
Complications of enteral feeding (pneumothorax, pleural effusion, sinusitis, aspiration, diarrhea)
Complications of parenteral feeding (pneumothorax, sepsis, hyperglycemia, hyperosmolar coma, hypophosphatemia, liver function test abnormalities)
Complications of refeeding (hypercapnia)
Other
Psychiatric (anxiety, depression, confusion, sleep dysfunction, psychosis)
Hematological (anemia, thrombocytopenia)

Chapters 144 and 145. In addition, new approaches to the use of intravenous sedation, namely, daily interruption of the infusion, has been shown to reduce both the duration of mechanical ventilation and length of stay in the intensive care unit.

Common device-related complications include those due to pulmonary artery flotation catheters, endotracheal intubation, and tracheotomy.

Cardiovascular

Common cardiovascular complications in patients with acute respiratory failure include hypotension, reduced cardiac output, arrhythmias, pericarditis, and acute myocardial infarction. These complications may be related to the underlying disease process, mechanical ventilation, or use of pulmonary artery flotation catheters.

Gastrointestinal

A variety of gastrointestinal complications of acute respiratory failure, particularly during mechanical ventilation, have been well described. The major ones include hemorrhage, gastric distention, ileus, diarrhea, and pneumoperitoneum. "Stress" ulceration is extremely common in patients with acute respiratory failure. Associated risk factors include trauma, shock due to a variety of causes, sepsis, renal failure, and liver disease.

Infectious

Nosocomial infections are a frequent complication of acute respiratory failure. Principal among these are pneumonia, sepsis, and urinary tract infections. Each typically occurs with the use of mechanical devices, including endotracheal and tracheotomy tubes, indwelling central venous and pulmonary artery catheters, and urinary bladder catheters.

The incidence of nosocomial pneumonia in the critically ill may be as high as 70 percent for patients in intensive care units, particularly in those with ARDS. The need for prolonged mechanical ventilation is a harbinger for development of nosocomial pneumonia. Not unexpectedly, nosocomial pneumonia occurring in the medical intensive care unit is associated with a significantly increased length of stay and higher mortality. Guidelines have been developed for treatment of patients with ventilator-associated pneumonia.

Renal

Acute renal failure and abnormalities in electrolyte and water homeostasis are not uncommon in critically ill patients with acute respiratory failure; the former is observed in approximately 10 to 20 percent of patients in intensive care units. Development of acute renal failure in a patient with acute respiratory failure carries a poor prognosis and a high mortality. The causes of acute renal failure are numerous and include prerenal azotemia and acute tubular necrosis due to hypotension or use of nephrotoxic drugs.

Nutritional

Nutritional complications of acute respiratory failure include the effects of malnutrition on respiratory performance and complications related to the administration of enteral or parenteral nutrition. Complications of enteral nutritional support relate to initial insertion of the catheter (e.g., tracheal or pleural space penetration, pneumomediastinum, pneumothorax, and pleural effusion) and its maintenance (e.g., paranasal sinusitis and aspiration). In addition, vomiting, abdominal distention, and diarrhea are common. Complications of parenteral nutrition are mechanical (e.g., pneumothorax during catheter insertion), infectious (e.g., catheter-related sepsis), or metabolic (e.g., metabolic acidosis, hyperglycemia and hyperosmolar coma, and hypophosphatemia). Hypercapnia, induced by enteral as well as parenteral nutrition, can complicate management of patients who have limited ventilatory reserve.

PROGNOSIS

Interpretation of studies addressing the prognosis of patients with acute respiratory failure is subject to a number of constraints, including marked clinical variability in the patients studied, predominance of studies from intensive care units in large university teaching hospitals, and variability in treatment methods employed over the time span of studies performed. In addition, many studies report only hospital mortality, not long-term survival or quality of life. Finally, findings from large-population studies are difficult to extrapolate to prediction of outcome in a single patient. Nonetheless, several generalizations can be made regarding the prognosis of patients hospitalized with acute respiratory failure.

Morbidity and Mortality in Acute Hypoxemic Respiratory Failure

As expected, mortality in hypoxemic respiratory failure depends on the underlying cause. A number of studies have addressed outcome in patients with ARDS.

Mortality in ARDS appears to have improved in recent years, with overall survival now at about 60 percent. Patients who develop sepsis after trauma have a lower mortality than do patients with sepsis that complicates medical disorders. Not surprisingly, younger patients (those under the age of 70 years) have better survival rates than do older patients. Notably, patients with preexisting lung disease, higher F_{IO_2} or PEEP requirements, or a lower Pa_{O_2} may not necessarily have a poorer chance of survival.

Approximately two-thirds of patients who survive an episode of ARDS will manifest some impairment of

pulmonary function one or more years after recovery. The abnormalities include both obstructive and restrictive defects, as well as a reduction in diffusing capacity. The pulmonary function findings do not appear to correlate with whether low or high tidal volumes were used during mechanical ventilation. Pulmonary function abnormalities that persist beyond one year after recovery are unlikely to resolve thereafter. Furthermore, despite recovery of pulmonary function, many survivors of ARDS have persistent functional disabilities one year after discharge, largely due to muscle wasting and weakness.

Approximately three-fourths of survivors of ARDS have neurocognitive findings at hospital discharge; in about one-half, the findings persist at 2 years postdischarge. Indeed, reduced quality of life and persistent neurocognitive defects represent long-term morbidities of survival in ARDS.

Morbidity and Mortality in Acute Hypercapnic Respiratory Failure

In general, several parameters presage a higher mortality in patients admitted with hypercapnic respiratory failure: (1) the patient's "physiological reserve," as determined by concurrent cardiopulmonary, renal, hepatic, or neurological disease and the patient's age; (2) the underlying cause of the acute deterioration; (3) the severity of the respiratory failure, as defined by arterial pH and P_{CO_2}; and (4) development of complications after onset of acute respiratory failure—e.g., sepsis, pneumonia, renal failure, or gastrointestinal bleeding. Cachexia and home confinement before hospitalization may also presage a poorer outcome. These harbingers appear to hold true regardless of whether the patient requires mechanical ventilation.

For patients with COPD and acute respiratory failure, overall mortality has declined from approximately 26 percent to 10 percent according to more recent studies. Not unexpectedly, older patients who are significantly more acidemic, hypotensive, or uremic appear to have a higher mortality. The magnitude of the hypoxemia or hypercapnia at the time of presentation may not reliably foretell mortality.

Acute Respiratory Distress Syndrome: Pathogenesis

Michael A. Matthay

This chapter focuses on the pathogenesis of acute lung injury (ALI) and the acute respiratory distress syndrome (ARDS). Chapter 145 discusses clinical features and clinical management.

PATHOPHYSIOLOGY OF PULMONARY EDEMA IN ACUTE LUNG INJURY

Pulmonary edema occurs when fluid is filtered into the lungs faster than it can be removed. Accumulation of fluid may have major consequences on lung function because efficient gas exchange cannot occur in fluid-filled alveoli. Lung structure relevant to edema formation and the forces governing fluid and protein movement in the lungs has been the subject of classic and more recent reviews and chapters, as noted in the "Suggested Reading" included at the end of this discussion.

Vascular Fluid and Protein Exchange

The essential factors that govern fluid exchange in the lungs are expressed in the Starling equation for the microvascular barrier:

$$Jv = LpS[(Pc - Pi) - \sigma d(\pi c - \pi i)] \quad (1)$$

where

- Jv = the net fluid-filtration rate (volume flow) across the microvascular barrier
- Lp = the hydraulic conductivity ("permeability") of the microvascular barrier to fluid filtration (a measure of how easy it is for water to cross the barrier)
- S = the surface area of the barrier
- Pc = the pulmonary capillary (microvascular) hydrostatic pressure
- Pi = the interstitial ("perimicrovascular") hydrostatic pressure
- πc = the capillary (microvascular) plasma colloid osmotic (or oncotic) pressure
- πi = the interstitial (perimicrovascular) fluid osmotic pressure
- σd = the average osmotic reflection coefficient of the barrier (a measure of the effectiveness of the barrier in hindering the passage of solutes from one side of the barrier to the other)

The Starling equation predicts the development of two different kinds of pulmonary edema. *Increased pressure pulmonary edema* occurs when the balance of the driving forces increases,

forcing fluid across the barrier at a rate that can no longer be accommodated by lymphatic drainage. *Increased permeability pulmonary edema* occurs in the presence of ALI that damages the normal barriers to fluid filtration and allows increased flux of liquid and protein into the extravascular compartments of the lungs.

Thus, pulmonary edema results from increases in either hydrostatic driving pressures (increased pressure edema) or barrier conductance (increased permeability edema), or both. What distinguishes the two types is barrier permeability, which is normal in increased pressure edema, but abnormal in increased permeability edema. Fluid flow into the lungs is driven across the barrier in both types of edema by the balance of pressures. ALI or ARDS results primarily from an increase in lung vascular permeability, although some cases may be made worse by the presence of elevated lung vascular hydrostatic pressures.

Increased Permeability Pulmonary Edema

Increased permeability pulmonary edema is caused by an increase in liquid and protein conductance across the barriers in the lungs. The essential feature is that the integrity of the barrier to fluid and protein flow into the lung interstitium and the alveoli is altered. Increased permeability edema is sometimes called *noncardiogenic pulmonary edema*, and the resulting clinical syndromes in humans are commonly lumped together as *acute lung injury* or the *acute respiratory distress syndrome*.

Accumulation of fluid and protein increases when the lung endothelial and epithelial barriers are injured. If the rate of fluid accumulation exceeds the rate at which it can be removed, increased permeability edema occurs. Because the barriers limiting fluid and protein flow into the lungs do not function normally when the lungs are injured, the lungs are not protected against edema by the usual safety factors. Although increases in fluid and protein filtration across the lung endothelium can be removed by lymphatics and drained away from the alveolar walls as in increased pressure edema, much more fluid and protein are filtered at any given sum of driving pressures because the barriers to their flow are much less restrictive than normal. Edema formation in injured lungs is very sensitive to hydrostatic driving pressures. Driving pressures are often increased when the lungs are injured because of the vasoconstrictive effects of inflammatory mediators such as thromboxanes, which may shift the main site of resistance to postcapillary venules, thus increasing hydrostatic pressure at the microvascular fluid exchange sites, or because of effects on the heart as well as on the circulation. For example, elevated left atrial pressure, pulmonary venoconstriction, or an increase in cardiac output in sepsis can increase hydrostatic pressure at the microvascular fluid exchange sites.

Because the barriers are leaky, the protective osmotic pressure differences across them are lost; driving pressure is unopposed by osmotic pressure, and even normal hydrostatic pressure results in significant fluid and protein extravasation into the interstitial and alveolar spaces. The ability of the lymphatics to pump the excess filtrate away is increased when the lungs are injured. Maximal lung lymph flow increases more when the microvascular wall has been injured than when hydrostatic pressure alone is increased, but even this augmented lymphatic-pumping capability is taxed at lower driving pressures. If the epithelial barrier is injured, edema may accumulate readily in alveoli, because most of the resistance to fluid and protein flow into the alveoli is in the epithelial barrier. Increased permeability edema is often rapid in onset and progression because injured barriers offer much less resistance to flow and because hydrostatic driving pressure is unopposed by increases in osmotic pressure difference. Clinically, many patients with increased permeability edema have a low intravascular hydrostatic pressure, commonly measured as a low or normal pulmonary capillary wedge pressure. In some cases, this reflects the low intravascular pressures associated with the underlying disease process, such as sepsis.

Lung Physiology

The effects of increased permeability edema on lung mechanics and gas exchange depend, in part, on the magnitude of edema accumulation. As with increased pressure edema, the major effects on pulmonary mechanics occur with alveolar flooding. In experimental lung injury, functional residual capacity is decreased as a consequence of alveolar flooding; the loss of units which can be ventilated accounts for most of the decrease in static lung compliance. Computed tomography has provided new insights into structure-function relationship in human ALI. In the early stage of lung injury, when alveolar edema predominates, the lungs are characterized by a more homogeneous alteration of vascular permeability, and edema can accumulate evenly in all lung regions with a nongravitational distribution.

Measurements of pulmonary mechanics in mechanically ventilated patients with ALIs show a decrease in static lung compliance as a consequence of the loss of ventilated lung units. In addition, airflow resistance is increased as a result of decreased lung volume. Bronchospasm may add to the increase in airflow resistance and may be partially reversed in some patients by administration of inhaled bronchodilators. Chest wall compliance is reduced, probably because of alterations in the intrinsic mechanical properties of the chest wall by abdominal distention, chest wall edema, and pleural effusion. Some investigators have reported differing respiratory mechanics and response to positive end-expiratory pressure (PEEP) during mechanical ventilation in patients with ARDS originating from pulmonary disease (e.g., pneumonia, which causes consolidation) versus ARDS due to extrapulmonary disease (which causes edema and subsequent alveolar collapse).

Although the effects of surface forces on decreased lung compliance in ALI were once believed to be small, results of experiments in isolated rabbit lungs indicate that increased permeability edema may produce more severe mechanical

changes than equivalent degrees of increased pressure edema. In contrast, experiments in awake sheep have demonstrated that similar degrees of pulmonary edema, regardless of mechanism, cause similar changes in compliance and gas exchange. Other studies indicate that dynamic and static lung compliances are decreased early in evolving lung injury.

Surfactant is strongly thromboplastic, and coagulation may compound surfactant depletion when plasma proteins enter the airspaces. The injured lung may release substances that can interfere with the normal, low surface tension in the alveoli. In addition, activated neutrophils may impair surfactant function in vitro and degrade major surfactant apoproteins through a combination of proteolysis and oxidant-radical–mediated mechanisms. In studies using bronchoalveolar lavage, human lung surfactant obtained from patients at risk for ALI and from those with established ALIs has been reported to be abnormal in chemical composition and functional activity. Abnormalities may also be caused by interactions between surfactant and edema proteins, since plasma proteins (especially fibrin monomers, but also fibrinogen and albumin) interfere with surfactant function. Proteinaceous edema fluid has been associated with surfactant inhibition in several experimental models.

Gas exchange is severely compromised in increased permeability edema because of both intrapulmonary shunting of blood and ventilation-perfusion inequalities. New evidence indicates that patients with early ALI have a marked increase in pulmonary dead space fraction. This finding indicates that many ventilated lung units are not well perfused, although intrapulmonary shunting may also contribute to the elevated dead space. Not surprisingly, minute ventilation is typically twice normal (approximately 12 L/min) at the onset of ARDS.

MECHANISMS OF ACUTE LUNG INJURY

This section focuses on the characteristic pulmonary pathological findings in patients with ALI and ARDS and the mechanisms responsible for ALI.

Pathological Findings

Based on several studies that included a preponderance of postmortem pathology, the light and electron microscopic appearances of human and animal lung tissue in ALI have been described. Exudative, proliferative, and fibrotic changes usually appear in sequence.

The earliest changes are marked by widespread alveolar and interstitial edema and hemorrhage. Hyaline membranes, composed of precipitated plasma proteins, fibrin, and necrotic debris are frequently found (Fig. 144-1). The alveolar epithelium may be more extensively damaged than is the vascular endothelium, even if the underlying insult is bloodborne. Widespread, local areas of destruction of type I alveolar epithelial cells alternate with normal-appearing alveoli. The injured alveolar epithelium is swollen, disorganized, discontinuous, and, frequently, detached from basement membranes, which may be otherwise intact. The alveolar surface may be covered by hyaline membranes. Type I cells are more severely damaged than type II cells. The thin cytoplasmic extensions of cells far from the nucleus, which cover the thin side of the alveolar-capillary barrier, may be most severely affected. The interstitium is widened by edema (especially in peribronchovascular cuffs) and may be filled with leukocytes, platelets, red blood cells, fibrin, and debris (especially near the alveolar walls). The microvascular endothelium is relatively preserved; it usually shows little other than irregular, focal thickening due to cytoplasmic swelling or vacuoles and greater numbers of luminal leukocytes.

After about 5 to 10 days, the exudative phase is followed by a proliferative phase. The relative contributions of the original insult, repair processes, and effects of therapies on this and subsequent phases are not well known. Some abnormalities occurring after the initial exudative phase appear to be related to effects of traditional modes of mechanical ventilation that used tidal volumes between 12 and 15 ml/kg predicted body weight.

Reabsorption of some of the edema fluid characterizes the proliferative phase. Fibrin may be prominent in alveoli and interstitium, and infiltration with inflammatory cells and fibroblasts, which may have been activated very early in the course of lung injury, may be seen. The alveolar epithelium is often cuboidal and made up largely of proliferating type II cells. The air-blood barrier may be thickened by interstitial and epithelial enlargement. The pulmonary vascular bed may be partially or completely disrupted, and structural alterations may reduce its surface area.

Approximately 2 weeks after the initial insult, a final stage may be observed in which fibrotic changes of the alveolar ducts, alveoli, and interstitium predominate. Alveoli may be obliterated, alveolar walls coalesced, and functional lung units lost. The lungs may be emphysema-like, with extensive bullous changes. Notably, even severe changes at any stage may be reversible during a slow recovery back toward normal lung function.

Mediators

The most common clinical disorders associated with the development of ALI are pneumonia, sepsis, gastric aspiration, and major trauma. Other, less common causes include transfusion-associated lung injury, drug overdose, severe acute pancreatitis, and near drowning. The initiating insult to the lungs occurs either via the airways or the bloodstream.

The exact mechanisms by which the lungs are injured have been the subject of intense investigation in humans, animals, and cellular systems. Human studies have provided descriptive data about the events that occur in the airspaces before and after the onset of lung injury. Studies using bronchoalveolar lavage or collection of pulmonary edema fluid

in patients following the onset of ALI have demonstrated a major acute inflammatory response beginning prior to clinical recognition of ALI. The response peaks during the first 1 to 3 days of clinically defined ALI and resolves slowly over 7 to 14 days in patients who remain intubated. These studies have shown the complexity of the evolving inflammatory responses, characterized by accumulation of acute response cytokines and their naturally occurring inhibitors, oxidants, proteinases and antiproteinases, lipid mediators, growth factors, and the collagen precursors involved in the repair process.

Hypotheses regarding the mechanisms of lung injury have been tested in animal models and in vitro studies, and several reviews have summarized the findings. The existing animal models do not completely reproduce all of the aspects of ALI in humans, in part because human ALI evolves over a longer period of time than can be studied in the laboratory. In addition, the lungs of humans are exposed not only to the initial injurious insult, but also to the therapies that are used to treat ALI, such as mechanical ventilation. Experiments using isolated cells have been helpful in testing specific concepts, but the complexity and redundancy of intact biologic systems is not reproduced in simplified experimental systems. By design, most experimental work limits study to one causative agent, thereby reducing actual clinical complexity to the simplicity of a single experimental pathway. Increased permeability edema in humans is likely to be caused by interactions among a number of different pathways acting in parallel or series.

Studies in isolated organs and small animals in which hemodynamic variables are not measured can be difficult to evaluate. Indices of lung injury, usually measured by the appearance of markers in lungs, lavage fluid, or perfusate, are not determined solely by the barrier function of the microvasculature. Indeed, when vascular endothelium is injured, fluid and protein movement from the vascular space into the lungs is sensitive to hydrostatic driving pressures and filtration surface area. Hence, the effects of experimental interventions may be caused by changes in these parameters and not by changes in microvascular barrier function.

The effects of microvascular driving pressures and surface area can be difficult to evaluate, even in large, instrumented animals. In sheep and goats, interpretation of lung lymph fluid and protein flow changes are further complicated by contributions of extrapulmonary lymphatics, physical forces acting on lymphatics, and possible intranodal modification of lymph. Data from experimental animal models suggest that at least two broad categories of mechanisms of ALI are operative: (1) those that are *indirect* (i.e., require the participation of intermediary mechanisms, e.g., host defenses); and (2) those that are *direct* (i.e., do not require intermediary mechanisms; injury probably occurs as a result of contact between an offending substance and lung tissue). These categories overlap, since once the lungs are injured, inflammatory responses occur, which may compound the primary mechanism of injury. Three major hypotheses regarding the mechanism of ALI are discussed below. Although discussed separately, they are interrelated.

Role of Infection

ALI develops in 20 to 45 percent of patients with severe sepsis. Increased microvascular permeability to albumin has been shown to accompany human sepsis, and infection and the sepsis syndrome are major causes of ALI in humans. Patients who develop shock in response to known or suspected infection have a particularly high incidence of ALI, and the mortality of patients with ALI associated with infection (i.e., sepsis syndrome) is increased. ALI also appears to predispose the lungs to infection, and delayed infection is an important cause of morbidity in patients who survive the initial lung insult.

The mechanism by which infection and sepsis syndrome injure the lungs is not certain. The lung injury is likely related to factors other than direct damage by bacteria or other microorganisms, since the prognosis appears unrelated to documented bacteremia or pneumonia. In experimental animals, intravenous infusions of live *Pseudomonas aeruginosa* or endotoxins from *Escherichia coli* or surgically induced peritonitis result in increased permeability pulmonary edema. Instillation of endotoxin into the airways of sheep also leads to lung inflammation with variable degrees of lung injury. *P. aeruginosa* produces lung injury in pigs, and *E. coli* endotoxin administration injures the lungs of baboons and dogs; neutrophilic alveolitis is observed in rats and mice. ALI caused by endotoxin in sheep is thought to be an inflammatory response mediated, at least in part, by neutrophils and tumor necrosis factor (TNF). Endotoxin may also affect the clotting system and metabolic functions of the lungs, as well as predispose the lungs to development of pulmonary infections by increasing adherence of bacteria to injured endothelium. Exoproducts of bacteria, such as elastase and *Pseudomonas* exoenzyme U, also have been shown to injure the lungs.

In addition to a direct role in the pathogenesis of lung injury, bacterial products may also have an indirect role by sensitizing the lungs to the effects of mechanical stretch. Gram-negative lipopolysaccharide causes an acute inflammatory response in the lungs of humans. Bacterial endotoxin enhances the responses of human alveolar macrophages to positive pressure ventilation; pretreatment of rats with intravenous endotoxin enhances cytokine production in the lungs during mechanical ventilation ex vivo. Furthermore, mechanical ventilation using moderate or large tidal volumes increases the sensitivity of lung macrophages to endotoxin in vitro and the expression of the endotoxin recognition molecule, CD14, on lung cells in vivo. Endotoxin recognition pathways are increased in the lungs of patients with ARDS, and the biologic effects of endotoxin are amplified in the lungs of patients with lung injury. The synergism between bacterial products and mechanical stretch suggests that interrupting these pathways might limit some forms of ALI in humans.

Increased permeability edema is associated with impaired antibacterial defenses. In animal models, bacterial infections worsen ALI. The cause of impaired bacterial defenses in acute ALI is not known. Bactericidal properties of the alveolar lining material might be altered in injured or flooded lungs, and alterations in surfactant concentration and function may be important. Although neutrophils may be present in large numbers in the bronchoalveolar lavage fluid of patients with ALI, evidence indicates that the function of the neutrophils is compromised.

Role of Inflammation

Substantial evidence implicates host defenses and inflammatory responses in the underlying mechanism of many ALIs. Neutrophils are a vital component of host defenses, and patients with severe neutropenia are at increased risk of bacterial and fungal infections. On the other hand, neutrophils release toxic oxygen radicals, proteases, and other biologically active mediators that initiate inflammation. Other important cells in pathogenesis include alveolar and pulmonary intravascular macrophages, and eosinophils.

Normally, the pulmonary circulation contains a very large pool of marginated neutrophils that change shape in order to squeeze through the lung capillaries. When neutrophils are activated, they stiffen and become less distensible. These neutrophils are retained for longer periods of time in the pulmonary microcirculation. Endothelial activation leads to increased expression of leukocyte adhesion molecules, providing a second mechanism to slow the transit of neutrophils. Trapped neutrophils respond to chemotactic

gradients generated by chemokines produced by alveolar macrophages and mesenchymal cells and migrate into the airspaces. Activated neutrophils generate and release toxic substances (e.g., oxygen metabolites and granular constituents, such as proteases, and cationic lysosomal enzymes) that disrupt the function of the microvascular and epithelial barriers. Normally, these barriers limit liquid and protein flow out of the vascular space and into the alveolar spaces, mitigating development of permeability edema.

Inflammatory responses also have the potential to induce lung cell injury by activating cell death pathways, leading to apoptosis. Bacterial products, such as *Pseudomonas* Exoenzyme U and mechanical stretch, may lead to direct cellular necrosis. Apoptosis is mediated by a family of death receptors, including TNF and Fas receptors. The Fas ligand (FasL) is a 45 kD peptide that is shed from the cell surface by the action of metalloproteinases. Biologically active soluble FasL (sFasL) accumulates in the lungs of patients with ARDS, inducing apoptotic death of human lung epithelial cells in vitro. Human sFasL induces epithelial cell death in the lungs of rabbits; a monoclonal antibody that activates membrane Fas causes alveolar wall apoptosis and fibrosis in the lungs of mice.

Apoptosis and inflammation pathways intersect, as stimulation of membrane Fas induces cytokine production in human macrophages and inflammation in the lungs of rabbits and mice. In addition, lung injury may be able to trigger apoptosis pathways in distant organs, such as the kidney, perhaps by increasing the concentrations of circulating sFasL. Thus, inflammatory responses may trigger cell death pathways, and cell death pathways triggered by sFasL may induce inflammation in the lung alveolar environment. Recent human studies implicate apoptosis in human lung injury.

Role of Direct Toxicity

Inflammation is not required for all forms of ALI. ALI or ARDS can develop in neutropenic patients. A clinical trial using granulocyte colony-stimulating factor to increase the number and activation state of circulating neutrophils in patients with severe pneumonia was not associated with an increased incidence of ARDS. Lung injuries that do not require the participation of neutrophils have been described in animal models.

Direct lung injury is also thought to occur in humans. Putative agents that directly injure the lungs include mechanical forces during mechanical ventilation, toxic and corrosive chemicals and gases (e.g., hydrochloric and other acids, ozone, ammonia, chlorine, phosgene, nitrogen dioxide, the vapors of cadmium and mercury, combustion products, and oxygen, especially at high concentrations), ionizing radiation, aspiration of fresh water (near drowning) or hydrocarbon compounds (e.g., kerosine, gasoline, and dry-cleaning fluid), high temperatures (parenchymal lung burns from fires or explosions), and mechanical injuries (e.g., lung contusion from nonpenetrating chest trauma or blast injury from explosions or lightning). Many of these injuries develop rapidly, supporting the idea that injury is caused directly by contact with the respiratory epithelium in the airways and/or alveolar walls.

Inflammatory pathways are likely to be rapidly activated following many types of direct lung injury, as probably occurs following aspiration of gastric secretions—one of the most common clinical causes of ALI. Lung injury occurs rapidly, especially to the epithelium. The injury is probably related, in part, to the low pH of the aspirated stomach contents (aspiration of gastric contents with pH greater than 2.5 is relatively benign; aspiration of gastric contents with pH less than 2.5 causes severe pulmonary injury). Aspirated acid is almost immediately neutralized. However, within hours, proinflammatory mediators are released, the injured lung is infiltrated with neutrophils, fibrin accumulates in the alveolar spaces, and further structural damage is seen on histological examination.

Biologic Markers

Considerable interest exists in finding a simple test of blood, urine, or bronchoalveolar lavage fluid that would identify patients at risk for, or in the earliest stages of, ALI, or that might predict clinical outcome.

Although products of complement activation have been proposed as markers, their serum levels correlate poorly with lung injury. Measurement of circulating endotoxin is not appropriately sensitive or specific for the presence or risk of developing lung injury. The same is true for measurements of release or activity of angiotensin-converting enzyme. Von Willebrand factor (VWF) antigen may be useful as a plasma marker of impending ALI in patients with nonpulmonary sepsis. Recent work confirms that VWF levels are elevated in the edema fluid and plasma of patients with ALI and correlate with poor clinical outcomes. While increases in other biochemical and inflammatory markers, including surfactant protein D and interleukin-6, correlate somewhat with lung injury and mortality, no simple biologic marker currently serves in the same diagnostic capacity as do cardiac enzymes in evaluation of suspected acute myocardial infarction.

Because neutrophils are implicated in the mechanism of many lung injuries, their detection in the lungs, assessment of their function, or assay of the toxic metabolites they release might be useful. For example, increased hydrogen peroxide levels have been measured in the breath and urine of patients with ALI, presumably reflecting the presence of oxygen metabolites in the injured lungs. Evidence of increased oxidant activity has been reported in bronchoalveolar lavage fluid in patients with lung injury.

Finally, other mediators of inflammation in ALI have been studied. For example, increased levels of TNF are detected in blood and bronchoalveolar lavage fluid in lung injury, but an association between TNF levels and development of ARDS has not been found. Furthermore, elevated TNF levels are found in patients with severe congestive heart failure. Lipoxygenase products of arachidonic acid metabolism have been detected in pulmonary edema fluid, bronchoalveolar lavage fluid, plasma, and urine, and elastase has been

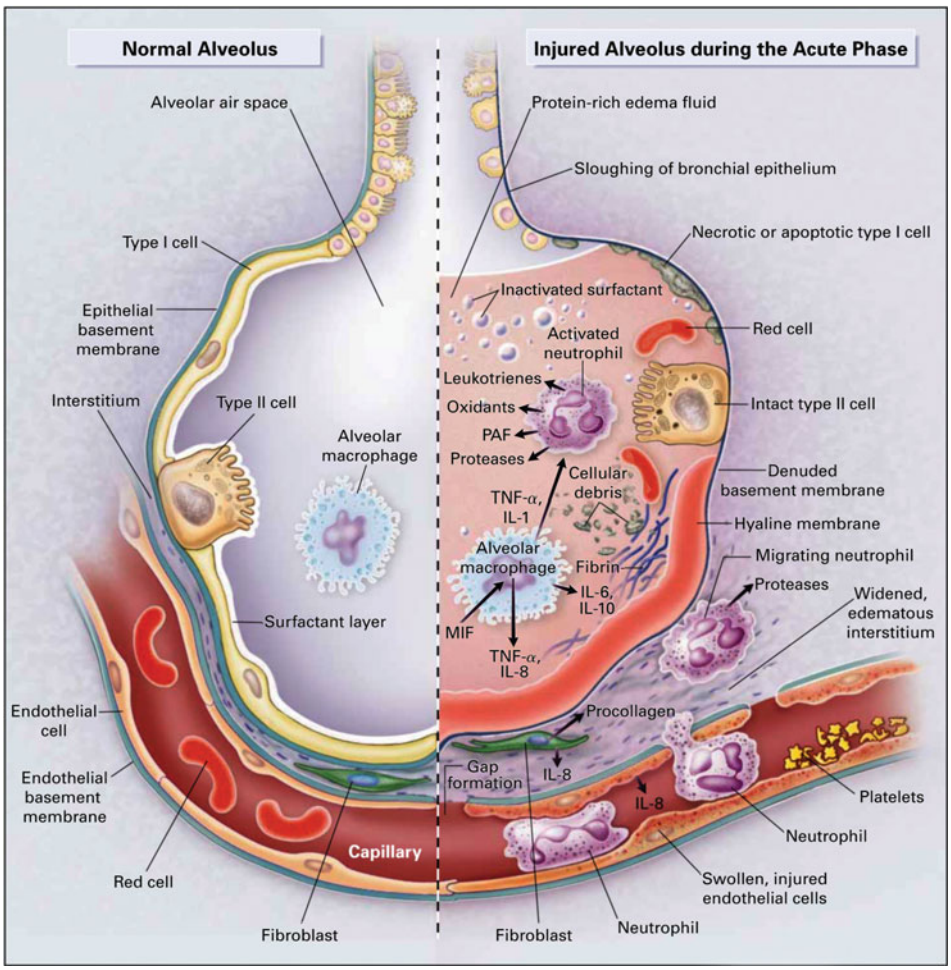

Figure 144-2 Multiple cellular responses and mediators contribute to alveolar-capillary membrane injury (*right-hand side*) and the transition from normal alveolar structure and function (*left-hand side*) in the acute phase of ALI/ARDS. Original investigations of the pathogenesis of ALI/ARDS searched for single mediators that provided final common pathways to inflammation and alveolar edema. Current concepts of pathogenesis involve multiple molecular factors of several classes, a variety of responding cells, and an imbalance between injurious and reparative signals and pathways. See text and Ware & Matthay (2000) and Matthay & Zimmerman (2005). *(Reprinted from Matthay MA, Zimmerman GA: Acute lung injury and the acute respiratory distress syndrome: Four decades of inquiry into pathogenesis and rational management.* Am J Respir Cell Mol Biol *33:319–327, 2005, with permission.)*

detected in bronchoalveolar lavage fluid in the setting of lung injury.

ALI follows a wide variety of insults of varying severity. Furthermore, many abnormalities detected in ALI are found in other diverse, severe illnesses that do not involve the lungs. Therefore, the likelihood that any single marker that unequivocally identifies the risk or the presence of ALI will be found seems remote. An investigative focus on particular subgroups of patients with common causes of injury, coupled with study of much larger groups of more definitively diagnosed patients, might prove helpful. An approach that has not received much attention is investigation of the sensitivity and specificity of combinations of biologic markers. The new field of proteomics will expand this type of investigation and, perhaps, identify patterns of protein abnormalities that can be found in plasma, urine, edema fluid, and bronchoalveolar lavage in patients with ARDS.

Figure 144-2 depicts multiple pathways involved in the pathogenesis of ALI and ARDS in the context of normal and injured alveoli. Emphasis is placed on potential pathways for injury across the vascular endothelium and alveolar epithelium.

VENTILATOR-ASSOCIATED LUNG INJURY

The most important development of the last 10 years in our understanding of the pathogenesis and treatment of ALI is recognition that the long-standing practice of mechanically ventilating patients with ALI or ARDS using high tidal volumes and airway pressures actually worsens the injury. Animal studies first suggested the potential contributory role of high tidal volumes and elevated airway pressures in the

pathogenesis of lung injury; subsequently, clinical trials confirmed the findings.

Animal Studies

Animal experiments have shown that ventilation using high tidal volumes may increase vascular filtration pressures; produce stress fractures of microvascular endothelium, alveolar epithelium, and basement membranes; and cause lung rupture (so-called ventilation-induced lung injury). The injury appears to be due to increased lung excursions at high volumes ("volutrauma"), rather than the high-airway pressure, per se, since it can be prevented by limiting thoracic motion (e.g., by placing the chest in a cast). The concept of volutrauma was first established in 1974 when investigators found that modestly elevated tidal volumes, especially in the absence of PEEP, caused lung edema in rats. Several years later, additional animal studies further demonstrated the potential injurious role of high tidal volumes and elevated airway pressures, an effect termed *ventilator-induced lung injury* (VILI). Subsequent experiments demonstrated that VILI could also induce release of several proinflammatory cytokines, injuring the lung and other organs—a process referred to as "biotrauma." These animal studies stimulated clinical investigation that revolutionized the care of patients with ALI or ARDS.

Clinical Studies

The compelling evidence from animal experiments and small clinical trials prompted clinical studies aimed at testing the potential benefit of lower tidal volumes and reduced airway pressures in management of ALI or ARDS. In a large, multicenter, National Heart Lung and Blood–sponsored trial of 861 patients, mortality was reduced from 40 to 31 percent using a tidal volume of 6 ml/kg/ideal body weight and a limited plateau airway pressure of less than 30 cm H_2O. In this trial, use of small tidal volumes was associated with a lower incidence of nonpulmonary organ failure. The protocol for carrying out the lung protective ventilatory strategy is described in detail in Table 144-1. The results of the trial have transformed the management of patients with ALI or ARDS. A follow-up clinical trial has shown that ventilation using the limited tidal volume and plateau pressure of the original study is associated with an overall reduction of mortality to 26 percent. In the follow-up study, although elevated levels of PEEP did not decrease mortality, the basic lung protective strategy was validated as effective.

The beneficial mechanism underlying the low tidal volume strategy is unclear. An Italian study has shown that use of low tidal volumes in patients with ARDS attenuates the inflammatory response in both lungs and bloodstream, as measured by reductions in neutrophil and cytokine concentrations in bronchoalveolar lavage and cytokines in circulating blood. Other studies have confirmed a number of these findings. In addition, a reduction in alveolar epithelial injury appears likely, based on a decline in plasma surfactant protein D levels. Additional clinical and experimental studies are underway. A reduction in lung endothelial and epithelial injury, attenuated inflammatory responses, reduced edema formation, and more rapid resolution of lung edema are likely part of the mechanism(s).

RESOLUTION OF ACUTE LUNG INJURY

In the last two decades, considerable progress has been made in understanding the mechanisms responsible for resolution of lung edema. More limited progress has been made in understanding the resolution of lung inflammation.

Considerable advances have been made in our understanding of the clearance of fluid and solute from alveoli. Active sodium and chloride transport across the alveolar and distal airway epithelial barriers into the interstitium drives edema fluid removal from the airspaces. The uninjured alveolar epithelium has a remarkable ability to rapidly clear fluid from the airspaces. Even when mild-to-moderate alveolar injury occurs, salt and water transport capacity is often preserved. In severe injury, when the barrier is disrupted, the capacity to clear edema is lost. The vascular endothelium becomes the limiting barrier between the vascular space and airspace. Clinically, the capacity to remove some alveolar edema fluid (as indicated by increase in edema fluid to plasma protein concentration ratio) in the first 12 hours following ALI is a favorable prognostic finding; the associated mortality rate is only 20 percent. In contrast, an inability to resorb alveolar edema fluid early in the course of injury is associated with a mortality of nearly 80 percent. Thus, the function of the alveolar epithelial barrier early in the course of ALI may be a useful prognostic index, serving as a marker of the severity and extent of injury.

In uninjured, ex vivo human lungs, alveolar fluid clearance is increased by administration of salmeterol. In addition, experimental studies have shown that even in the presence of ALI and alveolar edema, alveolar fluid clearance can be increased pharmacologically (e.g., by catecholamines), thereby representing a potential therapeutic intervention.

Clearance of protein from flooded alveoli is much slower (1 to 2 percent per hour) than clearance of fluid (10 to 20 percent per hour), resulting in an increased concentration of protein in airspaces. If the alveolar edema formed during increased lung vascular permeability clots, its removal from flooded alveoli may be slowed. Clotting may occur because extravasation of plasma into airspaces can lead to clotting system activation by surfactant or macrophage-derived procoagulants.

Most of the interstitial water in pulmonary edema lies in the peribronchovascular loose connective-tissue spaces, rather than in alveolar walls. Because the lymphatic capillaries are arranged to drain only the alveolar wall interstitium, this route for edema removal is not significant for most interstitial edema. A study in goats showed that lung lymph originates mainly from alveolar wall interstitial fluid. The contribution

of the lung lymphatic system to clearance of interstitial edema in bronchoalveolar cuffs and interlobular septa is small. The maximum possible contribution by lung lymphatics to clearance of interstitial edema liquid is less than 10 percent, with airway loss of liquid through evaporation occurring at about twice the rate of lymphatic clearance.

In a study of in situ perfused sheep lungs with experimentally induced low- and high-protein pulmonary edema, interstitial liquid was resorbed into the circulation in inverse proportion to its protein concentration. Only a very small fraction of interstitial edema was cleared by the lung lymphatics during recovery from either type of edema.

Some fluid from the loose peribronchovascular interstitium may drain directly into the bloodstream by crossing the walls of blood vessels in the lungs. A study of isolated sheep lungs made edematous by raising vascular pressures showed that the primary route of edema clearance is by vascular resorption (60 percent of filtered water cleared over 3 hours, including 42 percent by resorption into the bloodstream and 18 percent by lymphatic, pleural, and mediastinal drainage).

Edema may also drain into the pleural space. Pleural effusions are more common in increased pressure pulmonary edema (25 to 50 percent of patients; usually on the right if unilateral). However, they occur in ALI as well (35 percent of patients). As much as 25 to 30 percent of edema fluid may leave the lungs through the pleural space. A significant portion of the interstitial edema probably follows the prevailing pressure gradient in the lungs to drain into the mediastinum, where it may be picked up by the lymphatics.

Short-term alveolar protein clearance appears to proceed primarily by paracellular diffusion. The process depends

on the size of the proteins. Most proteins are cleared intact, rather than as degraded, smaller fragments. However, a few specific proteins (e.g., vasoactive intestinal peptide and gastrin) are degraded before being cleared.

Receptor-mediated clearance may play a role. An albumin-binding protein (albondin) is expressed on lung microvascular endothelial cells. An antibody to this protein reacts with cellular proteins of alveolar epithelial cells, which also appear to have albondinlike binding sites for albumin. In addition, a polymeric immunoglobulin receptor has been described. The significance of these receptors in protein clearance is, however, unclear.

Finally, the general consensus is that transcytosis (transport via vesicles) is not a major mechanism for clearing bulk quantities of albumin or other proteins from the alveolar space. Over the long term, phagocytosis and catabolism by macrophages account for most protein clearance from the alveolar spaces. All insoluble, precipitated proteins are removed in this way. Macrophages are also ultimately responsible for removing senescent and dead neutrophils and other debris. The presence of a small, ciliated surface area of the distal airspaces suggests that the mucociliary route accounts for only a minor fraction of alveolar protein clearance. Complete clearance of alveolar protein from pulmonary edema by any route is slow.

Little is known about the mechanisms and signals that regulate endothelial barrier function or how increased endothelial permeability is returned to normal.

CONCLUSIONS

Among the major advances in respiratory medicine and physiology over the last three decades has been the acquisition of important new knowledge on the physiology of fluid, solute, and protein transport in healthy and diseased lungs. Pulmonary edema, defined as the abnormal accumulation of extravascular lung fluid, is a pathological state that occurs when fluid is filtered into the lungs faster than it can be removed.

The many causes of pulmonary edema are grouped into two main pathophysiological categories: (1) increased pressure edema, which results from an increase in hydrostatic or osmotic forces (or both) that act across the barriers that normally restrict movement of fluid and solutes in the lungs; and (2) increased permeability edema, which is seen in ALI in which a breakdown of the normal barrier properties of lung endothelium or epithelium develops. Although these two different types of pulmonary edema share many features, usually they can be distinguished by careful clinical, radiological, and physiological evaluation. They also differ in treatment and prognosis.

Major advances in the treatment of ALI have occurred because of the successful application of lung protective ventilatory strategies early in the course of the illness (Table 144-1). A low tidal volume (6 ml/kg/ideal body weight), coupled with a plateau pressure limit (less than 30 cm H_2O) has resulted in the first therapy demonstrated to reduce mortality in patients with ALI.

Recently, the National Heart, Lung, and Blood Institute Acute Respiratory Distress Syndrome Network published the results of the Fluid and Catheter Treatment Trial (FACTT), a large randomized trial comparing a liberal fluid management strategy to a conservative fluid management strategy in patients with ALI. Patients were also randomized to receive either a pulmonary arterial catheter or a central venous catheter for monitoring and fluid management. There were no differences in clinical outcomes between the pulmonary or central venous catheter utilization. In contrast, there was a marked difference in outcome between the liberal and the conservative fluid management arms of the study. Patients in the conservative fluid management arm had 2.5 more ventilator-free days than those in the liberal fluid management arm with concordant improvements in pulmonary physiology. There was also a 2.9 percent reduction in the 60-day mortality rate in the conservative fluid management arm compared with the liberal fluid management arm, although this difference did not reach statistical significance.

New insights into the pathogenesis of ALI suggest that other therapies may also prove to be efficacious in reducing mortality in this common form of severe acute respiratory failure. A major development has been the ability to conduct large, prospective, randomized, clinical trials (e.g., those sponsored by the National Heart, Lung, and Blood Institute) to test a variety of therapies important in supportive patient care, including use of mechanical ventilation, intravenous fluids, and a variety of pharmacologic agents. Such trials have led to a better understanding of the pathogenesis of human ALI and have confirmed the importance of ventilator-associated lung injury. In addition, ancillary pathogenetic studies carried out on biologic samples from clinical trials have advanced our understanding of underlying mechanisms. In the future, additional human studies will be needed to explore new therapeutic strategies suggested by basic investigation conducted in animal models of ALI.

Acute Lung Injury and the Acute Respiratory Distress Syndrome: Clinical Features, Management, and Outcomes

Jason D. Christie • Paul N. Lanken

DESCRIPTION AND DEFINITIONS

In 1967, Ashbaugh and co-authors described a syndrome characterized by the acute onset of dyspnea, severe hypoxemia, diffuse lung infiltrates, and decreased respiratory system compliance in the absence of evidence for congestive heart failure. The syndrome, initially called acute respiratory distress in adults (to contrast it with acute respiratory distress in neonates), is now known as the acute respiratory distress syndrome (ARDS). Following the initial report, other authors utilized various definitions that incorporated elements related to time of onset, presence of hypoxemia and radiographic infiltrates, and absence of overt congestive heart failure.

In 1988, Murray and others introduced the Lung Injury Score (LIS), an assessment tool for ARDS that reflects the extent of radiographic infiltrates, severity of hypoxemia and reduced respiratory system compliance, and level of positive end expiratory pressure (PEEP) used in mechanically ventilating affected patients. The LIS incorporates these four parameters that are graded on a scale of 0 to 4: (1) the ratio of Pa_{O_2} to FI_{O_2} (Pa_{O_2}/FI_{O_2}); (2) total respiratory compliance; (3) level of PEEP; and (4) extent of radiographic infiltrates (assessed by noting the number of quadrants in the chest radiograph containing infiltrates). The LIS equals the sum of the scores for the four variables divided by four. In clinical studies, a score of 2.5 or more is generally used as a threshold for severe disease.

Consensus Definitions of Acute Lung Injury and Acute Respiratory Distress Syndrome

Prior to 1994, published studies used non-uniform definitions of ARDS, prompting an American European Consensus

Table 145-1

American European Consensus Conference Criteria for Acute Lung Injury (ALI) and the Acute Respiratory Distress Syndrome (ARDS)

Clinical Variable	Criteria for Acute Lung Injury	Criteria for Acute Respiratory Distress Syndrome
Onset	Acute	Acute
Hypoxemia	$Pa_{O_2}/FI_{O_2} \leq 300$mm Hg	$Pa_{O_2}/FI_{O_2} \leq 200$ mmHg
Chest radiograph	Bilateral infiltrates consistent with pulmonary edema	Bilateral infiltrates consistent with pulmonary edema
Noncardiac cause	No clinical evidence of left atrial hypertension or, if measured, pulmonary artery occlusion pressure $\leq$ 18mmHg	No clinical evidence of left atrial hypertension or, if measured, pulmonary artery occlusion pressure $\leq$ 18 mmHg

Source: Bernard GR, Artigas A, Brigham KL, et al: The American-European Consensus Conference of ARDS: Definitions, mechanisms, relevant outcomes, and clinical trial coordination. Am J Respir Crit Care Med *149:818, 1994.*

Conference (AECC) to develop standardized definitions for ARDS and acute lung injury (ALI): a broader category that encompasses ARDS. The AECC definitions included the acute onset of illness, bilateral chest radiographic infiltrates consistent with pulmonary edema, poor systemic oxygenation, and absence of evidence for left atrial hypertension (Table 145-1). The syndrome is ALI when the ratio of Pa_{O_2} to FI_{O_2} (Pa_{O_2}/FI_{O_2}) is less than or equal to 300 and ARDS when the ratio is less than or equal to 200.

The AECC coined the term ALI to facilitate diagnosing patients earlier in the course of their ARDS and identify patients who have a milder form of acute hypoxemic respiratory failure than ARDS. The AECC definitions of ALI and ARDS are intentionally broad in order to encompass different types of acute hypoxemic respiratory failure occurring in a wide variety of settings. Most patients with ALI progress to ARDS, prompting some to use the composite abbreviation ALI/ARDS to describe all patients with a Pa_{O_2}/FI_{O_2} less than or equal to 300 who meet the other AECC criteria (Table 145-1).

Limitations of Consensus Definitions

Despite standardization of definitions of ALI and ARDS, little data are available to support their reliability and validity. In fact, various components of the definitions remain problematic: (1) The chest radiograph is subject to variability in interpretation; (2) Pa_{O_2}/FI_{O_2} may vary according to ventilator parameters, e.g., PEEP, and at extremes of FI_{O_2}; and (3) accuracy in excluding the presence of heart failure may be influenced by measurement methodology and timing, as discussed below.

Although interpretation of chest radiographs can be inaccurate and variable among observers, formal training can reduce variability.

The Pa_{O_2}/FI_{O_2} criterion is influenced by the level of PEEP and other transient factors, including the presence or absence of airway secretions or inadequate sedation. Increasing PEEP generally increases Pa_{O_2} at a given FI_{O_2}. The consequent increase in Pa_{O_2}/FI_{O_2} may result in a ratio that no longer meets inclusion criteria for ALI. Conversely, without any PEEP, values of Pa_{O_2}/FI_{O_2} less than 300 may reflect simple atelectasis rather than ALI or ARDS. Adding PEEP may recruit sufficient atelectatic lung to raise Pa_{O_2}/FI_{O_2} greater than 300, thereby excluding such patients from meeting this criterion for ALI.

Finally, diagnostic criteria for left atrial hypertension on purely clinical grounds may be inaccurate. Use of a pulmonary artery catheter may also be inconclusive, since the pulmonary artery occlusion pressure (PAOP) in ALI/ARDS may be higher than 18 mm Hg due to intravascular volume loading, particularly in the setting of goal-directed management paradigms for sepsis (see Chapter 146). Conversely, some patients with pulmonary edema due to congestive heart failure and high left atrial pressures have normal pulmonary artery occlusion pressures by the time the catheter is inserted and PAOP is measured.

Several clinical trials have used the aforementioned standardized definitions of ALI and ARDS to specify study inclusion criteria for their study populations. Using the AECC definitions of ALI and ARDS in clinical trials that have shown therapeutic benefit adds important validity to the definitions. Clinicians can generalize the results of these trials to clinical decisions involving their own patients if they meet the same criteria for ALI or ARDS as used in the clinical trial. Further refinement of the reliability and validity of definitions of ALI and ARDS are important future directions for clinical studies. More reliable definitions will not only improve estimates of the public health impact of these syndromes, but also will decrease misclassification errors that can be especially

problematic for research aimed at clarifying mechanisms in ALI and ARDS, e.g., genetic epidemiological studies.

EPIDEMIOLOGY

Over the last several decades, the epidemiology of ALI and ARDS has become more clearly delineated.

Incidence and Mortality Rate

A landmark epidemiologic study of the incidence of ALI and ARDS in the United States between 1999 and 2000—the King County Lung Injury Project (conducted in King County, Washington)—represents the first broad, population-based epidemiological study of ALI and ARDS in the United States using standardized definitions. Study results included an estimated incidence of ALI of 78.9 per 100,000 person-years and an age-adjusted incidence of 86.2 per 100,000 person-years. The incidence of ARDS was estimated as 58.7 per 100,000 person-years with an age-adjusted incidence of 64.0 per 100,000 person-years. The incidence of ALI increased dramatically with age, with an incidence of 306 per 100,000 person-years for ages 75 through 84 years. By extrapolation, an estimated 190,600 cases of ALI and 141,500 cases of ARDS occur each year in the United States (Table 145-2).

Table 145-2

Estimated Incidence, Hospital Days and Intensive Care Unit (ICU) Days for Acute Lung Injury (ALI) and Acute Respiratory Distress Syndrome (ARDS) in the United States (US)

Variable	ALI	ARDS
Crude incidence, per 100,000 person-years	78.9	58.7
Age-adjusted incidence, per 100,000 Person-years	86.2	64.0
Estimated annual Number of cases in US	190,600	141,500
Estimated annual number of hospital days in US	3,622,00	2,746,000
Estimated annual number of days in ICU in US	2,154,000	1,642,000

From Rubenfeld GD, Caldwell E, Peabody E, et al: Incidence and outcomes of acute lung injury. N Engl J Med *353:1685, 2005.*

Although prior estimates of the incidence of ALI and ARDS had been lower, those studies were limited by incomplete and nonvalidated data, inaccuracies in the definition of the syndromes, and use of administrative coding. Thus, the estimates from King County Lung Injury Project serve as the best indicator of the public health impact of ALI and ARDS in the United States.

During the time of observation in the King County Lung Injury Project study, the mortality from ALI was 38.5 percent and from ARDS was 41.1 percent. These figures translate into an estimated 74,500 annual deaths from ALI in the United States. To put this mortality rate in perspective, more people die annually from ALI than from AIDS, asthma, and breast cancer combined. Other than lung cancer, ALI is responsible for more annual deaths than any cause of cancer, including lymphomas, leukemias, and breast, prostate, colon, ovarian, and pancreatic cancers (Table 145-3). Although the mortality rates from ALI and ARDS may have fallen since the King County Lung Injury Project was conducted in 1999–2000 (due to usage of low tidal volume ventilation strategies), ALI and ARDS likely still have a major public health impact.

Table 145-3

Estimated Annual Number of Deaths in the US from Selected Causes

Cause	Number of Deaths
ALI*	74,500
ARDS	59,000
Asthma	4,621
AIDS	18,017
Breast cancer	40,870
Leukemia	22,570
Lung cancer	163,510
Lymphoma	20,610
Ovarian cancer	16,210
Pancreatic cancer	31,800
Prostate cancer	30,350

** Includes 59,000 deaths from ARDS.*
Source: Data for ALI and ARDS are from Rubenfeld GD, Caldwell E, Peabody E, et al: Incidence and outcomes of acute lung injury. N Engl J Med *353:1685, 2005; all other are from CDC National Center for Health Statistics* (http://www.cdc.gov/nchs/).

Furthermore, as the population of the United States becomes older, the incidence of ALI and its associated annual death rate can be expected to rise.

Precipitating Causes

The severe extensive lung inflammation in ALI and ARDS represents the common final pathogenetic process in response to a large variety of precipitating causes, which result in either direct or indirect (systemic) lung injury. In general, *direct* causes of ALI include those that originate within the lung, such as aspiration of gastric contents or viral pneumonia. Examples of *indirect* causes include severe systemic inflammatory response syndrome (SIRS) or severe sepsis, ingested toxins, hypotension, and ischemia-reperfusion injury. Although some causes of ALI may fit into either category (e.g., multilobar pneumonia with septic shock), the classification scheme is useful both for considering the many predisposing causes of ALI and their varying mechanisms of lung injury and for future development of therapies aimed at different categories of ALI. Table 145-4 lists precipitating causes of ALI and ARDS according to this construct.

Factors Influencing Risk of ALI and ARDS

Not all patients with an underlying cause (e.g., sepsis) for ALI or ARDS develop the syndrome. In addition to inherent risk differences within at-risk populations, specific clinical variables may be important.

Clinical variables found to be associated with an increased risk of ARDS include chronic alcohol abuse, hypoproteinemia, advanced age, increased severity, and extent of injury or illness as measured by injury severity score (ISS) or APACHE score, hypertransfusion of blood products, and possibly, cigarette smoking. Diabetes mellitus decreases the risk of ALI. Since many of the studies addressing this issue are retrospective or based on a single center's experience, the consistency and generalizability of identified risk factors have not been confirmed. Nonetheless, the mechanistic underpinnings of these probable associations are the subject of ongoing research.

Factors Influencing Mortality from ALI and ARDS

Clinical variables at the onset of ALI and ARDS that are associated with increased mortality include advanced age, lower Pa_{O_2}/FI_{O_2}, high plateau pressure (i.e., low respiratory system compliance), greater extent of pulmonary infiltrates, chronic liver disease, nonpulmonary organ dysfunction, increased global severity of illness, hypoproteinemia, and greater length of hospitalization prior to onset of ALI/ARDS. In addition, an increased dead space fraction has been identified as a risk factor for increased mortality, possibly indicating the importance of early loss of the pulmonary vascular bed as a sign of greater disease severity. Although various precipitating causes of ALI and ARDS carry somewhat different prognoses, the strategy of low tidal volume ventilation utilized by the National Institutes of Health (NIH) National Heart, Lung, and Blood Institute (NHLBI)–sponsored ARDS Clinical Trials Network (ARDSNet) as part of its clinical trials appears to be equally efficacious in all subgroups.

Table 145-4

Common Direct and Indirect (Systemic) Precipitating Causes of ALI and ARDS

Direct Precipitating Cause	Indirect (Systemic) Precipitating Cause*
Aspiration of gastric fluids	Acute pancreatitis
Bacterial pneumonia (diffuse), e.g., Legionnaire's disease	Blood transfusions with transfusion-related acute lung injury (TRALI)
Chest trauma with lung contusion	Post-cardiopulmonary bypass
Near-drowning	Primary graft failure of lung transplantation
Pneumonia due to *Pneumocystis carinii*	Severe sepsis and septic shock
Toxic inhalations, e.g., smoke inhalation, inhaled crack cocaine	Toxic ingestions, e.g., aspirin, tricyclic antidepressants
Viral pneumonia, e.g., influenza, severe acute respiratory syndrome (SARS)	Trauma with multiple fractures and the fat-emboli syndrome

** In indirect or systemic mechanism of lung injury, the lung injury results from deleterious effects on the alveolar epithelium by inflammatory or other mediators delivered via the pulmonary circulation (see Chapters 144 and 146 Matthay Deutschman for details).*

Source: Christie JC, Lanken PN: Acute lung injury and the acute respiratory distress syndrome, in Hall JB, Schmidt GA, Wood LDH (eds): Principles of Critical Care, *3d ed. New York, McGraw-Hill, 2005; p 518, reproduced with permission.*

CLINICAL PRESENTATION AND DIAGNOSIS

The clinical presentation and diagnosis of ALI/ARDS are fundamentally related to the syndrome's pathophysiological changes, regardless of the underlying etiology. A brief description of the pathology and pathophysiology is provided before a detailed discussion of clinical aspects of the disorder. The reader is also referred to Chapter 144 for additional details on disease mechanisms.

Pathology and Pathophysiology

A number of inter-related mechanisms contribute to the development and clinical course of ALI and ARDS. Inflammatory cytokines, oxygen radicals, activation of coagulation and complement, platelet and immune cell activation, generation of proteases, and abnormal fluid fluxes resulting in edema fluid generation and defective epithelial alveolar fluid clearance have all been hypothesized to play a role in the early stages. In addition, factors specific to apoptosis, edema fluid resolution, and fibrosis and repair, as well as the response to mechanical ventilation are likely to play a role in the pathophysiology of the later phases of ALI and ARDS.

Pathologically and clinically, ALI can be divided into *early* and *late phases* of lung injury (Fig. 145-1). In the early phase (first few hours or days), light microscopy shows interstitial and alveolar edema, capillary congestion, and intra-alveolar hemorrhage with minimal evidence of cellular injury. Electron microscopy reveals changes of endothelial cell swelling, widening of intercellular junctions, increased numbers of pinocytotic vesicles, and disruption and denudation of the basement membrane. Inflammatory cell infiltration of the lung interstitium may also be seen. Protein-rich pulmonary edema and its clinical effects are most pronounced in the early exudative phase. Hyaline membranes containing condensed fibrin and plasma proteins form over the next several days. Later in the exudative phase, inflammatory cells become more numerous within the lung interstitium, and extensive necrosis of type I alveolar epithelial cells is present.

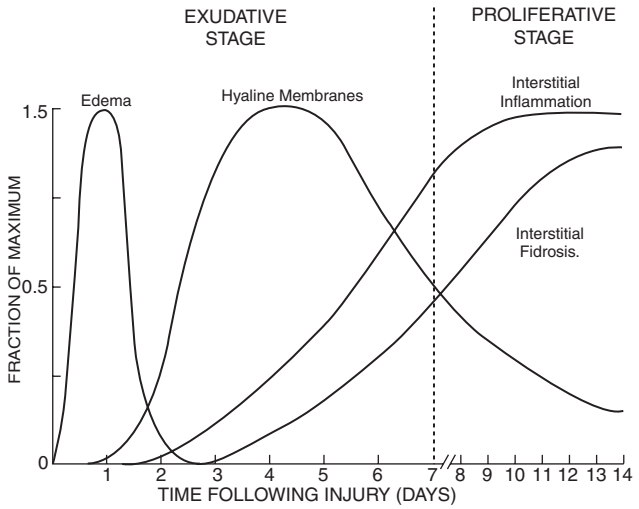

Figure 145-1 Schematic representation showing time course of evolution of the acute respiratory distress syndrome (ARDS). The early or exudative phase is characterized by a pulmonary capillary leak with interstitial and alveolar edema and hemorrhage followed by hyaline membrane formation. Within as short a period of time as 7 to 10 days, a proliferative phase may appear with marked interstitial and alveolar inflammation and cellular proliferation, followed by fibrosis and disordered healing (see text for discussion). *(Reproduced with permission from Katzenstein AA, Askin FB: Surgical Pathology of Non-Neoplastic Lung Diseases, 2nd ed. Philadelphia, Saunders, 1990.)*

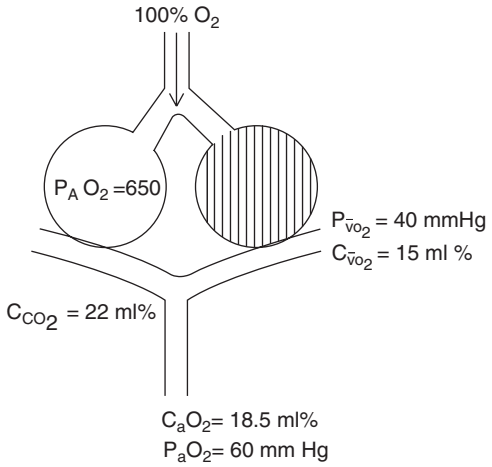

Figure 145-2 Diagram of a two-compartment model of lung perfusion and ventilation demonstrating basis for failure of oxygenation in ALI and ARDS. When large portions of the lung are nonventilated due to alveolar collapse or flooding (hatched area), blood flow to these units with mixed venous P_{O_2} ($P\bar{v}_{O_2}$) of 40 mmHg and content of 15 vol percent is effectively "shunted" through the lungs without being resaturated. Thus, despite a high concentration of supplemental oxygen (100 percent in this example) and high alveolar P_{O_2} in ventilated unit, these blood flows mix in accord with their oxygen contents, i.e., the resulting left atrial blood has an oxygen content that is the weighted mean of the oxygen content of the shunted and non-shunted blood. In this example of a 50 percent shunt, the left atrial and systemic arteries have an arterial P_{O_2} of 60 mmHg. CaO_2 = arterial oxygen content; C_{CO_2} = capillary oxygen content; $C\bar{v}O_2$ = mixed venous oxygen content; P_A = alveolar pressure; Pa_{O_2} = arterial P_{O_2}; $P\bar{v}_{O_2}$ = partial pressure of oxygen in the mixed venous blood. *(Reproduced with permission Christie JD, Lanken PN: Acute Lung Injury and The Acute Respiratory Distress Syndrome, in Hall JB, Schmidt GA, Wood LDH (eds.): Principles of Critical Care, 3rd ed. New York, McGraw-Hill, 2005; p 516.)*

Pathologists refer to this constellation of findings as *diffuse alveolar damage* (DAD).

Pathophysiologically, in the exudative phase, alveolar edema and alveolar collapse, i.e., atelectasis due to loss of normal surfactant-related stabilization of alveoli, interfere with oxygenation. Surfactant is both washed out of alveoli and inactivated by the alveolar edema. The hypoxemia in ALI/ARDS is typically resistant to supplementary oxygen, reflecting an increased right-to-left shunt (Fig. 145-2). Continued perfusion of alveoli that lack ventilation because of alveolar edema results in ventilation-perfusion ($\dot{V}/\dot{Q}$) ratios of zero, thereby defining physiological shunt. Furthermore, the effects of this type of shunt are exacerbated by shuntlike contributions from alveoli with very low ventilation-perfusion ratios.

Disordered healing and proliferation of fibrous tissue dominate the late phase of ARDS or persistent ARDS, i.e., the *proliferative or fibroproliferative* phase. Type II alveolar cells, fibroblasts, and myofibroblasts proliferate in this phase, which can occur as early as 7 to 10 days after initial injury. The late phase of ARDS is characterized by an increased dead space fraction, high minute ventilation requirement,

pulmonary hypertension, and further reduction in lung compliance.

Clinical Presentation

The development of ALI and ARDS usually follows a rapid course, occurring most often within 12 to 48 hours of the predisposing event. At its onset, patients with ALI and ARDS often become anxious, agitated, and dyspneic. Inflammatory changes in the lung decrease lung compliance, which, in turn, leads to an increased work of breathing, small tidal volumes, and tachypnea. Marked tachypnea and dyspnea are invariably present in subjects with ALI. If breathing ambient air or low-flow supplementary oxygen, patients with ALI typically have initial arterial blood gas results showing a Pa_{O_2} less than 50 to 55 mm Hg and pulse oximetry recordings of less than 85 percent arterial O_2 saturation. The hallmark of ALI and ARDS is hypoxemia that is resistant to oxygen therapy because of the large right-to-left shunt (Fig. 145-2).

Initially, patients may be able to compensate by hyperventilating, thereby maintaining an acceptable Pa_{O_2} with an acute respiratory alkalosis. Typically, patients deteriorate over several hours, requiring endotracheal intubation and mechanical ventilation. However, the need for mechanical ventilation is not necessary for establishing the diagnosis of ALI or ARDS. Selected patients with milder lung injury and a normal level of consciousness can be treated successfully with high-flow oxygen therapy, with or without a continuous positive airway pressure (CPAP) mask, or noninvasive assisted ventilation.

Differential Diagnosis

The differential diagnoses for acute hypoxemic respiratory failure, in general (Table 145-5), and for ALI and ARDS, in particular (Table 145-6), are extensive. Identifying the specific etiology of the diffuse infiltrates in ALI or ARDS is important because several, e.g., acute eosinophilic pneumonia or diffuse alveolar hemorrhage, have specific therapies. Table 145-6 lists the major clinical and diagnostic characteristics of these disorders.

The setting in which respiratory failure occurs usually provides important diagnostic information. ALI and ARDS commonly arise following development of a typical predisposing factor (Table 145-4). Sepsis, pneumonia, trauma, transfusion of blood products, and gastric aspiration account for the majority of cases.

When an inciting event is obvious and diagnostic criteria (Table 145-1) are met, establishment of a clinical diagnosis of ALI or ARDS is not difficult. Under such circumstances, management can be instituted immediately. However, in the absence of a clear predisposing event, or when conflicting or ambiguous information exists, the other causes listed in Table 145-6 should be considered and relevant clues from the history and physical examination sought. For example, cardiogenic edema is most often accompanied by systolic left ventricular or valvular dysfunction, and the appropriate history and physical findings (e.g., a heart murmur or ventricular gallop) are often present. Electrocardiographic and laboratory-based evidence (e.g., serum troponin I levels) of cardiac ischemia suggest cardiogenic edema as a likely cause. Additional important tests that help to differentiate ALI and ARDS from other causes of acute hypoxemic respiratory failure are discussed below.

Table 145-5

Differential Diagnosis of Acute Hypoxemic Respiratory Failure (AHRF)

1. ALI or ARDS
2. Acute (or "flash") cardiogenic pulmonary edema
3. Bilateral aspiration pneumonia
4. Lobar atelectasis of both lower lobes
5. Severe unilateral lower lobe atelectasis, especially when patient is receiving vasodilators, such as intravenous nitrates, calcium-channel blockers, or sodium nitroprusside, that blunt hypoxic vasoconstriction
6. Acute loss of ventilation to one lung due to complete or near-complete obstruction of its mainstem bronchus, e.g., due to a mucus plug or blood clot
7. Loss of ventilation to one or both lungs due to large pneumothorax/pneumothoraces
8. Loss of ventilation to one or both lungs due to large pleural effusion(s)
9. Diffuse alveolar hemorrhage, especially in patients post–bone marrow transplantation
10. Massive pulmonary embolus
11. Acute opening of a patent foramen ovale in patient with preexisting pulmonary hypertension

Abbreviations: ALI = acute lung injury; ARDS = acute respiratory distress syndrome.

Approach to Clinical Diagnosis

A number of diagnostic methods are extremely valuable in evaluating suspected ALI or ARDS. Each is briefly described below.

Chest Radiograph

The chest radiograph is a simple and widely available test used to assess patients with acute hypoxic respiratory failure. In cases of *established* ALI or ARDS, the chest radiograph typically demonstrates findings of diffuse, bilateral alveolar infiltrates consistent with pulmonary edema (Fig. 145-3). However, especially early in the course of the disorder, the infiltrates associated with ALI and ARDS may be variable: mild or dense, interstitial or alveolar, patchy or confluent.

Table 145-6

Differential Diagnosis of ALI and ARDS

Disorder	Characteristics	Comments
Pulmonary edema due to left heart failure.	History of cardiac disease, enlarged heart on chest radiograph, third heart sound.	Rapid improvement with diuresis and/or afterload reduction.
Noncardiogenic pulmonary edema	History of one or more precipitating causes (Table 145-4), crackles absent or not prominent, normal cardiac size on chest radiograph.	Usual etiology for ALI and ARDS. Rarely some patients with ALI or ARDS have no obvious precipitating cause.
Diffuse alveolar hemorrhage (DAH)	Often associated with autoimmune diseases (e.g., vasculitis) or following bone marrow transplantation. Often patients do not have bloody sputum. Renal disease or other evidence of systemic vasculitis may be present. Hemosiderin-laden macrophages in bronchoalveolar lavage fluid can confirm diagnosis of DAH. May respond to apheresis, corticosteroids, or cyclophosphamide, depending on etiology.	May meet diagnostic criteria for ARDS (Table 145-1), but has different pathophysiology and management.
Acute eosinophilic pneumonia	Cough, fever, pleuritic chest pain, and myalgia are often present. Patients often do not have peripheral blood eosinophilia, but generally have greater than 15% eosinophils in bronchoalveolar lavage fluid. Usually responds rapidly to high-dose corticosteroid therapy.	May meet diagnostic criteria for ARDS (Table 145-1), but has diffeent pathophysiology and management.
Lupus pneumonitis	Usually associated with active lupus. May respond to high-dose corticosteroid therapy or cyclophosphamide	May meet diagnostic criteria for ARDS, but has different pathophysiology and management.
Acute interstitial pneumonia (AIP)	Slower onset than ARDS (over 4–6 weeks) with progressive course. However it may present in advanced state, mimicking ARDS.	Associated with >90% mortality. AIP includes Hamman-Rich syndrome.
Pulmonary alveolar proteinosis (PAP)	Slower onset than ARDS (over 2–12 months) with progressive course. Can be treated with whole lung lavage.	Characteristic "crazy paving" pattern on high-resolution CT scan of chest.
Bronchiolitis obliterans with organizing pneumonia (BOOP) or cryptogenic organizing pneumonia	May be precipitated by viral syndrome. Slower onset than ARDS (over >2 weeks) with progressive course. However it may present in advanced state, mimicking ARDS. May respond to high-dose corticosteroid therapy.	

(*Continued*)

Table 145-6

(*Continued*)

Disorder	Characteristics	Comments
Hypersensitivity pneumonitis	Typically slower onset than ARDS (over weeks) with progressive course. However, it may present in advanced state, mimicking ARDS. May respond to high-dose corticosteroid therapy and removal from offending agent.	
Leukemic infiltration	May be rapid in onset during active disease states. Usually leukemia is clinically apparent.	
Drug-induced pulmonary edema and pneumonitis	May follow use of heroin, other opioids, overdose of aspirin, tricyclic antidepressants, or exposure to paraquat.	May progress to overt ARDS.
Acute major pulmonary embolus (PE)	Occurs acutely, occasionally accompanied by severe hypoxemia that may be resistant to O_2 therapy like ARDS, and by hypotension, requiring pressors, mimicking ARDS with sepsis. Patients typically have risk factors for acute PE and may not have common precipitating causes of ARDS.	Chest radiograph in ARDS should have bilateral infiltrates consistent with pulmonary edema. Chest radiograph in acute major PE may have unilateral or no infiltrates. Acute major PE needs a confirmatory study, e.g., CT scan with pulmonary embolism protocol.
Sarcoidosis	The onset is not acute, but its clinical recognition may be. Oxygenation is often impaired and the chest radiograph can be diffusely abnormal.	Historical features and the frequent presence of hilar adenopathy in sarcoidosis usually eliminate confusion with ARDS.
Interstitial pulmonary fibrosis	The onset is not acute, but its clinical recognition may be. Oxygenation is often impaired and the chest radiograph can be diffusely abnormal.	Prior chest radiographs and a history of chronic and progressive dyspnea characterize the collection of diseases causing interstitial pulmonary fibrosis.

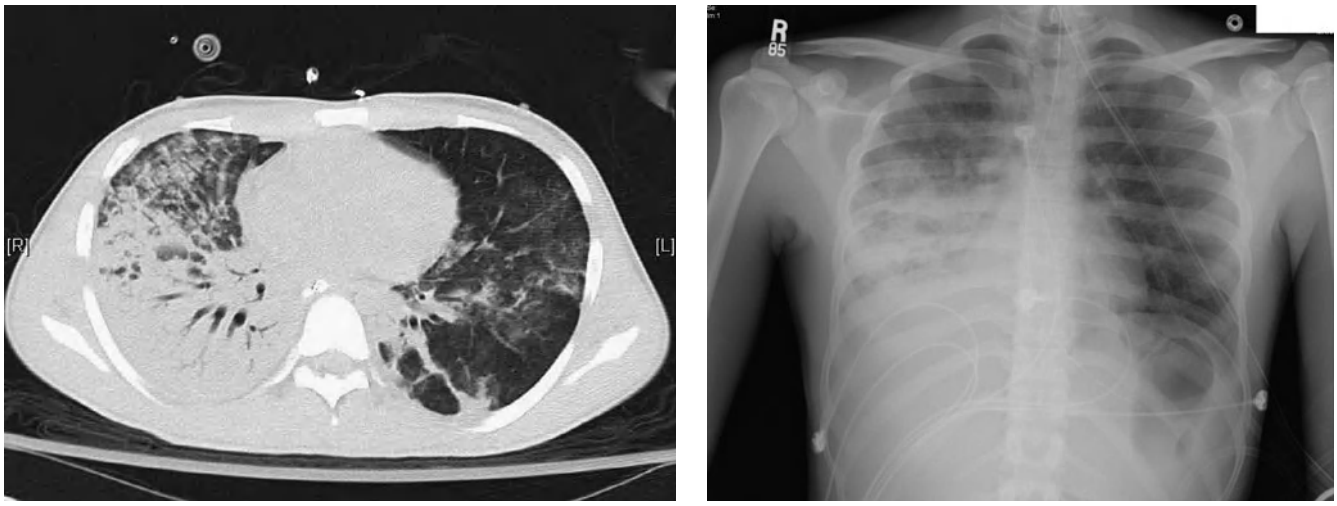
Abbreviations: AIP = acute interstitial pneumonia; ARDS = acute respiratory distress syndrome; CT = computed tomography; DAH = diffuse alveolar hemorrhage.

Source: Christie JD, Schmidt G, Lanken PN: Acute respiratory distress syndrome. http://pier.acponline.org/physicians/diseases/d349/d349.html, *July 2004. Physicians' Information and Education Resource. Philadelphia, American College of Physicians, reproduced with permission.*

In addition, the radiographic infiltrates may not correlate well with the degree of hypoxemia. For example, a patient with early ALI and ARDS may have profound hypoxemia in the setting of patchy asymmetrical infiltrates that may be interpreted as pneumonia or segmental atelectasis. Routine chest radiographs cannot reliably distinguish hydrostatic edema, i.e., cardiogenic edema, from ALI and ARDS. Nonetheless, several criteria suggest *cardiogenic* edema: increased heart size, increased width of the vascular pedicle, vascular redistribution toward upper lobes, the presence of septal lines, or a perihilar ("bat's wing") distribution of the edema. Lack of these findings, in conjunction with patchy peripheral infiltrates that extend to the lateral lung margins, suggests ALI or ARDS. In the proper clinical setting, despite a variable radiographic appearance, the presence of bilateral infiltrates and moderate or severe hypoxemia ($Pa_{O_2}/F_{I_{O_2}}$ less than or equal to 300 mmHg) should raise the possibility of ALI or ARDS.

Laboratory Studies

Although no laboratory test is specific for the diagnosis of ARDS, arterial blood gas analysis is essential for confirming the diagnosis of ALI or ARDS. $Pa_{O_2}/F_{I_{O_2}}$ is markedly abnormal in patients with ALI and ARDS (Table 145-1). In addition to the profound oxygen therapy–resistant hypoxemia that is the hallmark of ALI and ARDS, acute respiratory alkalosis



A *B*

Figure 145-3 Chest CT and plain radiograph in ARDS. *A*. Chest CT scan reveals asymmetric lung injury, with dense consolidation at the right base, patchy alveolar infiltrates in the right anterior lung field, and patchy ground-glass infiltrates throughout the right lung. *B*. Chest radiograph obtained concurrently with chest CT scan shown in panel (*A*). Dense infiltrates at right base, patchy infiltrates in the right upper lung zone, and more subtle infiltrates in the left lung are demonstrated. The panels illustrate the subtle findings of lung injury that are more apparent on the CT scan than on the chest radiograph.

may also occur in the early stage. If a patient with ALI and ARDS then develops respiratory muscle fatigue, hypercapnia results. In late-stage ALI, patients typically have increased minute ventilation requirements due to an increasing dead-space fraction, despite possible improvement in oxygen exchange.

In addition to arterial blood gas measurements, several other laboratory studies may be helpful in investigating other causes of respiratory failure and evaluating additional aspects of critical illness associated with ALI or ARDS. For example, cardiac enzymes (creatine phosphokinase and troponins) are useful for evaluating the presence of myocardial infarction or cardiac ischemia in patients at risk because of increased age or other factors. The results should be interpreted in conjunction with electrocardiographic findings, since elevations in cardiac enzymes, especially troponins, have been reported in patients with sepsis or septic shock in the absence of coronary artery disease.

Another cardiac-related laboratory test that may be useful in this clinical context is plasma brain natriuretic peptide (BNP), which is secreted by the cardiac ventricles, and, to a lesser extent, the atria. BNP measurements are often utilized in the evaluation of acute shortness of breath in patients presenting to an emergency department. In this group, a BNP greater than 500 pg/ml indicates that congestive heart failure (CHF) is likely with a positive predictive value greater than 90 percent. In the same group, a BNP less than 100 pg/ml suggests that congestive heart is unlikely with a negative predictive value greater than 90 percent. However, interpretation of an elevated BNP in patients who are critically ill is problematic. Reports indicate that BNP increases with renal failure, and that elevations of BNP greater than 500 pg/ml may occur in patients with sepsis and normal left ventricular function. Nonetheless, one can reasonably exclude a cardiac cause for acute pulmonary edema in patients in the intensive care unit if BNP is less than 100 pg/ml.

Echocardiography

Echocardiography is a useful noninvasive method to evaluate potential cardiac causes of acute hypoxemic respiratory failure. Cardiogenic pulmonary edema is suggested by echocardiographic findings of mitral valve stenosis or regurgitation, left ventricular dilatation and systolic dysfunction, or regional left ventricular wall motion abnormalities. Although these findings do not rule out coexisting lung injury, they are helpful in the initial evaluation and management, even in the presence of ALI or ARDS.

Invasive Hemodynamic Monitoring

Although right-heart catheterization has been performed often in patients with pulmonary edema, the benefits of the procedure are controversial and the topic of recent investigations (see Chapter 152). Several studies have demonstrated that physician interpretation of data obtained from right heart catheters is inconsistent and often erroneous. Furthermore, one observational study suggested that routine right-heart catheterization is harmful in critically ill patients with acute hypoxemic respiratory failure.

The utility of the pulmonary artery occlusion pressure, also known as pulmonary artery wedge pressure (PCWP), in the diagnosis of ALI or ARDS is questionable. Studies have shown that many patients who originally met criteria for ALI or ARDS (i.e., had a pulmonary artery occlusion pressure less

than or equal to 18 mm Hg) often have subsequent measurements with the PAOP greater than 18 mm Hg.

Finally, recent results from the ARDSNet Fluid and Catheter Treatment Trial (FACCT) support the contentions that the AECC's decision to use a PAOP of greater than 18 mmHg to exclude ALI/ARDS was arbitrary and that the threshold of greater than 18 mmHg needs re-examination.

FACTT was a large, randomized clinical trial that used a two-by-two factorial design to test a fluid-conservative management strategy against a fluid-liberal management strategy in ALI and ARDS and to assess safety and efficacy of a central venous catheter (CVC) or pulmonary artery catheter (PAC) to guide fluid management. In FACTT, 29 percent of 513 patients enrolled in the PAC arm of the trial were found to have a PAOP greater than 18 mm Hg at the time of initial measurement (following passage of the catheter shortly after enrollment and randomization). Before enrollment, FACTT investigators believed that these patients lacked a primary cardiogenic cause for their pulmonary edema. Approximately one half of these subjects had PAOPs of 19 or 20 mmHg. Since the vast majority (97 percent) of this group had a normal cardiac index (greater than or equal to 2.5 $L/m^2/min$), and a mortality similar to other subjects in FACTT, the elevated PAOP (greater than 18 mmHg) likely reflected intravascular volume loading rather than cardiogenic pulmonary edema.

Bronchoalveolar Lavage

Bronchoscopy with bronchoalveolar lavage (BAL) is an important tool in the evaluation of patients who have ALI or ARDS of unclear origin. In general, BAL can be performed safely in patients with ALI or ARDS, except in those with a very low Pa_{O_2} or requiring high levels of PEEP. The principal reason for performing bronchoscopy in ALI or ARDS is to rule in or rule out acute processes that may have specific therapies.

For example, acute eosinophilic pneumonia is a rare disorder characterized by diffuse eosinophilic infiltrates in the lungs (Table 145-6). When the precipitating cause for ALI or ARDS is uncertain, performance of BAL and measurement of the percent eosinophil count in the lavage fluid is helpful in establishing a diagnosis of this corticosteroid-responsive disorder.

Likewise, BAL can be diagnostic for diffuse alveolar hemorrhage (see Chapter 77). In this case, the bronchoscopy may or may not reveal fresh blood in the trachea and major bronchi. However, BAL generally demonstrates a blood-tinged fluid, which contains red blood cells and hemosiderin-laden macrophages. Diffuse alveolar hemorrhage may occur following bone marrow transplantation or as a result of rheumatologic or other immunologic disorders, including Goodpasture's syndrome, Wegener's granulomatosis, systemic lupus erythematosus, or anti-phospholipid antibody syndrome.

APPROACH TO TREATMENT

Goals of Management

Management of patients with ALI or ARDS can be complicated and challenging because clinicians are often faced with simultaneous failure of both respiratory and nonrespiratory organ systems (Table 145-7). Unfortunately, only a limited set of controlled clinical trials are available to support an evidenced-based approach. For example, even large, multicenter, randomized clinical trials, such as those done by ARDSNet, are limited in the number of variables that can be tested. As a result, patient management rests on a combination of relevant evidence-based medicine, extrapolations from basic and clinical research, and experience-based approaches.

Diagnosis and Treatment of Precipitating Causes and Other Comorbidities

The first step in the therapy of ALI or ARDS is identification and treatment of the precipitating cause(s) and any other life-threatening medical or surgical issues (Fig. 145-4).

Table 145-7

Goals of Management of Patients with ALI and ARDS

Treatment of respiratory system abnormalities
Diagnose and treat the precipitating cause of ALI/ARDS, if possible (Table 145-8)
Maintain oxygenation, preferably using nontoxic $F_{I_{O_2}}$ (<0.7), PEEP, or mechanical ventilation
Prevent ventilator-induced lung injury (VILI) by using a low tidal volume ventilatory strategy (Table 145-9) with a limit ($\leq$30 cm H_2O) on static end-inspiratory airway pressure (plateau pressure)
Keep pH in normal range without compromising goal to prevent VILI (but reverse a life-threatening acidosis, even if it prevents meeting goal to prevent VILI)
Enhance patient-ventilator synchrony and patient comfort by use of sedation, amnesia, opioid analgesia, and pharmacological paralysis, if necessary
Liberate or wean from mechanical ventilation when patient can breathe without assisted ventilation
Treatment of non-respiratory system abnormalities
Support or treat other organ system dysfunction or failure
General critical care (preventive and homeostatic measures)
Adequate early nutritional support

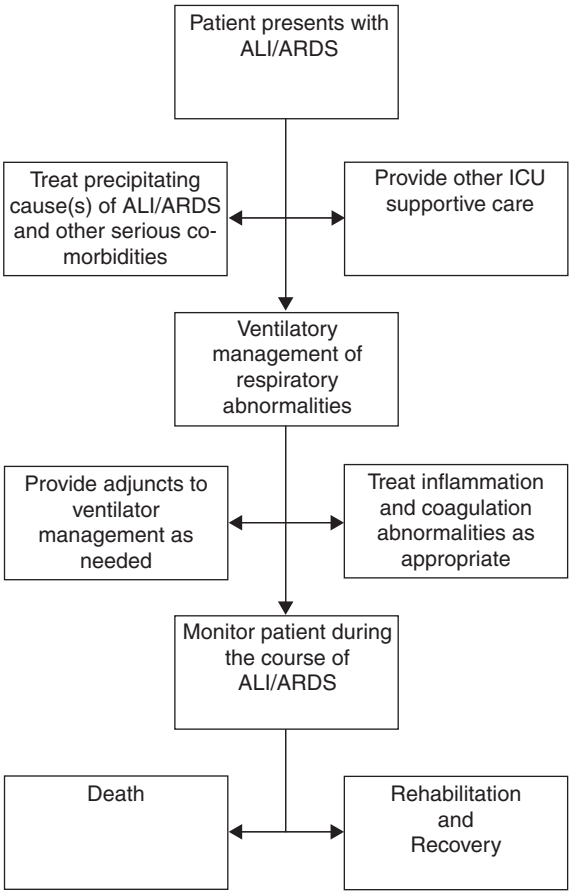


Figure 145-4 Summary of treatment approach to ALI and ARDS. Note that, "Treat inflammation and coagulation abnormalities as appropriate," is currently limited. Examples include treatment of patients with severe sepsis and multiple organ dysfunction using recombinant drotrecogin alpha (activated) and administration of replacement-dose corticosteroids in patients with severe sepsis and septic shock who have relative adrenal insufficiency. In the ARDSNet "LaSRS" clinical trial, physiological improvement, but no mortality benefit, was found with high-dose corticosteroid therapy for persistent (late phase) ARDS (see text for details). *(Reproduced with permission Christie JD, Lanken PN: Acute lung injury and the acute respiratory distress syndrome, in Hall JB, Schmidt GA, Wood LDH (eds): Principles of Critical Care, 3rd ed. New York, McGraw-Hill, 2004; p 525.)*

Since ALI and ARDS are *syndromes* based on nonspecific radiographic and physiologic criteria, establishing a diagnosis of ALI or ARDS is *not* equivalent to diagnosing the precipitating cause. The fact that early identification and treatment directed at the inciting cause(s) of ALI and ARDS are imperative for resolution of lung injury and respiratory failure cannot be overemphasized. Treatable inciting causes of ALI and ARDS include a variety of infectious and noninfectious disorders (Table 145-8).

Management of Respiratory Failure

Management of respiratory failure in ALI or ARDS rests on assurance of adequate oxygenation and carefully crafted ventilatory strategies, as outlined below.

Table 145-8

Treatable Inciting Causes of ALI and ARDS

Infectious etiologies
Bacterial or other sepsis, e.g., fungemia, responsive to antimicrobial therapy
Diffuse bacterial pneumonias, e.g., Legionella species
Diffuse viral pneumonias, e.g., cytomegalovirus, influenza A
Diffuse fungal pneumonias, e.g., Candida species, Cryptococcus
Pneumocystis carinii pneumonia
Other diffuse lung infections, e.g., military tuberculosis
Noninfectious etiologies
Diffuse alveolar hemorrhage post–bone marrow transplantation
Diffuse alveolar hemorrhage due to vasculitis, e.g., Goodpasture syndrome
Acute eosinophilic pneumonia
Lupus pneumonitis
Toxic drug reactions, e.g., aspirin

Source: Christie JD, Lanken PN: Acute lung injury and the acute respiratory distress syndrome, in Hall JB, Schmidt GA, Wood LDH (eds.): Principles of Critical Care, 3rd ed. *New York, McGraw-Hill, 2004; p 525, reproduced with permission.*

Maintaining Adequate Oxygenation

As noted, the pathophysiological hallmark of ALI and ARDS is hypoxemia that is resistant to oxygen therapy. Maintaining adequate arterial oxygenation is the primary goal of both traditional and newer ("lung protective") approaches to assisted ventilation.

As expected with shunt physiology, administration of supplementary oxygen provided by high-flow oxygenation systems, e.g., a non-rebreather face mask, is generally ineffective in reversing the oxygenation deficit. Exceptions to this rule are some patients with mild or transient cases of ALI or ARDS that are otherwise uncomplicated by other organ system failures.

In order to reduce the shunt, positive end-expiratory pressure (PEEP) is employed. When utilized in sufficient amounts, PEEP generally results in correction of the hypoxemia to patients with ALI, thereby allowing $F_{I_{O_2}}$ to be lowered from high potentially toxic concentrations. Although PEEP is usually used in conjunction with mechanical ventilation, in selected cases it may be effective when applied by means of a continuous positive airway pressure (CPAP) mask or as the lower level of bilevel noninvasive ventilation. The effect of PEEP-induced improvement in arterial oxygenation is attributed predominantly to recruitment of collapsed alveoli. However, application of PEEP may also mediate a redistribution of alveolar fluid into the interstitium and decrease the absolute magnitude of shunt by reducing cardiac output.

Acutely ill patients in intensive care units typically receive assisted ventilation via an endotracheal tube. In selected non-ARDS disorders, e.g., COPD or acute cardiogenic pulmonary edema, noninvasive ventilation has been shown to be as effective as invasive ventilation. Although the routine use of noninvasive ventilation for patients with ALI or ARDS lacks compelling evidence, the data are limited. One reason for limited study of noninvasive ventilation in ALI or ARDS is concomitant nonrespiratory organ failure (e.g., due to septic shock). Except for select subgroups, e.g., immunosuppressed patients with hypercapnic respiratory failure who are hemodynamically stable, one should generally avoid use of noninvasive ventilation for patients with ALI and ARDS.

Lung-Protective Mechanical Ventilation

As described in Chapter 153, over the past 30 years investigators have convincingly shown that large tidal volumes delivered during mechanical ventilation can injure lungs of normal animals, producing a pathologic pattern resembling ALI in humans. In animal models of acute lung injury, use of large tidal volume ventilation has been found to augment preexisting injury. In addition, repetitive opening and closing of alveoli during inspiration and expiration induces acute lung injury in normal animals. The injury can be prevented by application of sufficient PEEP. Finally, overexpansion of alveoli in normal lungs of sheep induces multiorgan failure, with recent studies of other species showing that lung overexpansion results in systemic release of proinflammatory cytokines—providing a likely mechanism for these remote deleterious effects. These observations support the concept that the lung, rather than the gut, is the "engine of inflammation."

Concurrent with the previously described observations, clinical investigators studying patients with ALI or ARDS using computed tomography observed that, in contrast to the typical diffuse-appearing pattern noted on plain chest radiographs, the pattern of consolidation, atelectasis, and normal alveoli is actually heterogeneous (Fig. 145-3). The key physiological implication of these observations is that a ventilator-delivered tidal volume is preferentially distributed to the open alveoli, which represent only a small fraction of the entire lung. Reference by Gattinoni, Pesenti and coworkers to this fraction as "the baby lung" emphasized the potential danger of delivering traditional tidal volumes of 10 to 15 ml/kg actual body weight and the associated risk for alveolar overexpansion and lung injury. Notably, tidal volumes of 10 to 15 ml/kg actual body weight (equivalent to approximately 12 to greater than 15 ml/kg predicted body weight) were used originally in critically ill patients with ALI or ARDS as a complementary strategy to PEEP in recruiting atelectatic alveoli.

These productive lines of basic and clinical research strongly support the hypothesis that mechanical ventilation using limited tidal volumes should be less injurious to the lungs of patients with ALI and ARDS and should result in better outcomes (i.e., decreased mortality) compared with use of traditional, large tidal-volume ventilation.

In summary, the goals of lung-protective ventilation are to avoid injury due to overexpansion of alveoli during inspiration (so-called "volu-trauma") and injury due to repetitive opening and closing of alveoli during inspiration and expiration (so-called "atelecta-trauma") (Fig. 145-5). The injurious effects of mechanical ventilation on the lung have been referred to as "ventilator-induced lung injury or VILI." The term "bio-trauma" encompasses the direct lung injury and the concomitant release of inflammatory cytokines that produce remote cell death or organ injury. Clinical strategies underlying contemporary applications of mechanical ventilation in treatment of ALI or ARDS are described below.

ARDSNet Ventilator Strategies: Low vs. Traditional Tidal Volumes

Based on the aforementioned considerations, the ARDSNet conducted a randomized trial (ARMA) in the mid-to-late 1990s to test the hypothesis that low tidal volume ventilation, combined with limited end-inspiratory (plateau) pressure, would lower mortality and ventilator days among survivors of ARDS compared with use of traditional tidal volumes. The trial included 861 subjects. The low tidal volume arm consisted of a tidal volume of 6 ml/kg predicted body weight, as long as the end-inspiratory pressure (Pplat) was 30 cm H_2O or less; if Pplat exceeded 30 cm H_2O, the tidal volume could be decreased to as low as 4 ml/kg. The traditional tidal volume arm used a tidal volume of 12 ml/kg predicted body weight, as long as the Pplat remained less than 50 cm H_2O. Both arms included explicit goals and protocols as the bases for ventilator adjustments and determination of the time and means of weaning (Table 145-9).

Important results of this clinical trial are summarized in Table 145-10. The difference in actual tidal volumes resulted from protocol-driven target tidal volumes in each study arm. As expected, the mean plateau pressure for the lower tidal volume group was less than 30 cm H_2O (25 cm H_2O), since the protocol required decreasing the tidal volume from 6 ml/kg predicted body weight to as low as 4 ml/kg if Pplat exceeded 30 cm H_2O. Of note, the traditional tidal volume group had a mean Pplat of 33 cm H_2O on study day one—a value less than the threshold of 35 cm H_2O that some clinicians had believed represented a safe threshold.

Despite the fact that the clinical trial used an arbitrary threshold of 30 cm H_2O for Pplat in the lower tidal volume arm, it should not be assumed that any Pplat at or below 30 cm H_2O is safe. If a "safe" upper limit of Pplat exists, its value is unknown. Lack of such a safe threshold is supported by the finding of an absence of any significant interaction between differences in mortality and quartiles of static respiratory compliance (Fig. 145-6*A*) or quartiles of plateau pressures (Fig. 145-6*B*). These results suggest that the lower tidal volume ventilatory strategy tends to be effective across a wide range of baseline static compliances and plateau pressures. Likewise, a statistical model of mortality proportion vs. Day 1 Pplat that combined data from both arms of this clinical trial suggests that, in general, the lower Pplat the lower the associated mortality (Figure 145-7).

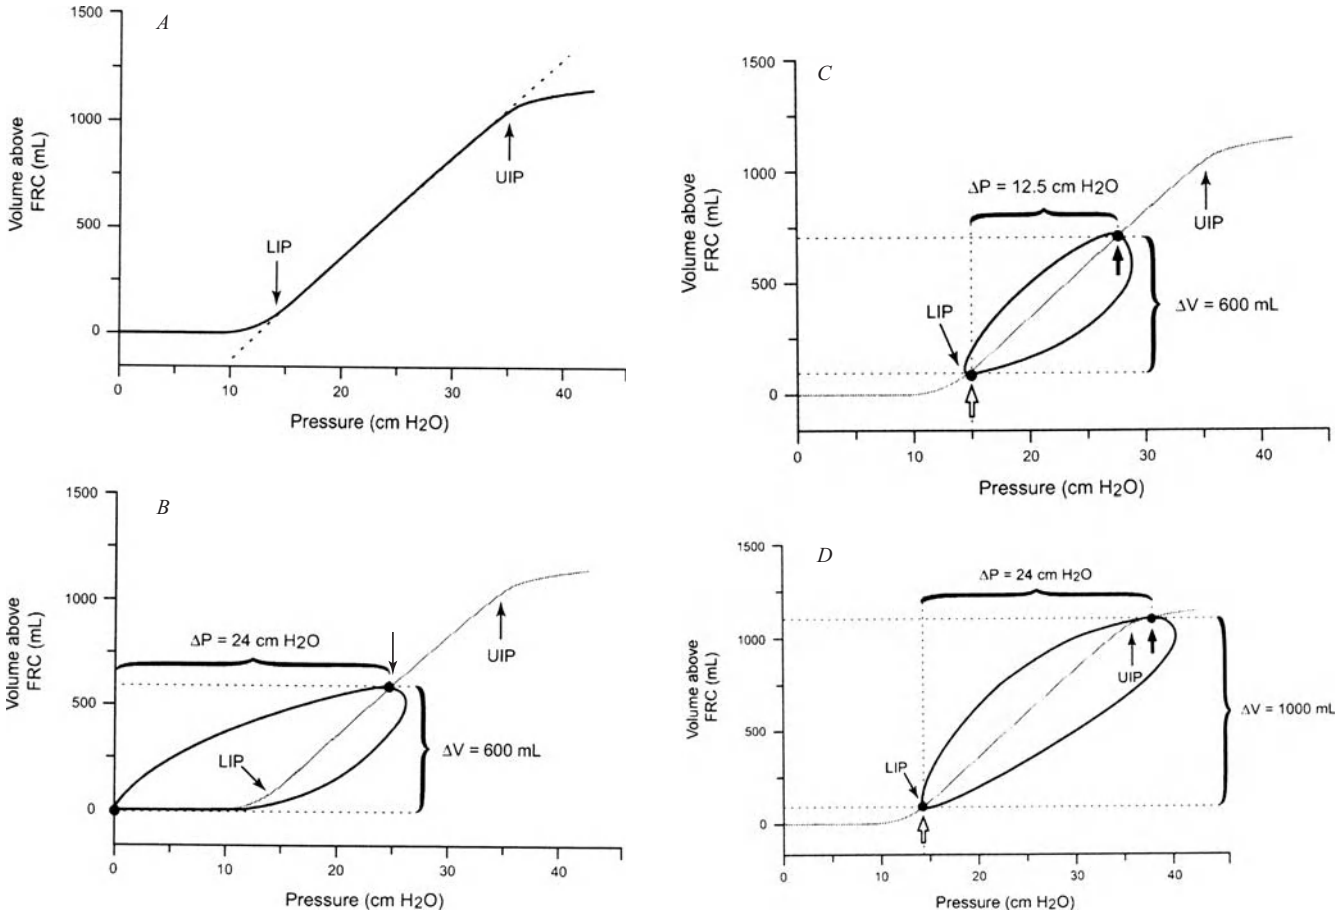

Figure 145-5 *A.* Schematic inspiratory static pressure-volume (P-V) curve of the respiratory system (lung and chest wall combined) in ARDS. Lower inflection point (LIP) is approximately 14 cm H_2O, and upper inflection point (UIP) is approximately 35 cm H_2O. Abscissa is respiratory system recoil pressure; ordinate is lung volume above functional residual capacity (FRC) *B.* Same static P-V curve as (*A*), plus dynamic P-V curve of 600 mL tidal volume starting below the LIP (PEEP = 0). This tidal volume results in a plateau pressure (closed arrow) below the UIP (24 cm H_2O). Static compliance (Cstat = $\Delta V/\Delta P$ = 600 ml/24 cm H_2O) is 25 ml/cm H_2O. *C*. PEEP of 15 cm H_2O has moved the starting point for the 600 ml tidal volume up the static P-V curve to a new FRC (open arrow), which is at the LIP. The tidal volume results in a plateau pressure of 27.5 cm H_2O (closed arrow), which is well below the UIP. Cstat ($\Delta V/\Delta P$ = 600 ml/12.5 cm H_2O) is increased to 48 ml/cm H_2O. D. Dynamic P-V curve of a 1000 ml tidal volume, starting at 14 cm H_2O PEEP, results in a plateau pressure of 37.5 cm H_2O (closed arrow). Despite an increase in Cstat ($\Delta V/\Delta P$ = 1000 ml/24 cm H_2O = 41.5 ml/cm H_2O), compared with Cstat derived from the 600 mL tidal volume in (*B*), the plateau pressure associated with the 1000 ml tidal volume exceeds the UIP. Delivery of an inflation volume that results in a plateau pressure exceeding the UIP implies alveolar overdistension and is believed to put the lung at risk for ventilator-induced lung injury (see text). *(Reproduced with permission from Lanken PN: Acute respiratory distress syndrome, in Lanken PN, Hanson CW III, Manaker S (eds): The Intensive Care Unit Manual. Philadelphia, Saunders, 2001, pp 824–825.)*

These considerations are important, since some clinicians may believe that they can achieve the improved mortality rate simply by lowering tidal volumes to the point where Pplat is at or slightly less than 30 cm H_2O, instead of following the ARDSNet low tidal volume strategy of using a tidal volume of 6 ml/kg predicted body weight. In addition, recognition of the need to use predicted, rather than actual, body weight is important, since the latter has been estimated to be about 20 percent greater than the former (due to fat and extravascular fluid). In summary, clinicians should employ the *entire* ARDSNet protocol (Table 145-9) rather than selected parts in attempting to achieve comparably favorable mortality results.

Lung Protection due to Higher PEEP

The initial ARDSNet trial (ARMA) described above did not address the question of whether application of higher levels of PEEP than used traditionally is beneficial. The possibility of improved outcomes using higher levels of PEEP was suggested by both basic and clinical studies conducted by Amato and colleagues in the early 1990s. To address whether higher levels of PEEP combined with low tidal volumes decreases

Table 145-9

NIH NHLBI ARDS Clinical Trials Network Low Tidal Volume Ventilation Strategy

Part I: Ventilator setup and adjustment

1. Calculate ideal body weight (IBW)* (also known as predicted body weight [PBW])
2. Use Assist/Control mode and set initial TV to 8 ml/kg IBW (if baseline TV >8 ml/kg)
3. Reduce TV by 1 ml/kg at intervals ≤2 h until TV = 6 ml/kg IBW
4. Set initial rate to approximate baseline $\dot{V}_E$ (but not >35 bpm)
5. Adjust TV and RR to achieve pH and plateau pressure (Pplat) goals below.
6. Set inspiratory flow rate above patient demand (usually >80 L/min); adjust flow rate to achieve goal of I:E ratio of 1:1.0–1.3

Part II: Oxygenation goal: Pa_{O_2} = 55–80 mmHg or Sp_{O_2} = 88–95%

1. Use these incremental F_{IO_2}-PEEP combinations to achieve oxygenation goal:

F_{IO_2}	0.3	0.4	0.4	0.5	0.5	0.6	0.7	0.7
PEEP	5	5	8	8	10	10	10	12
F_{IO_2}	0.7	0.8	0.9	0.9	0.9	1.0	1.0	1.0
PEEP	14	14	14	16	18	20	22	24

Part III. Plateau pressure (Pplat) goal: ≤ 30 cm H_2O

1. Check Pplat (use 0.5-sec inspiratory pause), Sp_{O_2}, total RR, TV and ABG (if available) at least every 4 h and after each change in PEEP or TV.
2. If Pplat >30 cm H_2O, decrease TV by 1 ml/kg steps (minimum 4 ml/kg IBW)
3. If Pplat <25 cm H_2O and TV < 6 ml/kg, increase TV by 1 ml/kg until Pplat > 25 cm H_2O or TV = 6 ml/kg.
4. If Pplat < 20 cm H_2O and breath stacking occurs, one may increase TV in 1 ml/kg increments (to a maximum of 8 ml/kg)

Part IV. pH goal: 7.30–7.45

Acidosis management: pH < 7.30

1. If pH = 7.15–7.30, increase RR until pH > 7.30 or Pa_{CO_2} < 25 mmHg (maximum RR = 35); if RR = 35 and Pa_{CO_2} < 25 mmHg, may give NaH_{CO_3}.
2. If pH < 7.15 and NaH_{CO_3} considered or infused, TV may be increased in 1 ml/kg steps until pH > 7.15 (Pplat goal may be exceeded)

Alkalosis management: pH > 7.45: Decrease RR, if possible

**Male IBW = 50 + 2.3 [height (inches) − 60]; female IBW = 45.5 + 2.3 [height (inches) − 60]*

Abbreviations: ABG = arterial blood gas; RR = respiratory rate on ventilator; SpO_2 = Oxygen saturation by pulse oximetry; TV = tidal volume; $\dot{V}_E$ = minute ventilation.

From the NIH NHLBI ARDS Clinical Trials Network (Complete protocol is available at www.ardsnet.org*).*

mortality, the ARDSNet conducted a second ventilator clinical trial (ALVEOLI) in which each of two groups received the same low tidal volume ventilatory strategy, but one group was treated using an additional 4 to 5 cm H_2O of PEEP. Mortality rates at day 60 were below 30 percent for both groups and were not significantly different, even after adjustment for imbalances in baseline variables. Similarly, ventilator-free days were not significantly different. Therefore, at present, whether maintenance of PEEP above a certain point (corresponding to the lower inflection point in Fig. 145-5) improves clinical outcome is unknown. Recent studies by Gattinoni and co-workers showed that, while some patients with ALI have little or no recruitment (opening previously collapsed or fluid filled airspaces) with increased levels of PEEP, in others PEEP shows marked recruitment. This suggests that future clinical trials using higher PEEP be restricted to subjects with ALI in whom PEEP increments can reliably result in recruitment.

Recommended Core Ventilator Management

We recommend that as the core ventilator management in ALI and ARDS clinicians follow the ARDSNet low tidal volume ventilatory strategy (Table 145-9). Because higher levels of

Table 145-10

Results of NIH NHLBI ARDS Clinical Trials Network Low Tidal Volume vs. Traditional Tidal Volume Clinical Trial ("ARMA")

Variable or Outcome	Units	Low Tidal Volume Ventilatory Strategy Mean ± SD	Traditional Tidal Volume Ventilatory Strategy Mean ± SD	*p* Value
Tidal volume on day 1	mL/kg PBW	6.2 ± 0.9	11.8 ± 0.8	<0.05
Plateau pressure on day 1	cm H_2O	25 ± 7	33 ± 9	<0.05
PEEP on day 1	cm H_2O	9.4 ± 3.6	8.6 ± 3.6	<0.05
Pa_{O_2}:FI_{O_2} on day 1		158 ± 73	176 ± 76	<0.05
Pa_{CO_2} on day 1	mmHg	40 ± 10	35 ± 8	<0.05
Death before discharge or 180 days	%	31.0	39.8	0.007
Breathing without assistance at day 28	%	65.7	55.0	<0.001
No. of ventilator-free days by day 28		12 ± 11	10 ± 11	0.007
No. of days without failure of nonpulmonary systems by day 28		15 ± 11	12 ± 11	0.006

Abbreviations: PBW = predicted body weight (see footnote of Table 145-9 for details); PEEP = positive end expiratory pressure; SD = standard deviation; ventilator-free days by day 28, number of days alive and not receiving assisted ventilation between days 1 and 28.

PEEP have not yet been found to improve outcomes, unless new evidence arises to the contrary, we also recommend that clinicians follow the same combinations of FI_{O_2} and PEEP used in the first ARDSNet trial, ARMA (Table 145-9).

Because of constraints of sample size, the ARDSNet trial tested the low-volume strategy only against use of tidal volumes of 12 ml/kg predicted body weight. Notably, a strategy using 6 ml/kg has not been shown to be superior to a strategy using tidal volumes of 8 to 10 ml/kg. However, based on the previous descriptions of ventilator-induced lung injury and bio-trauma, we believe it is prudent for clinicians to strictly follow the ARDSNet protocol as their core management strategy in ALI or ARDS. Modifications should be considered only in special cases, e.g., when contraindications for permissive hypercapnia exist (Table 145-11).

Other Approaches to Ventilator Management

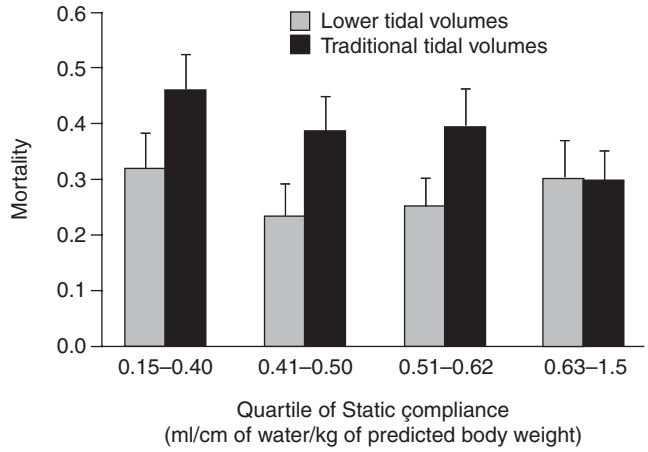
In addition to the low-volume protocol described, several additional approaches may be used in the management of ALI or ARDS and are discussed briefly below.

Pressure Control Mode

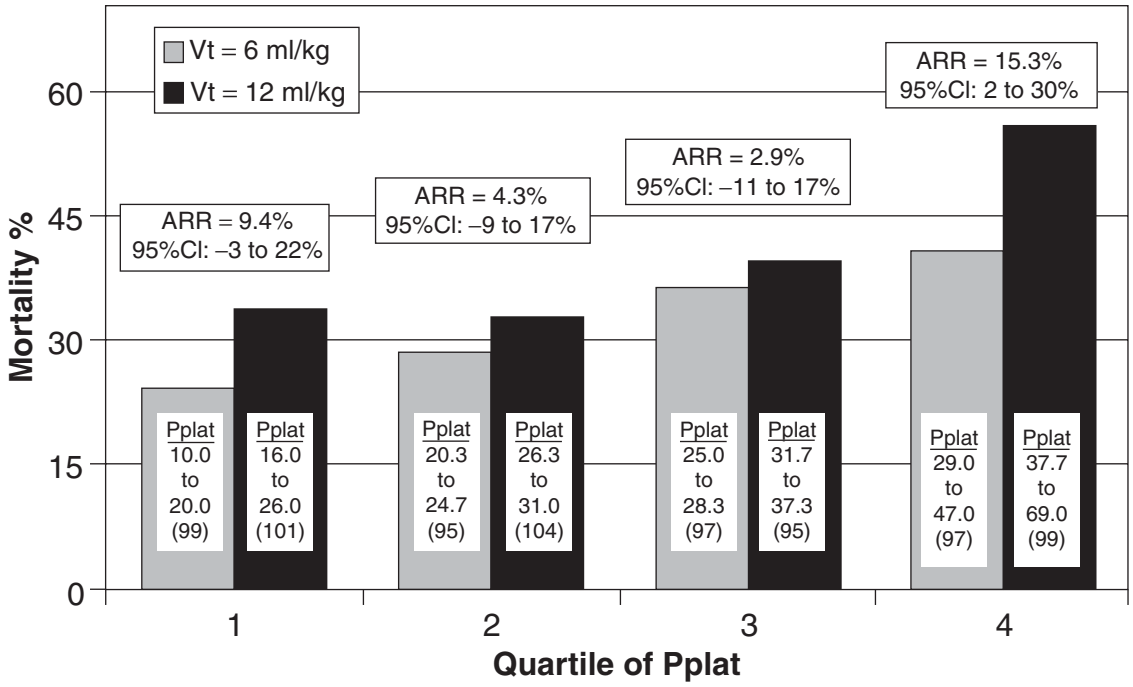
The ARDSNet low tidal volume strategy used the volume-assist-control mode—a familiar device setting and the only ventilator intervention that has been shown thus far to improve long-term survival in patients with ALI and ARDS. However, other modes of ventilation can also provide low tidal volume ventilation, including pressure control ventilation (PCV).

PCV can limit maximal peak airway pressure as well as end-inspiratory pressure (Fig. 145-8A) and, hence, is favored by some clinicians. However, the end-inspiratory pressure in PCV can be underestimated. For example, using PCV with an inspiratory pressure of 30 cm H_2O and a PEEP of 10 cm H_2O, the end-inspiratory pressure is 40 cm H_2O (the sum of the two pressures). Some may misinterpret this combination as equivalent to a Pplat of 30 cm H_2O and assume that it is a "safe" value according to interpretation of ARDSNet results. As discussed previously, however, no Pplat is known to be safe, even when end-inspiratory pressure is calculated correctly. Furthermore, use of PCV to mimic both tidal volume and Pplat used in the ARDSNet trial remains problematic. The benefit seen from using the ARDSNet strategy may have been due as much to the use of low tidal volume as to lower Pplat.

Inverse ratio ventilation (IRV) with PCV is based upon an inspiratory time (I) greater than expiratory time (E), i.e., I:E greater than 1 (Fig. 145-8B). Some case reports identify



A



B

Figure 145-6 ARDSNet ARMA study. *A*. Mortality rates (mean ± SE) according to quartile of static respiratory system compliance before randomization and subsequent treatment group. Data represent a subset of 861 subjects enrolled, including 257 patients assigned to the low tidal volume ventilatory strategy and 260 to the high tidal volume strategy. Mortality in the low tidal volume group was at least 30 percent lower than for those receiving traditional tidal volumes in each of the lowest three quartiles. Although the low tidal volume strategy was not advantageous for patients in the quartile with the highest static compliance, a test for interaction between treatment group and static compliance quartile at baseline was not statistically significant. Results support the concept that the low tidal volume ventilation strategy is beneficial for patients with ALI or ARDS across a spectrum of static compliances, not just for those with the stiffest lungs. (*Reproduced with permission from Acute Respiratory Distress Syndrome Network*. N Engl J Med *342: 1301, 2000.*) *B*. Mortality according to quartiles of end-inspiratory pressure (plateau pressure, Pplat) and treatment group on study day 1 in 787 subjects for whom Pplat data are available (including 270 subjects for whom pre-randomization static compliance measurements were not available). Pplat was measured using protocol-dictated tidal volumes (rather than clinician-determined tidal volumes, as used in assessing static respiratory system compliance). Subjects with the stiffest lungs are likely to have Pplat in the fourth quartile (far right). Range of Pplat (cm H_2O) and number of subjects (parentheses) are shown in each bar of the graph (ARR = absolute risk reduction; CI = confidence interval). Lower tidal volume ventilation appears to benefit patients with ALI or ARDS across a range of Pplat. The hypothesis that a "safe" upper limit exists for Pplat, below which ventilator-induced lung injury does not occur, is *not* supported by the data. *(Reproduced with permission from Hager DN, Krishnan JA, Hayden DL, et al: Am J Respir Crit Care Med 172:1241, 2005.)*

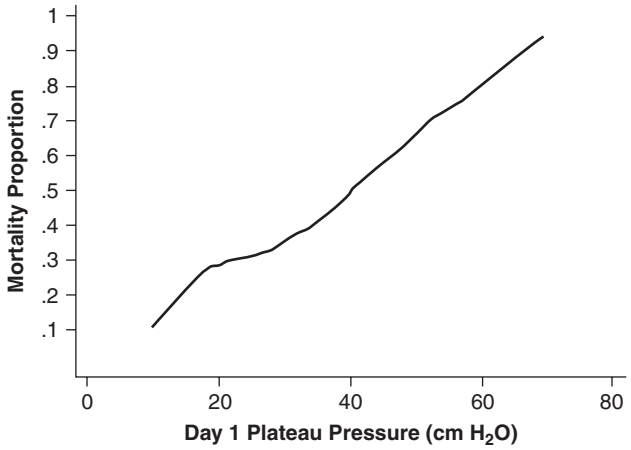


Figure 145-7 Lowess (locally weighted regression and smoothing) plot (bandwidth, 0.4) of mortality proportion and day 1 plateau pressure (Pplat, cm H_2O) for 787 patients enrolled in the ARDSNet ARMA study. Plot includes same subjects and Pplat shown in Fig. 145-6B. When expressed using this estimating method, the data do not support a safe upper limit for Pplat, the presence of which would be suggested by a leveling in mortality proportion, rather than a further decrease, as the plot demonstrates. The Lowess method is a nonparametric smoother that uses overlapping neighborhoods of data to estimate a local effect. A bandwidth of 0.4 means that 20 percent of the data on either side of a given Pplat contribute to a local estimate of mortality at that Pplat; data at the high and low ends of the curve represent fewer observations. As data are smoothed using a tricubic weight function, points furthest from the Pplat of interest are assigned the least weight and approach zero. *(Reproduced with permission from Hager DN, Krishnan JA, Hayden DL, et al: Tidal volume reduction in patients with acute lung injury when plateau pressures are not high. Am J Respir Crit Care Med 172:1241, 2005.)*

Table 145-11

Contraindications for Permissive Hypercapnia and Acute Respiratory Acidosis

Increased intracranial pressure from any cause (trauma, mass lesion, malignant hypertension)
Acute cerebrovascular disorders, e.g., stroke
Acute or chronic myocardial ischemia
Severe pulmonary hypertension
Right ventricular failure
Uncorrected severe metabolic acidosis
Sickle cell anemia
Tricyclic antidepressant overdose
Patients taking beta-blockers
Pregnancy (due to potential for decreased fetal blood flow from vasodilation-induced steal syndrome; in addition, shift to the right of the O_2 dissociation curve decreases the maternal-fetal gradient for O_2)

patients with refractory hypoxemia who responded to PCV-IRV. This may be due to effects of auto-PEEP (intrinsic PEEP) or other mechanisms involving alveolar recruitment following prolonged exposure to IRV. IRV with auto-PEEP plus applied PEEP may compromise cardiac output and increase the risk of nonpulmonary organ dysfunction. Clinicians should consider using PCV-IRV only as a "salvage" mode of ventilation (Table 145-12).

Modes That Allow Spontaneous Breathing during Positive Pressure Ventilation

Two ventilatory modes of modern microprocessor-based devices that permit spontaneous breathing to occur at any phase of the respiratory cycle during assisted ventilation include biphasic airway pressure (BIPAP) and airway pressure release ventilation (APRV). In each, airway pressure cycles between higher and lower levels of PEEP at preset time intervals. Controlled studies using these ventilator modalities are limited. One report found that use of APRV in patients with ARDS decreased intrathoracic pressure, improved ventilation-perfusion mismatch and cardiac output, and decreased shunt and dead space fractions compared with pressure support ventilation (matched for the same airway pressure limits or minute ventilation). However, clinically important outcomes were not compared.

BIPAP and APRV can be expected to decrease the use of neuromuscular blocking agents in patients with ALI or ARDS since both allow spontaneous breathing and potentially less patient-ventilator dyssynchrony. However, whether such newer modes of ventilation are better than, equal to, or worse than the ARDSNet lower tidal volume ventilatory strategy remains unknown. Until more clinical evidence supports their superiority or equivalency, their routine use cannot be recommended.

High Frequency Oscillatory Ventilation Mode

The U.S. Food and Drug Administration has approved an adult high frequency oscillatory ventilator (HFOV) for management of patients with ARDS. Theoretically, HFOV may be regarded as the ultimate low tidal volume ventilator with a capacity to ventilate a patient using a very small tidal volume midway between the upper and lower inflection points of the pressure-volume curve (Fig. 145-5).

Clinically, use of HFOV has been shown to be equivalent to "usual" care. However, the trial comparing HFOV with usual care was conducted at a time when usual care did *not* include low tidal volume ventilation. Since its application generally requires neuromuscular paralysis, HFOV is unlikely to be utilized in patients with mild ALI or ARDS because of the risk of paralytic agent–related quadriparesis and lack of

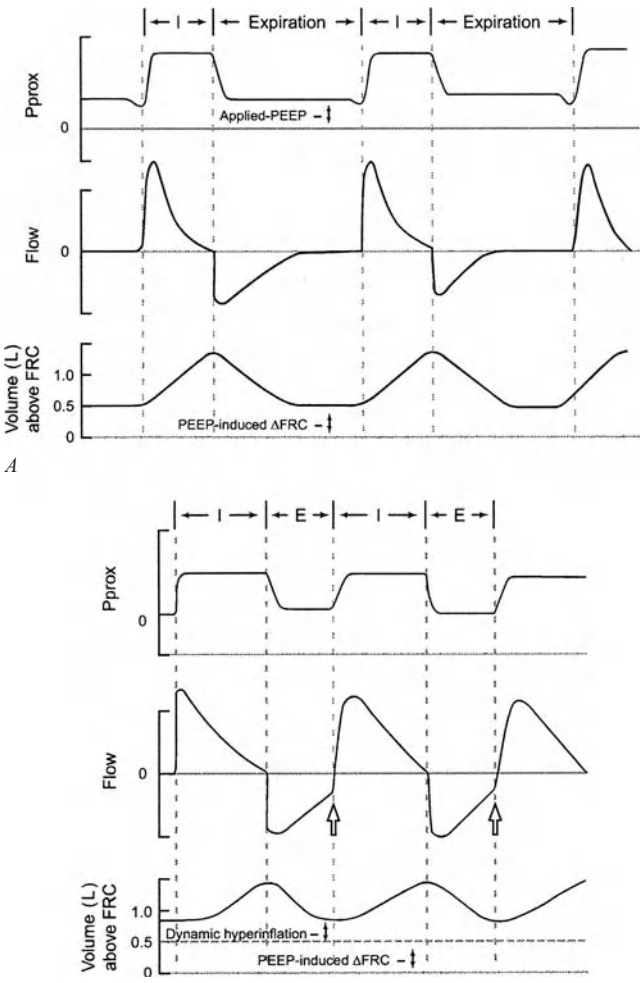

Figure 145-8 Schematic depiction of pressure, flow, and volume waveforms during pressure control ventilation (PCV) with applied PEEP. Abscissa is time and ordinates (from top to bottom) are proximal airway pressure (P_{prose}), inspiratory flow and volume above functional residual capacity (FRC). Other abbreviations: I, inspiration, ΔFRC, change in FRC. *A*. The inspiratory-to-expiratory (I:E) time is about 1:2. The pressure waveform resembles pressure support ventilation, and the flow pattern is characterized by marked deceleration. Applied PEEP increases FRC (PEEP effect). *B*. I:E time is reversed (I > E), representing pressure-controlled inverse ratio ventilation (PC-IRV). As a result, the next breath starts before expiratory flow has returned to zero (open arrows), resulting in auto-PEEP and dynamic hyperinflation. The latter is superimposed on the increased FRC due to the applied PEEP. *(Reproduced with permission from Lanken PN: Acute respiratory distress syndrome, Lanken PN, Hanson CW III, Manaker S (eds): The Intensive Care Unit Manual. Philadelphia, Saunders, 2001, p 829.)*

efficacy data comparable to the ARDSNet protocol used in ARMA (Table 145-9). Some clinicians may use high frequency ventilation as a "salvage" mode (Table 145-16). However, its use, even in those circumstances, is not supported by controlled clinical trials.

Adjuncts to Lung Protective Mechanical Ventilation

A number of adjunctive measures to mechanical ventilation have assumed importance in the management of patients with ALI and ARDS. In some cases, the physiological or pharmacologic basis for the measure's beneficial effect is apparent; in others, the mechanism is unknown.

Overview

Use of adjuncts to lung protective ventilation is generally based on extrapolations from animal or basic studies, or from clinical studies using physiological markers as surrogates for clinically meaningful endpoints, e.g., mortality or ICU length of stay or ventilator-free days. However, extrapolation from such studies to clinical practice is problematic. For example, the only intervention that thus far proved to result in improved survival in ALI and ARDS—the ARDSNet low tidal volume ventilatory strategy—also resulted in patients in the low-volume group with significantly lower Pa_{O_2}/FI_{O_2} after enrollment compared with those receiving traditional tidal volume ventilation (Table 145-10). If the trial had used improvement in Pa_{O_2}/FI_{O_2} as a surrogate marker for better survival, the results would have been interpreted as showing that low tidal volume ventilation results in *higher* not a *lower* mortality.

In general, both efficacy and safety data supporting use of the following adjunctive therapies in ALI or ARDS are lacking. Thus, these interventions should be used cautiously, if at all.

Permissive Hypercapnia

Permissive hypercapnia is defined as clinician-allowed hypercapnia during assisted ventilation, despite an ability to achieve a level of minute ventilation sufficient to maintain a normal Pa_{CO_2} (36 to 44 mmHg). Because patients may develop hypercapnia during lower tidal volume ventilation, which is recommended as the core ventilator strategy, permissive hypercapnia should no longer be considered an "adjunct." (Although the ARDSNet lower tidal volume strategy did stipulate maintenance of minute ventilation while decreasing tidal volume in order to decrease the secondary rise in Pa_{CO_2}, permissive hypercapnia was allowed as a consequence of the protocol. The response to the resulting respiratory acidosis was left to the local investigator's discretion.)

Fluid Management

The ARDSNet Fluid and Catheter Treatment Trial (FACTT), which used a two-×-two factorial design, tested the hypothesis that a management strategy of fluid restriction (conservative fluid management) would improve clinically important outcomes in ALI compared with more generous fluid management strategy (liberal fluid management). Although the strategy of liberal fluid management was based upon a protocol to determine fluid balance, patients' net fluid balance during the first 7 days of the trial resembled that resulting from the non–protocol-directed care in the first two ARDSNet clinical trials (ARMA and ALVEOLI).

FACTT investigators developed a detailed fluid management protocol that, except for patients in shock (MAP less

than 60 mmHg or on vasopressors for hypotension), used four basic input variables (assessed every 1 to 4 hours) to determine the fluid management instructions: (1) mean arterial blood pressure (MAP); (2) urine output; (3) effectiveness of circulation; and (4) intravascular pressure (central venous pressure [CVP] or pulmonary artery occlusion pressure [PAOP]). In both arms of the study, the protocol goals were MAP greater than 60 mmHg (or vasopressor independence); urine output greater than 0.5 ml/kg predicted body weight/hour; and evidence for effective circulation, including a cardiac index greater than or equal to 2.5 L/min/m^2in patients with pulmonary artery catheters (PACs) or, in those with central venous catheters (CVCs), absence of physical examination findings indicating hypoperfusion of extremities. In the group randomized to conservative fluid strategy, the target intravascular pressure was a CVP less than 4 mmHg or PAOP less than 8 mmHg. In contrast, for those randomized to the liberal fluid strategy, targets were a CVP of 4 to 8 mmHg or PAOP of 8 to 12 mmHg.

Despite marked differences in cumulative net fluid balance between the conservatively and liberally managed groups, the two showed no statistically significant difference in mortality at 60 days, which was the study's primary outcome (Table 145-12). Nonetheless, compared with the liberal strategy, the conservative strategy resulted in statistically significant improvements in several clinically important outcomes, including decreased duration of assisted ventilation and length of stay in the intensive care unit (Table 145-12). Moreover, the conservative strategy did not worsen the incidence of shock, number of days in shock, frequency or extent of other organ system failures, or rate of use of dialysis. These results support the use of a conservative fluid strategy in managing patients with ALI or ARDS who are not in shock.

Table 145-12

Results of ARDSNet FACTT (Fluids and Catheter Treatment Trial): Conservative Fluid Management Stategy vs. Liberal Fluid Management Strategy

Result	Conservative Strategy ($n = 503$)	Liberal Strategy ($n = 497$)	p Value

† This includes the sheath for PAC, PAC, and CVC for subjects in the PAC group and sheath (n = 6) and CVC for subjects in the CVC group.

Hemodynamic Management

Using the trial's two-×-two factorial design, the ARDSNet FACTT investigators also compared the safety and efficacy of PACs with CVCs in directing fluid and hemodynamic protocols, as described. Mortality and other important clinical outcomes, such as ventilator-free days, ICU-free days, and organ-failure-free days by study day 28 were no different in patients managed with a PAC versus a CVC (Table 145-13). However, use of the PAC was associated with a significantly higher complication rate during catheter insertion—primarily, cardiac arrhythmias. The excess events were attributed principally to the need for passing both a sheath and catheter; none of the adverse events was fatal.

Based on the results, the FACTT investigators recommend using a CVC to guide a hemodynamic and fluid management. However, in specific cases, clinicians may elect to use a PAC in selected circumstances, e.g., in addressing the response to volume resuscitation, determining the adequacy of cardiac output, measuring the oxygen saturation of mixed venous blood, calculating the degree of intrapulmonary shunt, or searching for equalization of diastolic pressures during suspected cardiac tamponade.

Prone Positioning

About two-thirds of patients with ALI or ARDS improve their oxygenation after being placed in a prone position. Mechanisms that may explain the improvement include: (1) increased functional residual capacity; (2) change in regional diaphragmatic motion; (3) perfusion redistribution; and (4) improved clearance of secretions. Studies of the distribution of ventilation-to-perfusion ratios in animal models suggest that gravity is less influential on the distribution of perfusion in the prone rather than supine position. This finding, coupled with the observation that edema fluid migrates to the dependent portions of the lung (as demonstrated on computed tomography) in patients with ALI who have been turned prone, suggested that ventilation-perfusion relationships might be favorably altered in the prone position.

Patients managed in the prone position need special attention to prevent pressure necrosis of the nose, face, and ears. Extra care is also needed to ensure security and patency of the endotracheal tube. Pressure on the eye may result in retinal ischemia, especially in hypotensive patients. Others may experience cardiac arrhythmias or hemodynamic instability when turned prone.

In a large clinical trial of prone positioning in patients with ALI and ARDS published in 2001 by Gattinoni and colleagues, subjects were randomly placed prone for 6 or more hours daily for 10 days or were left in the supine position. Although the investigators found that oxygenation was transiently improved with prone positioning, they demonstrated no survival advantage. A more recent study of prone positioning in children with ALI also demonstrated lack of benefit.

Because no controlled clinical trial has showed improved survival with prone positioning, and because the technique carries known risks, even in experienced hands, it cannot be recommended for routine use in patients with ALI or ARDS. However, some clinicians may opt to use

prone positioning as salvage therapy for severe hypoxemia (Table 145-16).

Recruitment Maneuvers

Lung recruitment maneuvers are defined as the application of continuous positive airway pressure (CPAP) aimed at "recruiting" or opening totally or partially collapsed alveoli. The alveoli are then kept inflated during expiration using an appropriately high level of PEEP. In one study of a "lung protective" strategy utilizing low tidal volume ventilation and extra-high PEEP, recruitment manuvers were performed by maintaining a CPAP level of 35 to 40 cm H_2O for 30 seconds. Others advocate application of equivalent or higher pressures for longer periods.

No controlled clinical trial supports the efficacy of recruitment maneuvers alone to improve clinically important outcomes, such as mortality or ventilator-free days. Studies of recruitment maneuvers have generally used physiological end points, e.g., improvement in oxygenation. In a subset of patients treated with high levels of PEEP in the ARDSnet trial comparing high versus low PEEP in ARDS, no clinically relevant improvements in arterial saturation were noted. However, complications such as transient hypotension and slight drops in arterial saturation during the manuver were reported. On the other hand, other clinical studies have reported that recruitment maneuvers improve oxygenation in patients on relatively low levels of PEEP, receiving large tidal volumes, or maintained on paralytics.

Because no controlled clinical trials demonstrate efficacy in clinically relevant end points and there are potentially adverse effects, routine use of recruitment maneuvers is not recommended in ALI or ARDS. Likewise, in the absence of data showing efficacy, routine use of ventilator "sighs" exceeding peak pressures of 30 cm H_2O (the threshold used in the ARDSnet clinical trial that showed improved survival) is also not recommended. Some clinicians may use recruitment maneuvers with higher pressures as part of salvage therapy for patients with severe refractory hypoxemia (Table 145-16).

Inhaled Nitric Oxide

In 1993 Roissant and colleagues published a study of inhaled nitric oxide (NO) as a novel therapy for ARDS. Given via inhalation, NO selectively vasodilates pulmonary capillaries and arterioles that subserve *ventilated* alveoli, diverting blood flow to these alveoli and away from areas of shunt. Lowering of the pulmonary vascular resistance, accompanied by lowering of the pulmonary artery pressure, appears maximal at very low concentrations (0.1 ppm) in patients with ARDS. Beneficial effects on oxygenation take place at somewhat higher inspired concentrations of NO (1 to 10 ppm).

Table 145-14

Results of ARDSNet Late Steriod Rescue Study ("LaSRS") in Patients with Persistent ARDS: *A Priori* Protocol-Defined Outcomes and Adverse Events

Rapid inactivation of NO by hemoglobin prevents unwanted systemic hemodynamic side effects, but also requires continuous delivery of gas through the ventilator circuit. Thus, if continuous delivery of NO is interrupted (e.g., during patient transport or due to NO supply exhaustion), precipitous and life-threatening hypoxemia and right-sided heart failure may occur.

Inhaled NO has been studied in one large contolled clinical trial in patients with ALI and ARDS (not due to sepsis) who had no other organ failures. Inhaled NO did not improve survival, although some patients experienced transient improvements in oxygenation. Based on this trial, the routine use of inhaled NO in ALI is not recommended.

Some clinicians may consider using inhaled NO as a salvage intervention (Table 145-16). However, a much less costly alternative, inhaled prostacyclin (epoprostenol/ilo- prost), is available. The initial daily cost of inhaled NO is several thousands of dollars, while the daily cost of inhaled prostacyclin is several hundreds of dollars. Although less well studied than inhaled NO, inhaled prostacyclin seems to improve oxygenation to the same degree in a majority of patients with ALI or ARDS.

Tracheal Gas Insufflation

Tracheal gas insufflation (TGI) consists of delivering fresh gas through a modified endotracheal tube at a point just above the carina. The additional gas flow (i.e., flow provided in addition to the standard tidal volumes delivered by the ventilator) tends to remove CO_2-rich gas from the trachea and smaller airways. It has the effect of reducing anatomic dead space. Although acute lung injury decreases the ability of TGI to reduce Pa_{CO_2}, permissive hypercapnia and higher Pa_{CO_2} values increase its relative effectiveness. For example, in one study of patients with ARDS, TGI using 100 percent humidified oxygen, delivered throughout the respiratory cycle at a flow of 4 L/min, lowered Pa_{CO_2} from 108 to 84 mmHg.

Because TGI carries a number of potential risks (e.g., tracheal erosion, oxygen toxicity related to an increased $F_{I_{O_2}}$, and hemodynamic compromise or barotrauma due to TGI-induced auto-PEEP and a larger tidal volume than the ventilator is set to deliver), its routine use is not recommended. However, once again, some clinicians may employ it as a salvage intervention for patients with high levels of Pa_{CO_2} (e.g., greater than 100 mmHg).

Extracorporeal Membrane Oxygenation (ECMO) or Extracorporeal CO_2 Removal ($ECCO_2R$)

The use of extracorporeal gas exchange, such as ECMO or $ECCO_2R$, is based on the hypothesis that more patients will survive if the lung is allowed to recover from its injury by "resting" it by using extracorporeal gas exchange temporarily. Although this hypothesis was initially stimulated by the desire to decrease the risk of pulmonary oxygen toxicity, its assessment can now be justified in regard to the techniques' potential roles in reducing ventilator-induced lung injury (VILI).

In the 1970s, a large-scale study on use of ECMO in patients with severe ARDS demonstrated that it offered no survival benefit to patients whose mortality was extremely high (approximately 90 percent). Similarly, a randomized controlled trial in severely ill patients with ARDS reported in 1994 did not find improved survival using $ECCO_2R$. Despite these findings, some clinicians believe that ECMO, with its continually improving technology, may be beneficial in subgroups of patients with ARDS when treated before 7 days of mechanical ventilation. A number of related techniques also have been utilized, including veno-venous ECMO to assist in CO_2 elimination. Some specialized centers continue to offer ECMO to adults with severe ARDS and consider the technique as a safe life-saving salvage intervention (Table 145-16).

Corticosteroids

The general consensus among intensivists is that corticosteroids have little or no role to play in treating the acute phase of ALI or ARDS. However, the role of corticosteroids in later phases of ALI or ARDS has been controversial.

A number of small case series suggest that high-dose corticosteroid therapy may be beneficial during the proliferative phase of ARDS, based on the rationale of preventing lung scarring that occurs during this phase of ALI as a result of alveolar inflammation. Potential risks include immunosuppression of debilitated, instrumented patients managed in environments harboring multiple antibiotic-resistant organisms and potential long-term neuromuscular weakness associated with use of high-dose corticosteroids and paralytic agents.

In 2006, the ARDSNet investigators published results of a double blind, random, controlled clinical trial (Late Steroid Rescue Study or LaSRS) designed to evaluate benefits and risks of moderately high doses of corticosteroids in 180 patients with persistent ARDS (ARDS lasting 7 to 21 days) (Tables 145-15 and 145-16). It found no differences in 60- or 180-day mortality rates. Although parameters of respiratory function, including $Pa_{O_2}/F_{I_{O_2}}$, plateau pressure, respiratory system compliance, and time to, and rate of, liberation from mechanical ventilation improved after corticosteroid administration, the corticosteroid treated group included more patients who returned to assisted ventilation. Furthermore, no statistically significant differences between treated and untreated groups in ICU or hospital days by 180 days were observed. In addition, more adverse events related to weakness occurred in the treated group than in those receiving placebo. Finally, patients treated with corticosteroids after 14 days of persistent ARDS had a significantly increased mortality (Table 145-15). Hence, the results of this study do not support the routine use of steroids for late-phase ARDS in general, and they argue against their use if ARDS has been present for 14 days or longer.

Beta-Agonists

Basic research supports the hypothesis that beta-agonists may improve the outcomes of patients with ALI or ARDS. Beta-agonists stimulate removal of fluid from flooded alveoli by stimulating the epithelial sodium pump and promoting active

Table 145-15

Results of ARDSNet Late Steroid Rescue Study ("LaSRS") in Patients with Persistent ARDS: *Post-hoc* Analyses of Outcomes and Adverse Events at 180 Days

transport of sodium out of the alveoli (with water following passively according to osmotic gradients). This mechanism is possible, however, only with an intact epithelial membrane. Following preliminary reports suggesting that use of beta-agonists may be effective in fluid removal in patients with ALI or ARDS, the ARDSNet clinical investigators began a large, randomized, double-blinded, controlled clinical trial of inhaled albuterol to test the hypothesis in 2006. Their results are pending.

Experimental Adjuncts to Lung-Protective Ventilation

Two experimental adjuncts to lung-protective ventilation deserve comment: use of exogenous surfactant and partial liquid ventilation.

Exogenous Surfactant

Both animal and human studies have shown that in ALI surfactant levels are decreased or proportions of various surfactants are abnormal, resulting in decreased surface tension-lowering activity. Surfactant therapy in infants with respiratory distress syndrome (RDS) due to prematurity improves gas exchange and lung mechanics, decreases the requirement for CPAP, lessens barotraumas, and improves survival. However, results of trials using surfactant therapy in adults with ALI or ARDS have been disappointing to date.

The first large, prospective, randomized controlled trial of inhaled surfactant in patients with ARDS due to severe sepsis was reported in 1996 and showed no benefit. Concerns about appropriate dosing of the agent, alternative modes of agent delivery, timing of therapy, types of subjects treated, and the precise surfactant formulation employed prompted investigators to view the study as inconclusive with regard to advising against use of exogenous surfactant in adults with ARDS. However, another large randomized, controlled trial reported in 2004 also found no improvement in survival; additional trials are underway.

In contrast, in children (infants to adolescents), one encouraging report on use of exogenous surfactant in ALI or ARDS demonstrated improvement in overall mortality, but not in ventilator-free days, which was the study's primary end point. Further positive studies in children likely will be necessary to gain FDA approval for this indication.

Table 145-16

"Rescue" or "Salvage" Interventions Used in Patients with ARDS and Severe Hypoxemia Resistant to Conventional Mechanical Ventialation and PEEP

Corticosteroids
Extracorporeal CO_2 removal ($ECCO_2R$)
Extracorporeal membrane oxygenation (ECMO)
High frequency oscillatory ventilation (HFOV)
Inhaled nitric oxide (NO) or inhaled prostacyclin (epoprostenol/iloprost)
Pressure controlled inverse ratio ventilation (PC-IRV)
Prone positioning
Recruitment maneuvers
Tracheal gas insufflation (TGI)

Currently, exogenous surfactant for adults is available only as an experimental agent.

Partial Liquid Ventilation

Clinical studies on use of partial liquid ventilation using oxygen-carrying perfluorocarbons instilled into the trachea of adults and children with ALI suggest that this mode of therapy has the potential to improve gas exchange. Partial liquid ventilation may improve oxygenation in part because the perfluorocarbon, by virtue of the hydraulic column created, is able to recruit dependent alveoli that PEEP is not. A practical problem with the technique is that agent used (perflubron) is radiodense, thereby complicating interpretation of chest radiographs in detecting infection or in following resolution of the ALI or ARDS. One clinical trial reported in 2006 reported that patients treated with partial liquid ventilation showed trends to worse survival, longer ventilator-free days and more complications.

CLINICAL COURSE, OUTCOME, AND LONG-TERM SEQUELAE

The clinical course and outcomes of ALI and ARDS have been better delineated in recent years. Both pulmonary and nonpulmonary outcomes have been investigated.

Clinical Course and Duration

The course of illness varies considerably in severity and duration among patients. ALI and ARDS may last for a few days or even less (e.g., ARDS from opioid exposure, with the patient recovering rapidly after the initial insult). Alternately, ARDS from other causes may last several months and involve a prolonged ICU course. Patients can recover or die at any point in the course of ALI or ARDS. The median duration of mechanical ventilation is approximately 9 days. Up to 20 percent of patients remain on mechanical ventilation for longer than 2 weeks, and about 10 percent still require assisted ventilation at 28 days (representing approximately 15 percent of those still alive at 28 days). Notably, as shown in LaSRS, a longer duration of mechanical ventilation for ALI/ARDS does not translate into a higher mortality. Most ARDS-related deaths occur within the first 2 weeks, with one-third occurring by day 7, two-thirds by day 14, and three-fourths to four-fifths by day 28.

The mortality rate of patients on mechanical ventilation after 2 to 4 weeks of persistent ARDS is about 30 percent over the ensuing 2 to 6 months. These rates are similar to the overall mortality rate (at 180 days) for patients enrolled in ARDSNet clinical trials in which low tidal volume ventilation was used. The findings highlight the importance of continued supportive care in the ICU and vigilance aimed at reducing nosocomial complications.

Trends in Mortality Rates

Mortality rates for patients with ARDS have decreased since the early 1980s. In one hospital using the same definition of ARDS throughout the period analyzed, the mortality rate was 68 percent in 1982, 29 percent in 1996, and in the mid–30 percent range in 1997 and 1998. Obviously, the decrease cannot be ascribed to widespread application of low tidal volume ventilation strategies, since the decline was observed prior to publication of the ARDSNet ARMA study in May 2000. The improvement is likely attributable to improvements in general ICU care, including prevention of nosocomial pneumonias and other infections, earlier institution of enteral nutrition, routine use of stress ulcer prophylaxis, and improved ICU teamwork. Notably, however, the case fatality rate for patients with ARDS due to sepsis remained the same over this time frame, while that for patients with ARDS due to trauma or other causes decreased significantly.

Mortality rates for patients with ALI but without ARDS (see previously described definitions in Table 145-1) are lower by about one-third than for those with ARDS. The decreased mortality presumably reflects the decreased severity of the oxygenation defect in ALI compared with ARDS (Table 145-1).

Causes of Death

Approximately one-third of ARDS-related deaths occur in the first 7 days. Most are related to the underlying disease

or injury, i.e., to events occurring before the onset of ARDS. The majority of patients who die succumb after 7 days, with these late deaths also commonly due to the underlying injury or illness. Other causes include complications occurring contemporaneously with or after the onset of ARDS. The most common cause of death in this group of patients is sepsis and associated multiple organ system failure. Of note, only a relatively small fraction of patients—10 to 20 percent of all patients with ARDS—die a respiratory death due to irreversible hypoxemia or refractory respiratory acidosis. Therefore, not surprisingly, clinical trials of interventions aimed selectively at improving gas exchange (e.g., use of inhaled nitric oxide or exogenous surfactant) have not demonstrated improved survival.

Long-Term Sequelae

Recent studies indicate that many survivors of ALI have medical problems and a compromised quality of life both of which persist well beyond their initial ICU stay. Impaired pulmonary, neurologic, musculoskeletal, cognitive, and psychosocial functions have been documented in ALI survivors. Furthermore, survivors have a poorer quality-adjusted survival than do critically ill subjects without ALI.

Research into these disorders is in the early stages; the etiology and pathophysiology of are incompletely understood. Recognition of the problems affecting ALI survivors and referral for appropriate evaluation and therapy constitute important components of overall care. With improved therapy of ALI resulting in greater survival rates, clinicians should anticipate an increase in the prevalence of long-term sequelae.

Health-Related Quality of Life

Health-related quality of life (HRQL) has become increasingly recognized as important to the evaluation of patient-centered outcomes in recovery from a variety of illnesses. A number of studies have evaluated HRQL in ALI survivors. Tools used to assess HRQL include the Medical Outcomes Study 36-Item Short Form Health Survey (SF-36), St. George's Respiratory Questionnaire, Quality of Well Being Scale, and Sickness Impact Profile. Each has illustrated impaired quality of life in survivors of ALI compared with various control populations, including critically ill subjects without ALI and patients with chronic diseases (including cystic fibrosis). In general, impairments in HRQL improve over the first 3 months following discharge from the ICU and appear to plateau by 1 year. Studies of interventions to improve HRQL are under way.

Pulmonary Sequelae

Studies of pulmonary function following ALI and ARDS are affected by inconsistent disease definitions, methodological problems due to lack of patient follow-up, and heterogeneity of preexisting pulmonary diseases. Consequently, a range of lung function impairments has been reported following recovery. Although a proportion of survivors of ALI may have impaired diffusion capacity or restrictive or obstructive abnormalities, restoration of normal lung function occurs in a substantial proportion. In the Toronto ARDS Outcomes study, restrictive and diffusion abnormalities observed at 3 months improved toward normal by 1 year. Given the severely impaired physical function domains reported in HRQL surveys and the relatively mild pulmonary impairment, investigation has more recently focused on other limitations and causes of symptoms in ALI survivors (see below).

Physical and Neuromuscular Sequelae

In the previously noted Toronto ARDS Outcomes study, persistent physical impairment in survivors of ARDS was assessed. Despite improvement in pulmonary function at 1 year following their ICU stay, this cohort had low exercise capacity, weakness, and decreased muscle mass. Risk factors for these findings included multiorgan dysfunction in the ICU, prolonged duration of ARDS, treatment with corticosteroids during the ICU stay, and increased co-morbid disease burden. Although the basis for many of the abnormalities is not clear, a number of patients demonstrated a range of abnormalities, including critical illness polyneuropathy, ICU-acquired myopathy (critical illness myopathy), entrapment neuropathy, and heterotopic ossification.

Cognitive and Psychological Sequelae

Cognitive impairments can cause major limitations in the ability to return to work, affect mood, and lead to increased health care expenditures. Study of long-term cognitive function in ARDS survivors indicates that many have impaired memory, reduced attention, and decreased concentration and processing speed. The abnormalities were associated with the number and severity of hypoxemic episodes in the ICU. Similar to physical abnormalities, cognitive dysfunction seemed to be worse in the first 3 months following hospital discharge; it improved until 1 year and then reached a plateau.

Depression and anxiety are frequent following ARDS. Several studies indicate that the prevalence of depression symptoms is as high as 50 percent following recovery. These emotional problems are likely multifactorial, including prior hypoxic brain injury and delirium and subsequent limitation of physical function. In addition, some authors have suggested the presence of a major component of post-traumatic stress disorder (PTSD) in survivors of ALI. Because these disorders are potentially treatable using pharmacological, behavioral, and cognitive therapies, clinicians should ask ARDS survivors about possible depression and anxiety, which, in turn, may improve HRQL.

Finally, in accord with the concept that the ICU team treats patients as well as their families, clinicians need to be aware that familial caregivers of patients who are survivors of ALI or ARDS experience long-term health effects. In particular, they are at increased risk for emotional distress (associated with various factors, including patient depression) and a lower HRQL over all domains tested on the Medical

Outcomes Short Form 36. Clinicians providing long term follow-up care for patients with ALI or ARDS should aim to ensure adequate social and other support for their familial caregivers.

Sepsis, Systemic Inflammatory Response Syndrome, and Multiple Organ Dysfunction Syndrome

Stuart F. Sidlow • Clifford S. Deutschman

The systemic inflammatory response syndrome (SIRS) and multiple organ dysfunction syndrome (MODS) are diseases of medical progress. Prior to advances in critical care medicine that have characterized the past three decades, SIRS and MODS were unknown. However, our ability to treat shock, manage acute renal insufficiency, support patients in pulmonary failure, and even to transplant organs such as the liver has unmasked these new syndromes. Indeed, initial reports on MODS, which, at the time was called *sequential system failure* or *multiple system organ failure,* heralded the ability to rescue patients from such diverse catastrophic events as ruptured abdominal aortic aneurysm, severe trauma, pancreatitis, multiple transfusions, and progressive infections. Attempts to manage MODS have led, in turn, to a host of important biochemical, metabolic, and physiological discoveries.

This chapter defines the clinical findings that constitute sepsis, SIRS, and MODS and places these disorders in context by relating them to a continuum of clinical abnormalities and syndromes. In addition, the natural history of these disorders is reviewed briefly. Several pathogenic hypotheses, management strategies, and intriguing new forms of therapy are examined.

DEFINITIONS, NATURAL HISTORY, AND EPIDEMIOLOGY

The characteristic response to inflammatory stimuli, including surgery and trauma, classically has been referred to as *the stress response* (Fig. 146-1)—the evolutionary importance of which is facilitation of survival and tissue repair. Initially, an orchestrated neural-endocrine-humoral response directs substrate delivery to the most vital organs—the heart and brain. This response is accomplished through

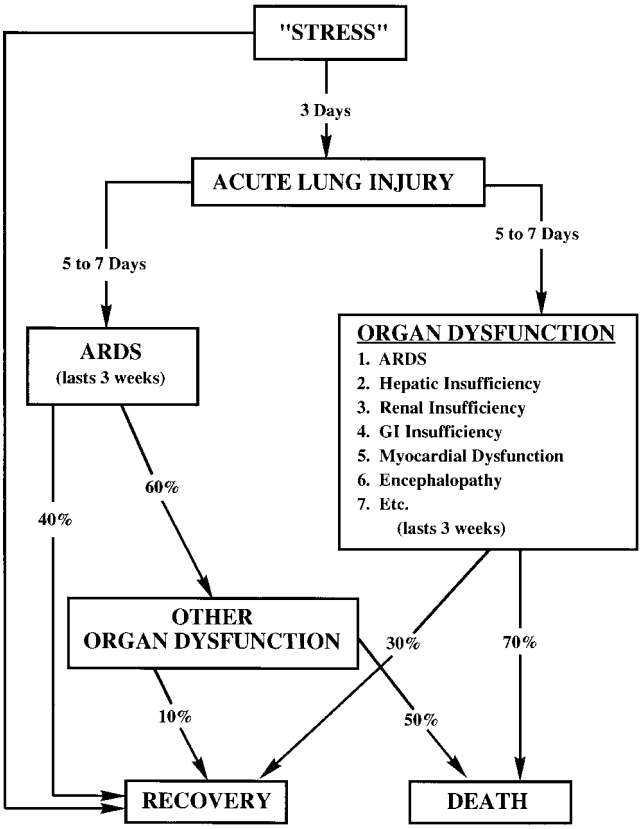

Figure 146-1 Diagrammatic representation of the two classic patterns of MODS pathogenesis. Percentages indicate the proportion of patients following the pathway. Patients develop respiratory insufficiency after an initial insult. In some cases (left side of diagram) this persists for 2 to 3 weeks, and the patients then rapidly develop abnormalities of other organ systems. Over the course of the next week, patients either recover or die. In a second group of patients, multiple-organ dysfunction rapidly follows the onset of respiratory insufficiency. These abnormalities persist for 2 to 3 weeks. Over the next week, patients then either recover or die.

Table 146-1

Diagnostic Criteria

SIRS
Temperature >38°C or <36°C
Heart rate >90 beats/minute
Respiratory rate >20 breaths/min or P_{CO_2} <32 mmHg
WBC $>12\times10^9$/L or $<2\times10^9$/L or >10% immature forms

Sepsis
SIRS + identified or suspected infection

Sever Sepsis
Sepsis + dysfunction of 1 or more organ systems

Septic Shock
Sepsis + hypotension (BP <90 mmHg or a reduction of >40 mmHg from baseline in the absence of other causes) despite adequate fluid resuscitation and perfusion abnormalities (e.g., lactic acidosis, oliguria, altered mental status)

MODS
No current definitions

From Levy MM, Fink MP, Marshall JC, et al: 2001 SCCM/ESICM/ACCP/ATS/SIS International Sepsis Definitions Conference. Crit Care Med *31:1250–1256, 2003.*

vasoconstriction, fluid retention, and translocation of intracellular water to the vasculature. In the absence of exogenous support, death from shock ensues if these endogenous mechanisms are inadequate. Following resuscitation from the initial period of shock, hypermetabolism develops. The driving force behind this second phase is repair of damaged tissue, with white blood cells serving as the primary effectors of the process. To support the increased white blood cell mass, substrate is mobilized from endogenous sources and glucose reserves are rapidly depleted. Because white blood cells are obligate glucose users, muscle (both skeletal and smooth) is broken down to provide precursors for hepatic gluconeogenesis. In addition, amino acids are used to synthesize structural proteins and enzymes. Energy to support the liver, heart, and other organs is derived from fat and amino acids, since utilization of glucose by tissues other than blood cells and neurons is blocked. Generalized capillary recruitment and leak allows glucose delivery to the avascular tissue of the wound. The amount of fluid in the extracellular compartment, particularly in the extravascular matrix, increases dramatically. Continued fluid retention and movement of water out of cells fill the dilated, leaky vasculature. Vasodilatation is accompanied by an increase in cardiac output, which further facilitates delivery of substrate.

By the fourth day after injury or surgery, neovascularization of damaged tissue occurs. Along with a sharp increase in substrate delivery to the tissue of the newly vascularized wound, a decrease occurs in capillary leak accompanied by generalized increases in vascular tone and in the mobilization and excretion of fluid in the matrix. Water also returns to cells. In most cases, the patient recovers uneventfully.

In an unknown percentage of patients, the inflammatory process becomes persistent, progressing to the systemic inflammatory response syndrome, or SIRS. This process is defined by the presence of two or more of the criteria listed in Table 146-1. Because these are normal responses postsurgery or following trauma, these criteria must persist beyond days 3 to 5 for the disorder to be termed SIRS.

Although SIRS is a useful term in comparing studies in the literature, some have challenged the notion that it is a useful diagnostic entity. One alternative approach is the so-called "PIRO" classification system (Table 146-2), which considers **P**redisposition, **I**nfection, **R**esponse, and **O**rgan Dysfunction in evaluating patients in the context of a systemic

Table 146-2

The PIRO system for Staging Sepsis

Domain	Present	Future	Rationale
Predisposition	Premorbid illness with reduced probability of short-term survival. Cultural or religious beliefs, age, sex.	Genetic polymorphisms in components of inflammatory response (e.g., TIR, TNF, IL-1, CD14): enhanced understanding of specific interactions between pathogens and host diseases.	In the present, premorbid factors impact on the potential attributable morbidity and mortality of an acute insult; deleterious consequences of insult heavily dependent on genetic predisposition (future).
Insult infection	Culture and sensitivity of infecting pathogens; detection of disease amenable to source control.	Assay of microbial products (LPS, mannan, bacterial DNA): gene transcript profiles.	Specific therapies directed against inciting insult require demonstration and characterization of that insult.
Response	SIRS, other signs of sepsis, shock, CRP.	Nonspecific markers of activated inflammation (e.g., PCT or IL-6) or impaired host responsiveness (e.g., HLA-DR); specific detection of target of therapy (e.g., protein C, TNF, PAF).	Both mortality risk and potential to respond to therapy vary with nonspecific measures of disease severity (e.g., shock); specific mediator-targeted therapy is predicated on presence and activity of mediator.
Organ dysfunction	Organ dysfunction as number of failing organs or composite score (e.g., MODS, SOFA, LODS, PEMOD, PELOD).	Dynamic measures of cellular response to insult—apoptosis, cytopathic hypoxia, cell stress.	Response to preemptive therapy (e.g., targeting micro-organism or early mediator) not possible if damage already present; therapies targeting the injurious cellular process require that it be present.

TLR, Toll-like receptor; TNF, tumor necrosis factor; IL, interleukin; LPS, lipopolysaccharide; SIRS, systemic inflammatory response syndrome; CRP, C-reactive protein; PCT, procalcitonin; HLA-DR, human leukocyte antigen-DR; PAF, platelet-activating factor; MODS, multiple-organ dysfunction syndrome; SOFA, sepsis-related organ failure assessment; LODS, logistic-organ dysfunction system; PEMOD, pediatric multiple-organ dysfunction; PELOD, pediatric logisticorgan dysfunction.

SOURCE: *Table created using data from Angus et al (2003); Gerlach et al (2003); Vincent, Opal et al (2003); and Vincent, Wendon et al (2003).*

inflammatory response. While not yet widely accepted, this classification system has the potential to address some of the concerns over the SIRS designation.

Whatever one calls the syndrome that develops when inflammation becomes persistent, the clinical entity does exist, often driven by an underlying source, such as a nidus of infection or in undrained hematoma. Such occurrences generally reflect extensive trauma, delayed resuscitation, surgery complicated by extensive, rapid blood loss, or inflammation, as occurs with pancreatitis or aspiration pneumonitis. If a clear source of infection is present, the disorder is classified as sepsis. Further details are summarized in Table 146-3. Although sepsis or SIRS may be complicated by hypotension, lactic acidosis, acute lung injury, or oliguria, obvious organ dysfunction is not present. When organ dysfunction does arise, the syndrome is termed "multiple-organ dysfunction syndrome", or MODS.

STRESS RESPONSE, SIRS, SEPSIS, AND MODS

Virtually all organs become dysfunctional in MODS. However, defining which abnormalities in individual organs constitute dysfunction is problematic. Although many different criteria have been used, none are universally accepted. Indeed, two Consensus Conference Committees of the American College of Chest Physicians (ACCP) and the Society for Critical

Table 146-3

General Criteria for Organ Dysfunction

System	Mild	Severe
Pulmonary	Hypoxia/hypercarbia requiring assisted ventilation for 3–5 d	ARDS requiring PEEP >10 cm H_2O and F_{IO_2} >0.5
Hepatic	Bilirubin 2–3 mg/dl or other LFTs twice normal, PT elevated to twice normal	Jaundice with bilirubin >8–10 mg/dl
Renal	Oliguria (<500 ml/d) or increasing creatinine (2–3 mg/dl)	Dialysis
Gastrointestinal	Intolerance of GI feeding >5 d	Stress ulceration with need for transfusion, acalculous cholecystitis
Hematologic	PTT >125% of normal, platelets <50,000–80,000 per mm^3	DIC
CNS	Confusion	Coma
PNS	Mild sensory neuropathy	Combined motor and sensory deficit
Cardiovascular	Decreased ejection fraction, persistent capillary leak	Hypodynamic state not responsive to pressors

ARDs = acute respiratory distress syndrome; PEEP = positive end-expiratory pressure; LFTs = liver function tests; PT = prothrombin time; PTT = partial thromboplastin time; DIC = disseminated intravascular coagulation; CNS = central nervous system; PNS = peripheral nervous system.

Care Medicine (SCCM) declined to recommend the adoption of specific definitions. The basis for this position may reflect the understanding that just as MODS falls along a continuum of abnormalities, so, too, is there spectrum of abnormalities in each organ system. Furthermore, the transition from adaptive response to organ dysfunction may be clinically obscure, and distinctions among sepsis, SIRS, and MODS are often simply semantic.

Some generally used criteria for organ dysfunction in other systems are detailed in Table 146-3. However, these criteria reflect the gaps in our understanding of MODS. More detailed investigations into the pathobiology of MODS should provide more useful diagnostic criteria.

CLINICAL PATTERNS OF SIRS AND MODS

Two well-defined forms of SIRS/MODS are recognized (Fig. 146-1). In either, development of acute lung injury or the acute respiratory distress syndrome (ARDS) is of key importance to the natural history. ARDS is the earliest manifestation in almost all cases.

In the more common form of SIRS/MODS, damage to the lungs predominates and often is the only evidence of organ dysfunction until very late in the disease. This predominantly pulmonary form of MODS is identical to ARDS, which is described in depth elsewhere (see Chapters 144 and 145). However, it is important to point out that the natural history of patients with this type of MODS is well established. Most often, these patients present with an initiating pulmonary affliction (e.g., pneumonia, aspiration, lung contusion, near-drowning, exacerbation of COPD, lung hemorrhage, or pulmonary embolism) that progresses to a condition that meets the diagnostic criteria for ARDS. Ventilator-dependent pulmonary dysfunction, often accompanied by encephalopathy and a mild coagulopathy, persists for some time. At some point, the patient either begins to recover or progresses to develop fulminant dysfunction in other organ systems, most often hepatic, renal, or cardiovascular. A large proportion of patients with multiple organ involvement do not survive. The pulmonary origin of this form of SIRS/MODS is useful diagnostically since the population at risk can often be defined; data indicate a better prognosis in this subgroup.

Diagnosis of the second form of SIRS/MODS is more problematic. Although the earliest manifestation of the syndrome continues to be pulmonary, most often there is an underlying source that is remote from the lung. This group consists of patients who have experienced major trauma (including isolated head injuries, intra-abdominal sepsis,

extensive blood loss, pancreatitis, vascular catastrophes, such as ruptured or dissecting aneurysms, and a host of other conditions). Acute lung injury and ARDS develop early, but dysfunction in other organs soon becomes evident.

Most studies have found the liver to be the next most commonly involved organ. Indeed, if one considers bleeding associated with an elevated prothrombin time to reflect a hepatic abnormality, the liver may well become dysfunctional even in cases classified as primary pulmonary MODS. Gastrointestinal, cardiovascular, and renal dysfunction are cited equally as the next most common signs of organs failure.

Compensated organ dysfunction persists for some time before the patient either recovers or deteriorates further and dies. The diversity of the population at risk makes early diagnosis of the second form of SIRS/MODS difficult. Furthermore, since many of these patients have undergone surgical procedures, development of mild hypoxemia and increased lung water—normal findings after surgery—may obscure early recognition of ARDS. Thus, SIRS/MODS may not be appreciated until dysfunction in several organ systems has become well established.

Improvements in our ability to support patients with MODS have led to recognition of a third syndrome—referred to (for lack of a better term) as "chronic critical illness." At some point, critically ill patients may become quite stable (i.e., unchanging), but their physiology remains remarkably abnormal. Typically, they require exogenous support of major organ systems. A "hyperimmune" state gives way to one of immunosuppression. Most hormonal systems cease to work properly either because of resistance to hormonal effects or to depletion of hormonal synthesis and storage. These abnormalities reflect a state of endocrine "burn-out" that currently has no specific treatment.

EPIDEMIOLOGY

Accurate determination of the incidence of SIRS/MODS is difficult, predominantly a reflection of the diverse etiologies of the syndromes. The incidence of primary pulmonary SIRS/MODS (i.e., ARDS) is estimated to be in excess of 150,000 cases per year. With regard to the second form of SIRS/MODS, the estimated number of cases in the United States is 750,000 per year. The incidence of MODS following trauma that necessitates admission to the ICU may be as high as 14 percent.

Mortality from MODS remains distressingly high. Estimated mortality from ARDS per se is approximately 35 to 40 percent. Involvement of additional organ systems increases the likelihood of a poor outcome; the presence of dysfunction in three or more organ systems virtually ensures death. Some investigators have reported lower mortality rates; others have shown that mortality is a function of the duration of organ failure. The incidence and mortality of MODS may be increasing. Although there is a lack of consensus in this regard, clearly, once the disease has progressed to the point of multi-organ failure, the patient is at substantial risk for death.

PATHOPHYSIOLOGY

The major factor limiting treatment of MODS is the lack of a clear understanding of the underlying pathophysiological defect. In fact, if not viewed carefully, the changes associated with SIRS/MODS may simply resemble an extension of those observed after uncomplicated stress. Thus, patients recovering from major surgery undergo increases in metabolic rate, oxygen consumption, and carbon dioxide production. Relative glucose intolerance and hyperglycemia also occur. The vasculature is dilated, and the cardiac output increases to promote oxygen transport. In fact, lactate production may increase, reflecting the overall increase in metabolism rather than tissue hypoxia.

Although simple stress and SIRS/MODS have in common altered intermediary metabolism, a hyperdynamic circulation, and systemic signs of inflammation, two important distinctions have been consistently observed. First, noted previously, they differ in time course. Whereas postoperative hypermetabolism runs its course over 5 to 7 days and resolves with neovascularization, the time course of SIRS/MODS is longer, usually 3 to 4 weeks. The second distinction consists of subtle differences in metabolic and physiological parameters. In simple stress and early SIRS, the increase in metabolic demand can be met by an increase in oxygen supply or in oxygen extraction. However, as the disease progresses toward MODS, the ability to extract, and possibly, utilize, oxygen is lost in some tissue beds. This situation is unstable, because oxygen demand on the cellular level is increased. Similarly, in simple stress there appears to be a block in peripheral glucose utilization.

Glucose intolerance becomes more pronounced in SIRS/MODS, possibly because of a defect in the enzyme pyruvate dehydrogenase, which catalyzes conversion of pyruvate to acetyl coenzyme A (acetyl CoA). As a result, increases in tissue metabolic demand cause an increase in the activity of the Krebs cycle and in the generation of lactate (aerobic glycolysis). Consequently, serum lactate increases in direct proportion to the increase in pyruvate. If a microcirculatory perfusion deficit develops, increases in lactate exceed increases in pyruvate. These changes in glucose metabolism become progressively less responsive to modulation by insulin. Ultimately, futile cycling occurs of alanine and lactate between the liver and periphery.

The onset of hepatic dysfunction is heralded by increments in serum lactate that are disproportionate to the increments in pyruvate. Fat metabolism is markedly altered as well. Stress is characterized by levels of ketosis that are disproportionately low for the degree of starvation. It also elicits an increase in hepatic gluconeogenesis, which, in turn, causes hyperinsulinemia.

Stress is associated with lipolysis, decreased lipogenesis, and increased oxidation of long- and medium-chain triglycerides. In early SIRS/MODS, lipogenesis undergoes further decrease. However, oxidation of long-chain triglycerides by the liver also decreases, in association with a decrease in expression of key beta-oxidative enzymes. Ultimately, fat intolerance arises as the liver continues to fail.

In the setting of SIRS/MODS, with significant abnormalities of both glycolysis and beta-oxidation, amino acids become an important source of fuel. As oxidation of amino acids increases, so does urea production. Exogenous protein can be an important energy source, but ultimately, hepatic failure compromises ureagenesis and limits this energy source, as well.

On the physiological level, vasodilatation and peripheral edema become more pronounced. Cardiac output increases as afterload decreases, but ultimately, the heart also fails as energy sources are depleted. Renal mechanisms are then called upon to conserve fluid and to excrete urea. The generalized edema limits the ability to concentrate the urine maximally, thereby leading to two incompatible goals. As a result, the renal system also becomes dysfunctional. One additional hallmark of progressive SIRS/MODS is a loss of the normal hormonal modulation of cellular processes. Thus, insulin-mediated glucose uptake decreases and blood pressure becomes unresponsive to all but the most potent vasopressors, while a glucagon-induced alteration in gluconeogenesis disappears. The mechanisms by which these changes occur are unknown.

A large number of hypotheses have been advanced to explain the pathophysiology of SIRS/MODS. From these have emerged two general concepts concerning etiology. In one, the predominant effect is in the microcirculation: along with an overall decrease in peripheral vascular tone, demand and supply at the microcirculatory level are mismatched, resulting in misdistribution of flow. In the second, the defect is predominantly one of cellular and, indeed, mitochondrial, metabolism. All hypotheses invoke a process that "activates" an inflammatory cascade that "mediates" end-organ responses. In time, these responses become dysfunctional. It is generally accepted that dysfunction in some way results from an inability to meet metabolic demands because of either inadequate flow or direct metabolic block.

HYPOTHESES OF UNDERLYING MECHANISMS

A number of hypotheses have been advanced regarding the underlying basis of SIRS/MODS.

Cytokine Hypothesis

Cytokines are mediators produced and secreted by a number of cells, most notably inflammatory and endothelial cells. These mediators bind to receptors on the cell membrane and initiate intracellular events that alter cell behavior. The cell whose behavior is altered may be the same cell that produces the cytokine (autocrine), a nearby cell (paracrine), or a distant cell (endocrine). Cytokines activate a number of intracellular signal transduction pathways. The ultimate effect may be direct (e.g., activation of membrane channel or an intracellular protein) or may result in stimulation of gene expression. Cytokines that have been implicated in SIRS/MODS include tumor necrosis factor-α (TNF-α), interleukin-1 (IL-1), IL-6, and interferon-γ (INF-γ).

Following simple stress, TNF-α or IL-1 are produced by inflammatory cells drawn to the site of injury or inflammation and by local endothelial cells. These cytokines are then released into the circulation and affect distant organs. The behavior of TNF-α on the liver serves as a useful paradigm.

A 26-kD form of TNF-α is produced by local cells and is expressed on the cell surface. This form of TNF-α is, through unknown mechanisms, active in control of debridement and infection at the local level. Ultimately, however, 26-kD TNF-α is cleaved by a matrix metalloproteinase to a 17-kD circulating form. The blood carries the 17-kD form from remote organs. The 17-kD form is capable of not only producing vasodilatation (perhaps, via a nitric oxide-linked pathway), but also of stimulating other inflammatory and noninflammatory cells. For example, in the liver, TNF-α stimulates resident macrophages (Kupffer cells) to produce more TNF-α, as well as other cytokines, such as IL-1 and especially IL-6. TNF-α, IL-1, and IL-6 then induce hepatocytes to express the genes for a number of proteins called acute-phase reactants. These secreted proteins have diverse activities that help control the inflammatory response. Since low levels of TNF-α (and IL-1) are released from the initial site of inflammation, the process should be self-limited.

In the cytokine theory of MODS, over-production of TNF-α, IL-1, or IL-6 and resultant uncontrolled inflammation are postulated. The net result is prolonged, uncontrollable vasodilatation and damage to viable organs by activated macrophages and other inflammatory cells.

In support of this theory, high levels of circulating TNF-α, IL-1, IL-6, and INF-γ have been found in fulminant septic shock (e.g., as in disseminated meningococcemia). Similarly, in animal models in which endotoxin is administered intravenously, serum levels of TNF-α and IL-1 are increased. Studies in animals and human volunteers indicate that TNF-α is probably the most proximal mediator, initiating the expression and release of the other cytokines. TNF-α is cytotoxic to a number of cells, initiating programmed cell death (apoptosis) in culture. Antibodies to TNF-α are protective in lethal endotoxemic and bacteremic animal models, while certain intracellular proteins can block TNF-α–induced apoptosis. Finally, administration of TNF-α to animals results in a syndrome that mimics septic shock, whereas giving low doses of this cytokine to humans mimics certain metabolic aspects of SIRS. Substantial data indicate, however, that this view of SIRS/MODS is simplistic.

In animal models of bacterial peritonitis, neutralizing TNF-α in the serum increases mortality. Reported levels of cytokines in the blood of septic patients vary considerably among studies. Also, clinical trials of anti-TNF-α in human SIRS have been disappointing. Recent data indicate that serum levels do not reflect tissue levels, and that the cell-associated, 26-kD form (and not the 17-kD circulating form) of TNF-α mediates organ injury. Evidence from studies of IL-6 knockout mice indicates that this cytokine is an important component of hepatic regeneration; therefore, it may be protective, rather than injurious. Since a host of other mediators and pathways are activated in SIRS, a reasonable conclusion is that cytokines are important mediators of certain aspects of SIRS/MODS, but that other factors are at work.

Microcirculatory Hypothesis

The common link in the microcirculatory hypothesis is that the failure of cells or organs to receive adequate levels of oxygen or some important nutrient or substrate triggers SIRS/MODS. Low blood flow, as is likely to occur in hypotension or shock, contributes to cellular dysfunction. However, the release of vasoactive mediators and vascular congestion secondary to microthrombi and leukocytes are also held to be important.

Reperfusion of ischemic tissue may be as important a determinant of tissue injury as decreased flow itself. In particular, the generation of oxygen free radicals and peroxidation of membrane lipids following reperfusion may contribute to tissue injury. Sources of free radicals include the conversion of molecular oxygen to superoxide by xanthene oxidase, activated leukocytes, mitochondria, and prostaglandin synthase. The first two sources are probably the most important.

Circulatory shock, microvascular compromise, and free radical generation are likely to affect the endothelium directly. Endothelial cells are active in free radical formation, provide a point of attachment for leukocytes, and may be exquisitely sensitive to hypoxia. Furthermore, they not only produce, but are also affected by, vasoactive mediators. These interactions provide the link between the cytokine and microvascular hypotheses.

Cytokines activate endothelial cells to elaborate other vasoactive substances and to express surface proteins that promote leukocyte adhesion; endothelial cells are also important participants in the formation of microthrombi. In support of the microvascular hypothesis, circulatory shock often occurs before MODS; autopsy data indicate the presence of microvascular injury in patients with MODS; and microthrombi containing platelets, neutrophils, and fibrin are common in MODS. Antibodies to CD18, which block leukocyte adhesion, do occur in circulatory shock and are protective in some forms of ischemia-reperfusion injury; they are not protective against liver injury or leukocyte adherence in experimental sepsis. The microthrombi, microvascular constriction, and free radicals are valuable in limiting the spread of infection.

Gut Hypothesis

The syndrome that is now designated as SIRS once was believed to be the result of uncontrolled infection, presumably due to the endotoxin released by gram-negative bacteria. However, organisms other than gram-negative bacteria have been implicated, and in many patients, neither microorganisms nor a source of bacteria can be identified.

The gut hypothesis contends that inflammation is due, in part, to bacteria in the gastrointestinal tract (or their associated endotoxin) that translocate to the mesenteric lymph nodes, liver, and circulation. Various insults have been shown to lead to such translocation of bacteria or endotoxin, and the intestinal barrier is disrupted in many clinical situations that can precede MODS. As a rule, translocation involves a combination of insults, including an alteration in the indigenous gastrointestinal flora, that results in bacterial overgrowth, impaired host defenses, and physical disruption of the intestinal barrier.

The gut hypothesis overlaps the cytokine and microcirculatory hypotheses. Bacteria or endotoxin activates white blood cells and induces production of cytokines. Each can alter the behavior of both endothelial cells and the coagulation system, leading to microvascular aggregation and production of free radicals, which can, in turn, create a self-sustaining cycle that culminates in MODS. Exposure to intestinal flora activates hepatic macrophages (Kupffer cells), releases cytokines, and damages hepatic cells, reinforcing the hypothesis that translocated bacteria are important in the pathogenesis of SIRS/MODS.

"Two-Hit" Hypothesis

A second insult, subsequent to an initial "hit," may be of major importance in the pathogenesis of SIRS/MODS. According to this hypothesis, an initial period of hypotension "primes" the trauma patient for SIRS/MODS (i.e., the initial insult activates other processes that amplify the effects of the initial event, however mild).

Priming could involve activation of white blood cells or platelets, disruption of the intestinal mucosal barrier, or the induction of free radicals and the enzymes (such as xanthene oxidase) that produce these reactive species. Although this hypothesis overlaps with others, such as the cytokine, microcirculatory, and gut hypotheses, animal studies in which a single insult is followed by a second, more severe insult have shown that the first "hit" is actually protective.

Connectionist Hypothesis

By viewing biologic systems as composed of oscillators, with the oscillations reflecting a continuously changing series of external events, we can regard the loss of either the external stimuli or the ability to respond to these stimuli as pathological. On the basis of this approach, and with the application of nonlinear modeling, the transition from SIRS to MODS has been depicted as an erosion in the ability of different organs to

communicate with each other. For example, in experimental sepsis, hepatocellular metabolic pathways, such as glucogenesis, respond inadequately to hormonal stimulation. Similarly, beat-to-beat cardiac variability in human volunteers is lost during experimental endotoxemia. The connectionist hypothesis supplements, rather than substitutes for, the hypotheses presented above.

Other Hypotheses

Other hypotheses are being explored. For example, one possibility under investigation is that the seemingly diffuse abnormalities in SIRS and MODS may be related to deficits in hepatic metabolism. Consistent with this hypothesis is the observation that gluconeogenesis, beta-oxidation, and ureagenesis are impaired in septic animals. These alterations are due, in part, to a decrease in the transcription of genes coding for key enzymes in each pathway. Furthermore, when important transcription factors are examined, a potential link between pulmonary and hepatic dysfunction becomes clear.

Similarly, another theory holds that dysfunction at the mitochondrial level may be responsible for the improper response in MODS—specifically, inadequate oxygen utilization by cells may be operative. This mechanism, coupled with inadequate oxygen delivery (as described in the microcirculatory hypothesis) results in a mismatch between oxygen demand or supply and oxygen utilization. Recent studies reveal a defect in cytochrome oxidase, the terminal complex in the electron transport chain, in septic myocardium.

Regardless of which is the dominant "cause" or "effect" of SIRS or sepsis, the net result is that dysfunction of multiple systems results in physiological detriment to the patient and threatens survival.

MANAGEMENT

Management of patients with SIRS/MODS is challenging and focuses on treatment of major end-organ damage.

Pulmonary Dysfunction

Pulmonary dysfunction most often takes the form of secondary ARDS. This topic is covered in depth in Chapter 145.

Source Control

The key to prevention and elimination of SIRS/MODS is source control. The clinician must exhaustively search for and eliminate the nidus of inflammation, whether it is a hematoma, abscess, wound infection, or sinusitis. This is critical to reversing the process. While conducting the search for the offending source or microorganism, empiric use of broad-spectrum antibiotics is advised; subsequently, the regimen is tailored based on culture and sensitivity reports from the microbiology laboratory.

Perfusion Management

In the face of inflammation, perfusion should be optimized. It is nearly impossible to restore the body to pre-insult hemodynamic status until the inflammatory response has run its course. Supportive care is key. That inadequate tissue perfusion potentiates SIRS and may catalyze progression to MODS should be recognized. This is especially true for the kidneys, which are sensitive to hypoperfusion, even in the absence of underlying renal pathology. Moreover, hypoperfusion of the kidneys activates the renin-angiotensin-aldosterone system. Since angiotensin II is the major determinant of portal perfusion of the liver, and since hepatic dysfunction figures prominently in MODS, disturbances in the renin-angiotensin-aldosterone system may contribute to disturbance in hepatic function. Disturbances in ventilation-perfusion relationships secondary to pulmonary hypoperfusion may contribute to arterial hypoxemia.

Fluids should be administered liberally in SIRS/MODS. Determination of the appropriate volume of fluid to administer is problematic, however, largely because end-organ function, the best index of adequate perfusion, is already impaired. One practical rule of thumb is to achieve a stroke volume of approximately 1 ml/kg of body weight. If the administration of fluid does not increase stroke volume, cardiac dysfunction is probably present and administration of additional fluid is not likely to be helpful.

Rational Use of Inotropes and Vasopressors

Animal and human studies indicate that SIRS/MODS renders the cardiovascular system relatively resistant to the effects of native and synthetic catecholamines. Therefore, powerful agents are required to achieve any hemodynamic effect. Also, the vasodilatation may represent a compensatory response to a metabolic defect; hence, induced vasoconstriction may worsen this defect.

One practical expedient is to treat hypotension when evidence of myocardial ischemia develops, usually at a diastolic pressure of about 40 mmHg. Norepinephrine is the drug of choice. This agent constricts somatic (muscle) beds, but it appears to spare the splanchnic circulation, thereby transferring fluid from the periphery to the central, visceral compartment. As a second-line therapy to increase visceral tone once maximum effect using norepinephrine has been achieved, a low, nontitrated dose of vasopressin at 0.01 to 0.04 units/h may be added. Endogenous vasopressin release is diminished in sepsis, suggesting a role for vasopressin "replacement," rather than "therapy." Dopamine, which had long been a preferred agent in sepsis, is no longer advocated, since it is a nonspecific agonist and may cause maldistribution of flow. Dopamine has been demonstrated to be detrimental to renal function. If cardiac output remains low despite adequate fluid resuscitation and vasopressor therapy, an inotrope,

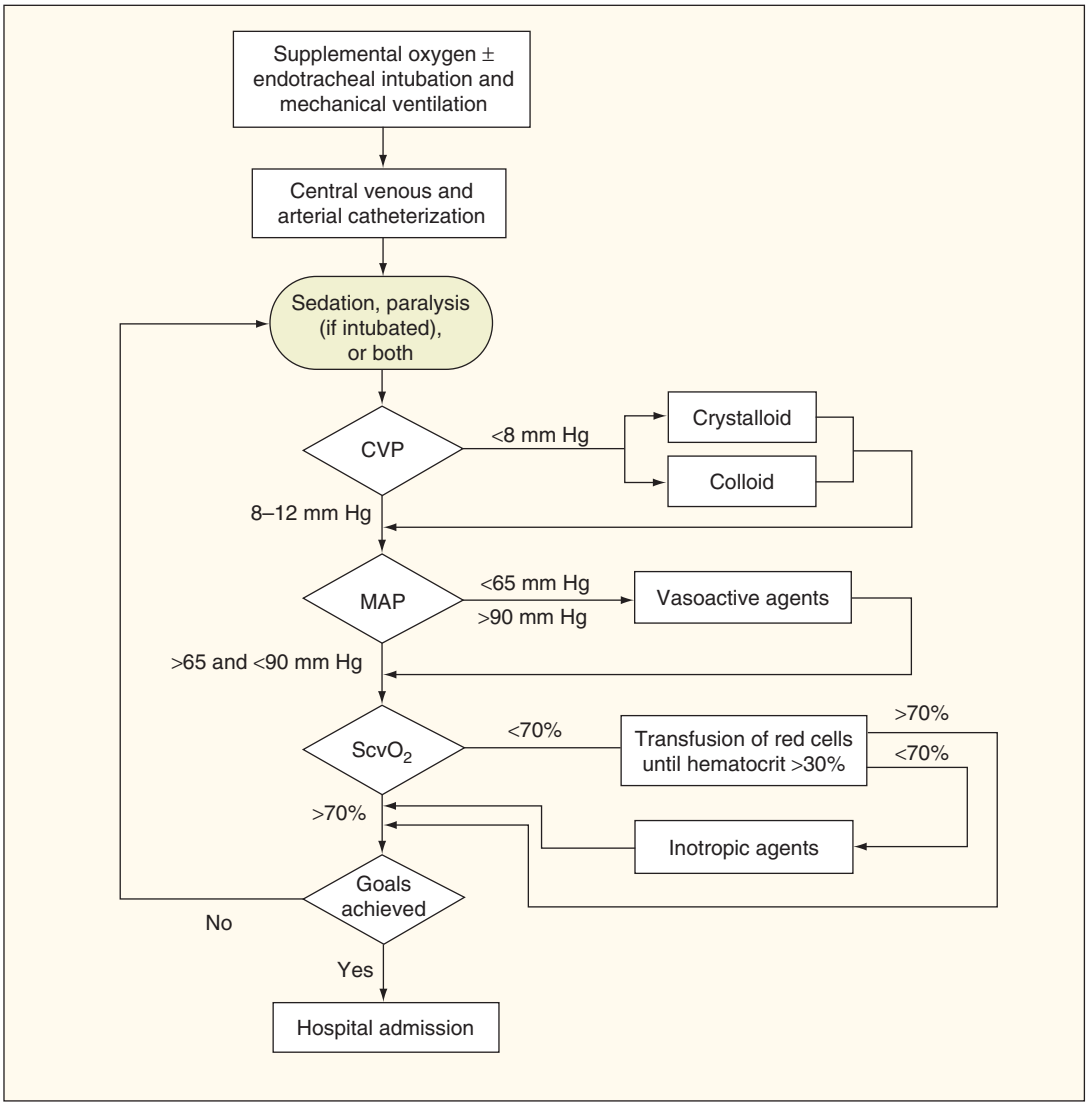

Figure 146-2 Goal-directed therapy for septic shock. *(From* Clinical Practice Guidelines, *Hospital of the University of Pennsylvania.)*
Resuscitation in Septic Shock: Hemodynamic Considerations in Goal-Directed Therapy
Resuscitation should continue with predetermined end points:

1. Target mean arterial pressure (MAP) of 65 mmHg
2. Urinary output of >0.5 ml/kg/h
3. Central venous pressure (CVP) of 12–15 mmHg
4. Stroke volume (SV) of 0.7–1.0 ml/kg

If early aggressive fluid resuscitation does not restore MAP within 30 min (refractory shock), add norepinephrine.

If norepinephrine dose exceeds 10 μg/min, add nontitrated dose of vasopressin at 0.04 μg/min.

If patient remains hyperdynamic with impaired myocardial contractility, add inotrope with goal SV of 0.7–1.0 ml/kg. Dobutamine is first line, followed by epinephrine. Impaired myocardial contractility is defined as decreased ejection fraction (EF), ventricular dilation, impaired contractile response to volume loading, or low peak systolic/end-systolic volume ratio.

End points for assessing resuscitation are arterial blood pressure, heart rate, urinary output, and skin perfusion.
From Clinical Practice Guidelines, *Hospital of the University of Pennsylvania, Philadephia, PA.*

such as dobutamine, may be added to increase cardiac contractility.

Recent studies emphasize *goal-directed therapy* in the management of sepsis (Fig. 146-2). This includes promptly achieving a mean arterial pressure (MAP) greater than 65 mmHg, a central venous pressure (CVP) of 8 to 12 mmHg, a venous oxygen saturation (Sv_{O_2}) greater than 70 percent, a hemoglobin concentration greater than 10 g/dl, and a lactate concentration less than 4.0 mm. After initial resuscitation, unless there is active cardiac disease, acute hemorrhage, or continuing lactic acidosis, a hemoglobin concentration of 7 g/dl is acceptable.

Metabolic Management

As SIRS progresses to MODS, the intrinsic metabolic defect associated with the disorder worsens. Although glucose intolerance is apparent very early in the course of the disease, progressive hyperglycemia may develop. Additionally, there is progressive azotemia as amino acids are deaminated and carbon skeletons enter the Krebs cycle. Ultimately, hepatic dysfunction becomes so severe that even this process becomes impaired. The intrinsic defect appears to be a decrease in the transcription of genes encoding certain key enzymes in metabolic pathways. Although compensation can occur early in the course, ultimately this fails.

To meet caloric needs, most clinicians rely on a formula that is relatively hypocaloric and protein-rich. The resultant increase in blood urea nitrogen is generally well tolerated in adequately hydrated patients. This contrasts with the results of overfeeding with fat or glucose. However, if the increase in blood urea nitrogen is a manifestation of uremia, rather than an isolated consequence of protein overfeeding, dialysis may become necessary.

We believe that administration of exogenous insulin should be avoided early in SIRS/MODS. Most often, the need is precipitated by use of fluids that contain exogenous glucose. Employment of tight glycemic control is controversial in sepsis, although it has been shown to be effective overall in critically ill patients. These studies show an improvement primarily in patients in the ICU for more than 5 days. Thus, it is our belief that "insulin resistance" represents one additional manifestation of "endocrine burn out" in chronic critical illness.

In the acute phase of critical illness, insulin may lower serum glucose levels, but it does so by driving glucose into fat cells. Insulin does not increase glucose oxidation in any tissue. Moreover, even though insulin may block catabolism of skeletal muscle, it does not have this effect on smooth muscle. Therefore, vascular and gastrointestinal smooth muscle may be mobilized, worsening the defects in these organ systems.

Use of corticosteroids in sepsis is another controversial topic. Patients requiring high doses of vasopressors may have a component of adrenal insufficiency. However, the criteria for defining adrenal insufficiency in critically ill patients are difficult to define. If normal diagnostic criteria are met (low baseline cortisol or failure to increase serum levels 30 to 60 minutes following administration of adrenocorticotropic hormone [ACTH] or an ACTH analogue), corticosteroid administration is reasonable. Adrenal insufficiency, too, may be a manifestation of endocrine burnout in chronic critical illness.

Novel Medications

Recent studies have evaluated the use of recombinant human Activated Protein C (rhAPC) in patients who are in severe sepsis or MODS. The rationale for use is that the inflammatory response results in a procoagulant state. By reversing this response, patients may have a greater survival rate. Indeed, in carefully selected subgroups (those who are less severely ill, with Acute Physiology, Age, and Chronic Health Evaluation (APACHE) scores under 25), administration of rhAPC modestly increases survival. Furthermore, low-risk patients do not benefit.

The specifics of renal replacement therapy are beyond the scope of this chapter. However, in acute renal failure from MODS, the replacement of choice is early continuous venovenous hemodialysis (CVVHD). Hemodynamic stability is greater with CVVHD than with intermittent hemodialysis. In addition, animal studies have demonstrated a shortened course of sepsis using hemodiafiltration. Unfortunately, these results have not been confirmed in human studies.

CONCLUSION

SIRS/MODS represent a major cause of mortality and morbidity. The nature of the underlying pathological defect is unknown. Current treatment is supportive and centers on assurance of adequate ventilation and oxygenation, appropriate fluid resuscitation, metabolic support, an intensive search for an excisable or drainable inflammatory site, and avoidance of secondary organ injury.

Acute Respiratory Failure in the Surgical Patient

Robert M. Kotloff

Advances in surgical technique, anesthesia and analgesia, and postoperative supportive care have facilitated application of sophisticated surgical procedures to an expanding spectrum of patients. Emboldened by diminished operative mortality rates, clinicians are increasingly willing to subject older and sicker patients to rigorous, but potentially life-saving, surgical interventions. In most instances, the success or failure of the surgery is defined not in the operating room, but postoperatively, when the adverse effects of surgery may first become apparent and when intercurrent complications may jeopardize the patient's well-being.

The respiratory system is particularly vulnerable to the effects of general anesthesia and surgery, and postoperative respiratory impairment is common. While generally mild and well-tolerated in otherwise healthy, young patients, postoperative respiratory compromise may have serious consequences in the elderly and in patients with preexisting lung disease. Potentially devastating postoperative complications, such as pneumonia, aspiration, and acute respiratory distress syndrome (ARDS) may lead to respiratory failure independent of the patient's presurgical status. Overall, pulmonary complications account for approximately 25 percent of postoperative deaths. This figure is, in fact, conservative, since many patients with respiratory failure can be supported on mechanical ventilation, only to die of other nonrespiratory complications (e.g., sepsis, gastrointestinal bleeding, and multi-organ failure). In addition to their effect on mortality, respiratory complications exact a toll in lengthening ICU and hospital stay, delaying convalescence, and escalating the cost of care. Therefore, clinicians who provide preoperative evaluation and postoperative care must be familiar with the factors that predispose to pulmonary impairment in the surgical patient. Many of these concepts are considered in Chapter 38. This chapter focuses on the most serious of the perioperative respiratory complications—acute respiratory failure.

IDENTIFICATION OF THE HIGH-RISK PATIENT

In a review of over 7000 patients undergoing various gastrointestinal, urological, gynecological, and orthopedic procedures, respiratory failure requiring mechanical ventilation beyond 24 h occurred in only 0.8 percent. Among 81,719 patients undergoing both elective and emergency noncardiac procedures in hospitals belonging to the Veterans Affairs (VA) health system, respiratory failure (defined as mechanical ventilation beyond 48 h after surgery or need for reintubation) occurred in 3.4 percent. Though the overall risk of respiratory failure in these studies is relatively low, it is clear that risk varies markedly, depending on a number of factors related to the procedure and the patient. While risk of postoperative respiratory failure is negligible in the young, healthy nonsmoker undergoing elective knee surgery, it is significant in the elderly patient with underlying chronic obstructive pulmonary disease (COPD) undergoing emergent repair of a thoracoabdominal aortic aneurysm. Factors that have been most thoroughly studied in association with postoperative respiratory failure are discussed in greater detail below.

Type of Operative Procedure

Procedures that involve the upper abdomen or thorax are associated with the highest rates of postoperative pulmonary complications, including respiratory failure (Table 147-1). In large part, the risk is attributable to the profound derangement in pulmonary mechanics that accompanies these procedures (see below). Thoracoabdominal aneurysm repair carries the greatest risk of postoperative respiratory failure.

Table 147-1

Incidence of Respiratory Failure Following Various Surgical Procedures

Procedure	Incidence of Postoperative Respiratory Failure
TAAA repair	8–33%
AAA repair	5–24%
Lung resection	4–15%
CABG	5–8%
All types*	0.8%

TAAA = thoracoabdominal aortic aneurysm; AAA = abdominal aortic aneurysm; CABG-coronary artery bypass grafting.
**Refers to general survey of gastrointestinal, urological, gynecological, and orthopedic procedures.*

Given the need for both abdominal and thoracic incisions, as well as division of the diaphragm and costal margin, this observation is not surprising. Other procedures with significant risk include abdominal aortic aneurysm repair, upper gastrointestinal surgery, thoracotomy, and open heart surgery. Lower abdominal procedures carry a much smaller risk than those involving the upper abdomen; procedures involving the extremities carry a negligible risk.

In some cases, the surgical approach can be modified to lessen the risk of postoperative pulmonary complications in patients who are marginal operative candidates because of advanced age or co-morbid conditions. For example, use of a transverse abdominal incision appears to carry less risk than a vertical midline incision. Cholecystectomy performed by laparoscopic technique is associated with a lower incidence of pulmonary complications compared with the conventional open approach. For thoracic procedures, median sternotomy and muscle-sparing lateral thoracotomy are better tolerated than posterolateral thoracotomy. However, these approaches provide more limited access to the thorax than does the standard thoracotomy incision, and they are generally inadequate for resection of the left lower lobe or for tumors involving the posterior chest wall, diaphragm, or superior sulcus. Additionally, removal of bulky tumors via the muscle-sparing approach may be problematic. Video-assisted thoracoscopic surgery (VATS) also appears to be a less morbid thoracic procedure (Chapter 37). Studies suggest that VATS results in reduced postoperative pain and hospital length of stay compared with thoracotomy and may cause less early impairment in lung function. Whether this procedure carries a diminished risk of postoperative pulmonary complications has not been definitively established.

Chronic Obstructive Pulmonary Disease

In the previously noted study of over 80,000 patients undergoing noncardiac surgery in VA hospitals, multivariate analysis revealed that a history of COPD was an independent risk factor for postoperative respiratory failure. Overall, the risk of respiratory failure associated with COPD (odds ratio of 1.8) was considerably lower than that associated with the type of surgery (odds ratio of 14.3 for abdominal aortic aneurysm repair and 8.1 for thoracic surgery). Notably, preoperative pulmonary function parameters were not examined in this study, precluding assessment of the relationship between severity of COPD and risk of postoperative respiratory failure.

Studies focusing on outcomes following specific, high-risk procedures shed additional light on the risks posed by COPD. The incidence of respiratory failure following thoracotomy and lobectomy or pneumonectomy exceeds 50 percent for patients with COPD and a predicted postresection forced expiratory volume in 1 sec (FEV_1) less than 40 percent of normal, but it is minimal for those with more adequate pulmonary reserve. Within the subset of patients with a predicted postresection FEV_1 less than 40 percent, those who maintain an acceptable functional status (as indicated by peak oxygen consumption of greater than or equal to 10 to

15 ml/kg/min on cardiopulmonary exercise testing) appear to have a low risk of respiratory failure following definitive lung resection procedures. The use of VATS in combination with less extensive resection of lung tissue (e.g., wedge resection or segmentectomy) appears to be well tolerated by patients with severe lung disease, with only a 4 percent incidence of respiratory failure and a 1 percent mortality rate documented in one recent study of 100 patients with an FEV_1 less than 35 percent predicted.

Studies of the risk posed by COPD among patients undergoing thoracoabdominal aortic aneurysm repair have yielded conflicting results. In one prospective study of over 1400 patients, COPD was found to be an independent risk factor for respiratory failure, defined as the need for mechanical ventilation in excess of 48 h. Respiratory failure developed in 53 percent of patients with COPD and in only 23 percent of patients without this disorder. The risk of respiratory failure correlated linearly with preoperative spirometry, precluding identification of a particular set of "threshold" values. In contrast, two other studies of thoracoabdominal aneurysm surgery employing similar statistical methods did not identify COPD as a significant predictor of postoperative respiratory failure.

The impact of COPD on outcome following coronary artery bypass grafting (CABG) has also been examined. In one study, patients with a history of COPD had higher rates of mechanical ventilation exceeding 48 h (18.9 percent vs. 3.7 percent) and reintubation (13.5 percent versus 3.7 percent) compared with age-matched controls. In a recent study of over 8000 consecutive patients undergoing CABG, the incidence of postoperative respiratory failure was 5.6 percent. Among preoperative characteristics, COPD was identified as a risk factor for respiratory failure, with an odds ratio (OR) of 1.9. This was, nonetheless, considerably less than the risk posed by such factors as renal insufficiency (OR 3.9), congestive heart failure on admission (OR 4.1), and emergency (rather than elective) surgery (OR 5.8).

Following major abdominal vascular surgery, including abdominal aortic aneurysm repair and aortobifemoral bypass grafting, approximately 25 percent of patients require ventilatory support for more than 24 h. While an extensive smoking history and low preoperative Pao_2 are predictive of the need for prolonged postoperative ventilatory support, the severity of COPD, as defined by preoperative spirometry, is not. Indeed, no prospective evaluation of patients undergoing abdominal surgery of any type has shown that pulmonary function studies can reliably identify patients at increased risk of serious postoperative pulmonary complications.

What conclusions can be drawn from this complex and conflicting body of literature? Clearly, the presence of severe COPD with a predicted postoperative FEV_1 of less than 30 to 40 percent in association with poor functional status should be viewed as an absolute contraindication to thoracotomy and extensive lung resection (lobectomy or pneumonectomy). COPD appears to increase the risk of respiratory failure to a far lesser degree following other types of surgical procedures. Acknowledging current uncertainties about the full contribution of COPD to postoperative risk in these settings, the presence of significant lung disease should prompt a careful analysis of the necessity of the surgery planned. However, it should not preclude surgery deemed likely to extend patient survival or to markedly improve quality of life.

Patients with COPD scheduled for surgery should undergo a preparatory pulmonary regimen intended to optimize lung function and minimize airway secretions. This regimen should include smoking cessation, institution or intensification of inhaled bronchodilator therapy, and use of oral antibiotics in the presence of purulent secretions or a "loose" cough. Patients should be instructed on the use of incentive spirometry or cough and deep breathing techniques prior to surgery. A short course of oral corticosteroids should be considered in patients who have a significant bronchospastic component to their disease. Such a preparatory regimen is simple and inexpensive and has been shown to have a favorable impact on the incidence of postoperative pulmonary complications. Other than the assurance of strict compliance with the regimen, there is no reason to believe that hospitalization is superior to outpatient preparation of the patient.

Smoking

Smoking has been shown to be a risk factor for postoperative pulmonary complications in general and for prolonged ventilatory support in particular. Smoking does not appear simply to be a surrogate marker of COPD; rather it poses risk that is independent of the magnitude of pulmonary impairment. Detrimental effects of smoking include bronchial irritation with resultant excessive airway secretions, impairment in mucociliary clearance, and elevation of carboxyhemoglobin levels with consequent impairment in oxygen uptake and tissue oxygen utilization. While preoperative smoking cessation has been shown to diminish the risk of postoperative pulmonary complications, a minimum of 8 wk of abstinence is required to achieve this risk reduction (see Chapter 38 for additional details).

Predicting Risk of Respiratory Failure

Recently, a multifactorial risk index for predicting postoperative respiratory failure was published. The model was derived from analysis of the VA population of over 80,000 patients undergoing noncardiac surgery and was validated in a second VA population of nearly 100,000 patients. Preoperative variables independently predictive of an increased risk of postoperative respiratory failure (mechanical ventilation for greater than 48 h or reintubation) were identified by multivariate analysis, and each variable was assigned a point value reflecting the relative risk that it posed (Table 147-2). Based upon the total number of points, patients were assigned to one of five risk classes that predict the overall probability of respiratory failure (Table 147-3). The model performed well when validated in the second cohort of patients. However, as it was derived from a population of male patients cared for at VA facilities and did not include cardiac procedures, its applicability to

Table 147-2

Respiratory Failure Risk Index

Preoperative Predictor	Point Value

other patient populations is uncertain. Therefore, additional studies are required before use of this predictive index can be endorsed.

IMPACT OF ANESTHESIA AND POSTOPERATIVE ANALGESIA ON PULMONARY FUNCTION

An additional important consideration in patients undergoing surgical procedures is the effect of anesthesia on pulmonary function.

General Anesthesia

Use of general anesthetic agents is associated with a number of well-characterized alterations in pulmonary mechanics, gas exchange, and respiratory drive. In the controlled environment of the operating room, these physiological derangements are clinically inconsequential and easily overcome by simple adjustments of the ventilator. However, lingering effects of general anesthesia after completion of surgery may impede efforts to extubate the patient or may precipitate respiratory failure in the recovery room.

Administration of general anesthesia, whether by the inhaled or intravenous route, results in an almost immediate loss of diaphragmatic and intercostal muscle tone, a cephalad shift of the diaphragm, and a decrease in the transverse thoracic diameter. These dimensional alterations in thoracic volume result in a 20 percent reduction in functional residual capacity (FRC) and in development of compressive atelectasis. As demonstrated using computed tomography (CT) to image patients during and after general anesthesia, patients develop crescent-shaped areas of atelectasis in dependent areas of the lung within 10 min of induction. Atelectatic areas comprise approximately 2 to 10 percent of total lung volume and disappear with the application of positive end-expiratory pressure (PEEP). Dependent atelectasis develops after administration of either inhalational or intravenous anesthetics. A notable exception is ketamine, a drug that is unique in its maintenance of respiratory muscle tone. The degree of atelectasis appears unaffected by whether the patient is breathing spontaneously or is mechanically ventilated.

Areas of dependent atelectasis perturb the normal balance of ventilation and perfusion in the lung. Persistent perfusion of nonventilated atelectatic areas results in an increase in the shunt fraction, which may approach 15 percent. The magnitude of shunt correlates directly with the volume of atelectatic lung and may be further magnified by impairment of hypoxic pulmonary vasoconstriction induced by certain inhalational anesthetics. Elderly patients, those who are obese, and patients with underlying COPD are most likely to develop clinically apparent hypoxemia in response to general anesthesia; the effect may persist into the early postoperative period.

The inhaled anesthetic agents in common usage are respiratory depressants that blunt the response to both hypoxemia and hypercapnia. These agents depress the ventilatory response to CO_2 in a dose-dependent fashion. They have a negligible effect on the hypercapnic response at the low concentrations encountered during emergence from anesthesia. In contrast, hypoxemic drive is markedly attenuated even at very low, subanesthetic concentrations of the volatile agents. As a result of deposition of these agents in muscle and fat, concentrations sufficient to depress hypoxic drive persist for several hours after termination of anesthesia. This can result in significant postoperative respiratory depression in patients who, by virtue of chronic hypercapnia, are dependent upon a hypoxic ventilatory drive to breathe.

Neuraxial Anesthesia

It is common practice for those providing preoperative assessment of high-risk patients to recommend the use of neuraxial (i.e., spinal or epidural) anesthesia, predicated on the impression that this route of administration lessens the adverse impact of anesthesia on the respiratory system. Neuraxial anesthesia does possess a number of favorable physiological features. In contrast to the effects of general anesthesia, neuraxial anesthesia preserves diaphragmatic innervation and function. External intercostal muscle paralysis is induced by thoracic levels of neuraxial anesthesia, but the level is generally two dermatomes below the sensory level because of the lesser sensitivity of motor neurons to the effects of the anesthetic agent. Hypoxic pulmonary vasoconstriction is unaffected by neuraxial anesthesia, and the ventilatory response to CO_2 is unimpaired; indeed, the CO_2 response may be heightened. Despite the ostensibly favorable effects of neuraxial anesthesia on respiratory mechanics and respiratory drive, a clinically significant benefit over general anesthesia has not been consistently demonstrated. Pending further studies, neuraxial anesthesia should not be viewed as clearly superior to general anesthesia in the compromised patient.

Postoperative Analgesia

Postoperative analgesia is an essential component of the care of the surgical patient. Analgesia is important not only in ensuring patient comfort, but also in mitigating the adverse effects of pain on respiratory function and airway clearance. Inadequate pain relief can lead to splinting and patient reluctance to cough and deep breathe; the end result is promotion of retained secretions, atelectasis, hypoxemia, and, possibly, pneumonia. For major surgical procedures, particularly those involving the chest and upper abdomen, administration of opiates via the parenteral or epidural route has become the analgesic method of choice. Studies comparing the effect of epidural and parenteral opiates on pulmonary function are conflicting. While most have documented the superior analgesic effect of the epidural route, this has not invariably translated into improvement in respiratory mechanics and gas exchange or a lower incidence of postoperative pulmonary complications. This suggests that factors other than pain (see below) contribute significantly to alterations in pulmonary function that accompany thoracic or abdominal surgery. Nonetheless, this should not lead to the false impression that pain control is superfluous; failure to adequately control pain will exacerbate postoperative pulmonary dysfunction.

The use of narcotic analgesia in the postoperative period is associated with a small, but not insignificant, risk of precipitating respiratory depression. The reported incidence of respiratory depression varies based on the criteria employed. A meta-analysis of published studies revealed an incidence of 0.3 percent defined by the need to administer naloxone, 3.3 percent defined by the presence of hypercapnia, and 17 percent defined by oxygen desaturation. The risk may be slightly lower in association with the epidural, as opposed to parenteral, route of administration. Elderly patients are particularly susceptible to the respiratory depressant effects of opiates, likely reflecting an impaired ability to metabolize these agents. Respiratory depression in the postoperative patient is most likely to occur during the initial 24 h following surgery. It is typically accompanied by a decreased level of consciousness and a slow respiratory rate. Treatment consists of administration of naloxone in 0.1 to 0.4 mg aliquots. Ventilation should be supported with a face mask and Ambu bag, reserving intubation for failure of naloxone to swiftly rectify the problem.

IMPACT OF SURGERY ON POSTOPERATIVE PULMONARY FUNCTION

Surgery involving the upper abdomen and thorax results in a pronounced impairment in pulmonary function in the postoperative period. The impairment is more severe and prolonged than that due to administration of general anesthesia alone. Typically, upper abdominal and thoracic procedures are associated with a fall in lung volumes, development of atelectasis, and hypoxemia. These adverse effects commonly necessitate short-term administration of low-flow, supplemental oxygen, but when severe, or when accompanied by underlying lung disease, may precipitate respiratory failure.

Upper Abdominal Surgery

Vital capacity declines by 50 percent within 24 h following upper abdominal surgery. Although the vital capacity improves with time, marked impairment persists for as long as 7 d after the surgery. In contrast, vital capacity falls by only 25 percent following lower abdominal procedures; it returns to normal by the third postoperative day. Underlying these profound changes after upper abdominal surgery is the development of diaphragmatic dysfunction, as reflected in a reduction in transdiaphragmatic pressure with tidal respirations and in a shift from abdominal to rib cage breathing.

Two main theories have been proposed to explain the observed impairment in diaphragmatic function. One theory is that there is a primary alteration in diaphragmatic contractility induced by local irritation, inflammation, surgical trauma, or pain. This theory has been rendered improbable with the demonstration that external stimulation of the phrenic nerves produces normal peak transdiaphragmatic pressure in patients recovering from upper abdominal surgery. In other words, when maximally stimulated, the diaphragm functions in a normal fashion.

The alternative, and currently favored, theory proposes that diaphragmatic dysfunction results from diminished phrenic nerve output. The basis for the attenuation in neural drive remains a matter of speculation, although several putative pathways can be rationally eliminated. For example, general anesthesia is known to depress output from the central respiratory centers, as well as to inhibit synaptic transmission. However, as noted previously, the effects of general anesthesia on diaphragmatic tone are transient and modest. Additionally, the degree of dysfunction observed after upper abdominal procedures is not seen following general anesthesia for procedures on the lower abdomen and extremities. An inhibitory arc initiated by abdominal nociceptors for pain is unlikely, given that achievement of adequate pain control by epidural opiates fails to consistently improve pulmonary function or to normalize diaphragmatic performance. In contrast, the epidural administration of anesthetic agents such as bupivacaine does ameliorate diaphragmatic dysfunction following upper abdominal surgery. Since these agents produce sympathetic blockade in addition to pain control, it has been argued that visceral sympathetic afferents are responsible for providing an inhibitory signal that downgrades central neural drive and phrenic nerve activity, thereby leading to impaired diaphragmatic function. Supporting the notion of a reflex inhibitory arc mediated by visceral afferents is the demonstration in experimental animals that mechanical gallbladder stimulation strongly inhibits electromyographic activity and motion of the diaphragm.

Cardiac Surgery

Although CABG—the most commonly performed cardiac surgical procedure—has been most intensively scrutinized with respect to its impact on the respiratory system, other related cardiac procedures (e.g., valve replacement) are likely to have similar effects. Lung volumes decrease by approximately 30 percent after CABG; their return to preoperative values may take several months. Lung function may decline to a greater degree when internal mammary harvesting and grafting are employed. Gas exchange is also impaired after CABG, as evident in the development of hypoxemia and significant widening of the alveolar-arterial oxygen gradient. In 125 patients who had daily room air arterial blood gas determinations prior to and following CABG, Pa_{O2} fell from approximately 75 mmHg preoperatively to a nadir of 55 mmHg on postoperative day 2. The Pa_{O2} improved, but remained below preoperative values, at the end of the first postoperative week. A similar pattern and magnitude of decline in oxygenation have been demonstrated in other studies, with the development of hypoxemia associated with an increase in calculated shunt fraction from 3 percent preoperatively to a peak of 19 percent postoperatively. The increase in shunt fraction is readily accounted for on the basis of atelectasis, which is invariably present postoperatively, especially on the left side.

A number of factors have been implicated in the development of post-CABG pulmonary dysfunction and atelectasis. Alterations in chest wall compliance and motion may result from division of the sternum, harvesting of the internal mammary artery, and traumatic injury to the costovertebral joints and first rib induced by retraction. Intraoperative lung retraction may directly injure the left lower lobe, leading to contusion and atelectasis, and, perhaps, accounting for the predilection for radiographic infiltrates on the left side. An alternative explanation for post-CABG left lower lobe atelectasis is intraoperative injury to the left phrenic nerve and consequent diaphragmatic paralysis or paresis. The phrenic nerve is vulnerable to stretch and ischemic injury during sternal retraction, dissection of the left internal mammary artery, or prolonged distention of the pericardium. Additionally, thermal injury to the nerve may occur with the cardioplegic technique of instilling iced slush into the open pericardial sac. The actual incidence of phrenic nerve dysfunction after CABG is best defined in studies employing electrophysiological techniques, which have documented unequivocal evidence of phrenic nerve injury in 10 percent of patients. This suggests that phrenic nerve injury accounts for only a minority of the observed cases of left lower lobe atelectasis.

Finally, cardiopulmonary bypass (CPB) may contribute to pulmonary impairment after cardiac surgery. The duration of CPB has been linked to the severity of postoperative atelectasis; whether this relationship is causal is unclear. It has been hypothesized that the use of CPB leads to abnormal surfactant production—possibly due to ischemic, thermal, or toxic injury to the alveolar epithelium—predisposing to the development of atelectasis. More clearly established is the ability of the bypass pump to induce a capillary leak syndrome, marked by extravasation of fluid into the alveolar interstitium and, rarely, into the airspaces. This process is thought to result from exposure of blood to nonendothelial surfaces, resultant activation of neutrophils, complement and other inflammatory cascades, and sequestration of neutrophils within the microvasculature. While this rarely may lead to full-blown ARDS (see discussion below), the consequences are usually more subtle, manifesting as a widened arterial-alveolar oxygen gradient and diminished lung compliance. The recent introduction of "off-pump" CABG has permitted a greater appreciation of the adverse impact of CPB on postoperative lung function. For example, a recent large, multicenter comparative analysis from the United Kingdom of CABG with or without CPB demonstrated significant reductions in the rates of prolonged mechanical ventilation (more than 24 h), reintubation or tracheostomy, and ARDS or pulmonary edema

or pneumonia among the group that underwent off-pump CABG.

Lung Resection

Unique to lung resection surgery is the immediate loss of lung function due to removal of lung parenchyma. The magnitude of the loss can be estimated reliably from preoperative quantitative lung scanning in conjunction with standard spirometry (Chapter 38). The impact of lung resection on pulmonary function is further magnified in the perioperative period by other factors. For example, the standard posterolateral thoracotomy incision represents significant chest wall trauma, with rib retraction and resection, and transection of intercostal, latissimus dorsi, trapezius, and serratus anterior muscles. As a result, total respiratory compliance may fall by as much as 75 percent; work of breathing increases; and lung volumes decline dramatically, out of proportion to the surgical loss of functional lung. Following standard thoracotomy and lung resection (either lobectomy or wedge resection), FEV_1 and FVC fall to 25 percent of preoperative values at 1 hour, and to 30 percent at 24 h. When a more limited, muscle-sparing incision is used, the impact on pulmonary function is markedly attenuated.

As with cardiac and upper abdominal surgery, atelectasis is frequently present after lung surgery and results in impaired oxygenation. Phrenic nerve activity remains normal and diaphragmatic function during tidal breathing is preserved, although maximal diaphragmatic strength may be reduced.

CAUSES OF POSTOPERATIVE RESPIRATORY FAILURE

The development of acute respiratory failure in the surgical patient should prompt a systematic assessment of the likely causes (Table 147-4). In approaching this life-threatening problem, one must consider the nature and magnitude of preexisting pulmonary disease, type of surgery performed, drugs administered intra- and postoperatively, and predominant derangement in gas exchange (i.e., hypoxemia or hypercapnia). In conjunction with important information derived from the physical examination and chest radiograph, the analysis should readily identify factors responsible for, or contributing to, respiratory failure. The following discussion focuses on the more common or unique causes of postoperative respiratory failure in the surgical setting.

Atelectasis

Atelectasis is the most common pulmonary complication encountered in the surgical patient, particularly following thoracic and upper abdominal procedures. As discussed previously, anesthesia and surgical manipulation act in concert to produce regional atelectasis through incompletely defined mechanisms, including diaphragmatic dysfunction and diminished surfactant activity. The atelectasis is typically basilar and segmental in distribution, obscuring the hemidiaphragms radiographically. A distinct and less common cause of postoperative atelectasis is plugging of central airways by retained secretions. This problem is encountered in the surgical patient whose efforts to clear secretions are compromised by depressed consciousness, inadequate pain control, or a weak, ineffective cough. When situated in a mainstem bronchus, mucus plugs can result in collapse of an entire lung; more distal obstruction leads to lobar collapse. An abrupt termination of the proximal bronchial air shadow and the absence of air bronchograms within the atelectatic portion of the lung are clues to the possible presence of mucus plugging.

While often clinically insignificant, postoperative atelectasis may lead to severe hypoxemia and respiratory distress. The magnitude of hypoxemia is dictated by the extent of atelectasis, the presence and severity of underlying lung disease, and the integrity of the hypoxemic pulmonary vasoconstrictive response. Impairment of hypoxemic pulmonary vasoconstriction by vasodilatory drugs, commonly administered to surgical patients for treatment of underlying hypertension or ischemic heart disease, prevents the compensatory diversion of blood flow away from nonventilated areas of the lung and magnifies the shunt fraction.

Respiratory distress due to atelectasis usually evolves insidiously over the first several postoperative days. Supplemental oxygen requirements increase in association with worsening basilar infiltrates noted on the chest radiograph. The clinicoradiographic picture may be indistinguishable from that of pneumonia. While fever and leukocytosis suggest infection, these signs are common and nonspecific. When atelectasis is due to central airway occlusion by mucus plugs, hypoxemia and respiratory distress may develop quickly. A chest radiograph obtained immediately after the onset of symptoms may be surprisingly unrevealing if sufficient time has

Table 147-4

Causes of Postoperative Respiratory Failure

Factors extrinsic to the lung

- Depression of central respiratory drive (anesthetics, opioids, sedatives)
- Phrenic nerve injury or diaphragmatic dysfunction
- Obstructive sleep apnea

Factors intrinsic to the lung

- Atelectasis
- Pneumonia
- Aspiration of gastric contents
- Acute lung injury (ARDS)
- Volume overload or congestive heart failure (CHF)
- Pulmonary embolism
- Bronchospasm or COPD

not passed to permit resorption of gas from the airspaces of the nonventilated lung. Careful examination of the patient, however, will reveal an absence of breath sounds over the involved lung, providing an important clue to the presence of central airway obstruction and obviating pursuit of other considerations, such as pulmonary embolism.

Treatment of respiratory failure due to atelectasis is directed toward the combined goals of adequate oxygenation and re-expansion of lung segments. Supplemental oxygen should be titrated to achieve an arterial oxyhemoglobin saturation of at least 90 percent. Refractory hypoxemia, severe respiratory distress, progressive hypercapnia, or inability of the patient to clear copious airway secretions should prompt immediate intubation and mechanical ventilatory support. This life-saving intervention permits more efficient delivery of oxygen, secures access for suctioning of the airways, and facilitates performance of bronchoscopy should it be necessary. Moreover, the positive pressure and large tidal volumes delivered by the ventilator are often effective in rapidly re-expanding collapsed lung segments. In less dire circumstances, noninvasive delivery of continuous positive airway pressure (CPAP) via a nasal or face mask may be equally effective.

Fiberoptic bronchoscopy has a limited role in the treatment of serious postoperative atelectasis; its indiscriminate use should be avoided. The immediate use of fiberoptic bronchoscopy does not result in more rapid or complete resolution of acute lobar atelectasis when compared with standard chest physiotherapy consisting of deep breathing, coughing, suctioning of the intubated patient, aerosolized bronchodilator treatments, chest percussion, and postural drainage. Resolution of atelectasis appears to be dictated not by the treatment modality employed, but by radiographic evidence of central airway patency. In this regard, both chest physiotherapy and bronchoscopy are highly effective in the absence of an air bronchogram. In contrast, the presence of an air bronchogram, which indicates that the atelectasis is not due to proximal airway obstruction, is associated with minimal response to either modality. Therefore, simple and standard respiratory therapy techniques applied to either the spontaneously or mechanically ventilated patient form the mainstay of treatment for lobar atelectasis. Fiberoptic bronchoscopy should be reserved for those situations where chest physiotherapy is contraindicated (e.g., chest trauma, immobilized patient), poorly tolerated, or unsuccessful. In these circumstances, the decision to employ bronchoscopy should be tempered by the presence of an air bronchogram.

A number of other measures are commonly employed in the treatment of atelectasis. Judicious use of analgesia is an essential adjunct, permitting the patient to breathe deeply, cough forcefully, and comfortably participate in chest physiotherapy maneuvers. Care must be taken to avoid excessive sedation which will offset the beneficial effects of pain control. In the setting of marked hypoxemia, attempts should be made to discontinue vasoactive drugs with the potential to influence the pulmonary vascular bed; examples include nitrates, nitroprusside, calcium channel blockers, angiotensin-converting enzyme inhibitors, and hydralazine. Mucolytics, such as N-acetylcysteine, are commonly administered in an effort to promote clearance of tenacious secretions; however, their efficacy in this setting has not been well documented. Some clinicians and respiratory therapists advocate the use of nasotracheal suctioning of the nonintubated patient with a weak and ineffective cough. However, this technique is associated with considerable discomfort and, in the opinion of this author, is an inefficient and highly transient means of clearing secretions from the tracheobronchial tree.

The important role of prophylactic maneuvers in reducing the incidence and magnitude of postoperative atelectasis in high-risk patients should not be overlooked. These techniques, intended to promote periodic full lung expansion, include intermittent positive pressure breathing (IPPB), cough and deep breathing exercises, and incentive spirometry. All three techniques have been shown to be equally efficacious and superior to no therapy in the prevention of postoperative pulmonary complications following abdominal surgery, although their efficacy following cardiac surgery has recently been called into question. IPPB has largely been abandoned due to its expense, need for specially trained personnel and close patient supervision, and tendency to produce abdominal distention. For maximal benefit, prophylactic measures should be taught and instituted prior to surgery and used hourly in the postoperative period. Early ambulation of the postsurgical patient has been found to be as effective as respiratory therapy maneuvers in the prevention of postoperative atelectasis and should be strongly encouraged.

Pneumonia

Pneumonia is the second most common nosocomial infection and the most lethal, with an associated mortality rate of 20 to 50 percent. Pneumonia represents a principal cause of postoperative respiratory compromise and may precipitate acute respiratory failure, as well as complicate respiratory failure in the patient who is ventilator-dependent for other reasons. In epidemiological surveys, surgery has been identified as an independent risk factor for nosocomial pneumonia. In particular, the risk is greatest following standard thoracic and upper abdominal procedures, where an incidence of 15 to 20 percent has been documented. Lung transplant recipients represent an emerging population with a similarly high risk of postoperative pneumonia. In contrast, the risk of pneumonia is only 5 percent following lower abdominal surgery, and it is even less frequently encountered following procedures remote from the chest and abdomen. Overall, the incidence of nosocomial pneumonia is up to fivefold greater among patients in surgical ICUs than among patients in medical ICUs.

Epidemiological studies have identified a number of other risk factors for nosocomial pneumonia, but these studies fail to fully distinguish those factors that are causally linked from those that are simply surrogate markers. Factors reflective of poor preoperative health, including a low serum albumin level, presence of COPD, extensive smoking history, advanced age, protracted preoperative hospital stay, and high

status according to the American Society of Anesthesiologists' (ASAs) preanesthesia classification, have been linked to an excessive risk of pneumonia. A direct relationship between duration of surgery and incidence of postoperative pneumonia has been demonstrated. Other identified risk factors include presence of a nasogastric tube, use of antacids or H_2-blockers for stress ulcer prophylaxis, immunosuppression, impaired consciousness, and witnessed aspiration. Perhaps the most important and consistently identified risk factor is the need for prolonged mechanical ventilatory support. Overall, mechanically ventilated patients have a 3- to 21-fold increased risk of pneumonia compared with nonventilated patients. Moreover, the risk of pneumonia is linked to the duration of ventilatory support, approximating 1 percent per day on the ventilator.

The microbiological profile of nosocomial pneumonia is distinctly different from that of community-acquired infection. Gram-negative aerobic bacilli of the Enterobacteriaceae family prevail, collectively accounting for approximately one-third of all infections. Other highly virulent gram-negative rods which are commonly encountered are *Pseudomonas aeruginosa* and *Acinetobacter* species. Of the gram-positive organisms, *Staphylococcus aureus* predominates, while the pneumococcus, the most common bacterial respiratory pathogen in the community setting, plays an insignificant role. Often the pneumonia is polymicrobial; studies employing bronchoscopic culture techniques or postmortem cultures of lung tissue have identified more than one organism in up to 46 percent of cases.

While organisms may reach the lower respiratory tract by several routes, microaspiration of oropharyngeal secretions appears to be the predominant mechanism in the pathogenesis of nosocomial pneumonia. A critical initiating event in this pathway is colonization of the oropharynx with gram-negative aerobic bacilli, a process that characteristically occurs in response to serious illness or surgical stress. Clinically occult aspiration of these virulent organisms is facilitated by a number of iatrogenic measures imposed upon the surgical patient. Paramount among these is the placement of an endotracheal tube, which impairs swallowing, stents open the glottis, and permit pooling of secretions above the tube cuff. The inflated cuff is an imperfect barrier and allows intermittent seepage of secretions into the lower airways. Prolonged intubation has also been associated with postextubation swallowing dysfunction. Depressed consciousness as a consequence of general anesthesia and postoperative analgesia further contributes to the risk of aspiration.

Recent attention has focused on the stomach as an additional source of bacteria in the development of nosocomial pneumonia. While the acidic milieu of the stomach normally inhibits bacterial growth, the common use of H_2-blockers and antacids as stress ulcer prophylaxes overrides this natural barrier and promotes gastric colonization with gram-negative enteric organisms. Gastroesophageal reflux, a common feature of the critically ill patient, permits bacteria-laden gastric contents to enter the respiratory tract either directly or by first colonizing the oropharynx. This route of migration has been confirmed by recovery of technetium-99m (^{99m}Tc)-labeled gastric contents in endobronchial secretions and by the demonstration in some patients that organisms cultured from the airways first appeared in the stomach. Perhaps the most compelling, albeit circumstantial, evidence derives from several studies that have shown a higher incidence of nosocomial pneumonia in patients receiving H_2-blockers or antacids compared with those given sucralfate, a drug that does not result in alkalinization of gastric pH. However, conflicting data abound, and firm conclusions about the role of gastric colonization in the pathogenesis of nosocomial pneumonia await the outcome of larger and more methodologically rigorous studies.

The fate of organisms introduced into the lower respiratory tract is dependent upon the integrity of mechanical and immunologic pulmonary defense mechanisms. Impairment of the mucociliary escalator (e.g., due to recent cigarette smoking or underlying COPD), weak and ineffective cough, and use of immunosuppressive medications (e.g., corticosteroids) favor the proliferation of organisms and the development of pneumonia. It is widely held that postoperative atelectasis predisposes to pneumonia by entrapping bacteria. However, studies demonstrating a lack of concordance between the degree of atelectasis and the subsequent risk of pneumonia challenge this contention.

The constellation of fever, leukocytosis, purulent sputum, and radiographic infiltrates has traditionally defined the presence of pneumonia. While these diagnostic criteria are reasonably accurate in the previously healthy outpatient, they are notoriously nonspecific in the setting of recent surgery, particularly with prolonged use of mechanical ventilation. In one autopsy series, traditional clinical and radiographic criteria provided the correct antemortem diagnosis in only 70 percent of cases. Alternative etiologies of radiographic infiltrates include atelectasis, pulmonary edema, infarction or hemorrhage due to pulmonary emboli, pulmonary contusion, and chemical pneumonitis. Cultures of sputum and tracheal aspirates are poorly reflective of the bacterial flora of the distal airways, since these specimens are contaminated by colonizing organisms in the oropharynx and upper respiratory tract. In an attempt to enhance diagnostic certainty, bronchoscopic sampling of the distal airways using a sterile sheathed brush or bronchoalveolar lavage has been advocated. While the absence of a "gold standard" for the diagnosis of pneumonia has complicated attempts to define the accuracy of these techniques, rates of false-positive and false-negative results have generally fallen in the range of 30 percent. It is questionable, therefore, whether the performance of bronchoscopy actually contributes significantly to a reduction in the degree of diagnostic uncertainty. These concerns, coupled with the need to perform the procedure prior to institution of antibiotics and to collect and process specimens in a fastidious and standardized fashion, have severely limited the use and acceptance of currently available bronchoscopic techniques. Despite all of the pitfalls, most clinicians continue to rely on conventional assessment strategies in establishing a diagnosis of pneumonia and in determining the need for therapy.

Empiric treatment of nosocomial pneumonia is broad in spectrum and includes effective coverage of gram-negative organisms (including *Pseudomonas*) and *S. aureus*. The initial choice of antibiotics is influenced by the particular epidemiological profile and microbiologic susceptibility patterns at a given institution; many ICUs are currently plagued by highly resistant organisms, such as *Acinetobacter* and methicillin-resistant *Staphylococcus*, which have unusual, but predictable, susceptibilities.

Preventive strategies intended to diminish the risk of pneumonia are an important consideration in the care of the surgical patient. Prevention begins in the preoperative phase with emphasis on abstinence from cigarette smoking for a minimum of 8 wk prior to elective surgery. Following surgery, nasogastric and endotracheal tubes should be removed as soon as possible. Postoperative analgesia must be titrated to permit the patient to comfortably and vigorously cough, but excessive sedation impairing protection of the airway and enhancing the risk of aspiration must be avoided.

For the high-risk, ventilator-dependent patient, maintenance of a semierect position has been shown to diminish the magnitude of clinically occult aspiration of gastric contents and the incidence of pneumonia. While the use of sucralfate has been associated with a lower incidence of gastric colonization and nosocomial pneumonia compared with agents that raise gastric pH, additional corroborating studies are required before a firm recommendation to preferentially employ sucralfate in stress ulcer prophylaxis can be made.

An emerging approach to pneumonia prevention in the high-risk patient is selective digestive decontamination (SDD), intended to prevent or diminish the magnitude of gram-negative colonization of the aerodigestive tract. Regimens have varied among studies, but they typically consist of some combination of antibiotics applied topically to the oropharynx, instilled into the stomach as a slurry, and/or administered systemically. A recent meta-analysis of prospective, randomized trials concluded that SDD reduced the incidence of pneumonia and decreased overall mortality among critically ill surgical patients. Some studies have demonstrated emergence of resistant pathogens, while others have not. Despite the proven efficacy of this approach in high-risk surgical patients, SDD is not yet widely used.

Acute Lung Injury

The hallmark of acute lung injury is the presence of noncardiogenic pulmonary edema resulting from widespread damage to the alveolar-capillary membrane. Referred to clinically as acute respiratory distress syndrome (ARDS), the syndrome is defined by the constellation of hypoxemic respiratory failure, diffuse pulmonary infiltrates, and a normal pulmonary artery occlusion pressure or absence of clinical evidence of elevated left atrial pressure. ARDS represents the end result of a variety of insults that either involve the lung directly (e.g., aspiration of gastric contents) or trigger pulmonary inflammation as part of a systemic process (e.g., sepsis). Many of the risk factors associated with development of ARDS are commonly encountered in surgical patients (Table 147-5). In decreasing order of risk, these include sepsis, massive blood transfusion, pulmonary contusion, aspiration of gastric contents, and multiple fractures. Causes of acute lung injury of particular relevance to the surgical patient, and, in some cases, unique to this population, are described in greater detail below.

Table 147-5

Incidence of ARDS by Risk Factor

Risk Factor	Incidence of ARDS
Sepsis	41%
Massive transfusions	36%
Pulmonary contusion	22%
Aspiration	22%
Multiple fractures	11%

Sourc: Data adapted from Hudson LD, et al. Clinical risks for development of the acute respiratory distress dyndrome. Am J Respir Crit Care Med *151:293–301, 1995.*

Aspiration of Gastric Contents

Aspiration of gastric contents can rapidly lead to widespread acute lung injury and is an important cause of ARDS in the surgical patient. It is the third leading cause of anesthesia-related deaths, accounting for 10 to 30 percent of fatal outcomes. Aspiration typically occurs when the mechanisms of glottic closure and cough, which normally protect the airway, are compromised. In the surgical patient, the period of maximal vulnerability for aspiration spans from the induction of general anesthesia to full return of consciousness postoperatively. A number of factors combine to enhance the risk of aspiration during this period. Most important is the blunting of consciousness that accompanies induction and administration of general anesthesia. Insufflation of air into the stomach during induction may cause gastric distention and promote vomiting. Vomiting may also be provoked by noxious stimulation of the posterior oropharynx during intubation or extubation. Reflux of gastric contents is facilitated by medication-induced relaxation of the lower esophageal sphincter, placement of the patient in a supine position, and manipulation of the bowel during abdominal procedures. At the completion of surgery, extubation is commonly performed at a time when the patient, while able to ventilate adequately, may not yet be capable of fully protecting the airway. Indeed, upper-airway reflexes remain significantly impaired for up to 2 h after recovery from anesthesia, even at a time when mental alertness has returned. Moreover, translaryngeal intubation, even

when brief, may cause residual glottic dysfunction for up to 8 hours following removal of the tube. While the risk of aspiration diminishes beyond the immediate perioperative period, it remains a concern in the patient receiving narcotic analgesia, which may not only induce vomiting, but also depress consciousness.

The risk of aspiration during the immediate perioperative period was delineated in a survey of over 215,000 general anesthetic procedures performed at the Mayo Clinic. Aspiration was defined as the presence of bilious or particulate matter in the airways or the development of a new infiltrate on the immediate postoperative chest radiograph. The overall incidence of aspiration was only 0.03 percent, but the incidence was nearly fourfold higher (0.11 percent) in the setting of emergency surgery. In addition to the use of general anesthesia, other predisposing factors were present in over one-half of the patients who aspirated. These included gastrointestinal obstruction, swallowing dysfunction, altered sensorium, previous esophageal surgery, and a recent meal. The majority of events occurred during laryngoscopy (in preparation for insertion of the endotracheal tube) and during tracheal extubation. Twenty percent of patients who aspirated required postoperative mechanical ventilation in excess of 6 h; 5 percent died as a direct result of this complication.

Acidic gastric content introduced into the airways is rapidly disseminated throughout the bronchial tree and lung parenchyma, producing an almost instantaneous chemical burn. In addition, acid aspiration triggers a more delayed inflammatory response, with release of inflammatory cytokines and recruitment of neutrophils into the lung. The result is injury to the alveolar-capillary membrane, with flooding of the interstitium and airspaces by proteinaceous edema fluid. Surfactant levels drop precipitously due to both direct acid denaturation and diminished production, leading to alveolar instability and atelectasis. The magnitude of lung injury is directly related to the pH and volume of aspirated material. Initial studies in animals suggested that a pH of less than 2.5 and a volume in excess of 0.4 ml/kg are critical threshold values for the induction of lung injury. While these values are now often quoted in the literature, their validity has been challenged by more recent studies demonstrating significant injury in association with lower volumes and higher pH. In particular, aspiration of bile is capable of inducing widespread injury even at a pH as high as 7.19. The presence of large food particles may further exacerbate the problem by causing airway obstruction and atelectasis. Notably, infection does not normally play a significant role in the initial lung injury from aspiration of acidic gastric contents, as the low pH serves to maintain relative sterility of the inoculum. However, gastric colonization with bacteria can occur in patients maintained on acid suppressive agents, those receiving enteral feeds, and those with gastroparesis or small bowel obstruction.

The diagnosis of aspiration is most firmly established in the setting of witnessed vomiting or recovery of gastric contents from the airways. More often, the diagnosis is suspected circumstantially in a patient with risk factors and a compatible clinicoradiographic picture. Massive aspiration presents in a characteristic fashion, with the development of fever, tachypnea, and diffuse crackles within several hours of the event. Wheezing is appreciated in approximately one-third of patients and may be due either to obstruction of airways by particulate matter or, more commonly, to reflex bronchospasm. Hypoxemia is universally present with massive aspiration and is sufficiently severe in the majority of patients to mandate use of mechanical ventilation. The initial presence of apnea or shock is particularly ominous and portends a high risk of subsequent death. Initial radiographic patterns vary, depending upon the volume, causticity, and distribution of the aspirated material. However, three general patterns have been described: (1) extensive bilateral consolidation resembling diffuse pulmonary edema; (2) widespread, but discrete, patchy infiltrates involving dependent areas of the lung; and (3) focal consolidation, usually localized to one or both lung bases.

The clinical course following massive aspiration is variable, but it typically diverges along one of several pathways. A minority of patients follow a fulminant course marked by refractory hypoxemia and shock that eventuates in death within several days. More commonly, patients demonstrate progressive radiographic and clinical improvement over the first several days. Although most of these patients will go on to full recovery, a subset demonstrates secondary deterioration due to the development of ARDS or nosocomial pneumonia. The overall mortality rate associated with massive aspiration is approximately 30 percent and exceeds 50 percent in those patients with initial shock or apnea, secondary pneumonia, or ARDS.

Treatment of respiratory failure secondary to aspiration is supportive and includes mechanical ventilatory strategies generic to other forms of ARDS (detailed below). Bronchoscopy is indicated only when large-airway obstruction by particulate matter is suspected on the basis of a localized wheeze or lobar atelectasis. Because acid is disseminated and endogenously neutralized within seconds, large-volume bronchoalveolar lavage is ineffective in attenuating the degree of injury and is not recommended. Studies of the administration of systemic corticosteroids in the treatment of aspiration pneumonitis have been inconclusive and do not currently justify their use. Similarly, use of prophylactic antibiotics is generally discouraged in the absence of supportive data and because of fear that this practice will preferentially select more highly resistant organisms. Some authors do advocate use of empiric antibiotics for that subset of patients at risk for gastric colonization with bacteria, as described above. Additionally, up to 40 percent of patients will develop a superimposed bacterial pneumonia within several days of the aspiration event, often heralded by a new fever, new or progressive infiltrates, and purulent sputum. Broad-spectrum antibiotic therapy is indicated at that time.

The high morbidity and mortality associated with aspiration and the lack of effective therapy once the event has occurred have focused attention on measures to prevent this complication. The most straightforward and widely used measure is the convention of overnight fasting prior to

elective surgery. However, despite prolonged fasting, up to one-third of patients will maintain a gastric volume in excess of 0.4 ml/kg (approximately 25 to 30 ml in the average adult), and up to three-fourths will have a gastric pH below 2.5. Administration of H_2-blockers and proton-pump inhibitors can effectively raise the pH and reduce the volume of gastric contents, suggesting a potentially appealing strategy. Currently, prophylactic administration of antisecretory agents is recommended only for patients deemed to be at increased risk for aspiration. Unfortunately, there is generally insufficient time to allow these agents to act in the setting of emergency surgery, where the risk of aspiration is highest. In high-risk patients, rapid sequence induction of anesthesia should be employed to shorten the time between loss of consciousness and tracheal intubation. During induction, manual pressure should be applied to the cricoid cartilage (Sellick maneuver) and maintained until the endotracheal tube is in proper position and the cuff is inflated. Postoperatively, extubation should be performed only when consciousness and the gag reflex have returned to a level sufficient to permit adequate protection of the airway.

Postpneumonectomy Pulmonary Edema

Over the past 25 years, a number of published reports have documented the rapid development of pulmonary edema in the remaining lung of some patients following pneumonectomy. Initially attributed to overzealous fluid administration in the operating room, it has since been demonstrated that this complication occurs in the face of a normal pulmonary artery occlusion pressure. In addition, the edema fluid is protein-rich, arguing that the driving force behind edema formation is increased vascular permeability, rather than increased hydrostatic pressure. Postmortem studies confirm the universal presence of pathological features of acute lung injury. The exact mechanism responsible for lung injury after pneumonectomy remains obscure. One theory suggests that mechanical stress due to single lung ventilation in the operating room may cause ultrastructural damage to the alveolar epithelium, while diversion of the entire cardiac output through this remaining lung may similarly cause endothelial injury. Other factors that may contribute to edema formation include surgical trauma and disruption of lymphatic drainage.

In a study employing stringent criteria for excluding patients with congestive heart failure (CHF) or known risk factors for ARDS, the incidence of postpneumonectomy pulmonary edema was 2.6 percent. Other studies employing variable criteria have documented an incidence of 1 to 7 percent. For unclear reasons, the complication is encountered more frequently following right pneumonectomy. The observed mortality rate associated with postpneumonectomy pulmonary edema is in the range of 50 to 100 percent.

Cardiopulmonary Bypass

ARDS has been documented to develop immediately following use of cardiopulmonary bypass in approximately 1 percent of cases. While factors unrelated to the use of CPB may be at play, there is compelling evidence from both animal models and clinical studies to suggest that CPB activates a number of inflammatory mechanisms that could lead to acute lung injury. It is well established, for example, that CPB results in neutrophil activation, likely through mechanical sheer stress and exposure to the artificial surfaces of the bypass circuit. Additionally, an increased expression of cell surface adhesion molecules has been demonstrated, which may promote neutrophil binding to pulmonary endothelium and release of proteolytic enzymes and reactive oxygen species. The central role played by neutrophils in causing acute lung injury following CPB is supported by several lines of evidence: (1) bronchoalveolar lavage fluid from patients undergoing CPB contains an increased number of neutrophils; (2) plasma levels of neutrophil elastase and myeloperoxidase are increased; and (3) inhibition of neutrophil activation with pentoxifylline as well as neutrophil depletion attenuate the degree of pulmonary dysfunction. A number of other inflammatory mediators are released in association with CPB, including complement, proinflammatory cytokines, and prostaglandins.

Post-CPB ARDS is frequently accompanied by evidence of a systemic inflammatory response including fever, leukocytosis, and multi-organ system failure. Mortality associated with this complication is in the range of 60 to 90 percent.

Amiodarone

Amiodarone-induced pulmonary toxicity usually presents as a subacute illness characterized by cough, dyspnea, fever, and patchy pulmonary infiltrates. Less commonly, use of amiodarone has been linked to the development of ARDS immediately following cardiac and thoracic surgery. In most of the reported cardiac cases, amiodarone was administered preoperatively for varying periods of time for control of arrhythmias. The majority of patients had no evidence prior to surgery of the more indolent form of amiodarone pulmonary toxicity. More recently, development of ARDS has been described in patients whose only exposure to amiodarone occurred in the postoperative period, when the drug was initiated as prophylaxis or treatment for atrial arrhythmias following lung resection. In one report, postoperative ARDS developed in 11 percent of patients receiving amiodarone and in only 1.8 percent of untreated patients. The specific perioperative factors that act in concert with amiodarone to produce acute lung injury remain to be defined. Some authors have suggested that exposure to high levels of supplemental oxygen may be a contributing factor. The diagnosis rests on exclusion of other causes, rather than on specific diagnostic tests or histology.

Transfusion-Related Acute Lung Injury

The transfusion of blood and blood products has been linked to the development of ARDS in two ways. Epidemiologically, an association between massive blood transfusion (greater than 15 U/24 h) and ARDS has been noted, but it remains

unclear whether this link is truly causal or is indirect and reflective only of the critically ill nature of the patient requiring such massive transfusion support. More clearly defined mechanistically is the induction of acute lung injury by leukoagglutinating antibodies, a process that has been termed "transfusion-related acute lung injury" (TRALI). These antibodies are typically contained in blood products derived from multiparous female donors, whose exposure to foreign human leukocyte antigen (HLA) or granulocyte antigens occurred during prior pregnancies. When transfused into a recipient with these same antigens, these antibodies result in leukoagglutination and activation of recipient granulocytes or monocytes within the pulmonary microvasculature, triggering increased capillary permeability and development of noncardiogenic pulmonary edema. Less commonly, TRALI can be caused by the interaction between leukoagglutinating antibodies from the recipient and donor-derived leukocytes. TRALI has rarely been associated with infusion of biologically active mediators derived from breakdown of the cellular component of stored blood products.

The true incidence of TRALI is difficult to determine since this entity is underrecognized and frequently misdiagnosed. One study involving 36 cases over a 2-year period documented an incidence of 0.02 percent per unit and 0.16 percent per patient transfused. Most cases were detected in surgical patients in the immediate postoperative period, a fact that likely reflects the frequent need for transfusions in this setting and the close monitoring of cardiopulmonary function in the postanesthesia recovery area.

Mild episodes of TRALI may present as dyspnea and fever. More severe cases are characterized by the abrupt onset of respiratory distress, hypoxemia, and diffuse pulmonary infiltrates within 2 to 4 h of transfusion. Accompanying features include fever, chills, and hypotension; urticaria is present in a minority of patients. Respiratory distress and hypoxemia are of sufficient magnitude to require mechanical ventilatory support in most patients. The differential diagnosis includes volume overload, CHF myocardial infarction, and aspiration. The reaction tends to be self-limited and is typically characterized by rapid clearing of infiltrates and improved oxygenation within several days. However, a more protracted course of greater than 1 wk can be seen in approximately 20 percent of patients; a mortality rate of 5 to 10 percent has been reported.

When TRALI is suspected, the blood bank should be notified and all units that have been transfused should be assayed for the presence of leukoagglutinating antibodies. Any blood product containing plasma or plasma proteins is capable of inducing this reaction. Indeed, packed red blood cells, which contain only 60 to 100 ml of plasma, are one of the more common culprits.

Ischemia-Reperfusion Injury

The restoration of blood flow to previously ischemic tissue may, paradoxically, worsen tissue injury. This ischemia-reperfusion effect involves a "two-hit" mechanism. Tissue ischemia leads to formation of xanthine oxidase and its substrate, hypoxanthine, while reperfusion supplies molecular oxygen that fuels the reaction to produce oxygen free radicals injurious to cells. Neutrophils recruited to the site of ischemia-reperfusion serve as an additional source of oxygen free radicals, as well as proteolytic enzymes. Within the lung, ischemia-reperfusion produces diffuse injury to the alveolar epithelium and resultant noncardiogenic pulmonary edema. This mechanism underlies the development of acute lung injury in two important clinical settings: lung transplantation (Chapter 101) and pulmonary thromboendarterectomy.

Noncardiogenic pulmonary edema is a nearly universal feature of the freshly implanted lung allograft, but it is usually mild and self-limited. In approximately 10 percent of cases, however, the allograft is severely injured, with widespread and persistent alveolar edema causing profound hypoxemia and low pulmonary compliance, necessitating mechanical ventilatory support beyond the immediate posttransplant period. This entity, termed *primary graft dysfunction*, is nonimmunologic in nature and is believed to represent a severe form of ischemia-reperfusion injury. Primary graft failure occurs despite acceptable ischemic times below the perceived safe threshold of 6 h. Injury is manifest exclusively in the allograft, sparing the native lung in cases of single lung transplantation. The presence of unilateral lung injury may create difficulties in postoperative ventilator management. This is particularly true in the presence of underlying COPD, when positive-pressure breaths and PEEP are preferentially applied to the highly compliant emphysematous lung, leading to progressive hyperinflation, mediastinal shift, and potentially catastrophic impairment in gas exchange and hemodynamics. This situation can be effectively addressed with insertion of a double-lumen endotracheal tube, enabling use of independent lung ventilation and selective application of PEEP to the edematous allograft, while ventilating the native lung using low-airway pressures and a prolonged expiratory phase to minimize hyperinflation.

Pulmonary thromboendarterectomy is an established surgical technique for definitive treatment of chronic thromboembolic pulmonary hypertension (Chapter 82). Although operative mortality has decreased dramatically to less than 10 percent, reperfusion pulmonary edema remains a common postoperative complication. It is most often encountered within the initial 24 h after surgery, but its onset may occasionally be delayed for up to 72 h. A striking characteristic is the radiographic restriction of edema to those lung zones supplied by previously obstructed vessels. Exacerbating the degree of shunt and hypoxemia associated with this complication is the redistribution of blood from previously well-perfused segments to newly endarterectomized vessels supplying edematous areas of lung—a phenomenon referred to as "pulmonary artery steal." Fortunately, the degree of reperfusion edema and attendant hypoxemia is mild in the majority of cases. In approximately 10 percent of cases, however, the presence of severe hypoxemia necessitates prolonged mechanical ventilatory support with high levels of oxygen and application of PEEP.

Treatment and Outcome

Detailed discussion of the management of ARDS is beyond the scope of this chapter but is covered elsewhere in this text (Chapter 145) and in recent reviews. However, several fundamental aspects of care should be underscored. First and foremost, clinical management remains supportive; specific therapies aimed at ameliorating lung injury or accelerating healing are presently lacking. Care largely centers on use of mechanical ventilation, adjusted to maintain adequate gas exchange, while minimizing potentially harmful effects of high concentrations of oxygen, high tidal volumes, and high-airway pressures, all of which can induce further acute lung injury. To this end, efforts should be made to reduce the F_{IO_2} to 0.6 or less, accepting an arterial saturation in excess of 90 percent and using PEEP to recruit atelectatic areas of the lung and improve oxygenation. A "low stretch" ventilatory pattern should be employed, using tidal volumes of less than or equal to 6 ml/kg and limiting maximum plateau airway pressures to less than or equal to 30 cm H_2O. This ventilatory strategy, to which clinicians should strictly adhere, has been shown to decrease mortality associated with ARDS.

Inhaled nitric oxide preferentially vasodilates vessels supplying well-ventilated areas of the lung and has been shown to reduce shunt fraction and improve oxygenation in patients with severe ARDS. Unfortunately, these beneficial effects are typically short-lived, and multiple phase III clinical trials have failed to show a meaningful impact on duration of mechanical ventilation or mortality. Similarly, placing patients in the prone position can improve oxygenation but has not, to date, been shown to impact survival.

Sedatives should be administered to maintain patient comfort and promote synchronous breathing with the ventilator. Paralysis of the patient is occasionally required in the acute situation of life-threatening hypoxemia or hypercapnia, but prolonged use of neuromuscular blocking agents is discouraged because of the risk of a debilitating myopathy.

Despite aggressive support, the overall mortality from ARDS approximates 30 percent. The mortality rate is significantly higher in the elderly and in those with concurrent failure of other organ systems. On the other hand, patients with acute lung injury due to TRALI tend to have a more favorable prognosis.

Phrenic Nerve Injury and Diaphragmatic Dysfunction

Phrenic nerve injury is a well-described complication of CABG. In the past, this complication arose chiefly from the use of iced saline slush placed in the pericardium for topical cooling of the heart. Thermal injury causes both demyelination and axonal degeneration of the nerve, with slowing of conduction and impaired activation of the diaphragm. The use of topical cooling techniques has fallen out of favor largely because of this potential complication. However, the phrenic nerves can also be injured by traction, ischemia, use of diathermy, or transection during sternal retraction and harvesting of the internal mammary arteries. Unilateral phrenic nerve injury, typically involving the left phrenic nerve, has been reported in up to 10 percent of patients undergoing CABG. Bilateral phrenic nerve injury was reported to occur in 1 to 3 percent of cases in the era of widespread topical cardioplegia usage but is now a rare event. Phrenic nerve injury is not restricted to CABG; it is also seen in association with other cardiac procedures, thoracic surgery, neck surgery, and liver transplantation.

Although typically inconsequential in the otherwise healthy patient, unilateral diaphragmatic paralysis can lead to significant respiratory compromise in patients with underlying chronic lung disease or those who are otherwise marginal. In patients with COPD, for example, the duration of postoperative mechanical ventilation and the rate of reintubation are higher for those with than those without unilateral phrenic nerve injury following CABG. Bilateral diaphragmatic paralysis results in marked impairment in pulmonary function and frequently leads to respiratory failure. In the proper setting, phrenic nerve injury should be suspected when attempts to wean a postoperative patient from mechanical ventilation result in progressive hypercapnia or atelectasis. The spontaneously breathing patient will often complain of orthopnea, which may be misinterpreted by the unsuspecting clinician as indicative of CHF. However, orthopnea is actually due to further impairment in diaphragmatic function resulting from loss of gravitational assistance in the supine position. The detection of inspiratory thoracoabdominal paradox—an inward movement of the abdominal wall with simultaneous expansion of the thorax—is an important bedside clue to the presence of bilateral diaphragmatic paralysis and is best evoked in the supine position. The chest radiograph may also hold important clues, demonstrating either unilateral or bilateral elevation of the diaphragms and accompanying basilar atelectasis. However, these findings are not specific for phrenic nerve injury and may also be due to splinting or abdominal distention. A reduced maximum inspiratory pressure recorded at the mouth is another sensitive but nonspecific indication of significant diaphragmatic dysfunction.

Unilateral diaphragmatic paralysis can be readily diagnosed by fluoroscopic inspection, which reveals paradoxical upward movement of the affected hemidiaphragm with a maximal inspiratory effort ("sniff"). The situation is more problematic with bilateral diaphragmatic dysfunction. In this setting, patients often assume an altered breathing pattern marked by active contraction of the abdominal muscles during expiration, forcing the flaccid hemidiaphragms upward. With subsequent inspiration, the abdominal muscles relax and the hemidiaphragms descend briefly, potentially creating the false impression that they are functional. Because of this, fluoroscopy may not be confirmatory in these patients.

The "gold standard" for confirmation of phrenic nerve injury is electrophysiological testing, although even this methodology is occasionally flawed. The phrenic nerve is stimulated transcutaneously in the neck, and the diaphragmatic electromyogram (EMG) is recorded by surface

electrodes placed in the seventh intercostal space at the costochondral junction. Demonstration of a prolonged latency between nerve stimulation and diaphragmatic action potential confirms a diagnosis of demyelinating injury. It is more difficult to interpret the significance of diminished amplitude or complete absence of the surface recording of the diaphragmatic EMG. This finding could represent either phrenic nerve injury or transection or failure to properly localize the diaphragm, which is typically shifted caudally in the postoperative patient and, therefore, away from the surface electrodes. Direct puncture of the diaphragm with a recording electrode may be employed to clarify this issue, but the technique requires a high level of expertise and carries a risk of pneumothorax.

Nontraumatic causes of phrenic nerve injury and diaphragmatic dysfunction can also lead to prolonged respiratory failure and delayed weaning in the surgical patient. Phrenic neuropathy can be a component of a more generalized polyneuropathy of critical illness, commonly encountered in the wake of an episode of severe sepsis or systemic inflammatory response syndrome. A critical illness myopathy affecting the diaphragms and other muscles of respiration can be encountered under the same circumstances. Finally, diaphragmatic dysfunction can arise as a component of a myopathy induced by the concurrent use of high-dose systemic corticosteroids and neuromuscular blocking agents.

Patients with diaphragmatic dysfunction are generally well-suited for noninvasive positive pressure ventilatory support if they are awake and able to effectively handle respiratory secretions. Tracheostomy is indicated for patients with ineffective cough and those who cannot be weaned from conventional mechanical ventilation. The prognosis for patients with thermal or traction injury of the phrenic nerve is favorable; recovery is typically complete, but often protracted. In symptomatic patients with unilateral diaphragmatic paralysis due to transection of the phrenic nerve, surgical plication of the flaccid hemidiaphragm usually results in improved pulmonary function and can lead to successful liberation from mechanical ventilation.

Pulmonary Embolism

An increased risk of pulmonary embolism (PE) accompanies a number of surgical procedures, including upper abdominal, neurosurgical, cardiac, major urological, and lower extremity orthopedic procedures. Other, nonsurgical risk factors that predispose the patient to PE may also be present, including obesity, immobility, and underlying malignancy.

While alterations in gas exchange typify pulmonary embolism, frank hypoxemic respiratory failure is relatively uncommon and suggests massive clot burden. Lesser degrees of clot burden may produce equally devastating physiological impairment in patients with underlying pulmonary disease. In the presence of severe hypoxemia, there is little remaining cardiopulmonary reserve. Failure to establish a correct diagnosis and to swiftly and appropriately intervene can prove lethal.

Unfortunately, little information pointing specifically to a diagnosis of PE is easily gleaned at the bedside. The patient is often dyspneic, and tachypnea and tachycardia are observed on physical examination. However, these features are common in many postoperative patients because of pain and atelectasis. More informative, but infrequently detected, is evidence of acute cor pulmonale (e.g., distended neck veins, a parasternal heave, right-sided third heart sound, and accentuation of the pulmonic component of the second heart sound). An electrocardiogram may also demonstrate evidence of right heart strain, with an "S1Q3T3" pattern or new right bundle branch block. The chest radiograph is most suggestive of PE when it is normal in the face of severe hypoxemia. When abnormal, the greatest use of the chest radiograph is in identifying other causes of hypoxemia, such as pneumonia, pneumothorax, or ARDS. Echocardiography is commonly performed in the setting of hypotension; evidence of a dilated right ventricle in the face of a normal or underfilled left ventricle should raise suspicion for massive PE.

The choice of diagnostic studies is dictated by the urgency of the situation. In the setting of life-threatening hypoxemia or hemodynamic instability, pulmonary angiography provides the most definitive and expeditious means of establishing the diagnosis. Pulmonary angiography also permits the immediate placement of an inferior vena cava filter or performance of catheter embolectomy or thrombus fragmentation, as needed. In more stable patients, CT angiography is emerging as the imaging procedure of choice. Until its performance characteristics in the ICU patient population are better defined, however, a negative CT angiogram in the setting of high clinical suspicion should not necessarily be viewed as definitively excluding PE.

While anticoagulation with heparin forms the mainstay of therapy for the otherwise stable patient, the presence of life-threatening hypoxemia and/or hemodynamic instability should prompt consideration of alternative or additional interventions. Since additional clot burden could be fatal, insertion of an inferior vena cava filter is generally advised in this setting. Certainly this intervention is mandatory when anticoagulation is contraindicated. Thrombolytic therapy should also be considered in the critically ill patient, but its use in the postoperative period is limited by the risk of precipitating bleeding at the site of recent surgery. This risk appears to fall to an acceptable level beyond the seventh postoperative day; the exception is intracranial surgery, which contraindicates use of lytic agents for at least 2 months. Several interventional radiologic techniques—thrombus fragmentation, suction embolectomy, and intraembolic infusion of low-dose thrombolytics—as well as surgical embolectomy are alternative considerations in the deteriorating patient for whom systemic thrombolytics are either contraindicated or unsuccessful.

Obstructive Sleep Apnea

Obstructive sleep apnea (OSA) is a common disorder affecting 2 to 4 percent of the adult population. It is characterized by

repetitive upper-airway obstruction during sleep, resulting in periodic arterial desaturation, hypercapnia, and arrhythmias. Because of alterations in oropharyngeal anatomy that commonly accompany obesity and OSA, orotracheal intubation at the time of induction may be difficult. The immediate postoperative period is a particularly precarious time for patients with this disorder, as the use of volatile anesthetics, opioids, and sedatives diminish the activity of the upper-airway musculature and increase the frequency and duration of obstructive apneas. Failure to recognize and appropriately support patients with OSA in the perioperative period can lead to serious complications, including respiratory arrest, hypoxemia, confusion, and ventricular arrhythmias. Institution of nasal continuous positive airway pressure immediately after extubation permits safe administration of analgesic and sedative agents, without undue risk of precipitating life-threatening airway obstruction. It is estimated that as many as 80 percent of patients with OSA are undiagnosed; a high index of suspicion, therefore, is required in the surgical patient to intervene appropriately when upper-airway obstruction is anticipated or observed.

USE OF NONINVASIVE POSITIVE PRESSURE VENTILATION

For patients with respiratory failure refractory to conservative measures, endotracheal intubation is the standard means to facilitate mechanical ventilatory support. However, in recent years, a greater appreciation for the untoward effects of endotracheal intubation has emerged. In addition to airway trauma, these include an increased risk of nosocomial pneumonia and sinusitis and the frequent need for heavy sedation that, while addressing patient discomfort, often prolongs the process of weaning and extubation. The desire to avoid endotracheal intubation has prompted interest in the use of noninvasive positive pressure ventilation (NIPPV), employing a tight-fitting nasal or full-face mask as the interface between patient and ventilator.

There is ample evidence supporting the benefits of NIPPV in the treatment of a variety of causes of respiratory failure in the medical patient, but only recently have data emerged confirming its safety and efficacy in the postoperative setting. The most compelling study randomized patients with hypoxic respiratory failure following lung resection surgery to standard therapy (supplemental oxygen, bronchodilators, chest physiotherapy) with or without NIPPV. Compared to the control group, the use of NIPPV was associated with a marked reduction in the need for endotracheal intubation (20.8 percent versus 50 percent) and in mortality at 3 months (12.5 percent versus 37.5 percent). While there has been concern about using NIPPV following esophageal or gastric surgery, recent experience suggests that this can be accomplished safely. In this setting, care must be taken to avoid gastric distention, using a nasogastric tube for decompression if necessary, and the magnitude of positive pressure ventilation employed should be limited to less than 12 cm H_2O. Since NIPPV often requires a period of acclimation, it should not be used in unstable patients. Other contraindications to its use include depressed or agitated mental status, inability to protect the airway, and compromised airway clearance due to copious secretions or weak cough.

CHAPTER

Pump Failure: The Pathogenesis of Hypercapnic Respiratory Failure in Patients with Lung and Chest Wall Disease

Steven G. Kelsen • Nathaniel Marchetti

The ventilatory pump accomplishes bulk transfer of air to and from the alveoli. Accordingly, diseases that perturb the mechanical properties of any component of the ventilatory pump (i.e., the bony rib cage, the extra- and intrathoracic conducting airways, and the respiratory muscles) may interfere with CO_2 elimination and O_2 uptake. If disturbances in the function of the ventilatory pump are sufficiently severe, alveolar hypoventilation and respiratory acidosis may ensue.

Hypercapnic respiratory failure is defined as a steady-state Pa_{CO_2} while awake at more than 45 mmHg, the upper limit of normal. This definition is somewhat arbitrary but has proved clinically useful.

Conceptually, diseases that cause hypercapnic respiratory failure do so by deranging respiratory mechanics and lung dead-space volume (e.g., chronic obstructive pulmonary disease [COPD], asthma, or kyphoscoliosis) or by impairing the contractile properties of the respiratory muscles (e.g., neuromuscular disease). Diseases that impair respiratory mechanics increase the elastic or resistive load against which the respiratory muscles must contract. On the other hand, neuromuscular diseases impair the strength or endurance properties of the respiratory muscles and impair their ability to generate swings in intrathoracic pressure sufficient to maintain ventilation.

A variety of compensatory neural mechanisms that sense alterations in blood gas tensions or ventilatory performance elicit increases in the neuromuscular drive to breathe—which, in turn, helps preserve alveolar ventilation. In fact, in most patients, rather marked abnormalities in ventilatory pump performance are required before hypercapnic respiratory failure ensues. Conceptually, the susceptibility to develop CO_2 retention in the setting of lung, chest wall, or respiratory muscle dysfunction, therefore, depends on the balance between the severity of the derangement in ventilatory pump function and the intensity of the respiratory neuromuscular drive to breathe.

This chapter deals with the pathogenic mechanisms at work in the development of CO_2 retention in lung and chest wall diseases. The compensatory/adaptive mechanisms that help preserve ventilation (e.g., respiratory chemosensitivity, motor responses to alterations in the mechanics of breathing, and intrinsic changes in respiratory muscle strength and endurance) and the decompensating/maladaptive responses that predispose to CO_2 retention (e.g., respiratory muscle wasting and fatigue and a rapid, shallow pattern of breathing) will be discussed.

COMPENSATORY/ADAPTIVE MECHANISMS

Respiratory Chemosensitivity

Overview—Regulation of Ventilation

Hypoxia and hypercapnia stimulate chemoreceptors in the arterial circulation (peripheral chemoreceptors) and ventrolateral medulla (central chemoreceptors) that reflexively increase motor activity to the respiratory skeletal muscles of the chest wall and upper airway. Contraction of the muscles of the chest wall (e.g., diaphragm, intercostals, abdominals, and neck muscles) deforms the ventilatory pump and moves air. Contraction of the muscles of the upper airway (genioglossus, alae nasae, posterior arytenoids, pharyngeal dilators, sternohyoid, etc.) increases the caliber of the upper airway and diminishes its susceptibility to collapse during inspiration.

Chemoreceptor-induced increases in inspiratory and expiratory muscle activity are proportional to the severity of abnormalities in blood gas tensions and represent a feedback control loop that restores blood gas tensions toward normal by enhancing alveolar ventilation. The magnitude of the swings in intrathoracic pressure and resistance and compliance of the upper airway are determined by these changes in respiratory motor activity. The maintenance of blood gas tensions within a relatively narrow, normal range from neonatal life to senescence attests to the power of this homeostatic mechanism.

Hypoxic and hypercapnic chemical drives to breathe exert the following stereotypic effects on the activity of chest wall and upper-airway muscles. Peak respiratory muscle electrical activity and its rate of rise are increased. For the inspiratory muscles, these changes in muscle electrical activity increase the rate of change and peak inspiratory intrathoracic pressure, inspiratory airflow, and tidal volume. For the expiratory muscles, increased electrical activity enhances the rate of expiratory airflow. For the upper-airway muscles, the resistance to inspiratory airflow decreases.

Chemosensitivity-induced increases in respiratory activity also affect the timing of respiratory motor activity as reflected in the duration of inspiration (T_I) and expiration (T_E). Hypoxia and hypercapnia lead to decreased T_I and T_E, allowing the frequency of breathing to increase. Reductions in T_E are generally out of proportion to T_I, thereby increasing the fraction of the respiratory cycle spent in inspiration. This partitioning of the respiratory cycle is reflected in the T_I/T_T ratio, where T_T is the total breath cycle duration (i.e., the sum of T_I and T_E).

Hypoxia and hypercapnia differ in their effects on the activity of the inspiratory muscles after the cessation of inspiratory airflow, the so-called postinspiratory inspiratory activity (PIIA). Hypoxia increases PIIA in both chest wall inspiratory muscles and muscles that constrict the laryngeal aperture. Accordingly, hypoxia has a braking effect on the rate of expiratory airflow. As T_E decreases with increasing hypoxic drive, end-expiratory lung volume increases. PIIA-induced increases in lung volume increase the caliber of the intrathoracic airways and the O_2 content of the lung. Hypoxia-induced PIIA affects the load on the respiratory muscles in complex fashion; that is, PIIA reduces inspiratory resistive work of breathing but increases the inspiratory elastic and expiratory resistive work of breathing. It has been suggested, however, that the net effect of hypoxia-induced PIIA is a reduction in overall energy expenditure during breathing. In contrast, hypercapnia diminishes the duration of PIIA.

Indices of Respiratory Motor Output

Ventilation is a well-accepted index of respiratory motor output. Traditionally, ventilation was viewed as the product of tidal volume (V_T) and respiratory rate (which is equal to $60/T_T$). More recently, ventilation has been viewed as the product of separate "drive" and "timing" components. The

average rate of inspiratory airflow, V_T/T_I—which reflects the rate of rise of inspiratory muscle activity and intrathoracic pressure—is increased when blood gas tensions are deranged. Accordingly, V_T/T_I has been taken as a reflection of the activity of mechanisms that regulate the drive to breathe. Of note, V_T/T_I may also be increased by excitatory inputs arising from respiratory mechanoreceptor afferents (e.g., vagal irritant receptors) and higher central nervous system (CNS) structures engaged in thermoregulation and emotion (i.e., hypothalamic and limbic areas). Conversely, the T_I/T_T ratio has been taken as a reflection of the activity of mechanisms that regulate respiratory timing. The T_I/T_T ratio is strongly affected by afferent input from mechanoreceptors in the lungs, airways, and respiratory muscles, as well as increasing chemical drive. For example, T_I/T_T increases in anesthetized animals when vagal stretch receptors are stimulated by increases in lung volume and is decreased by bronchoconstriction-induced activation of vagal irritant receptors.

In subjects with normal lung function, V_T/T_I and ventilation are accurate reflections of inspiratory muscle electrical activity and the rate of rise of intrathoracic pressure. On the other hand, diseases that adversely affect the mechanical properties of the ventilatory pump (e.g., obstructive lung disease, kyphoscoliosis) interfere with the translation of changes in intrathoracic pressure into ventilation and airflow. Conversely, conditions that impair respiratory muscle contractility (e.g., neuromuscular diseases, respiratory muscle fatigue) interfere with the translation of inspiratory muscle electrical activity into intrathoracic pressure changes. Accordingly, V_T/T_I reflects the intensity of motor outflow to the inspiratory muscles produced by increasing chemical drive only when the mechanical properties of the ventilatory pump and inspiratory muscle strength are normal. When the ventilatory pump function is abnormal, respiratory motor outflow is best assessed from respiratory muscle electrical activity (i.e., diaphragm electromyography [EMG] activity), a complicated measurement largely confined to the research laboratory.

A simpler, clinically useful measurement that reflects the neuromuscular drive to breathe and the driving pressure to inspiratory airflow is the airway occlusion pressure. The occlusion pressure is the pressure generated at the airway opening 100 ms after the onset of an occluded inspiratory effort (i.e., P_{100} or $P_{0.1}$) initiated at end-expiratory lung volume. Since the airway is occluded, the inspiratory muscles contract quasi-isometrically, a condition in which muscle force correlates closely with muscle electrical activity. Measurements are made early in inspiration (100 ms) to prevent behavioral responses elicited in response to airway occlusion from altering the shape/trajectory of the pressure waveform. The lack of flow or volume change during the measurement means that the occlusion pressure is unaffected by abnormalities in the flow-resistive or compliance properties of the ventilatory pump. The occlusion pressure, therefore, has been used to assess the drive to breathe in patients with lung diseases (e.g., COPD and asthma) and chest wall diseases (e.g., kyphoscoliosis) during resting and chemically stimulated breathing. On the other hand, the occlusion pressure depends on the ability of the inspiratory muscles to convert neural activity into force and pressure. Accordingly, like ventilation, occlusion pressure may not reflect respiratory motor-neuron activity when the inspiratory muscles are weak (e.g., neuromuscular disease) or fatigued.

Hypoxic Response

Under isocapnic conditions, ventilation (or occlusion pressure) increases in curvilinear fashion as P_{O_2} falls. However, hypoxic responses depend importantly on the prevailing level of Pa_{CO_2} (i.e., the O_2–CO_2 interaction). When Pa_{CO_2} is in the hypocapnic range, arterial P_{O_2} must fall considerably (to approximately 55 to 60 mmHg or less) before respiratory activity increases. Hypercapnia profoundly increases the response to hypoxia by shifting the threshold of the response toward higher levels of P_{O_2} and augmenting the change in ventilation elicited for a given reduction in P_{O_2}.

Although the physiological stimulus for the hypoxic response is the Pa_{O_2} of the blood perfusing the peripheral chemoreceptors, for convenience the oxyhemoglobin saturation assessed with a pulse oximeter has been taken as a reflection of the stimulus. Use of the oxyhemoglobin saturation linearizes the relationship between the hypoxic stimulus, ventilation, and occlusion pressure. The intensity of the hypoxic response has been assessed from the slope of the change in ventilation (or occlusion pressure) relative to the change in O_2 saturation (i.e., $\Delta V_E/\Delta$ % O_2 sat) and from the intercept of the relationship (e.g., ventilation at O_2 saturation of 85 percent).

Hypercapnic Response

In contrast to the response to hypoxia, the ventilatory and occlusion pressure responses to hypercapnia under iso-oxic conditions are linear over a relatively wide range of Pa_{CO_2} above and below the resting level of 40 mmHg. The intensity of the ventilatory and occlusion pressure response to CO_2 has been assessed from the slope of the relationship of V_E to Pa_{CO_2} (i.e., $\Delta V_E/\Delta Pa_{CO_2}$) and from the intercept of the relationship (i.e., V_E at Pa_{CO_2} 50 mmHg).

The ventilatory response to hypercapnia is strongly affected by the prevailing level of Pa_{O_2} and is heightened as Pa_{O_2} decreases. In fact, hypoxemic and hypercapnic stimuli interact multiplicatively to enhance inspiratory and expiratory motor activity. Worsening hypoxemia enhances the ventilatory response to hypercapnia in accordance with the O_2–CO_2 interaction. The strength of a subject's chemosensitivity to O_2 and CO_2 and, in particular, to the O_2–CO_2 interaction is a powerful feedback mechanism opposing the tendency to retain CO_2 in patients with ventilatory pump dysfunction.

Consequently, treatment of the hypercapnic, hypoxemic patient with supplemental O_2 may decrease V_T/T_I and T_I/T_T and, hence, worsen hypercapnia in accordance with O_2–CO_2 interaction. Increases in Pa_{O_2} in hypoxic, hypercapnic subjects move the O_2 response to the right (less stimulus)

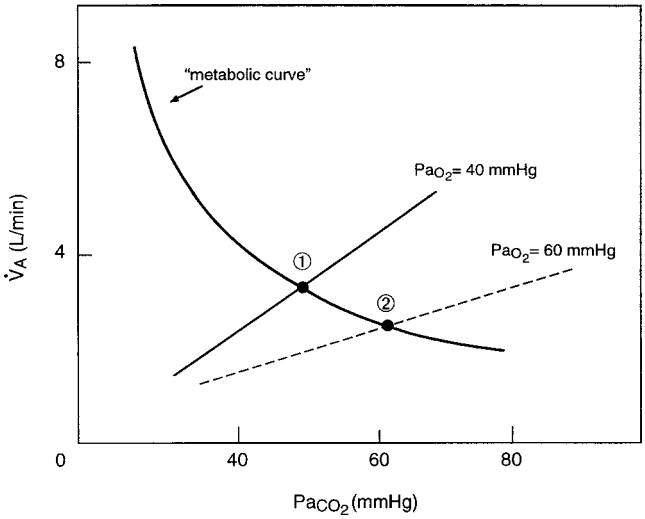

Figure 148-1 Theoretical effects of supplemental O_2 on the ventilatory response to CO_2 and steady-state arterial P_{CO_2} in subjects with COPD in hypercapnic respiratory failure. Increasing Pa_{O_2} decreases alveolar ventilation and increases Pa_{CO_2} as dictated by effects of O_2 on the CO_2 ventilatory response. The two straight lines represent hypercapnic ventilatory response curves at Pa_{O_2} of 40 and 60 mmHg. As may be seen, increasing Pa_{O_2} produces a downward, rightward shift of the ventilatory response. In contrast, the hyperbolic line intersecting the ventilatory response lines is the metabolic CO_2–ventilation curve, which represents the effect of increasing alveolar ventilation (independent variable) on Pa_{CO_2} (the dependent variable) when CO_2 production is normal (~200 ml/min). Steady-state alveolar ventilation and Pa_{CO_2} at rest are dictated by intersection of the ventilatory response curves with the metabolic curve (points 1 and 2). Note the increase in Pa_{CO_2} as the ventilatory response with Pa_{O_2} 60 mmHg intersects at a lower alveolar ventilation and higher Pa_{CO_2} (point 2) compared to the higher ventilatory response when Pa_{O_2} was 40 mmHg (point 1).

and decrease the slope and shift the intercept of the ventilatory response to *hypercapnia* to the right (Fig. 148-1). Shifts in the CO_2 response with increases in the prevailing Pa_{O_2} mean that a higher CO_2 stimulus is required to maintain ventilation at the baseline level. Accordingly, ventilation falls and Pa_{CO_2} rises. The magnitude of the rise in Pa_{CO_2} in patients with COPD in acute respiratory failure produced by supplemental O_2 varies widely among subjects as determined by their chemosensitivity.

Of note, hypercapnia induced by supplemental O_2 in patients with COPD is multifactorial and reflects increases in lung dead-space volume as well as reductions in alveolar ventilation. Hypoxemia causes bronchoconstriction via increases in parasympathetic outflow to airway smooth muscle. Accordingly, relief of hypoxemia causes bronchodilation and increased dead-space volume.

Role of Blunted Chemosensitivity in Development of Respiratory Failure

Chemosensitivities to hypoxemia and hypercapnia are hereditofamilial and ethnic traits that vary widely interindividually

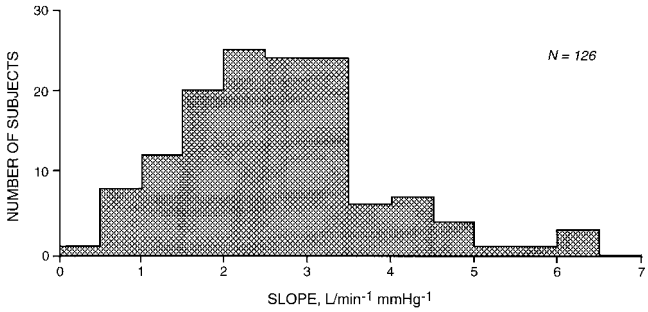

Figure 148-2 Variability of the slopes of the ventilatory responses to progressive hypercapnia (i.e., V_E/P_{CO_2}) in a normal population. Shown is the frequency distribution histogram of the slopes in 126 normal South African medical students. Note the considerable interindividual variation in CO_2 responsiveness. In some healthy subjects, the ventilatory response is blunted to less than 1 L/min/mmHg P_{CO_2}. *(Based on data from Irsigler GB: Carbon dioxide response lines in young adults: The limits of the normal response. Am Rev Respir Dis 114:529–536, 1976, with permission.)*

(Fig. 148-2). In a given subject, responses to hypoxemia and hypercapnia correlate weakly, so that subjects with strong responses to hypercapnia also tend to have strong responses to hypoxia. Respiratory chemosensitivity to both hypoxemia and hypercapnia declines with age. The decline in chemosensitivity with aging may explain why elderly subjects with lung disease (e.g., COPD) or chest wall disease (e.g., kyphoscoliosis) develop hypercapnic respiratory failure more frequently than young adults. When chemosensitivity is low, subjects with diseases of the ventilatory pump are predisposed to develop hypercapnic respiratory failure.

In patients with advanced COPD, the severity of airway obstruction required to cause CO_2 retention varies widely from subject to subject (Fig. 148-3). Subjects with the greatest respiratory effort responses to changes in Pa_{CO_2}—as measured by diaphragm EMG, respiratory work of breathing, or occlusion pressure—have arterial Pa_{CO_2} values closer to normal than subjects with blunted responses to CO_2 but the same severity of lung dysfunction. Accordingly, when chemosensitivity is low, subjects with diseases of the ventilatory pump are predisposed to develop hypercapnic respiratory failure. However, since CO_2 retention per se may blunt the response to acute hypercapnia, studies in patients in respiratory failure have not been able to determine whether blunted CO_2 responses are a cause or consequence of respiratory failure.

The tendency for chemosensitivity to be inherited has been used in a number of subsequent studies to assess the role of hypoxic and hypercapnic responses in the pathogenesis of CO_2 retention in the setting of obstructive lung disease. Study of relatives with normal lung function and blood gases has been employed to circumvent the effects of CO_2 retention on respiratory chemosensitivity in patients with COPD.

In general, normal relatives of hypercapnic patients with COPD have lower ventilatory responses to hypoxia and hypercapnia than relatives of eucapnic patients with COPD

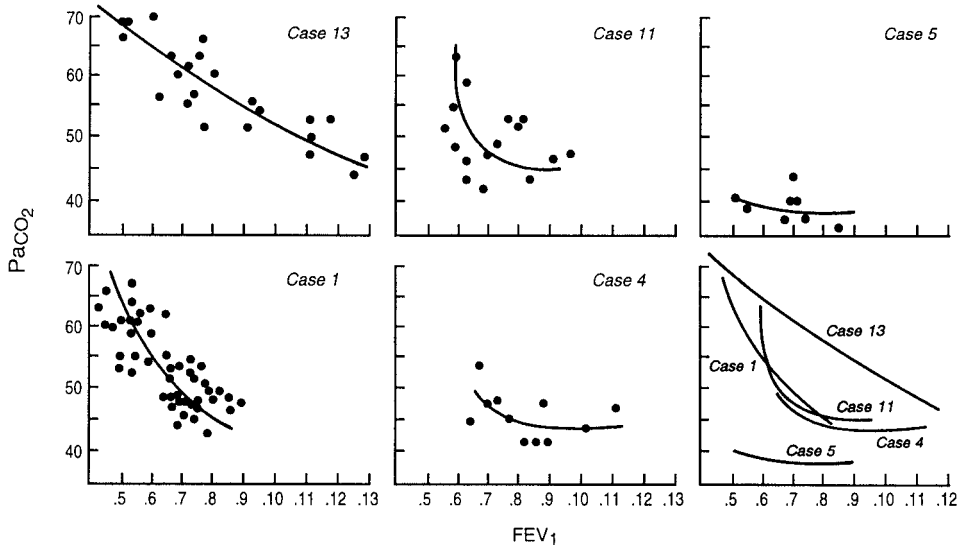

Figure 148-3 Results of repeated measurements of arterial P_{CO_2} and FEV_1 (liters) in five patients with advanced COPD. Free-hand curves of the data are shown plotted together in the lower right graph. Note that cases 1, 11, and 13 show marked increases in P_{CO_2}, with relatively small changes in FEV_1, whereas cases 4 and 5 do not. *(Based on data from Lane DJ, Howell JBL, Giblin B: Relation between airways obstruction and CO_2 tension in obstructive airways disease. Br Med J 3:707–709, 1968, with permission.)*

(Fig. 148-4). Among the offspring of patients with COPD with equally severe airway obstruction, the slopes of the ventilatory responses to isocapnic hypoxemia and hyperoxic hypercapnia are 30 to 40 percent lower in the offspring of hypercapnic patients than in offspring of eucapnic patients. Similarly, the slopes of the ventilatory and airway occlusion pressure responses to isocapnic hypoxia in the offspring of hypercapnic patients are approximately 40 percent of the values obtained in the offspring of normocapnic patients. In one study, the Pa_{O_2} of COPD patients while in a stable state and the Pa_{O_2} and Pa_{CO_2} during COPD exacerbations correlated with the

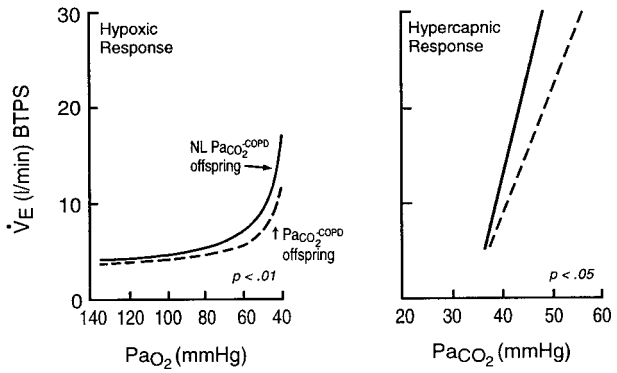

Figure 148-4 Mean isocapnic hypoxia and hyperoxic hypercapnic ventilatory response curves of 12 offspring of hypoventilating patients with COPD (solid line) and 10 offspring of eucapnic COPD patients (dashed line). Ventilatory responses to hypoxia and hypercapnia are significantly lower in the offspring of hypercapnic COPD than in the offspring of eucapnic COPD patients. *(Based on data from Mountain R, Zwillich CW, Weil JV: Hypoventilation in obstructive lung disease: The role of familial factors. N Engl J Med 297:521–525, 1978, with permission.)*

hypoxic ventilatory response of their sons. It appears that blunted chemosensitivities to hypoxia and hypercapnia are likely to be premorbid characteristics of hypercapnic patients with COPD, which contribute to the development of respiratory failure.

A number of reports describe patients with asthma and respiratory failure who had blunted ventilatory responses to hypoxia and hypercapnia and whose healthy immediate family members also showed blunted hypoxic and hypercapnic responses. Respiratory responses to hypoxia and hypercapnia in patients with asthma who have near-fatal attacks differ from those of asthmatics who did not have near-fatal attacks and age-matched, normal subjects. The slopes of the ventilatory and occlusion pressure responses to hypoxia in the patients with a history of near-fatal asthma are approximately 33 percent of the responses of the asthmatics without near-fatal attacks or normals, which are similar. Hypercapnic responses tend to be lower in the near-fatal asthmatic groups than in the other two groups, but the differences are smaller in magnitude.

Responses to Heightened Respiratory Load

A complex array of mechano- and proprioceptors whose afferents project to respiratory neurons in the brain stem and higher CNS structures provides the respiratory controller with information about the mechanics of breathing and performance of the ventilatory pump. The sensory receptors providing this afferent feedback and the CNS structures that integrate this feedback into a coordinated respiratory response (see below) are not perfectly understood. However, mechanoreceptors in the intercostal muscles that sense muscle tension and length (Golgi tendon receptors and spindle

organs, respectively) and pressure and flow sensors in the lower (vagal irritant receptors) and upper airway (larynx and mouth) clearly play a role in shaping the neuromuscular response to alterations in the mechanics of breathing.

Diseases of the airways (COPD and asthma) or chest wall (kyphoscoliosis) change the resistance and compliance properties of the ventilatory pump and, hence, stimulate mechanoreceptors in the ventilatory pump. In normal subjects and those with COPD, mechanoreceptor afferent inputs increase inspiratory neuromuscular output as reflected in airway occlusion pressure in response to bronchoconstriction or external resistances or elastance. Changes in ventilation during acute increases in airway resistance are inversely related to changes in occlusion pressure. Thus, the magnitude of the motor response to increases in respiratory load determines the ventilatory response.

External ventilatory loads that can be consciously detected and alter the intensity of the sensations associated with breathing elicit increases in respiratory effort as reflected by the diaphragm EMG and occlusion pressure. Increases in effort occur abruptly within the first loaded breath and in feedforward fashion; that is, the experience of the previous breath elicits a response in anticipation that the load will still be present. These responses are eliminated by general anesthesia and dulled if not absent in stages III and IV and REM sleep. The afferent input to the CNS elicited by external ventilatory loads probably arises from spindle and tendon organs in the respiratory muscles that project to the sensorimotor cortex and medullary respiratory neurons. The motor response to external ventilatory loads is thought to be behavioral.

The magnitude of the respiratory motor response to external loads varies widely from subject to subject and may be a hereditofamilial trait. Of considerable importance, some subjects with COPD demonstrate lesser occlusion pressure responses to acutely applied external resistive loads than age-matched normal subjects. It has been suggested that the blunted respiratory motor response to external loads may be a form of sensory adaptation to chronic increases in respiratory resistance. The fact that occlusion pressure responses of patients with COPD to external elastic loads and patients with asthma to external resistive loads are normal supports this concept. Of interest, the blunted motor response to external loads in some patients with COPD may reflect an increase in endogenous opiates within the CNS, since naloxone administration immediately enhances the response.

In subjects with COPD, bronchoconstriction increases airway occlusion pressure in proportion to increases in airway resistance and to a greater extent than with external flow-resistive loads. Bronchoconstriction increases the activity of vagal "irritant" receptors in the airway, which exert an inspiratory augmenting effect on breathing. Irritant receptors may also be excited chemically by inflammatory mediators (e.g., histamine, prostaglandin $F_{2\alpha}$) and, in contrast to external loads, elicit simple monosynaptic reflexes not abolished by sleep or anesthesia.

Mechanoreceptor inputs modify the respiratory motor responses to chemical stimuli to breathing. Increases in the elastic or resistive load to inspiration augment inspiratory muscle electrical activity and the airway occlusion pressures to hypoxia and hypercapnia. Subjects with asthma show heightened occlusion pressure responses to hypoxia and hypercapnia for this reason. Increases in the inspiratory neuromuscular drive to breathe allow ventilation to be maintained in the face of abnormalities in respiratory mechanics. Respiratory motor activity (i.e., occlusion pressure) also tends to be increased when the respiratory muscles are weak. In all likelihood, this reflects the fact that the maintenance of force output by a weakened muscle requires an increase in activation by the CNS.

Increased ventilatory loads also alter the pattern of breathing in load-dependent fashion. Subjects breathing against resistive loads breathe slowly and deeply, with an increase in tidal volume and prolongation of T_I and T_E. In contrast, subjects breathing against elastic loads tend to breathe with smaller tidal volumes and a reduced T_I and T_E; that is, they demonstrate a rapid and shallow pattern of breathing. Slow, deep breathing during resistive loading and rapid, shallow breathing during elastic loading diminish the resistive and elastic work of breathing, respectively. Alterations in breathing pattern when the mechanics of breathing are deranged are believed to be attempts to minimize the work of breathing, muscle tension, or energy expended.

Integrated Motor Responses

Respiratory motor responses to heightened chemical or mechanoreceptor drives to breathe elicit highly coordinated patterns of muscle activity that optimize the mechanical output of the respiratory musculature contracting in concert. These responses may take the following forms: (1) simple reflex-mediated recruitment of additional agonists, which exert similar mechanical effects on the chest wall; (2) sequential activation of inspiratory and expiratory muscles, which exert opposing effects on chest wall structures; and (3) complex behavioral acts that use nonrespiratory muscles to effect changes in body posture and expiratory airflow, minimizing dyspnea.

For example, hypercapnia and hypoxia recruit the external intercostal and parasternal muscles during inspiration in a stereotypic rostral-to-caudal direction, and the internal intercostals and triangularis sterni during expiration in the opposite direction. Preferential activation of the inspiratory external intercostal and parasternal muscles in the rostral-most interspaces decreases the impedance of the rib cage to rostral movement and, hence, facilitates thoracic expansion. Conversely, recruitment of the expiratory internal intercostals and triangularis sterni in the most caudal interspaces decreases the impedance to caudal movement and facilitates thoracic deflation. In addition, recruitment of the parasternal intercostal muscles facilitates inspiratory pressure as tidal volume increases. The parasternal intercostal muscle fiber length, which is optimum for tension development, is shorter than that of the diaphragm and occurs at higher lung volume. Accordingly, the parasternal muscles become mechanically more effective than the diaphragm as lung volume increases above functional residual capacity (FRC).

Moreover, hypercapnia and hypoxia increase phasic and tonic inspiratory activity in the dilator muscles of the upper airway (e.g., posterior arytenoid, alae nasae, genioglossus). Increases in activity of the dilator muscles of the upper airway decrease the load on the chest wall pumping muscles by decreasing the resistance to inspiratory airflow through the upper airway. Increased activity of these muscles also diminishes the susceptibility of the upper airway to collapse as inspiratory efforts become greater and subpharyngeal pressure becomes more subatmospheric.

In addition, phasic increases in abdominal expiratory muscle electrical activity during expiratory airflow accelerate lung emptying, thereby allowing the time of expiration to decrease. When sufficiently intense, activation of the abdominal muscles reduces end-expiratory lung volume and improves the ability of the diaphragm to generate pressure by favorably affecting its precontraction length, radius of curvature, and alignment with the rib cage. Reductions in end-expiratory lung volume achieved by the expiratory muscles also allow elastic work to be stored in the passive recoil of the chest wall and released suddenly at the onset of inspiration. Sudden release of the recoil pressure of the chest wall thereby "assists" the inspiratory muscles by contributing to the driving pressure to inspiratory airflow. A portion of the inspiratory load is thus assumed by the expiratory muscles.

Finally, hyperinflated, dyspneic patients with COPD often assume a stereotypic body posture that improves diaphragm, neck accessory, and pectoral girdle muscle mechanical advantage. This posture is forward flexion of the trunk, extension of the head and neck, bracing of the pectoral girdle by rounding of the shoulders, and grasping of the thighs with the arms. The effect of this posture is to increase abdominal pressure (thus increasing diaphragm precontraction length and radius of curvature); provide more favorable alignment of the scalenes and sternomastoid with the upper rib cage; and anchor the pectoral girdle muscles, allowing them to apply an inspiratory action on the rib cage. In this posture, transdiaphragmatic pressure is increased and diaphragm and sternomastoid muscle EMG activity is decreased. Patients with advanced COPD also spontaneously adopt pursed-lip breathing to slow expiratory airflow, thus minimizing dynamic airway compression.

Effects of Sleep

Responses to chemical stimuli to breathing are powerfully influenced by CNS state (e.g., sleep vs. waking). Slow-wave and REM sleep depress O_2 and CO_2 chemosensitivity, with greatest depression occurring in REM sleep. While the subject is awake, apnea does not occur in the presence of even marked hypocapnia, and ventilation is largely independent of changes in P_{CO_2}. Rather, ventilation persists even when Pa_{CO_2} is less than about 30 to 35 mmHg. Persistence of ventilation in the setting of hypocapnia (the so-called wakefulness drive to breathe) probably represents the effects on medullary neurons of inputs activated by auditory, visual, and tactile stimuli. In contrast, in the sleeping or anesthetized state, the ventilatory response to CO_2 extrapolates to zero ventilation in the hypocapnic range. In fact, apnea occurs when P_{CO_2} falls only 4 to 6 mmHg below waking eucapnic levels. Sleep-related changes in chemosensitivity, therefore, underlie the recurrent periods of apnea and hyperpnea and exaggerated hypercapnia that occur in some patients with diseases of the lung and chest wall.

The increase in respiratory motor activity induced by derangements in respiratory mechanics is also state-dependent; that is, heightened activity in awake subjects is absent in sleeping or anesthetized subjects. REM sleep, in particular, impairs the "load" response and causes collapse of the upper rib cage during inspiration, which adversely affects the level of ventilation as well as its distribution. Descending inhibitory drives to spinal α– and spindle γ– motor neurons in REM sleep cause atonia of all the respiratory muscles except the diaphragm. Muscle spindle γ-efferent activity determines spindle sensitivity by progressively contracting the intrafusal fiber. Accordingly, reductions in muscle spindle γ-efferent activity diminish spindle organ sensitivity and interfere with a mechanism for augmenting respiratory muscle spinal α– motor neuron activity. The diminished or absent load response during sleep and anesthesia probably explains the exaggerated increases in Pa_{CO_2} that occur during these periods in patients with lung and chest wall disease. In fact, REM sleep is the period in which Pa_{CO_2} is highest and Pa_{O_2} lowest in patients with stable COPD (Fig. 148-5).

Changes in Respiratory Structure

Respiratory Muscles

The respiratory muscles are highly plastic and undergo changes in structure, biochemistry, and contractile properties in response to chronic increases in load or changes in precontraction length. Chronic increases in inspiratory muscle activity enhance their strength and endurance. In animal models, chronic increases in inspiratory load produced by emphysema or inspiratory resistive loading increase diaphragm endurance and the content of oxidant enzymes (e.g., succinic dehydrogenase and citrate synthase) essential for high-energy phosphate synthesis. In patients with chronic asthma, inspiratory and expiratory muscle endurance assessed from the time course of the fall in maximum static pressure is about 40 percent greater than in normal controls. The effect of COPD per se on inspiratory muscle endurance has not been assessed. In subjects with COPD, however, daily training with inspiratory resistive ventilatory loads increases inspiratory muscle strength by about 40 percent as reflected by maximum static inspiratory pressure ($P_{I_{max}}$) over an 8- to 10-week period.

Hyperinflation impairs the force- and pressure-generating ability of the inspiratory muscles by decreasing muscle precontraction length and unfavorably changing muscle alignment with the chest wall. In particular, severe hyperinflation alters diaphragm shape (i.e., flattening) and decreases the zone of apposition with the rib cage. Flattening of the diaphragm displaces the vector of contraction force from a rostral-caudal direction to a medial-lateral direction and diminishes the ability of the diaphragm to increase abdominal

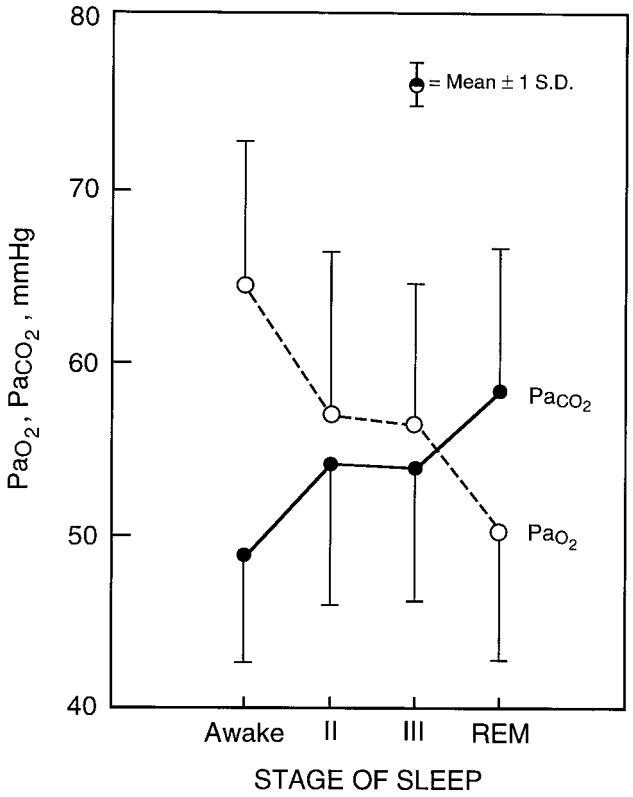

Figure 148-5 Changes in steady-state arterial P_{CO_2} during sleep in eight patients with stable COPD. Note that arterial P_{CO_2} increases and arterial P_{O_2} decreases during sleep. Greatest changes occur during REM sleep. For Pa_{CO_2}, average increase is 10 mmHg. *(Based on data from Koo KW, Sax DS, Snider GL: Arterial blood gases and pH during sleep in chronic obstructive pulmonary disease. Am J Med 58:663–670, 1975, with permission.)*

pressure. Reductions in the zone of apposition diminish the inflationary effects on the lower rib cage produced by increases in abdominal pressure induced by the diaphragm. In extreme cases of hyperinflation, the diaphragm may exert an expiratory action on the lower rib cage and retract the lower rib cage on inspiration (Hoover's sign).

In part, hyperinflation-induced impairment in the action of the diaphragm is compensated for by adaptive changes in the intrinsic muscle length–tension characteristic. In emphysematous animals, the active and passive length–tension curve of the costal diaphragm is displaced toward shorter lengths, thereby allowing maximum tension to be developed at significantly shorter lengths and higher lung volumes (Fig. 148-6). The shift in the length–tension curve appears to be the reverse of normal growth, in which muscle length is increased by addition of sarcomeres in series. A similar adaptation in the diaphragm seems to occur in chronically hyperinflated, stable outpatients with COPD.

Chest Wall Anatomy

Chronic hyperinflation elicits adaptive changes in the pressure-volume (P-V) characteristic of the passive chest wall. In animal models of emphysema, the static deflation, chest

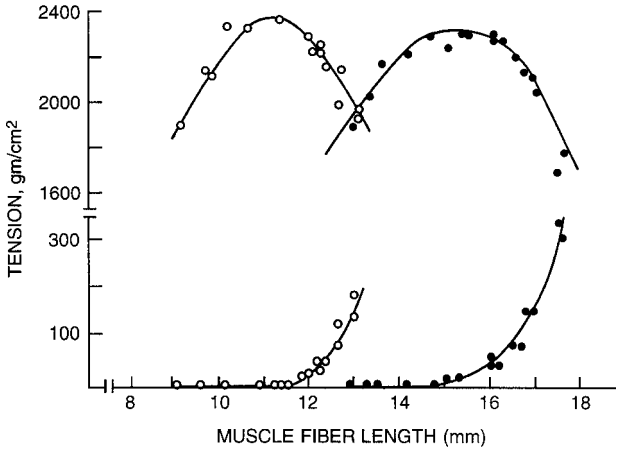

Figure 148-6 Active (upper trace) and passive (lower trace) length-tension (L-T) relationship of costal diaphragm of emphysematous (open circles) and normal hamsters (solid circles), assessed in vitro during electrical stimulation. Note that in emphysematous animals, the L-T curve is displaced toward shorter fiber lengths. This adaptive change in emphysematous animals allows the diaphragm to generate maximal tension (force) at shorter fiber lengths and helps preserve diaphragm contractile performance in the face of considerable hyperinflation. *(From Supinski GS, Kelsen SG: Effect of elastase-induced emphysema on the force-generating ability of the diaphragm. J Clin Invest 70:978–988, 1982, with permission.)*

wall P-V curve is shifted up and to the left, so there is a decrease in elastic recoil at any given lung volume. Shifts in the passive P-V curve are accomplished by a structural remodeling of the rigid structures in the chest wall. The length of the sternum and the lengths of the ribs in anteroposterior and transverse dimensions are increased. This displacement of the chest wall P-V curve diminishes the inspiratory elastic work of breathing during hyperinflation and preserves the zone of apposition of the diaphragm. An increase in the zone of apposition of the diaphragm in hyperinflation preserves the appositional force exerted by the diaphragm on the lower rib cage by virtue of changes in abdominal pressure. If present in patients with COPD, the process is reversible, since recent observations of the thorax after volume reduction surgery or lung transplantation for COPD indicate that the shape of the chest wall can quickly revert to normal.

DECOMPENSATING/MALADAPTIVE RESPONSES

Respiratory Muscle Fatigue

Overview/Definition

Studies in the laboratory and in the clinic indicate that the respiratory skeletal muscles, like muscles in the limbs, fatigue under conditions of intense activity, leading to respiratory failure. Conditions that increase the level of phasic inspiratory muscle activity, or the duty cycle of breathing, or that decrease the maximal pressure-generating capacity of

the muscle, make fatigue more likely. For example, derangements in the mechanical properties of the lung or chest wall or increases in ventilatory drive increase inspiratory muscle contractile activity. Of note, increases in ventilatory drive increase both the peak inspiratory pressure and T_I/T_T ratio, the latter by causing greater reductions in the duration of expiration than in that of inspiration.

Decreases in inspiratory muscle strength caused by aging, protein-calorie malnutrition, or electrolyte imbalances predispose to fatigue at any given level of inspiratory impedance or ventilation by decreasing $P_{I_{max}}$. Finally, on the basis of data from animal models, reductions in diaphragm blood flow are likely to decrease the level of muscle activity that leads to fatigue.

Respiratory muscle fatigue has been defined as a loss in muscle capacity to develop force or shorten, resulting from muscle fiber activity under load; it is reversible by rest. In contrast, respiratory muscle weakness has been defined as impairment in the capacity of a fully rested muscle to generate force.

Fatigue is viewed as developing when the muscle is highly active and generating appreciable levels of force. Recovery from fatigue is generally observed over a short time (e.g., minutes to hours). On the other hand, muscle weakness is commonly caused by muscle fiber atrophy, metabolic derangements that impair the ability of actomyosin cross-bridges to generate force (e.g., acidosis or electrolyte abnormalities that affect intracellular calcium flux), or chronic reductions in muscle precontraction length that impose a mechanical disadvantage (e.g., hyperinflation of the thorax and its effects on the inspiratory muscles). Implied in the definition of weakness is the idea that alterations in muscle function are secondary to alterations in muscle structure or lung volume and hence induce changes in muscle function that are more slowly reversible than fatigue (e.g., days to weeks). In the clinical setting, however, the distinction between muscle weakness and fatigue is difficult and not easily accomplished. Moreover, a close association exists between respiratory muscle weakness and respiratory muscle fatigue. In fact, weak muscles are predisposed to fatigue (see below).

Fatigue produces complex effects on muscle mechanical output. Fatigue prolongs contraction and relaxation time and depresses the force generated at a given stimulus frequency and fiber length, and reduces the velocity of shortening against a given load.

Depending on the cause of the fatigue, depression of force output can occur at primarily subtetanizing frequencies of muscle stimulation (e.g., less than 15 to 20 Hz), a condition called low-frequency fatigue, or at frequencies above 50 Hz, a condition called high-frequency fatigue (Table 148-1, Fig. 148-7). The biochemical and biophysical processes that underlie low-frequency and high-frequency fatigue differ. Muscle force responses to tetanizing frequencies of stimulation (i.e., above 50 Hz) are primarily determined by the processes of neuromuscular transmission and muscle excitation. In contrast, muscle mechanical output at subtetanizing frequencies is determined primarily by the processes of excitation-contraction coupling (e.g., calcium release from the sarcoplasmic reticulum, calcium-troponin interactions), perhaps caused, in part, by O_2 free radical–induced injury.

Table 148-1

Classification of Respiratory Muscle Fatigue

Central
Refers to decreases in phrenic motor output mediated by spinal or supraspinal mechanisms
Peripheral
Refers to fatigue occurring at the level of the muscle itself
Transmission
Failure of mechanisms operative in muscle excitation ("high-frequency" fatigue)
Contractile
Failure of mechanisms involved in excitation-contraction coupling or contractile protein function ("low-frequency" fatigue)

Of interest, recovery from high-frequency fatigue is more rapid (minutes) than recovery from low-frequency fatigue (hours) (Fig. 148-8). Moreover, the two forms of fatigue have different physiological consequences. High-frequency fatigue impairs muscle force output under conditions in which the muscle is maximally driven by the CNS (i.e., when muscle strength is being evaluated). Low-frequency fatigue, on the other hand, impairs force generation during resting breathing, when phrenic motor unit discharge rates are typically about 15 Hz. Since low- and high-frequency fatigue reflect impairments occurring at the level of the muscle, they have been termed *peripheral fatigue.*

Performance of strenuous ventilatory tasks may also elicit an additional, qualitatively different response—i.e., a reduction in central motor output and failure of the CNS to fully activate the respiratory muscles. That is, the diaphragm EMG or phrenic neurogram may decrease late in the performance of strenuous respiratory efforts before the point of exhaustion. This reduction in motor activity may limit task performance. The failure of CNS mechanisms to fully activate the muscle near the point of exhaustion has been termed *central fatigue.* The mechanisms underlying central fatigue are poorly understood. It is not clear whether central fatigue represents a behavioral response elicited by the unpleasant sensations present during ventilatory loading or is mediated reflexively or by changes in brain neurotransmitter levels.

Detection of Respiratory Muscle Fatigue

Diaphragm muscle fatigue has been diagnosed in humans from changes in the response of the muscle to electrical stimulation (i.e., the force-frequency relationship), the power

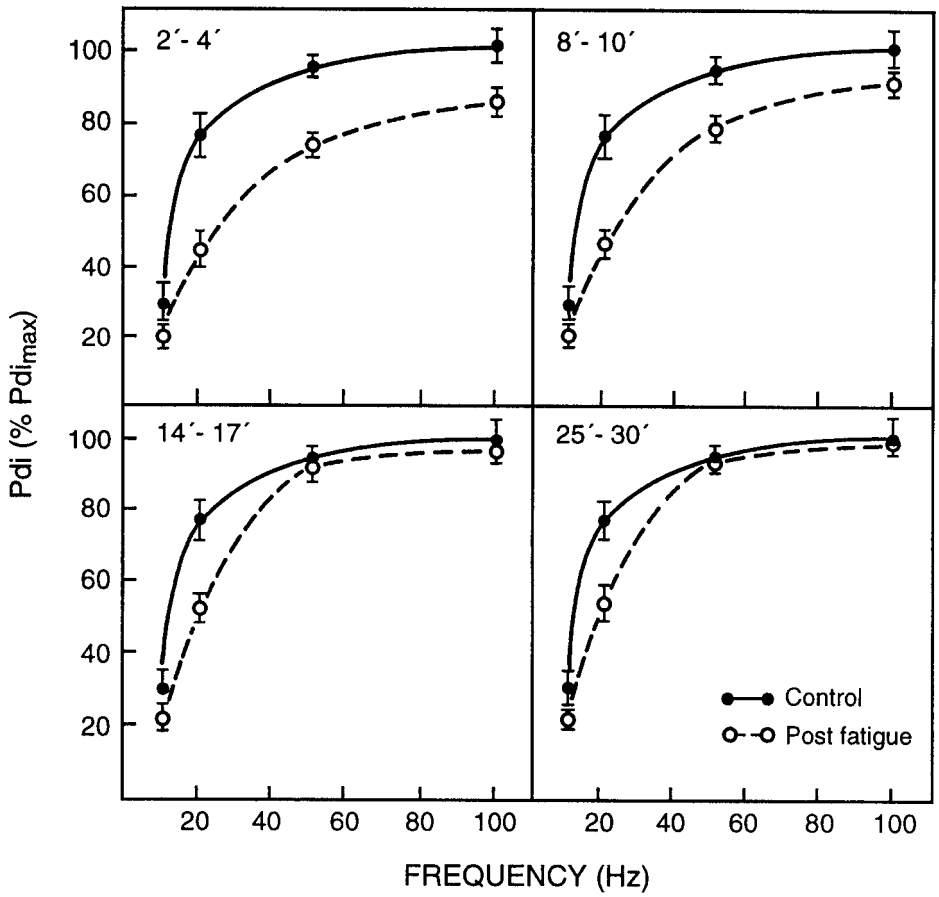

Figure 148-7 Force-frequency relationship of the human diaphragm during electrophrenic stimulation showing rate of recovery from high- and low-frequency fatigue. Data obtained in four subjects before and after a period of inspiratory resistive loading to exhaustion. At the point of exhaustion, the subject was unable to generate targeted values of transdiaphragmatic pressure (Pdi). Note the decrease in Pdi in response to low (20 Hz) and high (50 Hz) electrical stimulation immediately after loading, indicating the presence of both high- and low-frequency fatigue. Note also that high-frequency fatigue disappears within 14 to 17 min. In contrast, low-frequency fatigue persists beyond the period of observation (>30 min). *(Based on data from Aubier M, Farkas A, De Troyer RT, et al: Detection of diaphragmatic fatigue in man by phrenic stimulation. J Appl Physiol 50:538–544, 1981, with permission.)*

spectral content of the EMG, and $P_{I_{max}}$. As will be seen, the force-frequency relationship and EMG power spectrum analyses are complex and require sophisticated electronics and instrumentation. Consequently, their use has been confined to the research laboratory. On the other hand, $P_{I_{max}}$ is convenient and easily performed at the bedside but suffers from relative nonspecificity.

Electrical Stimulation

The force-frequency relationship represents a way of assessing muscle mechanical output over a wide range of stimulus intensities. Since fatigue shifts the force-frequency curve downward (and possibly to the left), the magnitude of the shift in the force-frequency relationship can be used to assess the severity of low- and high-frequency fatigue and the time course of recovery.

Electrical stimulation of the muscle of interest has several advantages. It allows the muscle to be activated in response to a standard stimulus without the cooperation of the subject. Hence, neurological deficits, decreased effort, and central fatigue, which may diminish muscle activation, are circumvented and peripheral fatigue can be detected.

EMG Power Spectrum

Fatigue alters the power-EMG spectral content of the raw EMG of the respiratory muscles analyzed by fast Fourier transform (Fig. 148-8). In the fresh diaphragm, the power (or voltage) contained in the EMG waveform reaches a maximum between approximately 85 and 105 Hz, and thereafter declines. (Maximum power in the EMG of the diaphragm, parasternal intercostal, and sternocleidomastoid occurs at somewhat different frequencies, however.) Fatigue-inducing contractions cause a leftward shift of the power spectral density, so that more of the power in the EMG is contained in a lower-frequency domain. The power-spectral density of the contracting diaphragm changes almost immediately with fatiguing contractions and considerably before the mechanical output of the muscle fails. The diaphragmatic EMG power

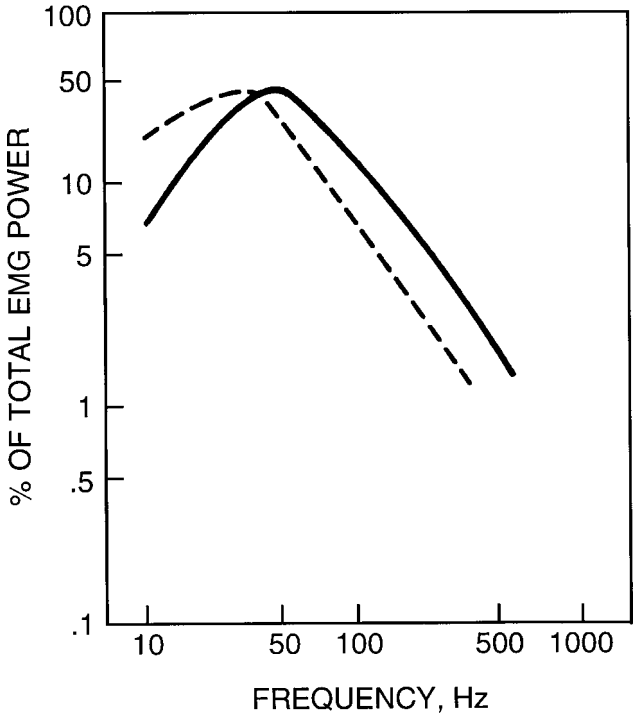

Figure 148-8 Schematic representation of the power-spectral density of a respiratory muscle EMG determined by fast Fourier transform. Note the concave appearance of the relationship. Note that fatigue (dashed line) decreases and increases power in the high- and low-frequency domains, respectively, thereby shifting the relationship toward the left. *(Based on data from Moxham J, Edwards RHT, Aubier M, et al: Changes in EMG power spectrum (high-to-low ratio) with force fatigue in humans. J Appl Physiol 53:1094–1099, 1982, with permission.)*

spectrum can be obtained from the raw EMG of the muscle, recorded from surface electrodes on the chest wall or within the esophagus. It is, therefore, relatively noninvasive and well tolerated. Moreover, the EMG power spectrum, unlike maximal static pressure, can be measured continuously—i.e., breath by breath—and does not require subject cooperation. Accordingly, the EMG power spectrum has proved to be a useful tool to study the pathophysiological mechanisms of human respiratory muscle fatigue. A significant caveat in the use of the power spectrum is the suggestion that it may be unable to detect low-frequency fatigue.

Pathogenesis of Respiratory Muscle Fatigue

Studies designed to examine the pathogenetic mechanisms that lead to respiratory muscle fatigue have largely focused on the diaphragm. The diaphragm has been the primary focus of attention for several reasons. First, it is the major respiratory muscle. Second, anatomic considerations allow the mechanical output of the diaphragm (i.e., transdiaphragmatic pressure) and its EMG, an index of phrenic motor outflow and fatigue state, to be assessed relatively easily. Finally, the cervical phrenic nerves can be electrically stimulated, thereby allowing the mechanical output of the muscle to be assessed under standard conditions as well as during volitional contractions.

Muscle Activity

In seminal studies, Roussos and Macklem observed that the time of onset of diaphragm fatigue was *not* related to the magnitude of the phasic inspiratory swings in Pdi during loading alone or to Pdi_{max} alone. Rather, the time of onset of mechanical failure of the diaphragm was a unique curvilinear function of the ratio of Pdi generated on each breath over Pdi_{max} (Pdi/Pdi_{max}) (Fig. 148-9). Values of Pdi/Pdi_{max} less than 40 to 50 percent could be maintained indefinitely; values greater than this threshold were associated with progressively more rapid exhaustion. These results made several important points. First, diaphragm fatigue depended on the relative intensity of contraction (i.e., muscle force output as a percentage of its strength). Second, contractions below some critical threshold could be sustained indefinitely and did not lead to fatigue.

Subsequent studies demonstrated that the timing as well as the intensity of diaphragmatic contractions determined the time of onset of mechanical failure of that muscle. Increases in the ratio of the T_I over the T_T increased the rapidity of onset of fatigue at any given Pdi/Pdi_{max} ratio. That is, increasing the duration of diaphragm contraction relative to the period during which the diaphragm is relaxed, the duty cycle of breathing, predisposes to fatigue. In fact, diaphragm fatigue appears to be largely a function of the product of $Pdi/Pdi_{max} \times T_I/T_T$, which has been termed the *diaphragm tension–time index* (TTI) (Fig. 148-10). The TTI is, in essence, the integrated area under the pressure waveform over time. The TTI is usually expressed not in absolute terms of pressure per unit of time but, rather, in relative terms as a dimensionless value (i.e., as a percentage of the maximum) to reflect the importance of relative changes in pressure and timing of contraction. The TTI determines muscle energy use as reflected in the O_2 consumption.

A threshold for the onset of fatigue occurs at a TTI of approximately 15 to 20 percent of maximum (Fig. 148-10). The greater the TTI above this value, the more rapidly fatigue ensues.

Subsequent studies in normal subjects demonstrated that mechanical failure of the inspiratory muscles as pressure generators can be accelerated at a given TTI by increasing the V_T/T_I. Increases in V_T/T_I reflect an increase in the velocity of inspiratory muscle shortening. Since the greater the velocity of shortening and the more rapid actomyosin cross-bridge cycling, the greater the rate of adenosine triphosphate splitting, this is not surprising. Also of interest, respiratory maneuvers associated with high levels of ventilation appear to selectively fatigue the diaphragm, whereas maneuvers that produce high levels of pressure primarily fatigue the intercostal and neck muscles.

Muscle Blood Flow

Diaphragm fatigue may relate, in part, to a compromise of muscle blood flow during intense contractions. The

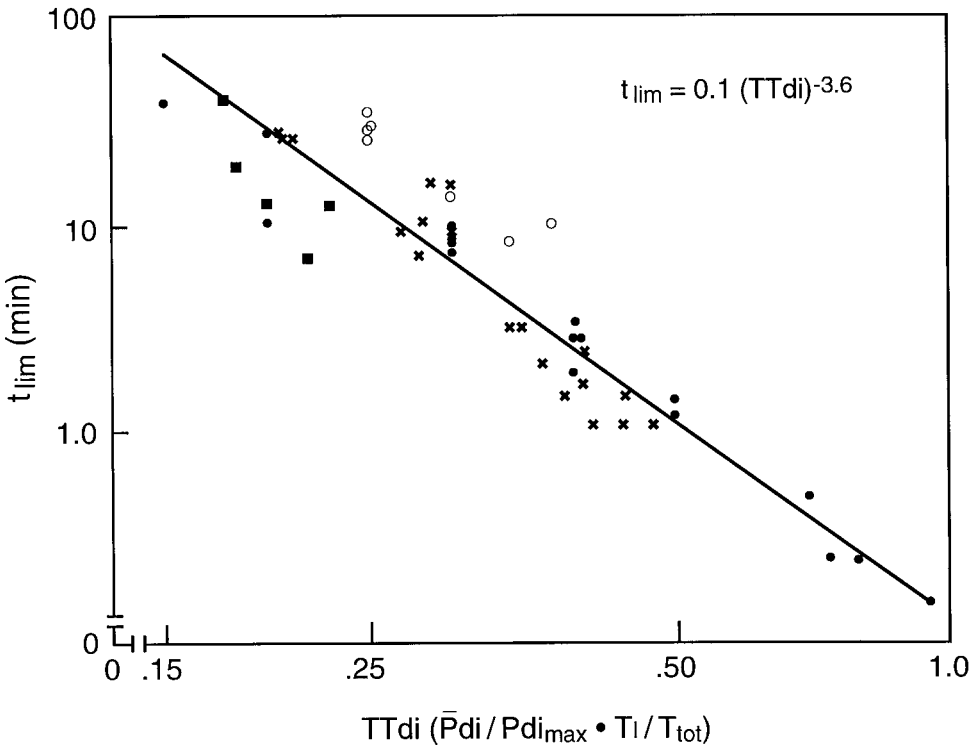

Figure 148-9 Relationship between the intensity of diaphragm contractile activity reflected in the diaphragm tension-time index (TTdi)—i.e., the product of $Pdi/Pdi_{max} \times T_I/T_T$ and the time of onset of mechanical failure of the diaphragm, Tlim. The two scales are logarithmic. Data obtained in normal subjects during strenuous volitional contractions during inspiratory resistive ventilatory loading. Note that above approximately 15 percent TTdi, Tlim decreases progressively with increasing TTdi. These data indicate that a fatigue threshold exists for the human diaphragm above TTdi 15 to 20 percent and that above this threshold, diaphragm endurance is a unique function of the TTdi. *(Based on data from Bellemare F, Grassino A: Evaluation of human diaphragm fatigue. J Appl Physiol 53:1196–1206, 1982, with permission.)*

relationship of diaphragm blood flow to muscle contractile activity is complex and depends, like fatigue itself, on both the intensity and timing of contractions. The level and pattern of diaphragm activation, therefore, determine not only muscle energy use but also the availability of metabolic fuel (i.e., glucose, free fatty acids, and other nutrients).

Contractions of low intensity increase blood flow. In contrast, contractions in excess of 20 to 30 percent of Pdi_{max} mechanically compromise blood flow and cause postcontraction hyperemia. When the diaphragm contracts rhythmically, the T_I/T_T also affects diaphragm blood flow. At Pdi/Pdi_{max} values that compromise blood flow during contraction (i.e., above 20 to 30 percent), blood flow occurs solely during the phase of muscle relaxation. Consequently, increases in the T_I/T_T ratio decrease overall blood flow by encroaching on relaxation time. Diaphragm blood flow is, therefore, a function of the TTI rather than Pdi/Pdi_{max} or the T_I/T_T alone. Blood flow increases up to a TTI of 20 to 30 percent and thereafter falls progressively with further increases in TTI. Compromise of diaphragm blood flow when TTI is greater than 20 to 30 percent of maximum may lead to a condition in which the metabolic needs of the muscle outstrip the availability of energy supply. Alternatively, the importance of blood flow may lie in washing out toxic metabolites (e.g., hydrogen and phosphate ions) from the muscle. The diaphragmatic TTI associated with limitation of blood flow is also a complex function of the level of systemic arterial pressure. Reductions in arterial pressure produced in animal models by bleeding decrease blood flow at any given level of TTI and reduce the Pdi value at which blood flow is mechanically impeded.

Of considerable importance, diaphragm blood flow may also be a determinant of steady-state diaphragm contractile function in COPD patients in acute respiratory failure. In small numbers of COPD patients, 30 to 50 percent increases in diaphragm blood flow with intravenous dopamine (8 μg/kg/min) caused rapid, approximately 40 percent increases in Pdi during electrophrenic twitch contractions. These findings require confirmation before vasodilator therapy to improve diaphragm function can be advocated. However, they suggest the possibility that diaphragm blood flow may be compromised by intense contractile activity in patients with severe lung disease.

Rapid, Shallow Breathing

Patients with abnormalities in ventilatory pump function breathe rapidly and shallowly in respiratory failure. Respiratory rate is increased and tidal volume is decreased.

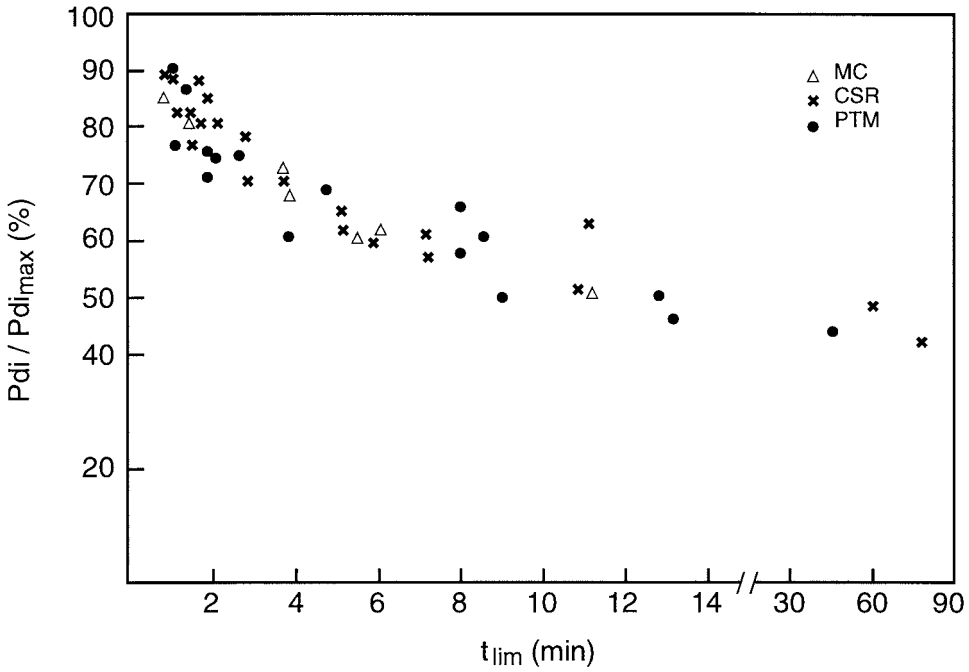

Figure 148-10 Effect of increasing Pdi/Pdi_{max} (i.e., the ratio of peak inspiratory Pdi) during resistance breathing over maximum static Pdi (ordinate) at the time of onset of mechanical failure of the diaphragm, Tlim (abscissa). Data from three normal subjects (shown as separate symbols). Note that progressive increases in Pdi/Pdi_{max} are associated with more rapid onset of diaphragm fatigue. Note also the curvilinear nature of the relationship, with apparent asymptote between 40 and 50 percent Pdi/Pdi_{max}, which represents a fatigue threshold. *(Based on data from Roussos CS, Macklem PT: Inspiratory muscle fatigue, in Macklem PT, Mead J (eds), Handbook of Physiology, section 3: The Respiratory System, vol III: Mechanics of Breathing, part 2. Bethesda, MD, American Physiological Society, 1986, pp 511–527, with permission.)*

Reductions in T_I are out of proportion to reductions in T_E, so the duty cycle of breathing (T_I /T_T) is reduced to less than normal values (below 40 percent). Average inspiratory airflow (V_T/ T_I) tends to be normal, despite abnormalities in mechanics, because of increases in the neuromuscular drive to breathe as reflected in the airway occlusion pressure. Reductions in T_I have the effect of increasing the dead-space-to-tidal-volume ratio (V_D/V_T) and predisposing to alveolar hypoventilation.

A rapid, shallow pattern of breathing with an abnormally low T_I/T_T ratio and reduced tidal volume is extremely common in patients with COPD during acute exacerbations and tends to get better with improvements in clinical condition. Rapid, shallow breathing appears to cause CO_2 retention rather than result from it. It can be produced in patients with COPD by histamine-induced bronchoconstriction and reversed by topical airway anesthesia. Patients with neuromuscular disease in whom the ability to generate inspiratory pressure is impaired require more intense motor outflow to the respiratory muscles to maintain tidal volume. Patients with respiratory muscle weakness also tend to breathe rapidly and shallowly.

The pattern of breathing has been quantified in adults receiving ventilatory support for acute respiratory failure from the ratio of respiratory rate (breaths per minute) divided by tidal volume (liters). This useful parameter has been termed the *rapid shallow breathing index* (RSBI). It has proved to be an extremely powerful way of assessing weanability in adults with a variety of medical and surgical conditions. The greater the value, the more rapid and shallow is the pattern of breathing. Values for the RSBI exceeding 100 are associated with a high probability of failure to wean from mechanical ventilation. The RSBI lends itself to a more general use in patients with disorders of the ventilatory pump not requiring mechanical ventilation.

Rapid, shallow breathing leading to CO_2 retention exerts a number of deleterious effects. First, CO_2 retention decreases Pa_{O_2} and arterial pH. Decreases in Pa_{O_2} result in accordance with the alveolar air equation. In general, a 1 mmHg increase in P_{CO_2} causes a 1.25 mmHg reduction in Pa_{O_2} (assuming a respiratory quotient of 0.8; larger respiratory quotient values are associated with smaller changes in Pa_{O_2}). Second, renal compensation for hypercapnia-induced respiratory acidosis stimulates bicarbonate resorption. Increases in body fluid bicarbonate restore pH toward normal values but blunt the ventilatory response to further increases in CO_2. Third, hypercapnia depresses diaphragm contractility; that is, Pdi is decreased at a given level of diaphragm electrical activity in proportion to the increase in P_{CO_2}.

However, rapid, shallow breathing may also confer beneficial effects to subjects with severe ventilatory pump dysfunction. First, CO_2 retention increases the CO_2 partial-pressure gradient between the alveolus and atmosphere. Accordingly, during hypercapnia the same volume of metabolically produced CO_2 can be excreted at a lower level

of alveolar and minute ventilation and O_2 cost of breathing than during eucapnia. As such, CO_2 retention affords a mechanism to diminish the activity level of the inspiratory muscles and their propensity to fatigue. Normal humans and animal models fatigued by inspiratory resistive loads in the laboratory spontaneously minimize the diaphragm TTI after fatigue by adopting a shallow, rapid pattern of breathing. In fact, a large study of stable outpatients with advanced COPD indicates that the inspiratory muscle TTI is below the fatigue threshold even in markedly hypercapnic (above 60 mmHg) subjects (see below). Second, rapid, shallow breathing minimizes the magnitude of dynamic hyperinflation in patients with severe COPD who breathe on the envelope of the maximum expiratory flow-volume loop; that is, reductions in tidal volume and decreases in the T_I /T_T ratio diminish the volume to be exhaled and prolong the expiratory time available to reach FRC.

The balance between the beneficial and deleterious effects of CO_2 retention is difficult to define with precision; however, the balance probably is determined by the magnitude and rapidity of the changes in Pa_{CO_2} and pH and their effect on the cardiovascular and central nervous systems. Relatively small (5 to 15 mmHg) changes in Pa_{CO_2}, produced gradually over days to weeks and leaving pH at levels of 7.25 to 7.30, are likely to be well tolerated and, on balance, beneficial. On the other hand, Pa_{CO_2} changes that occur rapidly and reduce pH to less than 7.25 are likely to exert net negative effects. In fact, respiratory acidosis to pH values under 7.25 is life-threatening and generally considered an indication for intubation and mechanical ventilation. Cardiac function and sympathetic regulation of peripheral vascular resistance are impaired at this level of pH. Patients become encephalopathic (i.e., somnolent and unable to care for themselves and control their airway secretions). Obviously, hypercapnia of such magnitude is to be avoided.

Pathogenesis of Rapid, Shallow Breathing

The neurophysiological mechanisms driving the altered pattern of breathing are obscure. Moreover, whether changes in breathing pattern in animal models and humans are reflexively induced or behaviorally mediated, or reflect changes in brain neurotransmitter levels (e.g., endorphins), is unclear. However, chemosensitivity-induced alterations in respiratory activity do *not* appear to be the explanation. Hypoxia- and hypercapnia-induced reductions in T_E are disproportionately greater than reductions in T_I, so the T_I/T_T ratio increases. Moreover, V_T/ T_I and the tidal volume increase rather than decrease.

Reflexes originating from mechanoreceptors in the contracting rib cage muscles and diaphragm (i.e., Golgi tendon organs, spindle organs, and type III and type IV endings) probably play a role in shaping the rapid, shallow pattern of breathing. In deeply anesthetized animals, stretch of the intercostal muscles or an increase in diaphragm tension may abruptly terminate inspiration. Activation of vagal irritant receptors in the airway may also produce rapid, shallow breathing. In animal models, rapid, shallow breathing produced acutely by inhalation of allergen or inflammatory mediators (e.g., histamine, bradykinin) can be prevented by vagal blockade. These observations suggest that rapid, shallow breathing in bronchoconstriction may be mediated by vagal sensory endings in the airways.

Finally, changes in the pattern of breathing may represent a behavioral response to minimize the sense of dyspnea. The sense of dyspnea is a complex perceptual construct that is not fully understood but is probably multifactorial. In fact, an important determinant of the sense of dyspnea is the magnitude of the CNS motor command to the inspiratory muscles as reflected in the peak inspiratory intrathoracic pressure. Studies indicate that the sense of breathlessness increases for any set of respiratory mechanical conditions with increases in peak inspiratory pressure, the duration of inspiration, or respiratory rate. In particular, the magnitude of the sense of dyspnea depends on inspiratory pressure (P) swings as a percent of maximum (P/P_{max}), the duration of inspiration relative to the total breath cycle (T_I/T_T), and the respiratory rate (freq). However, the relative importance of these three terms is quite different. The peak inspiratory pressure has a far greater effect than the duration of inspiration, which in turn has a greater effect than breathing frequency. The sensation of dyspnea can be expressed quantitatively by each of these parameters raised to a power:

$$\text{Dyspnea} = P^{1.3} \times {T_I/T_T}^{1.14} \times \text{freq}^{-0.97}$$

Increases in intrathoracic pressure required to maintain airflow and tidal volume in patients with abnormalities in ventilatory pump function increase the sense of dyspnea. Given the greater exponential value for P than for the timing variables, it can be seen that the magnitude of the swing in inspiratory pressure is the predominant determinant of dyspnea. Thus, at a given level of minute ventilation and set of respiratory mechanics, the pattern of breathing determines the intensity of breathlessness. When the mechanics of breathing are deranged by COPD or kyphoscoliosis, diminishing peak inspiratory intrathoracic pressure (i.e., tidal volume) and increasing respiratory rate (i.e., a rapid, shallow pattern of breathing) tend to minimize the sense of breathlessness.

At equivalent levels of airway resistance and inspiratory effort, the sense of dyspnea is greater during bronchoconstriction than during external resistive loading, probably because of the activation of vagal irritant receptors. Differences in the intensity of dyspnea at any given level of airway obstruction, therefore, may depend on the site of airway obstruction (i.e., intra- vs. extrathoracic). Also, the sense of dyspnea at a given level of peak intrathoracic pressure, T_I/T_T ratio, and frequency of breathing are increased in the setting of inspiratory muscle fatigue, probably because a greater motor command is required to generate a given level of intrathoracic pressure. Finally, it should be apparent from the above equation that the sense of dyspnea depends on the same variables that determine respiratory muscle fatigability. However, respiratory muscle fatigue, in contrast to dyspnea, does not

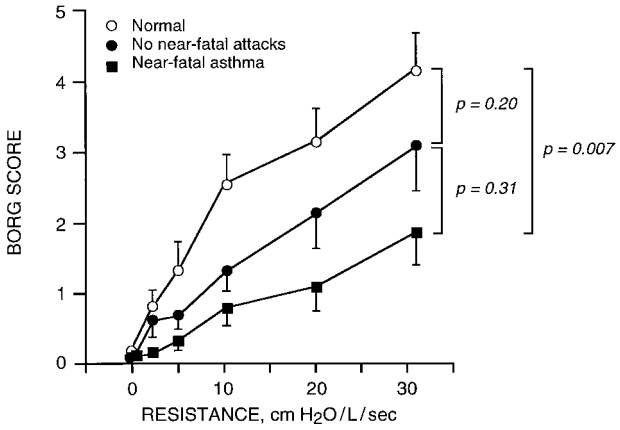

Figure 148-11 Severity of dyspnea experienced during breathing against external resistive ventilatory loads in normal subjects, patients with asthma but no near-fatal attacks, and patients with near-fatal asthma. Y axis indicates the intensity of dyspnea (i.e., Borg score). Increasing numerical values on the Borg score indicate increasing dyspnea. Note that at any given level of external resistance, dyspnea was significantly less in patients with near-fatal asthma than in the normal group. *(Based on data from Kikuchi Y, Okabe S, Tamura G, et al: Chemosensitivity and perception of dyspnea in patients with a history of near-fatal asthma. N Engl J Med 330:1229–1234, 1994, with permission.)*

appear to depend on the pattern in which TTI is developed; that is, whether a given TTI is arrived at by a higher P/P_{max} or a higher T_I/T_T is irrelevant in the development of fatigue, but it *is* important in the generation of respiratory sensations.

Perceptual acuity of the respiratory sensations elicited when the mechanical properties of the ventilatory pump are deranged is a major determinant of the pattern of breathing and tendency to develop CO_2 retention in subjects with COPD. For example, when airway resistance is increased experimentally, patients with COPD who retain CO_2 are those with the greatest perceptual acuity for changes in intrathoracic pressure. That is, spontaneous tidal volume and T_I are smallest in patients with COPD who have the highest perceptual acuity for changes in intrathoracic pressure.

On the other hand, when airway resistance was increased experimentally by external resistive loads, asthmatics with near-fatal attacks experienced less dyspnea at any level of resistance than normal subjects (Fig. 148-11). Accordingly, in patients with COPD the acuity of respiratory perception plays an important role in the pathogenesis of respiratory failure. The mechanism by which respiratory perception contributes to respiratory failure awaits clarification.

Undernutrition

Undernutrition, defined as a body weight less than 90 percent of the ideal, is extremely common in patients with COPD, occurring in about 25 percent of stable outpatients and about 40 percent of hospitalized patients. Undernutrition is an independent risk factor for mortality. For a given level of lung function, undernourished patients with COPD have a greater 5-year mortality than normally nourished subjects. The respiratory muscles, like skeletal muscles in other parts of the body, atrophy under conditions of chronic protein-calorie deficiency. In patients without lung disease, $P_{I_{max}}$ is significantly smaller in those who are undernourished than in those who are well-nourished. In those with COPD at autopsy, the mass (i.e., weight and thickness) of the diaphragm is diminished in undernourished compared to well-nourished subjects. Both slow and fast fibers in respiratory muscles (e.g., the diaphragm and intercostals) atrophy in subjects with advanced COPD. In patients with COPD, resting Pa_{CO_2} is inversely related to $P_{I_{max}}$. The weaker the subject, the greater the Pa_{CO_2}. Reductions in $P_{I_{max}}$ predispose to inspiratory muscle fatigue by increasing the Pdi/Pdi_{max} ratio and, hence, the TTI during breathing against a given set of lung mechanics. Of practical importance, aggressive nutritional repletion, which increases body weight, augments $P_{I_{max}}$ and Pdi_{max}. Thus, respiratory muscle wasting and atrophy are reversible in undernourished patients with COPD.

The pathogenesis of body wasting in subjects with chronic diseases like COPD is unclear. However, increases in the work of breathing and respiratory muscle activity increase resting energy expenditure by as much as 50 to 100 percent above normal. In normal subjects in whom basal energy requirements are similarly increased by heavy physical labor (e.g., lumberjacks), caloric intake is increased appropriately to meet metabolic demands and body weight is preserved. Accordingly, the root of the problem in undernourished patients with COPD may be "relative anorexia," so that increases in basal caloric requirements are not accompanied by adequate caloric intake. Undernourished patients with COPD have higher blood levels of the cachexia factor tumor necrosis factor-α than well-nourished COPD subjects.

SPECIFIC DISEASES

Chronic Obstructive Pulmonary Disease

Patients with advanced COPD develop CO_2 retention because of abnormalities in the gas exchange and mechanical properties of the lung. The relationship between the severity of COPD as reflected by the forced expiratory volume in 1 s (FEV_1) and steady-state resting P_{CO_2} is curvilinear (Fig. 148-12). In general, Pa_{CO_2} does not increase above normal until the FEV_1 decreases to about 20 to 25 percent of predicted normal values.

The effects of COPD on lung gas exchange are complex. Simply put, increases in lung dead space and abnormalities in ventilation/perfusion relationships impair CO_2 elimination and O_2 uptake. Increases in physiological dead space require greater than normal levels of ventilation and tidal volume to maintain eucapnia. Maintenance of "normal tidal volume" in the setting of increased dead space predisposes to CO_2 retention because of an unfavorable V_D/V_T. Normally, during resting breathing, ventilation is 4 to 5 L/min, of which alveolar ventilation is approximately 70 to 80 percent.

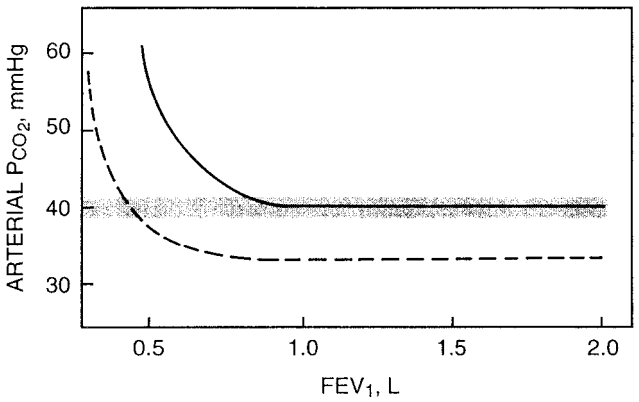

Figure 148-12 Relationship between the severity of airway obstruction reflected in the FEV_1 and steady-state arterial P_{CO_2} in COPD and asthma. Shaded area represents normal range of arterial P_{CO_2}. The relationship is curvilinear, so CO_2 retention occurs only after FEV_1 is considerably reduced. The asthmatic curve (dashed line) lies below and to the left of the curve for COPD, indicating that much greater levels of obstruction are necessary before arterial P_{CO_2} rises. *(From Fishman AP: Pulmonary Diseases and Disorders. New York, McGraw-Hill, 1980, vol 1, p 426, with permission.)*

In COPD, abnormalities in lung gas exchange for O_2 and CO_2 (i.e., increased dead-space volume and alveolar-arterial O_2 gradient) require greater than normal levels of ventilation to maintain eucapnia and euoxia. Consequently, in subjects with advanced COPD, minute ventilation is typically two to three times the normal value (i.e., 10 to 15 L/min). Minute ventilation is increased still further in hypoxemia. Increases in ventilation require increases in airflow, tidal volume, and the duty cycle of breathing.

Hyperinflation and heightened airway resistance are common in patients with advanced COPD. Hyperinflation and increases in FRC in patients with COPD are multifactorial. First, emphysema decreases lung (and possibly chest wall) elastic recoil pressure. Second, tonic activation of chest wall inspiratory muscles throughout the respiratory cycle enhances transpulmonary pressure. Third, activation of laryngeal constrictor muscles and pursed-lip breathing during expiration slow the rate of expiratory airflow. Fourth, severely obstructed patients breathing on the envelope of the maximum expiratory flow-volume curve may have insufficient time during expiration to exhale to passively determined FRC.

In advanced COPD, increases in airway resistance and hyperinflation require greater than normal swings in intrathoracic pressure to generate normal levels of airflow and tidal volume. In consequence, the respiratory neuromuscular drive to breathe, peak inspiratory intrathoracic pressure, and the TTI of the inspiratory muscles are increased considerably. Normally, at rest, respiratory muscle O_2 consumption is less than 2 percent of total body O_2 consumption (i.e., about 5 ml/min or less). In contrast, patients with advanced cardiopulmonary disease may have levels of respiratory muscle O_2 uptake greater than 50 percent of total body O_2 uptake (i.e., in excess of 125 ml/min).

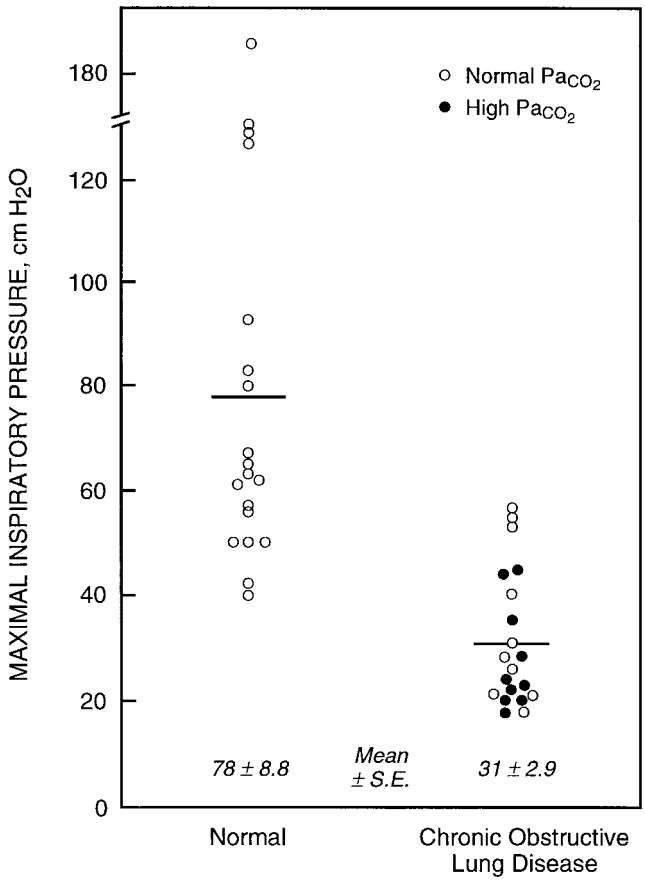

Figure 148-13 Inspiratory muscle strength as reflected in the maximum static inspiratory pressure ($P_{I_{max}}$) at functional residual capacity (FRC) in subjects with advanced COPD and age-matched normal subjects. Each symbol represents a single subject. Note that in COPD subjects, because of hyperinflation and muscle wasting, $P_{I_{max}}$ is reduced to approximately 40 percent of the value in normal subjects. Note the tendency for hypercapnic subjects to have even lower values of $P_{I_{max}}$ than eucapnic COPD subjects. *(Based on data from Sharp JT, van Lith P, Nuchprayoon C, et al: The thorax in chronic obstructive lung disease. Am J Med 44:39–46, 1968, with permission.)*

In subjects with severe COPD, hyperinflation reduces inspiratory muscle mechanical advantage, which decreases the capacity of the inspiratory muscles to generate pressure (P_{max}). P_{max} values in patients with COPD may be as low as one-third to one-half that of age-matched normal subjects (Fig. 148-13). Moreover, aging- and malnutrition-associated changes in the diaphragm may further impair Pdi_{max} in subjects with COPD. COPD typically becomes disabling in the sixth and seventh decades of life, a period of life at which Pdi normally falls. For example, Pdi_{max} is about 25 percent less in healthy men over 65 years of age than in healthy men under 35 years of age.

Respiratory Muscle Fatigue in COPD

Severe COPD is arguably the clinical condition most likely to cause inspiratory muscle fatigue. The combined effects of increases in inspiratory muscle activity and decreases in

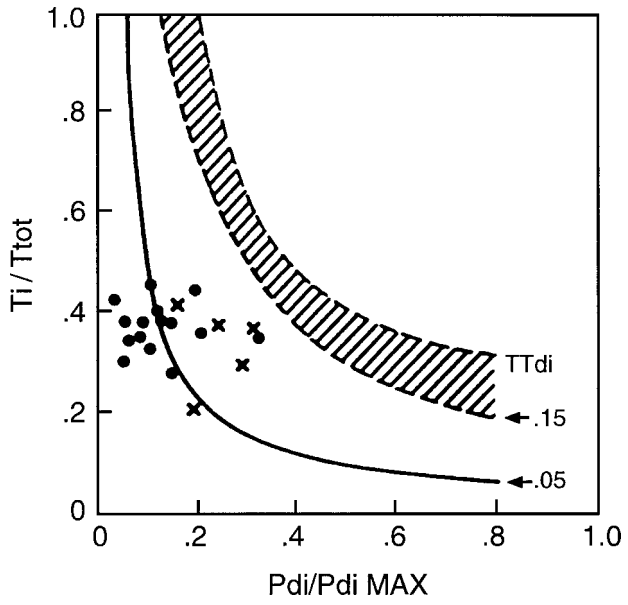

Figure 148-14 Diaphragmatic tension-time index (TTdi) in 20 stable outpatients with COPD breathing room air at rest. Each symbol represents a separate COPD subject. Shaded area represents the fatigue threshold in normal subjects. Most COPD subjects breathe well below the fatigue threshold and cluster around 0.05 TTdi. *(Based on data from Bellemare F, Bigland-Ritchie B: Central components of diaphragmatic fatigue assessed by phrenic nerve stimulation. J Appl Physiol 62:1307–1316, 1987, with permission.)*

muscle strength in severe COPD increase the diaphragm TTI during resting breathing in elderly COPD patients considerably above the normal value of 1 to 2 percent. The TTI may, in fact, approach the fatigue threshold (i.e., 15 to 20 percent) in patients with COPD (Fig. 148-14). These and similar data indicate that diaphragm activity is increased in patients with advanced COPD, and that the diaphragm is highly susceptible to fatigue when breathing is increased above spontaneous levels by minor increases in tidal volume or T_I/T_T. The diaphragm TTI is higher in hypercapnic than in eucapnic COPD subjects, but even in hypercapnic subjects it does not exceed the fatigue threshold. Mean TTI, even for hypercapnic subjects, is approximately 10 percent. Therefore, hypercapnia per se does not indicate the presence of diaphragm fatigue even in patients with severe COPD. Rather, hypercapnia may be a manifestation of a breathing strategy (i.e., rapid, shallow breathing) that minimizes inspiratory muscle activity and, hence, prevents fatigue.

On the other hand, inspiratory muscle fatigue may be a relatively common occurrence during the hyperpnea of exercise and could contribute to exercise limitation in COPD subjects. A high percentage (about 50 percent) of subjects with moderate to severe COPD demonstrate EMG evidence of scalene or diaphragm (or both) fatigue during exercise. Of interest, improvement in exercise performance and elimination of the EMG signs of fatigue can be achieved following inspiratory resistance training.

Subjects with COPD in acute respiratory failure requiring mechanical ventilation are more likely to show evidence of inspiratory muscle fatigue. During weaning from mechanical ventilation, diaphragm EMG changes indicative of fatigue precede the increases in Pa_{CO_2}. These findings suggest that diaphragm fatigue contributes to ventilator dependence after the onset of hypercapnic respiratory failure in at least some critically ill subjects.

In COPD patients being weaned from mechanical ventilation during a bout of acute respiratory failure, the tracheal occlusion pressure is usually greater than 6 cm H_2O and EMG evidence of diaphragm fatigue is present during spontaneous breathing. Patients with persistently elevated tracheal occlusion pressure values (above 6 cm H_2O) and EMG evidence of diaphragm fatigue generally cannot be successfully weaned from mechanical ventilation. In contrast, sternomastoid muscle fatigue is evident in fewer than 10 percent of COPD patients hospitalized for worsening respiratory distress.

In summary, most subjects with stable COPD adopt a pattern of breathing that minimizes the diaphragm TTI and prevents inspiratory muscle fatigue. Behavioral mechanisms may be operative in an attempt to minimize the sensation of dyspnea. On the other hand, inspiratory muscle fatigue contributes to the morbidity of a subgroup of patients with COPD by preventing weaning from mechanical ventilation, and possibly by impairing exercise performance. The reported number of COPD subjects with respiratory muscle fatigue is small, however, and may represent a highly select population. Further studies are needed to define the extent of this problem.

Asthma

The pathophysiology of CO_2 retention appears to be generally similar in patients with asthma and COPD, but the likelihood of developing CO_2 retention is less in asthma than in COPD. That is, the level of expiratory airway obstruction required to produce CO_2 retention in subjects with acute asthma is greater than that required in subjects with COPD (Fig. 148-14). Several possibilities may explain this tendency. First, it appears that inspiratory drive is higher in patients with asthma than in those with COPD. The airway occlusion pressure is considerably higher at any given level of Pa_{CO_2} in patients with asthma than in normal subjects or patients with COPD. The heightened inspiratory drive in patients with asthma may in part arise from irritant receptors within the airway, which have an augmenting effect on inspiratory motor neuron activity. Furthermore, the inspiratory muscles are stronger, and ventilatory responses to CO_2 and hypoxia are greater, in the younger asthmatic than in COPD subjects. These differences are not simply due to age, as the endurance of the inspiratory and expiratory muscles is greater in asthmatic than in age-matched normal subjects. The increased respiratory muscle endurance in subjects with asthma may be a response to chronic increases in inspiratory muscle load. Finally, greater lung elastic recoil in asthma than in COPD tends to preserve maximal expiratory airflow.

Neuromuscular Disease

Subjects with neuromuscular disease and weak inspiratory muscles tend to breathe rapidly and shallowly. Despite this breathing pattern, these subjects tend to have hypocapnia at rest, and hyperventilate at any given level of CO_2 during progressive hypercapnia. Increases in ventilation are associated with increases in airway occlusion pressure. Heightened occlusion pressure in the setting of weak inspiratory muscles suggests that the drive to the inspiratory muscles early in inspiration is greater than normal.

The pathogenesis of hypercapnic respiratory failure is very different in patients with neuromuscular disease than in patients with COPD. Patients with neuromuscular disease demonstrate an impaired ability to sigh (i.e., a greater than twofold increase in the tidal volume) because of inspiratory muscle weakness. Inability to sigh decreases lung compliance by interfering with the redistribution of surfactant within the alveolar space. Progressive stiffening of the lung leads to microatelectasis and ultimately lobar atelectasis. Breathing high concentrations of O_2 accelerates this process. In addition, expiratory muscle weakness impairs the cough mechanism and causes retention of secretions.

The best indicators of a tendency to develop CO_2 retention in patients with neuromuscular disease are reductions in inspiratory muscle strength ($P_{I_{max}}$) and forced vital capacity (FVC). Reductions in $P_{I_{max}}$ and FVC to less than 30 and 25 percent of predicted, respectively, are associated with CO_2 retention. Suffice it to say, hypercapnia is a late manifestation of neuromuscular disease and requires marked impairment in inspiratory and expiratory muscle function. With diaphragm dysfunction, hypercapnia may occur during sleep (especially REM sleep) even when the subject is eucapnic while awake.

Obesity

Obesity imposes a stress on the respiratory system both by altering lung mechanics and the work of breathing (see Chapter 92). The mass loads applied to the thorax and abdomen by excess fatty tissue decrease chest wall compliance and end-expiratory lung volume resulting in increases in the elastic and resistive work of breathing. Furthermore, by diminishing airway caliber, obesity predisposes to premature airway closure and even atelectasis. The resultant low ventilation-perfusion ratios of these lung regions increase alveolar-arterial O_2 gradient and cause arterial hypoxemia. In fact, hypoxemia is the most common respiratory abnormality in the morbidly obese.

In addition, the excessive body mass results in increased CO_2 production and O_2 consumption. Increases in metabolism may be two to three times normal in morbidly obese subjects. These metabolic changes require significant increases in minute and alveolar ventilation in order to maintain eucapnia and hence, increasing ventilatory demands. For example, a doubling in CO_2 production requires a doubling in alveolar ventilation to maintain eucapnia. Finally, arterial hypoxemia, which is common, induces a further increase in ventilation.

Given these stresses, the maintenance of normal blood gas tensions requires a considerable increase in respiratory motor output and the work of breathing. Increased work of breathing appears to explain the common occurrence of dyspnea in the morbidly obese person.

Not all morbidly obese subjects develop hypercapnic respiratory failure, however. Although body weight alone does not predict the development of hypercapnia, approximately 30 percent of severely obese subjects with a body mass index (BMI) of more than 35 kg/m^2 and almost 50 percent with a BMI of 50 kg/m^2 or greater have unexplained daytime hypercapnia. Observations of eucapnic and hypercapnic obese subjects demonstrate that eucapnic subjects have greater increases in diaphragm electrical activity with increases in CO_2 than hypercapnic subjects. Obese subjects with hypercapnic respiratory failure may have impaired chemosensitivity to hypercapnia and hypoxemia.

A subset of obese subjects with hypercapnia also have daytime hypersomnolence, polycythemia, pulmonary hypertension, and cor pulmonale. This constellation of signs and symptoms has been termed the *obesity hypoventilation syndrome* (see Chapter 92.) Of interest, leptin may be involved in the pathogenesis of hypercapnic respiratory failure in obese individuals. Leptin stimulates ventilation and a deficiency of leptin has been associated with hypoventilation. Clearly excessive body weight is the primary pathogenetic factor, since weight reduction into the normal range, however difficult this may be to accomplish, corrects the problem.

Kyphoscoliosis

Kyphoscoliosis decreases chest wall and lung compliance, presumably as a result of atelectasis and deformation of the lungs (see Chapter 92). The elastic work of breathing is markedly increased. In addition, the mechanical action of the respiratory muscles may be impaired by changes in configuration of the bony structures on which the respiratory muscles insert. Ventilation-perfusion mismatch and increase in the alveolar-arterial O_2 gradient are common. As expected in patients with diminished respiratory compliance, subjects with kyphoscoliosis breathe rapidly and shallowly. The tendency to develop CO_2 retention is a function of the severity of the restrictive process in kyphoscoliosis, as reflected in the Cobb angles, and is predicted separately for the magnitude of scoliosis and kyphosis.

Hypercapnic respiratory failure tends to develop late in life, even if the severity of the spinal deformity has not changed since childhood; that is, stability of the Cobb angles of kyphosis and scoliosis does not preclude development of hypercapnic respiratory failure. It is not clear why respiratory failure ensues late in life. However, several possibilities exist. Aging adversely affects compliance of the chest wall, leading to an increase in the elastic work of breathing. In addition, aging diminishes respiratory muscle strength. Finally, chemosensitivity to O_2 and CO_2 declines with advancing age, and it seems likely that the subject's ability to compensate

for derangements in blood gas tensions is progressively impaired.

ASSESSMENT OF PATIENTS WITH ABNORMALITIES OF THE VENTILATORY PUMP

Symptoms

Dyspnea appears to be an early manifestation of respiratory muscle impairment in neuromuscular disease and typically occurs before the development of CO_2 retention. Breathlessness in the supine position is characteristic of isolated diaphragm dysfunction. In the supine position, the increased hydrostatic pressure imposed by the abdominal viscera represents an increased inertial load on the diaphragm.

Physical Findings

Physical signs of ventilatory pump dysfunction revolve around evidence of accessory respiratory muscle recruitment, abnormal thoracoabdominal movement, and rapid, shallow breathing.

Use of Accessory Muscles

Inspection and palpation demonstrate accessory respiratory muscle use. Intense respiratory efforts are associated with visible activation of the neck accessory muscles, interosseous intercostals, and abdominal expiratory muscles and flaring of the alae nasae.

Abnormal Thoracoabdominal Movement

Normally, in the supine position, the anterior abdominal wall displays a prominent outward movement during inspiration. With impaired diaphragm function, as occurs in diaphragm weakness or fatigue, the abdominal wall may move inward on inspiration. This is called *abdominal paradox.* Abdominal paradox reflects cephalad movement of the contracting diaphragm in response to the negative intrathoracic pressure generated by the inspiratory action of the neck and intercostal muscles. Abdominal paradox may also be present in patients with marked derangements in lung mechanics, in whom inspiratory intrathoracic pressure swings exceed 30 percent of maximum. Abdominal paradox, therefore, is not specific for diaphragm weakness or fatigue.

Abdominal paradox, resulting from ineffectual contractions of the diaphragm, should be distinguished from *pseudo-abdominal paradox,* resulting from strong contractions of the expiratory muscles during expiration, with rapid relaxation during early inspiration. For example, intense contraction of the transverse abdominis muscles causes inward movement of the lateral abdominal wall and outward movement of the anterior abdominal wall during expiration. Subsequent relaxation of the abdominal muscles with the onset of inspiration causes outward movement of the lateral abdominal wall and inward movement of the anterior abdominal wall. Tenseness of the lateral abdominal wall during expiration easily distinguishes *pseudo-* from true *abdominal paradox.*

Maximum Static Inspiratory Pressure

Perhaps the most practical method of assessing the function of the inspiratory muscles contracting in aggregate is from the pressure generated during maximal volitional contractions against an occluded airway at FRC. This parameter is discussed in greater detail in Chapter 93. In brief, however, reductions in $P_{I_{max}}$ indicate inspiratory muscle weakness or high-frequency fatigue. Improvements in $P_{I_{max}}$ occurring over several hours to several days in a patient with COPD suggest that lung volume is improving toward normal and that the mechanical disadvantage imposed on the inspiratory muscles is disappearing. More rapid improvements (occurring over hours) may indicate resolution of high-frequency fatigue or elimination of the metabolic disturbances (e.g., hypercapnia or hypophosphatemia) that depress inspiratory muscle function. Of note, $P_{I_{max}}$ is not affected by low-frequency fatigue.

$P_{I_{max}}$ depends on patient cooperation and motivation. With training, however, patients can provide reproducible values. Performance of the maneuver at FRC, where respiratory system recoil is zero, is preferred; that is, at FRC, changes in airway pressure during inspiratory efforts equal the pressure generated by the inspiratory muscles (P_{mus}).

Maximum static expiratory pressure at FRC ($P_{E_{max}}$) has been used in the laboratory setting to assess the endurance properties of the expiratory muscles. The $P_{E_{max}}$ has not been used extensively in the clinical setting, however, because of the perception that it is more difficult to obtain consistent values than $P_{I_{max}}$ with breathless subjects.

TREATMENT

Abnormalities in respiratory mechanics and gas exchange are the most important pathogenetic factors in the development of respiratory failure. Accordingly, therapy should be directed toward achieving maximum improvement in airway, lung, and respiratory muscle function. For example, in patients with COPD or asthma, an intensive regimen of bronchodilators (e.g., β_2-adrenergic agonists, anticholinergics, and theophylline) and anti-inflammatory therapy (e.g., corticosteroids) can correct respiratory failure by diminishing airway resistance, FRC, lung dead-space volume, the alveolar-arterial O_2 partial-pressure gradient, and the work of breathing. Improvements in lung function in certain patients with advanced COPD and emphysema may also be accomplished by lung-volume reduction surgery (volume-reduction pneumectomy) or lung transplantation. Lung-volume reduction surgery removes 20 to 30 percent of the most emphysematous regions of lung and appears to improve

FRC, FEV_1, ventilatory capacity, inspiratory muscle function, and elastic recoil pressure of the lung. In patients with myasthenia gravis, cholinesterase inhibitors can improve inspiratory muscle strength and vital capacity and reverse atelectasis, which causes hypercapnia. Additionally, noninvasive positive-pressure ventilation (NIPPV) has become one of the most important modalities for treating hypercapnic respiratory failure (see below).

Abnormalities in Chemosensitivity

Respiratory failure caused by impaired chemosensitivity is difficult to treat, since drug treatments to improve chemosensitivity to hypoxia or hypercapnia are not very effective. Since it was observed that women exhibit alveolar hypoventilation during pregnancy and the luteal phase of the menstrual cycle, progestational agents have been used for many years to treat idiopathic hypoventilation syndromes. In some subjects, medroxyprogesterone acetate, given orally in a dose of 20 mg three times a day, acts centrally to augment the ventilatory responses to hypercapnia and hypoxemia and can improve resting arterial blood gas tensions. Medroxyprogesterone is generally well tolerated in women but may produce feminizing side effects in men. The onset of action of the drug is slow. Several weeks may be required before a response is observed. Theophylline, in doses that produce blood levels in the therapeutic range (10 to 15 μg/ml), also has weak respiratory stimulatory effects, which may contribute to a reduction in Pa_{CO_2} in patients with COPD. Theophylline also produces modest improvements (about 10 to 20 percent) in diaphragm contractile function in this population. Finally, in some patients with hypercapnia, elimination of medications having CNS respiratory depressant effects (e.g., opiate analgesics, benzodiazepine anxiolytics) can lead to improvements in Pa_{CO_2}.

Hypoxemia leading to pulmonary artery hypertension and cor pulmonale may be the most serious complication of chronic hypercapnic respiratory failure. Supplemental O_2 is usually indicated in patients with chronic hypercapnic respiratory failure. Supplemental O_2 may produce exaggerated increases in Pa_{CO_2} in patients with disorders of ventilatory control in whom the ventilatory response to CO_2 is blunted but the O_2 response is preserved. Accordingly, blood gas tensions should be monitored closely when O_2 is applied initially. During sleep, patients with disorders of the control of breathing typically display exaggerated increases in Pa_{CO_2} (e.g., 15 to greater than 30 mmHg) with hypoxemia and severe respiratory acidosis. In these subjects, mechanically assisted ventilation (typically with nasal positive-pressure ventilation), with or without O_2, may be required during the sleeping period. Nasal positive-pressure ventilation is an effective way of improving blood gas tensions during sleep. In fact, improvements in blood gas tensions achieved by nocturnal mechanical ventilation may carry over to the waking period in these patients, perhaps by preventing nocturnal increases in serum bicarbonate or hypoxic depression of CNS function.

Table 148-2

Principles of Therapy for Respiratory Muscle Fatigue

Decrease inspiratory swings in transdiaphragmatic pressure (Pdi)
Improve the mechanics of breathing (i.e., decrease airway resistance, improve thoracic compliance and static lung volume)
Decrease ventilatory drive (i.e., relieve hypoxemia, hypercapnia, metabolic acidosis, fever, pulmonary congestion/inflammation, acute respiratory distress syndrome
Increase Pdi_{max}
Correct hyperinflation
Correct muscle atrophy induced by protein-calorie deficiency
Correct electrolyte and blood gas abnormalities (i.e., hypoxemia, hypercapnia, hypophosphatemia, hypokalemia, hypocalcemia, hypomagnesemia)
Optimize muscle blood flow and substrate availability
Correct low cardiac output state (e.g., cardiogenic shock, hypovolemic shock).
Correct hypoxemia, anemia, hypoglycemia

Respiratory Muscle Weakness or Fatigue

The treatment of respiratory muscle weakness depends on pathogenic mechanisms. For example, inspiratory muscle weakness related to the hyperinflation of COPD is best treated by aggressive improvement of airway function. On the other hand, decreases in muscle strength caused by electrolyte abnormalities (e.g., hypophosphatemia) or protein-calorie malnutrition are best dealt with by repletion of the deficits.

The treatment of respiratory muscle fatigue has not been systematically studied. However, several approaches based on theoretical considerations appear to be applicable (Table 148-2). It is clear that diaphragm fatigue is a result of muscle overactivity (i.e., a TTI greater than 20 percent). Accordingly, attempts should be made to decrease the TTI of the inspiratory muscles to values below the fatigue threshold by improving lung mechanics or reducing ventilatory drive. In patients with abnormalities in airway resistance and hyperinflation secondary to severe COPD, this can best be accomplished with bronchodilators and corticosteroids. Reductions in ventilatory drive in hypoxic or febrile patients can be accomplished by administration of O_2 or antipyretics.

Unloading the inspiratory muscles by reducing the TTI may be sufficient to prevent or reverse fatigue and allow the muscle to recover. In some cases, however, respiratory muscle fatigue may be sufficiently advanced so that the muscle must

be placed at complete rest. Mechanical ventilation and ventilatory muscle rest are certainly indicated when the pH is less than 7.25 or the patient appears unable to maintain ventilation and stable blood gas tensions. The precise duration of mechanical ventilation to rest the inspiratory muscles in patients with respiratory muscle fatigue is unclear. However, no attempts at weaning should be made until the conditions that initiated fatigue are reversed. Since low-frequency fatigue persists for 24 h or more, it may not be advisable to wean patients with respiratory muscle fatigue from mechanical ventilation for at least 24 h, even if the factors that caused fatigue have been corrected.

Chronic Ventilatory Support/Nasal Positive-Pressure Ventilation

Mechanically assisted ventilation, especially at night, may be helpful in reducing arterial P_{CO_2} and increasing P_{O_2} in the chronically hypercapnic subject. Nasal positive-pressure ventilation (NPPV) affords an effective, practical approach to treat selected subjects with chronic hypercapnia secondary to either impaired chemosensitivity or abnormalities in respiratory mechanics. In particular, selected subjects with the obesity hypoventilation syndrome, kyphoscoliosis, or neuromuscular disease have been successfully maintained on NPPV for prolonged periods.

NPPV is particularly effective in hypercapnic respiratory failure. NPPV obviates the need for airway intubation, provides considerable patient comfort, and is easy to use. Many different types of masks exist. The most commonly used are oral or oronasal masks with a soft rubber seal. An oronasal mask may be more comfortable for mouth breathing patients. By setting the magnitude of the inspiratory positive airway (IPAP) and expiratory pressures (EPAP), tidal volume is determined. Small, portable, simple-to-operate bilevel ventilators (BiPAP) that deliver phasic pressure changes are available. Many bilevel machines allow manipulation of the pressure rise time during inhalation so that exhalation time and patient comfort can be maximized. No ideal pressure settings effective for all patients exist. Settings should be adjusted to maximize patient comfort and ventilation. The effectiveness of a given setting can be assessed by observing the degree of chest expansion and measuring the Pa_{CO_2}. Disadvantages of NPPV include aerophagia and air leaks secondary to poorly fitting masks.

The use of NPPV during acute hypercapnic respiratory failure secondary to COPD has been demonstrated repeatedly to reduce mortality, reduce the need for airway intubation, and rapidly improve respiratory rate, Pa_{CO_2}, and pH. Recently NPPV has been successfully used over a prolonged period for the treatment of the obesity hypoventilation syndrome. In morbidly obese patients (mean BMI 44 kg/m^2), NPPV decreased the Pa_{CO_2} by an average of 17 mmHg and increased the Pa_{O_2} by 24 mmHg after an average of 50 months.

NPPV is also used in neuromuscular disease, particularly for nocturnal hypoventilation or progressive hypercapnic respiratory failure (see Chapters 93 and 94). NPPV prolongs and improves the quality of life in amyotrophic lateral sclerosis. Its use in this disorder is discussed in detail in Chapter 94. Unfortunately, the majority of the neuromuscular disorders are progressive and many patients develop bulbar symptoms and thus have difficulty controlling their secretions.

CHAPTER

Oxygen Therapy and Pulmonary Oxygen Toxicity

Michael F. Beers

Following Joseph Priestley's discovery of molecular oxygen and Lavoisier's subsequent demonstration of respiratory gas exchange, use of inhaled oxygen in treatment of a variety of clinical disorders accelerated rapidly during the late eighteenth century. However, a backlash of criticism developed as studies demonstrated that, under ambient conditions, the oxygen-carrying capacity of arterial blood was nearly maximal, and that further increases in the fraction of inspired O_2 produced no appreciable additional physiological benefit. Furthermore, in 1899, Lorrain-Smith confirmed the early suspicions of Priestley, Lavoisier, and others regarding the potential toxicity of inhaled oxygen, describing the pulmonary

pathological alterations associated with excessive oxygen exposure. As a result of these observations, by the start of the twentieth century, use of oxygen as a therapeutic modality fell into disrepute.

However, in the early 1920s supplemental oxygen breathing was rigorously reevaluated. Through pioneering efforts by Meakins, Baruch, and others, the concept of a therapeutic window for oxygen inhalation was established. Many investigators independently demonstrated that a reduction in oxygen availability had serious physiological consequences, and that in pathological states, the detrimental consequences of hypoxia could often be circumvented by administration of oxygen. Thus, use of inhaled oxygen again became mainstream therapy, but as adjuvant treatment for cardiac and pulmonary diseases specifically accompanied by hypoxemia and hypoxia.

Over the past 80 years, with the advent of improved oxygen delivery systems, mechanical ventilation, the modern intensive care unit, and long-term home oxygen administration, oxygen has become widely available and frequently prescribed. Nevertheless, despite a large clinical experience, many persistent uncertainties inhibit rational use of supplemental oxygen. As with any drug, indications for, and contraindications to, its use exist. Consensus conferences and numerous studies have resulted in establishment of guidelines defining clinical criteria for proper use of supplemental oxygen. Unfortunately, in current practice, oxygen therapy is often prescribed without careful evaluation of its potential benefits and side effects and without adequate supervision. In a retrospective study of 90 consecutive hospitalized patients, oxygen therapy was prescribed inappropriately in 21 percent; monitoring was inadequate in 85 percent; and documentation of physiological criteria for termination of therapy was lacking in 88 percent of all patients. Prospective collected data have also indicated that less than 50 percent of hospitalized patients receiving supplemental oxygen do so at the prescribed dosage and flow.

This chapter provides the basis for the rational use of inhaled oxygen therapy. A review of the physiology of tissue oxygenation is followed by a discussion of the current indications and guidelines for acute oxygen therapy, the role of long-term oxygen therapy, and the pathophysiological basis for pulmonary oxygen toxicity. Because prescribed oxygen is administered typically under normobaric conditions, oxygen therapy and its toxic consequences are considered in this setting (i.e., at one atmosphere of pressure).

TISSUE OXYGENATION

The physiological basis for oxygen therapy has been well documented for over 40 years. While treatment and prevention of arterial hypoxemia are the most common indications for oxygen therapy, the ultimate goal in its use is correction or avoidance of tissue hypoxia. In 1965, Chance first demonstrated that a partial pressure of oxygen (P_{O_2}) in mitochondria of 18 mmHg or more is required to generate the high-energy phosphate bonds (as adenosine triphosphate) essential for all major cellular biochemical functions. At rest, the average adult man consumes about 225 to 250 ml of oxygen per min; this rate of consumption may increase as much as 10-fold during exercise. Ongoing oxygen utilization in peripheral tissues dictates a very small oxygen reserve which is consumed quickly (within 4 to 6 min of cessation of spontaneous ventilation). A complete understanding of the concepts of oxygen delivery and utilization is required for careful assessment of the hypoxic patient and implementation of proper therapy.

Oxygen Delivery and Utilization

Transport of oxygen from atmospheric air to tissue mitochondria (the ultimate sites of oxygen utilization) requires the integrated function of the pulmonary, cardiovascular, and hematologic systems. Under normal conditions, a pronounced drop in P_{O_2} between ambient atmosphere and tissues is observed (Fig. 149-1). The measured basal tissue P_{O_2} (i.e., mixed venous P_{O_2} or $\bar{v}_{O_2}$) is only marginally greater than the threshold value for mitochondrial anaerobic metabolism measured in vitro (as illustrated in Fig. 149-1 by the dashed line at a P_{O_2} of 20 mmHg). The consequence of such a steep oxygen concentration gradient and a marginal tissue reserve is that a variety of environmental and pathological factors can significantly impact on tissue oxygenation by altering P_{O_2} at one of these intermediary stages. Hence, tissue hypoxia develops whenever oxygen delivery is inadequate to meet metabolic demands.

Oxygen delivery to the periphery is determined by two major factors: (1) oxygen content of arterial blood and (2) blood flow (i.e., cardiac output). Oxygen delivery is calculated as the product of cardiac output and arterial oxygen content. Total oxygen delivery is calculated as:

$$D_{O_2} = CO \times Ca_{O_2} \times 10 \quad (1)$$

where

D_{O_2} = oxygen delivery, ml/min
CO = cardiac output, L/min
Ca_{O_2} = O_2 content of arterial blood, ml/dl

The oxygen content of arterial blood is determined by the hemoglobin concentration, its degree of saturation with molecular oxygen, and the fractional amount of oxygen physically dissolved in solution. The amounts of both bound and dissolved oxygen are related directly to the oxygen tension in arterial blood (Pa_{O_2}), while the percentage of hemoglobin saturated with oxygen is a function of Pa_{O_2}, as described by the oxyhemoglobin dissociation curve (see Chapter 13). In turn, the amount of oxygen dissolved in solution is a function of the solubility coefficient of oxygen and the Pa_{O_2}. Hence, total arterial oxygen content is calculated as:

$$Ca_{O_2} = ([Hgb] \times 1.34 \times Sa_{O_2}) + (Pa_{O_2} \times 0.0031) \quad (2)$$

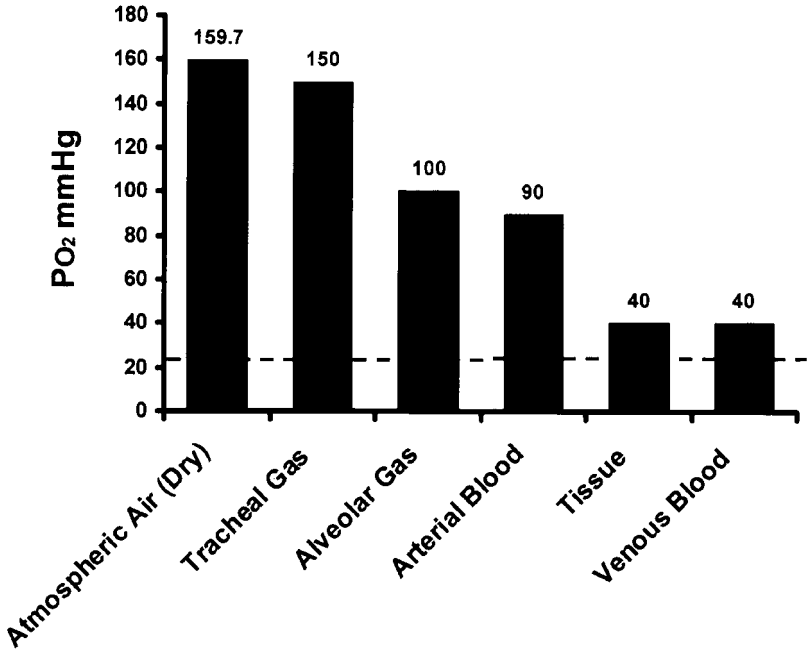

Figure 149-1 Graphical representation of sequential steps in the drop in oxygen tension (P_{O_2}) at various stages of oxygen transport from atmosphere to peripheral tissues. Values depicted are calculated using the alveolar gas equation and data from Chance (*J Gen Physiol* 49:163–195, 1965). Dashed line represents the approximate intracellular anaerobic threshold.

where

[Hgb] = hemoglobin concentration, g/dl
1.34 = O_2 carrying capacity of hemoglobin at 37°C, ml/g hemoglobin
Sa_{O_2} = measured $\%O_2$ saturation of hemoglobin
0.0031 = solubility coefficient for oxygen

Mechanisms of Hypoxia

Aerobic metabolism requires a balance between oxygen delivery (Do_2) and oxygen utilization ($\dot{V}o_2$). A biphasic relationship between Do_2 and $\dot{V}o_2$ has been observed (Fig. 149-2). During normal aerobic metabolism, oxygen transport and oxygen utilization are independent variables. Whereas the amount of oxygen delivered to tissues per unit time defines the upper limit of oxygen availability for the body's total metabolic needs, delivery of oxygen under normal circumstances always exceeds peripheral oxygen utilization. In this "supply-independent" region of the graph, oxygen consumption is commensurate with the rate of adenosine 5′-triphosphate (ATP) production and represents a measure of tissue cellular energy requirements. If oxygen delivery falls below a critical threshold (Do_2 critical), or if utilization exceeds delivery (e.g., during strenuous exercise), tissues must shift from aerobic to anaerobic metabolism to supply adequate energy for total metabolic needs. When an imbalance arises, excessive lactic acid production ensues, resulting in progressive acidosis, disrupted cellular metabolism, and, potentially, cell death.

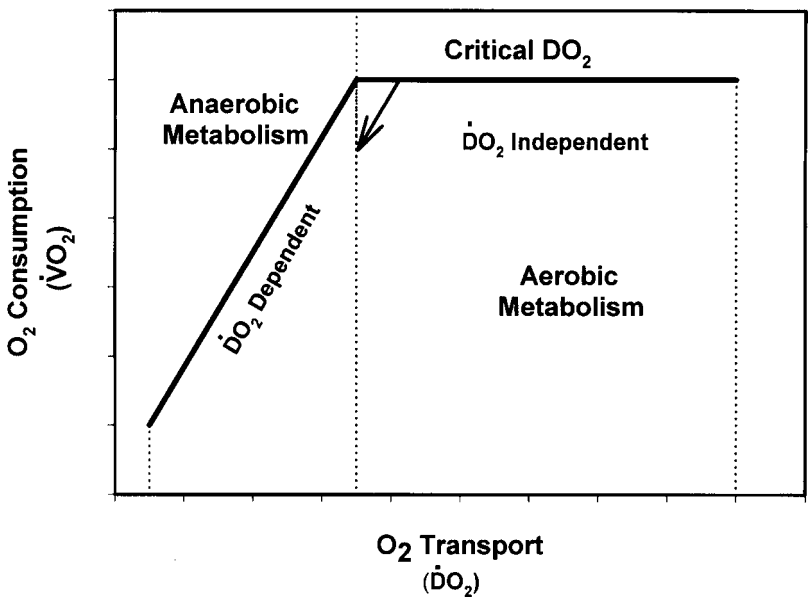

Figure 149-2 Relationship between oxygen consumption ($\dot{V}_{O_2}$) and oxygen transport (D_{O_2}). The critical D_{O_2}, indicative of the transition from supply-dependent to supply-independent conditions, is denoted by the arrow. Anaerobic metabolism exists under supply-dependent conditions and ensues when oxygen consumption exceeds oxygen supply.

Table 149-1

Causes of Tissue Hypoxia

Categroy	Clinical Correlate	Pa_{O_2}	$\bar{V}_{O_2}$	Cardiac Output
Hypoxemia	See Table 149-2	↓	↔ or ↓	↓ or ↑ or ↔
Impaired delivery				
Circulatory (forward flow)	Hypovolemia; heart failure	↔	↓	↓
Distributive	Sepsis; arterial insufficiency	↓ or ↔	↔ or ↓	↑ or ↔
Defective Blood-O_2 Transport	Inherited abnormal hemoglobins			
	Acquired abnormal hemoglobin (Carbon monoxide poisoning)	↔	↔ or ↓	↑ or ↓
	Anemia			

Table 149-1 lists the major causes of tissue hypoxia, which are mechanistically divided into three broad categories: (1) arterial hypoxemia, (2) reduced oxygen delivery, and (3) excessive or dysfunctional tissue utilization.

Maintenance of tissue oxygenation depends on the proper integration of three separate components: (1) the cardiovascular system, which determines cardiac output and blood flow distribution; (2) the blood, which determines hemoglobin concentration; and (3) the respiratory system, which determines Pa_{O_2}. Although causes of hypoxemia primarily reflect failure of proper oxygen loading of the blood (low Pa_{O_2}) due to abnormal function of the respiratory system, defects in oxygen transport may result from either dysfunction of the cardiovascular system or hematologic issues. Finally, "misuse" of delivered oxygen, resulting from either defects in cellular metabolism or excessive demand, represents another class of disorders characterized by hypoxia. Each of these three categories is discussed below.

Arterial Hypoxemia

Hypoxemia may be defined as a validated deficiency of oxygen tension in the arterial blood. A P_{O_2} below the range of normal for age-matched subjects establishes the presence of arterial hypoxemia. Table 149-2 summarizes the major causes of hypoxemia. Since the driving force for oxygen transport across the alveolar barrier into the blood depends on both the concentration of oxygen in the alveolus (Pa_{O_2}) and overall respiratory function, arterial hypoxemia results only from reduction of the inspired oxygen tension or respiratory dysfunction.

The most common pathophysiological causes of hypoxemia in lung disease include ventilation-perfusion mismatch, true shunt, or a diffusion barrier. In some

Table 149-2

Causes of Arterial Hypoxemia and Response to Oxygen Therapy

Cause	Clinical Examples	Effect of Oxygen Therapy
Decreased oxygen intake	Altitude	Rapid increase in Pa_{O_2}
Ventilation-perfusion imbalance	Chronic obstructive pulmonary disese	Moderately rapid increase in Pa_{O_2}
Shunt	Atrial septal defect Pulmonary arteriovenous fistula	Rapid but variable increase in Pa_{O_2} depending on size of shunt
Diffusion defect	Interstitial pneumonitis	Moderately rapid increase in Pa_{O_2}
Alveolar hypoventilation	Chronic obstructive pulmonary disease	*Initial response*: Increase in Pa_{O_2} *Late response*: Variable depending upon whether supplemental O_2 depresses minute ventilation

nonpulmonary disorders, a low mixed-venous oxygen tension is responsible (Chapters 11 and 12). Alveolar hypoventilation, which also results in hypoxemia, acts indirectly through mechanisms that increase alveolar P_{CO_2} and secondarily decrease alveolar P_{O_2}. To a varying degree, most causes of arterial hypoxemia (with shunt physiology as the exception) can be improved by administration of supplemental oxygen. However, the magnitude of the response differs, based on the etiology.

Reduced Oxygen Delivery

In the setting of a normal Pa_{O_2}, tissue hypoxia may result from abnormalities in any of the determinants of oxygen delivery, including circulatory causes, abnormal blood oxygen transport, or maldistribution of blood flow.

Circulatory hypoxia results when fully oxygenated blood is delivered to tissues in insufficient quantity or at an inadequate level to support tissue metabolic needs. Usual etiologies include low cardiac output states, systemic hypovolemia, and arterial insufficiency of peripheral tissues. Compensation is partially effected at the tissue level initially by increased oxygen extraction from blood, resulting in lowering of mixed-venous oxygen tension ($\bar{v}_{O_2}$). Thus, a low $\bar{v}_{O_2}$ is the hallmark of circulatory hypoxia. Because Pa_{O_2} may be normal and the hemoglobin normally saturated, oxygen administration is unlikely to be of great help in the majority of these disorders.

Tissue hypoxia may also result from *abnormal blood-oxygen transport,* in which the oxygen-carrying capacity of the blood is reduced, as manifested primarily by a decrease in the total hemoglobin content (i.e., anemia), or secondarily as a consequence of abnormal hemoglobin-O_2 affinity. States of abnormal hemoglobin-O_2 affinity are characterized by an inability to bind oxygen (e.g., hemoglobinopathies) or to release oxygen to tissues (e.g., low levels of 2,3-diphosphoglycerate). Acquired defects result typically from binding of a ligand with stronger affinity for hemoglobin than oxygen (e.g., carbon monoxide) or a toxic alteration in hemoglobin structure (e.g., methemoglobin). Under these circumstances, cardiac output is increased as an adaptive response, and $\bar{v}_{O_2}$ is normal or decreased. Although not a primary therapy, oxygen administration may play an adjunctive role. In certain situations, including carbon monoxide poisoning, hyperbaric oxygen therapy (Chapter 62) may be helpful.

Finally, tissue hypoxia may result from *maldistribution* of a normal or supranormal cardiac output. Examples include microvascular perfusion defects observed in classical septic shock or in the more recently recognized systemic inflammatory response syndrome (SIRS) (Chapter 146). Maldistribution of perfusion leading to tissue hypoxia has also been described in other situations, such as experimental interleukin-2 therapy. The hallmark of a maldistributive hypoxia is the development of precapillary shunting in peripheral tissues. Thus, cardiac output is normal or increased, and $\bar{v}_{O_2}$ is usually low. Because of the presence of peripheral shunting, supplemental oxygen is usually not effective in increasing local cellular oxygen tension.

Cellular Causes of Hypoxia

Hypoxia may also arise from misuse of oxygen at the tissue level. Cellular hypoxia results from inhibition of either intracellular enzymes or oxygen-carrying molecules involved in intermediary metabolism and energy generation. In hydrogen cyanide poisoning, Pa_{O_2}, hemoglobin concentration, percentage of hemoglobin saturation, and tissue perfusion are normal. However, peripheral utilization of oxygen is impaired as cyanide binds to cytochrome oxidase and inhibits intramitochondrial transport of electrons to molecular oxygen. This event blocks production of ATP via oxidative phosphorylation, resulting in lactic acidosis as anaerobic metabolism is triggered. In addition, oxygen extraction is often impaired, leading to a normal or increased $\bar{v}_{O_2}$. Although oxygen therapy is usually not effective, 100 percent oxygen is often administered while the patient is treated with specific antidotes.

"Demand hypoxia" results when tissue oxygen utilization is supernormal and exceeds the rate of oxygen delivery. Common causes include maximal exercise and hypermetabolic states, such as thyrotoxicosis. As in circulatory hypoxia, $\bar{v}_{O_2}$ is decreased, but in contrast, cardiac output is normal or, more likely, increased. Because oxygen-carrying capacity is normal, oxygen administration is often ineffective, and definitive treatment requires control of the underlying disorder.

RECOGNITION AND ASSESSMENT OF TISSUE HYPOXIA

The correct use of oxygen therapy requires clinical recognition of tissue hypoxia, careful evaluation of the pathophysiological basis for the hypoxia, understanding of factors that predict those hypoxic patients likely to receive benefit, and continued assessment of the optimal dosage. The benefit must be balanced against potential toxicity. In most circumstances, tissue hypoxia is not directly measurable, and detection is usually accomplished through a combination of clinical and laboratory parameters. In cases of isolated arterial hypoxemia, awareness of tissue hypoxia is enhanced through inference of abnormal measurements of arterial oxygen saturation.

Clinical Manifestations

Clinical manifestations of hypoxia are highly variable and nonspecific and depend on both duration of the hypoxia (acute or chronic) and the individual's fitness. Symptoms and signs associated with acute hypoxia, outlined in Table 149-3, include changes in mental status, dyspnea, tachypnea, respiratory distress, and cardiac arrhythmias. Alterations in mental status range from impaired judgment to confusion or coma. Cyanosis, often considered a hallmark of hypoxia, occurs only when the concentration of reduced hemoglobin

Table 149-3

Signs and Symptoms of Acute Hypoxia

System	Signs and Symptoms
Respiratory	Tachypnea, breathlessness, dyspnea, cyanosis
Cardiovascular	Increased cardiac output, palpitations, tachycardia, arrhythmias, hypotension, angina, vasodilatation, diaphoresis, and shock
Central nervous	Headache, impaired judgment, inappropriate behavior, confusion, euphoria, delierium, restlessness, papilledema, seizures, obtundation, coma
Neuromuscular	Weakness, tremor, asterixis, hyper-reflexia, incoordination
Metabolic	Sodium and water retention, lactic acidosis

in the blood is 1.5 g/dl or greater. However, this is not a reliable sign, as it is absent in anemia and during periods of poor peripheral perfusion.

Laboratory and Other Objective Assessments

Because of the variability of presentation and nonspecificity of the symptoms and signs of hypoxia, the laboratory assessment of the state of tissue oxygenation is desirable. Unfortunately, the current state of the art remains imprecise. Quantification of the degree of oxygenation of individual tissues is difficult. The $\bar{v}_{O_2}$ represents an approximation of mean tissue P_{O_2}, and a level of less than 30 mmHg indicates overall tissue hypoxia. However, measurements of $\bar{v}_{O_2}$ require pulmonary artery catheterization and, therefore, are limited to intensive care settings.

In most clinical situations, direct determinations of Pa_{O_2}, arterial hemoglobin oxygen saturation, and serum lactate levels are surrogate markers for tissue hypoxia. Pa_{O_2} determinations are made invasively with blood samples obtained from arterial puncture or indwelling arterial catheters, while noninvasive assessment of percent saturation of blood hemoglobin is routinely available by infrared pulse oximetry. Both are useful in excluding arterial hypoxemia; neither directly measures tissue P_{O_2}. Inadequate tissue oxygen delivery is inferred from moderate decreases in Pa_{O_2}, and the inference is usually warranted in acutely ill patients whose Pa_{O_2} is less than 50 mmHg or in whom blood lactate levels are elevated. However, this judgment may be unsubstantiated in patients who are chronically hypoxemic and who have developed compensatory mechanisms. In addition, assumptions about the adequacy of tissue oxygenation may not be warranted in clinical settings in which factors other than arterial hypoxemia are responsible for the development of hypoxia (Table 149-1).

INDICATIONS FOR OXYGEN THERAPY

In every sense, oxygen must be thought of as a drug having a therapeutic window based on the dose and duration of administration. In addition, the cost of both short-term oxygen therapy for hospitalized patients and long-term therapy for patients with chronic lung disease dictates a rational understanding regarding its administration. For example, in the United States, using data from the Health Care Financing Administration, total annual Medicare expenditures for therapy and equipment range from $1.3 to $1.8 billion. Thus, indications for use of supplemental oxygen must be clear. Oxygen should be administered in precise amounts, and patients should be monitored for both efficacy and toxicity of treatment. Despite the facts that the scientific foundation underlying these principles is incomplete and that all-inclusive guidelines have been difficult to develop, the economic implications and requirements for laboratory monitoring have prompted development of recommendations for oxygen therapy. These recommendations allow the physician flexibility in exercising appropriate clinical judgment in prescribing oxygen in a cost-effective manner, in both acute and chronic settings.

Short-Term Oxygen Therapy

Recommendations for administration of supplemental oxygen, based upon guidelines of the American College of Chest Physicians, the National Heart, Lung and Blood Institute, and other organizations, are summarized in Table 149-4.

Tissue Hypoxia Associated with Arterial Hypoxemia

In the acute setting, the most common indication for supplemental oxygen, regardless of the underlying etiology, is arterial hypoxemia. For a normal, middle-aged adult, the usual level of hypoxemia at which oxygen therapy is instituted is a Pa_{O_2} of less than 60 mmHg. Based on the oxyhemoglobin dissociation curve, this value for Pa_{O_2} results in a hemoglobin saturation of about 90 percent. Because of the sigmoidal shape of the curve at this Pa_{O_2}, a further decrease in oxygen tension results in a considerable drop in oxygen saturation.

Ventilation-perfusion mismatch is the most common pathophysiological cause of arterial hypoxemia (see Chapter 11). The magnitude of the response to administration of supplemental oxygen depends upon the range and degree of ventilation-perfusion mismatch within individual lung regions. Therefore, repeated measurements of Pa_{O_2} or Sa_{O_2}

Table 149-4

Guidelines for the Use of Acute Oxygen Therapy

Accepted Indications

Acute hypoxemia (Pa_{O_2} < 60 mmHg; Sa_{O_2} < 90%)
- Cardiac and respiratory arrest
- Hypotension (systolic blood pressure < 100 mmHg)
- Low cardiac output and metabolic acidosis (bicarbonate < 18 mmol/L)
- Respiratory distress (respiratory rate > 24/min)

Questionable Indications

- Uncomplicated myocardial infarction
- Dyspnea without hypoxemia
- Sickle cell crisis
- Angina

** Data from Fulmer JD, Snider GL:* Chest *86:234–247, 1984.*

should be performed to document an effective response to a particular F_{IO_2}.

Hypoxemia secondary to right-to-left shunting is often less responsive to administration of supplemental oxygen. Mixing of shunted and unshunted blood results in a large fall in Pa_{O_2}. When the shunt fraction is greater than 20 to 25 percent, hypoxemia may persist, despite an F_{IO_2} of 1.0.

Finally, alveolar hypoventilation is often easily corrected with supplemental oxygen. However, recognition and correction of the underlying cause and immediate restoration of ventilation are the primary aims of treatment.

Although a Pa_{O_2} of 60 mmHg is a reasonable goal in the initial treatment of arterial hypoxemia, in certain clinical situations the acceptable threshold level may be adjusted upward or downward. For example, in patients with low oxygen-carrying capacity (e.g., severe anemia), or in flow-limited states (e.g., acute angina pectoris), increases in Pa_{O_2} beyond 60 mmHg (yielding increases in Sa_{O_2} from 90 to 100 percent) may result in marginal, but potentially important, increases in tissue oxygen delivery. Conversely, the "acceptable" Pa_{O_2} may have to be set at a lower level in patients with abnormal control of respiration, such as those with an acquired reduced hypoxic ventilatory drive due to chronic carbon dioxide (CO_2) retention.

Tissue Hypoxia with Normal Pa_{O_2}

The efficacy of supplemental oxygen in diseases that cause arterial hypoxemia is well-established. However, in cases where tissue hypoxia may exist without concomitant arterial hypoxemia, treatment should be directed ultimately to correcting the underlying cause. In these cases, Pa_{O_2} is an inadequate index of the need for, or the potential to benefit from, oxygen therapy. When available, alternative indices of tissue oxygenation should be used; oxygen therapy should be initiated and modified, based on the indices. Nevertheless, in some disorders, oxygen therapy has often been used even if Pa_{O_2} is not at a substantially depressed level. There is not always a consensus about the proper uses of oxygen in these circumstances.

Acute Myocardial Infarction

Hypoxemia is extremely common in acute myocardial infarction. In such patients, oxygen administration is of unquestioned benefit. Data supporting use of oxygen therapy in nonhypoxemic patients with acute myocardial infarction is controversial. Double-blinded studies of the value of oxygen in uncomplicated myocardial infarction demonstrate no significant effects on morbidity or mortality.

Inadequate Cardiac Output (Low-Flow States)

Oxygen has been recommended for temporary treatment of inadequate systemic perfusion resulting from cardiac failure. Although this practice seems reasonable, no clinical studies to date have proved the value of oxygen therapy in this setting. Oxygen therapy is used in conjunction with inotropic agents and other devices to assist cardiac output as definitive treatment is undertaken.

Trauma and Hypovolemic Shock

Oxygen has been advocated as adjunctive therapy in the setting of acute trauma. The low-flow state induced by acute hemorrhage is best treated by increasing the supply of circulating hemoglobin. However, supplemental oxygen as supportive therapy seems warranted until red blood cells become available for transfusion.

Carbon Monoxide Intoxication

In carbon monoxide poisoning, the Pa_{O_2} is a poor guide to the need for oxygen therapy. Despite a normal or "supranormal" Pa_{O_2}, a state of significant tissue hypoxia exists, as often indicated by a severe metabolic acidosis. Because of the high concentration of carbon monoxide–bound hemoglobin (carboxyhemoglobin), administration of supplemental oxygen does not increase tissue oxygen delivery. However, administration of pure oxygen markedly shortens the half-life of circulating carbon monoxide (80 min vs. 320 min on room air). Thus, oxygen administration for carbon monoxide poisoning constitutes an accepted therapy. Hyperbaric oxygen administration represents the current standard of care for those patients with high carboxyhemoglobin levels and evidence of end-organ ischemia-reperfusion damage (Chapter 62).

Miscellaneous Disorders

Use of supplemental oxygen as adjuvant therapy in sickle cell crisis, in accelerating resorption of air in pneumothorax, and for relief of dyspnea without hypoxemia remains controversial.

Long-Term Oxygen Therapy

In recent years, use of long-term oxygen therapy in the chronically ill patient has increased. In the United States, over 800,000 patients currently receive long-term oxygen therapy; most are patients with arterial hypoxemia. Patients with chronic obstructive pulmonary disease (COPD) represent the largest group of patients, and most of the data regarding clinical efficacy of supplemental oxygen come from studies of these patients.

Early studies of oxygen therapy in COPD showed that continuous supplemental oxygen administered for 4 to 8 weeks decreased the hematocrit, improved exercise tolerance, and lowered pulmonary vascular pressures. In the early 1980s, two well-controlled studies demonstrated the value of long-term oxygen administration in patients with chronic hypoxemia due to COPD. Both the Nocturnal Oxygen Therapy Trial (NOTT) and the British Medical Research Council Domiciliary (BMRCD) study documented a significant reduction in mortality in patients receiving supplemental oxygen compared with controls who received no supplemental oxygen. Although the treatment groups in the two studies are not directly comparable (patients in NOTT received either continuous or nocturnal oxygen, whereas those in BMRCD received nocturnal oxygen or no supplementation), nocturnal oxygen (greater than 15 h/day) is better than no oxygen; continuous supplemental oxygen imparts the most benefit. The greatest efficacy is seen in patients with polycythemia, pulmonary hypertension, or hypercapnia. Although similar studies in other groups of patients with chronic hypoxemia are not available, extension of the concept of long-term oxygen therapy for patients with resting hypoxemia from a variety of cardiopulmonary diseases, including restrictive lung disease, cystic fibrosis, and chronic cardiac disease, has become widely accepted in clinical practice.

Table 149-5 lists the currently accepted indications for long-term oxygen therapy. In addition to chronic arterial hypoxemia at rest, continuous-flow oxygen therapy is indicated for patients with exercise-induced hypoxemia (i.e., exercised-induced arterial desaturation). Current data suggest that supplemental oxygen improves exercise endurance, as measured by either treadmill walking or bicycle ergometry. However, since ventilatory, rather than circulatory, factors often limit exercise in patients with airflow obstruction, increasing oxygen saturation is not a reliable predictor of improved exercise performance in all patients.

A third group of patients who benefit from chronic oxygen administration are those who develop significant decreases in arterial oxygen during sleep. Included are patients with primary sleep-disordered breathing (e.g., obstructive sleep apnea and obesity hypoventilation syndrome) and patients with primary lung disease who exhibit nocturnal desaturation. For the first part of this group, oxygen therapy may need to be coupled with invasive or noninvasive ventilatory support for treatment of hypercarbia; the latter part of the group can often make use of low-flow oxygen to blunt arterial desaturation.

Table 149-5

Indications for Long-Term Oxygen Therapy

Continuous Oxygen

1. Resting Pa_{O_2} < 55 mmHg or oxygen saturation < 88%
2. Resting Pa_{O_2} of 56–59 mmHg or oxygen saturation of 89% in the presence of any of the following indicative of cor pulmonale:
   a. Dependent edema suggesting congestive heart failure
   b. P pulmonale on the electrocardiogram (P wave > 3 min in standard leads II, III, or aVF)
3. Polycythemia (hematocrit > 56%)
4. Resting Pa_{O_2} > 59 mmHg or oxygen saturation > 89% reimbursable only with additional documentation justifying the oxygen prescription and a summary of more conservative therapy that has failed.

Noncontinuous Oxygen*

1. During exercise: Pa_{O_2} < 55 mmHg or oxygen saturation < 88% with a low level of exertion
2. During sleep Pa_{O_2} < 55 mmHg or oxygen saturation 88% with associated complications, such as pulmonary hypertension, daytime sommolence, and cardiac arrhythmias

** Oxygen flow rate and number of h-day must be specified.*

In all patients, the need for additional supplemental oxygen should be based on measurements of arterial saturation. Certificates of medical necessity can then be completed appropriately. Most data support the notion that strategies for delivery of long-term oxygen should include early follow-up for assessing efficacy, followed by routine reevaluation at fixed intervals.

TECHNIQUES OF OXYGEN ADMINISTRATION

In either the acute or chronic setting, once the need for supplemental oxygen is established, one of several types of delivery devices can be used to supply the patient with O_2-enriched gas. The choice of delivery system is based upon a variety of criteria, including: (1) the degree of hypoxemia, (2) the requirement for precision of delivery, (3) patient comfort, and (4) cost. The devices discussed below are reserved primarily for conscious patients who are capable of protecting their airways. Not included in the discussion are details on the use of endotracheal intubation (Chapter 151) or mechanical ventilation (Chapter 153).

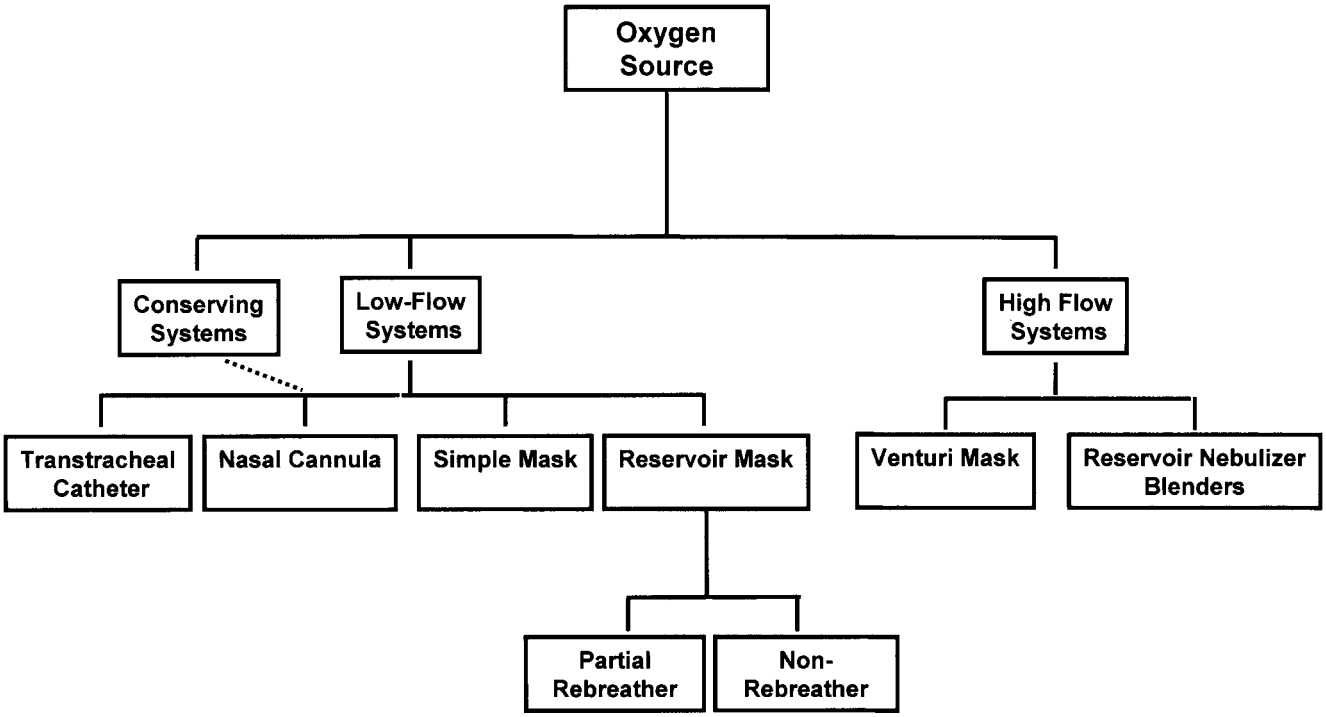

Figure 149-3 Commonly used classes of oxygen delivery systems. See text for complete descriptions.

Oxygen Delivery Systems in the Acute Setting

A variety of delivery systems are available for short-term oxygen administration. The systems vary in complexity, expense, efficiency, and precision of oxygen delivery. Other than anesthesia breathing circuits, virtually all oxygen delivery systems are non-rebreathing (full or partial). In non-rebreathing circuits, the inspiratory gas is not made up of any portion of the exhaled volume, and the only inhaled CO_2 is that which is entrained from ambient room air. Rebreathing is avoided through use of one-way valves to sequester expired from inspired gases. In addition, in all these systems, inspired gas mixtures must be presented in sufficient volume and at flows to allow compensation for the high-flow demands often exhibited by critically ill patients.

The major types of oxygen delivery systems are outlined in Fig. 149-3. They can be divided into low-flow and high-flow varieties, each of which can deliver humidified, inspired gases. Each has advantages and drawbacks.

Low-Flow Oxygen Devices

Low-flow oxygen delivery systems provide a fraction of the patient's minute ventilatory requirement as pure oxygen; the remainder of the ventilatory requirement is fulfilled by addition of another gas, usually entrained room air. Flows supplied through these devices are low (less than 6 L/min), and they cannot deliver constant inspired oxygen concentrations, since small fluctuations in each tidal volume lead to variations in the amount of entrained room air. Consequently, in patients with an abnormal or variable ventilation pattern, marked variation in the fraction of inspired oxygen may exist. Patient-related factors that affect the fractional concentration of inspired oxygen include: (1) shallow breathing, which results in entraining less room air and, therefore, a higher concentration of inspired oxygen; (2) deep, hyperpneic breathing, which enhances entraining of more room air; and (3) changes in respiratory frequency, which affect exhalation time, thereby producing variable filling of the device's inspiratory reservoir. When the delivery of a constant F_{IO_2} is required (e.g., in patients with chronic CO_2 retention), low-flow systems should not be used.

Nasal Cannulae

Nasal catheters and cannulae are the most widely used devices for delivering low-flow oxygen. They are simple, inexpensive, easy to use, and well-tolerated. As for all low-flow systems, the F_{IO_2} may vary greatly, depending on the oxygen flow, inspiratory flow, and minute ventilation. With low-flow nasal cannulae set to deliver oxygen to the nasopharynx at flows between 1 and 6 L/min, the F_{IO_2} ranges between 0.24 and 0.44 (Table 149-6). Flows above 6 L/min do not significantly increase F_{IO_2} above 44 percent; these higher flows may result in drying of mucous membranes.

Oxygen Masks

Simple plastic oxygen masks which cover the nose and mouth are capable of delivering concentrations of oxygen up to 50 to 60 percent. Depending on mask size, these devices provide a self-contained reservoir of 100 to 200 ml of additional gas,

Table 149-6

Approximate Fraction of Inspired Oxygen with Low- and High-Flow Oxygen Devices

100% O_2 Flow Rate (L/min)	F_{IO_2} (%)

thereby facilitating increases in the achievable fraction of inspired oxygen above 0.44. Simple face masks require a flow of inspired oxygen of 5 to 6 L/min to avoid accumulation of CO_2 within the mask.

Conventional oxygen masks suffer from the limitations of all face masks. They interfere with drinking, eating, and expectorating, and they can become displaced, particularly at night as the patient sleeps. In addition, use of face masks increases the risk of aspiration by concealment of vomitus or containment of regurgitant materials. Therefore, when using these devices, the risk-benefit ratio should be considered. As with nasal cannulae, respiratory mucous membrane drying from the inspired gas mixture is possible. Humidification of inspired gas reduces the magnitude of the problem.

Masks with Reservoir Bags

To deliver an F_{IO_2} of greater than 0.6 to patients who do not have artificial airways, a reservoir bag (600 to 1000 cc) can be attached to a simple face mask (Fig. 149-4). A source of continuous oxygen at flow rates of 5 to 8 L/min is needed to ensure adequate distention of the bag and to flush out CO_2 from the mask. If there are no one-way valves on the reservoir bag, the apparatus is referred to as a *partial non-rebreathing mask* (Fig. 149-4*A*). Partial non-rebreathing masks can deliver oxygen in concentrations of 80 to 85 percent. The true non-rebreathing mask makes use of a one-way valve between the mask and the bag so that the patient can only inhale from the reservoir bag and exhale through separate valves on either side of the mask (Fig. 149-4*B*). A very high F_{IO_2} can be achieved when these masks fit tightly against the patient's face. However, tight-fitting molded masks, including those used to deliver continuous positive airway pressure (CPAP), are often uncomfortable and are not suitable for use for more than a few hours.

High-Flow Oxygen Delivery Devices

High-flow oxygen delivery systems maintain the selected F_{IO_2} by incorporating a reservoir whose volume exceeds the patient's anatomic dead space or by delivering oxygen at a very high flow. In quantitative terms, the flow of all high-flow systems exceeds four times the patient's actual minute volume; otherwise, entrainment of room air at peak inspiration arises.

Common clinical indications for use of a high-flow oxygen delivery system are: (1) treatment of hypoxic patients who depend on their hypoxic drive to breathe but who require controlled increments in F_{IO_2}, and (2) young, vigorous patients with hypoxemia who have an abnormal ventilatory pattern and whose ventilatory requirements may exceed the delivery capabilities of low-flow systems. When a clinical indication exists for a tightly controlled, high F_{IO_2}, or when high flows are necessary, a high-flow delivery system should be used.

Jet-Mixing Venturi Masks

Another high-flow oxygen delivery device is the Venturi mask, the operation of which is based on the Venturi modification of the Bernoulli principle of fluid physics for gaseous jet-mixing (Fig. 149-5). As forward flow of inspired gas increases, the lateral pressure adjacent and perpendicular to the vector of flow decreases, resulting in entrainment of gas. In a Venturi mask, a jet of 100 percent oxygen flows through a fixed constrictive orifice, past open side ports, thereby entraining room air. The flow of jetting gas passing through, and then out of, the central orifice of the mask increases in velocity, and the resultant pressure drop along the sides of the jet draws room air into the face mask via the side ports. The amount of air entrained and, therefore, the resultant F_{IO_2}, depend on the size of the side ports and flow of oxygen. Since both of these parameters are fixed, the resultant oxygen-room air mixing ratio is held steady, resulting in a well-controlled, constant F_{IO_2}. Exhalation occurs through valved exhalation ports. The range of F_{IO_2} obtainable through adjustments in the amount

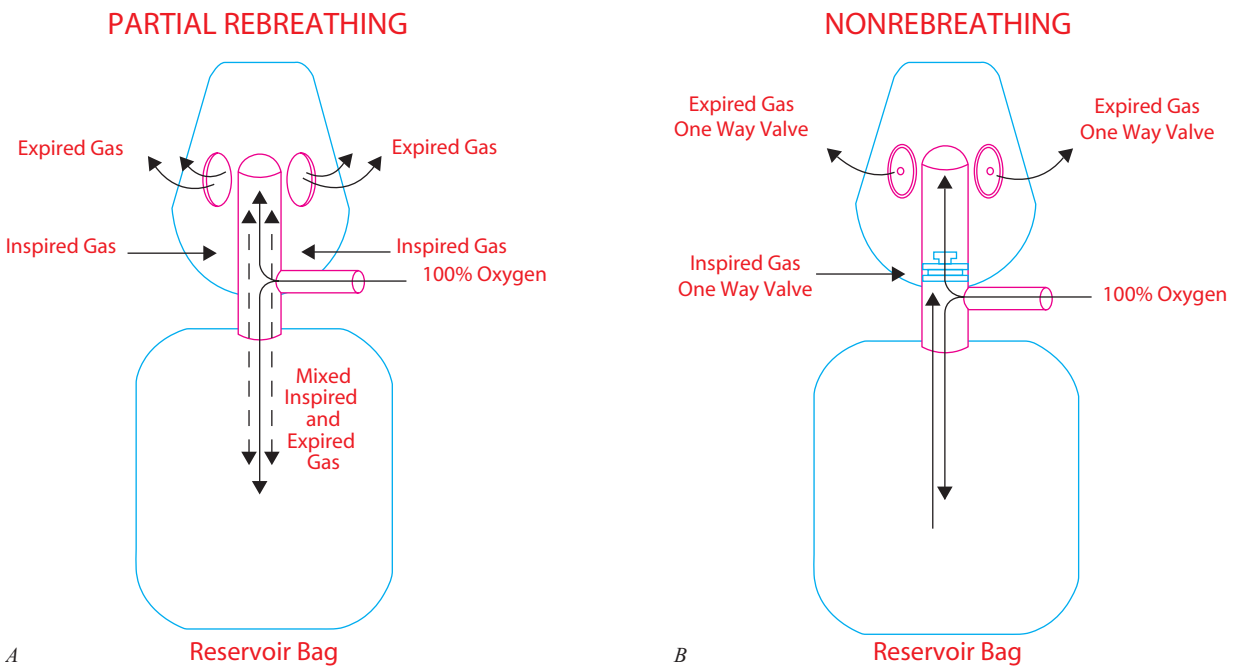

Figure 149-4 Mask-reservoir bag systems, illustrating airflows with partial rebreathing (*A*) and nonrebreathing (*B*) masks. Arrows indicate direction of airflow. See text for details.

of entrained room air and oxygen flow (i.e., the "entrainment ratio") is broad (Table 149-6). Masks currently in use deliver inspired gas with an F_{IO_2} between 0.24 and 0.50.

Since the Venturi mask reliably provides an accurate F_{IO_2} up to 0.50, it is an ideal device for use in treatment of hypoxemia in patients with COPD and chronic respiratory failure characterized by a blunted hypercarbic respiratory drive. Although the F_{IO_2} usually can be regulated precisely, technical factors can alter the value. For example, water drops may clog the oxygen injector device, resulting in changes in gas flow. In addition, development of back pressure by occluded exhalation ports may lead to decreases in the volume of entrained room air and a resultant increase in F_{IO_2}.

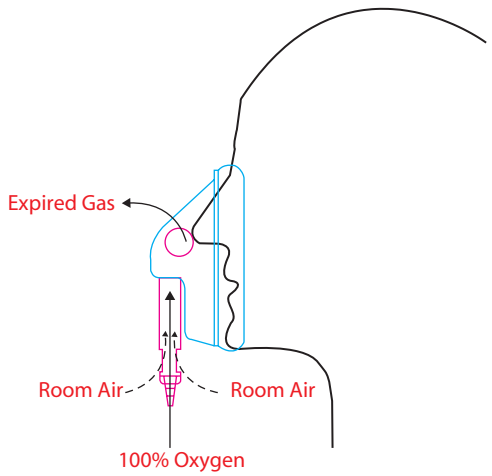

Figure 149-5 Venturi mask. Arrows denote direction of airflow. See text for details.

Other High-Flow Systems

Reservoir nebulizers and humidifiers are used to provide supplemental oxygen or highly humidified gas (including room air). Provision of high humidification is often important as adjuvant management of increased airway secretions. Usually, this delivery system is combined with endotracheal tubes or tracheostomy collars, and, therefore, its use is limited to patients with artificial airways. However, such delivery systems have also been used in combination with aerosol masks, face tents, and CPAP masks. If high-flow rates (in excess of 40 L/min) are supplied, they can usually provide a constant and predictable F_{IO_2}.

Air-oxygen blenders consist of precision metering devices that convert high-pressure wall sources of compressed air and oxygen (at 50 to 70 psi) to usable, predictable flows of up to 100 L/min at an F_{IO_2} ranging from 0.21 to 1.0. These devices also require pressure-reduction valves and an inlet pressure monitor to ensure consistency of F_{IO_2} against minor fluctuations in wall pressure. Although they provide a predictable F_{IO_2}, the devices have some disadvantages. They are noisy and require specialized personnel to set up and monitor the instrumentation.

Long-Term Oxygen Delivery Systems

A variety of modes of oxygen delivery and oxygen administration devices are available for use in the home and other chronic care settings. Gas supplies for long-term oxygen therapy include oxygen concentrators and compressed gas or liquid oxygen sources. Most patients requiring a stationary source of supplemental oxygen use oxygen concentrators.

Because the concentrators weigh about 35 lb and require wall current, their use is limited as a fixed source of oxygen. Unless patients are immobile or confined to bed, both stationary and mobile oxygen delivery systems should be employed. Both compressed gas and liquid oxygen portable systems are available, but the liquid system containers are easier to refill than high-pressure cylinders. The major disadvantages of liquid oxygen are higher cost and the requirement for pressure-relief venting.

The delivery devices for long-term oxygen therapy include most of the low-flow devices described previously. Most patients who receive chronic oxygen use nasal cannulae and oxygen flow rates of 2 to 4 L/min.

To improve the efficiency of oxygen delivery and to limit both the need for repetitive home delivery and cost, a number of devices have been designed to "conserve" home oxygen. These include reservoir nasal cannulae, electronic conserving devices, and transtracheal catheters.

The reservoir nasal cannulae have a pouch that stores 20 ml of extra oxygen during expiration and delivers the oxygen as a bolus at the onset of the next inspiration. Electronic demand devices, triggered by the onset of inspiration, deliver a pulse of oxygen early in the breath. Oxygen conservers include those that deliver a fixed volume per breath (pulse devices) and those that deliver a variable volume, which is commensurate with the length of inspiration (demand devices). Pulse-type devices deliver fixed volumes for each flow setting each time a pulse is triggered and do not deliver any more or less volume as the length of the patient's inspiration time varies. Some pulse devices deliver with every breath, others with alternate breaths. By comparison, demand devices vary the amount of oxygen delivered during each and every breath, consistent with the duration of inhalation. Following the initial gas bolus, demand devices deliver (at an equivalent flow) a continuous flow for the remainder of the inspiration. These devices provide a variable volume at each flow setting, depending on the length of inspiration, and they have lower levels of savings at low breath rates. In addition, demand devices tend to deliver volumes equal to or greater than those achieved using continuous flow therapy in most settings; in the event of conserver malfunction, they revert automatically to continuous flow without patient interaction.

Transtracheal catheters improve oxygen delivery by bypassing the anatomic dead space of the upper airway, effectively using the upper airway as an oxygen reservoir during inspiration and expiration. Transtracheal oxygen is delivered directly into the trachea via a hollow catheter implanted surgically under local anesthesia, or inserted percutaneously using the Seldinger technique. In numerous studies, transtracheal catheters have been shown to effect reductions in total oxygen usage of 50 to 75 percent. Other advantages of transtracheal oxygen systems include their inconspicuousness, lack of nasal or facial irritation due to oxygen flow, and infrequency of catheter displacement during sleep. Disadvantages include an increased incidence of infection, development of potentially fatal "mucus balls," and catheter breakage which necessitates replacement.

PULMONARY OXYGEN TOXICITY

Potential adverse effects of exposure to increased oxygen tensions at one atmosphere include alterations of normal physiological functions and oxygen-mediated tissue damage.

Physiological changes to high concentrations of oxygen involve perturbations of both pulmonary and extrapulmonary homeostasis; they are easily correctable, if recognized promptly. Extrapulmonary physiological effects of hyperoxia include suppression of erythropoiesis, systemic vasoconstriction, and depression of cardiac output. These effects are usually clinically insignificant. In contrast, pulmonary physiological effects of hyperoxia include depression of hypoxic ventilatory drive, pulmonary vasodilation, and absorption atelectasis. Each is clinically relevant.

In addition to producing adverse physiological effects, oxygen in high concentrations is cytotoxic. Whereas all respiring cells are potentially susceptible to the toxicity derived of hyperoxia, the major clinical adverse effects are related to lung damage.

Molecular and Cellular Mechanisms of Oxygen Toxicity

The molecular and cellular bases for tissue injury in oxygen toxicity are thought to be mediated biochemically by reactive free radicals, the formation of which directly depends on the oxygen concentration. Since oxygen concentration is directly proportional to partial pressure, breathing 100 percent O_2 at an altitude of 5000 feet (0.8 ata), 80 percent O_2 at sea level (1 ata), or 40 percent O_2 in a hyperbaric chamber (2 ata) for the same duration results in a similar toxicity profile.

Aerobic cells utilize oxygen both as a metabolic substrate for the generation of ATP via the electron transport chain, and as a cofactor in intermediary metabolism involving oxidation or hydroxylation of various substrates. Molecular oxygen (O_2), per se, is relatively nonreactive and nontoxic. However, modification of molecular oxygen by addition of electrons (e^-) can result in formation of highly reactive free radicals. The consequences of the sequential addition of single electrons to molecular oxygen are illustrated in the following reaction:

$$\begin{array}{cccc} e^- & e^- + 2H & e^- & e^- + H \\ & & O_2 \rightarrow O_2\cdot^- \rightarrow H_2O_2 \rightarrow OH\cdot \rightarrow H_2O & (3) \end{array}$$

Superoxide anion ($O_2^{\cdot -}$), hydrogen peroxide (H_2O_2), and hydroxyl radical ($OH\cdot$) represent 1-, 2-, and 3-electron reduction products of oxygen, respectively. Singlet oxygen ($O_2\cdot$), a potent electrophile, is also generated as a by product of oxygen-dependent metabolism. During normal cellular metabolism, almost all molecular oxygen is converted completely to water, and the enzymes responsible for the reduction reactions (e.g., cytochrome oxidase, cytochrome P450, dopamine-β-hydroxylase) release few or no O_2 intermediates. However, under certain conditions, these cellular

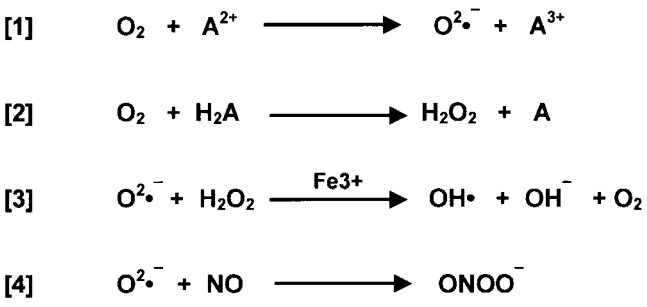

Figure 149-6 Generation of free radicals. Mechanisms for generation of toxic species of oxygen include: (1) superoxide anion (O_2^-) generation by 1-electron reduction of molecular oxygen (O_2) through a variety of electron donors (A^{2+}); (2) hydrogen peroxide (H_2O_2) generation by 2-electron reduction of O_2, usually via enzymatic catalysis; (3) interaction of superoxide and hydrogen peroxide in the presence of metals which generate hydroxyl radical; and (4) production of peroxynitrite by diffusion-limited reaction of superoxide and nitric oxide.

enzymes, as well as others, can be misused by serving as incomplete electron donors (i.e., fewer than four electrons) to molecular oxygen, generating and releasing the reactive O_2 intermediates shown in Eq. (3) above.

Figure 149-6 depicts general mechanisms responsible for generation of toxic metabolites of oxygen reduction. $O_2\cdot^-$ (reaction 1) and H_2O_2 (reaction 2) are each generated by both enzymatic and nonenzymatic processes. Although both molecular species may have direct toxic effects, their interaction via the Haber-Weiss cycle, in the presence of metal ions (typically, Fe^{3+}), may generate hydroxyl radicals (reaction 3) which represent the most highly reactive and potentially dangerous of the O_2-derived products.

Superoxide has also clearly been shown to interact with other molecular species, such as nitric oxide (NO), which result in production of the free radical, peroxynitrite (ONOO), as illustrated in reaction 4 in Fig. 149-6. The second-order rate constant for the reaction of NO and $O_2\cdot^-$ to form peroxynitrite is 6.7×10^9 $M^{-1}s^{-1}$. This represents a reaction rate that is three times faster than the clearance of superoxide by superoxide dismutase.

Mechanisms of Pulmonary Cellular Toxicity

The previously described generalized mechanisms of oxygen toxicity and metabolic intermediates are probably operative in the lung. Hyperoxia has been shown to stimulate increases in oxygen radical production in whole rat lungs, lung mitochondria, lung microsomes, lung nuclear membranes, and in cultured pulmonary endothelial cells, providing important support for the free radical hypothesis. Likewise, peroxynitrite formation has been detected in cultured cells in some animal models of acute lung injury, as well as in infants with bronchopulmonary dysplasia.

Mitochondria appear to be the major subcellular source of $O_2\cdot^-$ which is produced by the oxidation of ubisemiquinone as part of the normal mitochondrial electron transport chain and by autooxidation of NADH dehydrogenase. Additional $O_2\cdot^-$ is generated by: (1) the endoplasmic reticulum (and microsomes), through the auto-oxidation of flavins (e.g., cytochrome P450) or other components, as well as during turnover of NADPH-cytochrome c reductase; and (2) plasma membranes, by auto-oxidation of cytochromes and during prostaglandin synthesis. H_2O_2 is produced at most of the aforementioned sites by the dismutation of $O_2\cdot^-$ and via oxidase activity (e.g., urate oxidase) in peroxisomes. $HO\cdot$ is generated where concentrations of $O_2\cdot^-$ and H_2O_2 are greatest (i.e., near their production sites). Because peroxynitrite is generated by a diffusion-limited reaction, it may be formed as physiological pH at any cellular sites that contain significant amounts of NO and $O_2\cdot^-$.

The biochemical alterations produced by modification of cellular components by oxygen radicals and peroxynitrite are depicted in Table 149-7. Lipid peroxidation and protein oxidation are thought to represent important mechanisms

Table 149-7

Biochemical Alterations and Cellular Dysfunction from Free Radical Damage

Cell Component	Cellular Manifestation
Oxygen Radicals	
Lipids	Damage to cell and organelle membranes
Lipid peroxidation	
Surfactant	Altered lung mechanics
Eicosanoids	Changes in cellular metabolism and intracellular signaling
Proteins	Inactivation of enzymes and transport proteins; Altered cellular and intercellular permeability
Nucleic acids	Inhibition of cell growth and division
Pyridine nucleotides	Altered intermediary metabolism
Complex carbohydrates	Altered recognition of macromolecules
Peroxynitrite	
Proteins	
Nitrotyrosine formation	Inactivation of enzymes and transport proteins
Sulfhydryl groups	
Nucleic acids	
8-Nitroguanine formation	Cell death
Lipid peroxidation	Cell and organellar membrane damage

of direct O_2 radical toxicity. Lipids containing unsaturated fatty acids are particularly susceptible to injury. Lipid hydroperoxides produced as intermediates are extremely toxic and can propagate the peroxidation process in an autocatalytic manner. Proteins are inactivated by reaction of radicals with sulfhydryl groups, through cross-linkage of proteins, or oxidation of constituent amino acids. Destruction of lipid and protein results in damage to cellular and organellar membranes, inactivation of key enzymes, and disruption of cellular transport mechanisms. In addition, DNA, pyridine nucleotides, and complex carbohydrates are susceptible to oxidative processes, leading to mutagenesis, growth inhibition, and alteration of intermediary metabolism. Peroxynitrite is a powerful oxidant and, as such, has been shown to oxidize many cellular components. Of particular interest is its interaction with proteins, resulting in oxidation of sulfhydryl groups and formation of nitrotyrosine residues.

Cellular Antioxidant Defenses

The half-life and tissue levels of most reactive oxygen species are low, in part due to an elaborate network of cellular antioxidant defenses. Antioxidant mechanisms include any cellular process which (1) prevents formation of free radicals, (2) converts oxidants to less reactive species, (3) "compartmentalizes" reactive species away from important cellular structures, or (4) initiates repair of molecular injury by free radicals.

Cellular oxygen radical defenses are classified into three basic categories: (1) enzymatic scavenging systems, which directly catalyze removal of free radicals; (2) enzyme-cofactor systems, which use a recyclable (renewable) intermediate to remove or prevent formation of O_2 radicals; and (3) nonenzymatic free radical scavengers, which re-reduce O_2 radicals or quench radical-producing reactions.

The major enzymatic O_2 radical scavenger in the lungs is superoxide dismutase (SOD). SOD is a metalloprotein present in three distinct forms, each of which has a metallic cofactor. Copper-zinc SOD is a dimeric protein which is predominantly cytosolic; manganese SOD is found mainly in mitochondria. Copper SOD, a tetrameric peptide, has been isolated from plasma. All forms of SOD catalyze the dismutation of $O_2 \cdot^-$ to H_2O_2 at very high rates. Hydrogen peroxide is subsequently removed enzymatically by either the glutathione (GSH) redox cycle (see below) or by catalase.

The GSH redox cycle is the most important cellular scavenger of H_2O_2. It represents a unique system that uses multiple enzymes and a renewable, low-molecular-weight scavenger. GSH peroxidase removes both H_2O_2 and lipid peroxides at the expense of GSH oxidation. GSH is regenerated by GSH reductase, using NADPH as a cofactor.

Low-molecular-weight, nonenzymatic free radical scavengers include ascorbic acid (vitamin C), α-tocopherol (vitamin E), and β-carotene (vitamin A). These nonrecyclable compounds are derived from extrinsic (dietary) sources.

PATHOPHYSIOLOGY OF OXYGEN TOXICITY

The toxic effects of oxygen on the lung occur when free radical production during hyperoxic exposure overwhelms intrinsic antioxidant defenses. Excess free radicals interact with cellular components, resulting in cytotoxic events which produce a characteristic cascade of biochemical, cellular, morphologic, and physiological changes. The biochemical reactions, in turn, result in a sequence of characteristic cellular and morphologic changes.

Primary Morphologic and Cellular Changes

Based primarily on data from animal models and some limited human studies, four basic phases constitute the development of oxygen toxicity in lung tissue. The first three phases—initiation, inflammation, and destruction—occur during exposure to both lethal and sublethal doses of hyperoxia. The fourth phase—proliferation and fibrosis—occurs if there is re-exposure to sublethal oxygen levels. If lethal exposure persists, ongoing tissue destruction and death are observed.

Initiation Phase

The initiation phase of oxygen toxicity comprises the first few hours and continues throughout the duration of exposure. Initiation follows short-term exposure to lethal doses of O_2 and occurs over longer periods, with sublethal hyperoxia. In each setting, the initiation phase is associated with enhanced rates of oxygen radical formation; however, there is no significant evidence of morphologic injury. Decreased rates of protein synthesis, alterations in tracheobronchial clearance of particulates, and changes in endothelial cell function have been described.

Inflammatory Phase

The earliest morphologic changes in the lung in response to hyperoxia occur as a consequence of primary cellular damage. They involve subtle changes in endothelial cell structure, resulting in pericapillary accumulation of fluid. Increased leakage from the pulmonary microcirculation via disruptions in the endothelial lining follows, along with accumulation of proteinaceous fluid, formation of hyaline membranes, and an influx of inflammatory blood cell elements with release of mediators. This combination of events gives rise to a pathological picture resembling noncardiogenic pulmonary edema, including morphologic characteristics of diffuse alveolar damage—a process frequently associated with acute respiratory distress syndrome (ARDS) and other forms of lung injury (see Chapters 144 and 145).

Destruction Phase

Overt cellular destruction begins shortly after the inflammatory phase. From a large body of in vitro and in vivo evidence it now appears that two major patterns of cell death, apoptosis and necrosis, occur in the lung in response

to hyperoxia. Apoptotic signaling pathways appear to involve both the cell death receptor (CD40-CD40 ligand) and mitochondria-dependent pathways with activation of caspase family members. The earliest evidence for impending cellular destruction appears at the ultrastructural level. Observed changes in lung epithelial and endothelial cells include membrane damage, vacuolarization of cytoplasm, mitochondrial swelling, and nuclear degeneration. Soon thereafter, frank cell death is seen, and exposure of the basement membrane occurs.

Proliferation and Fibrosis Phase

If exposure to toxic levels of O_2 is terminated, a subacute or chronic stage, termed the *proliferative phase,* develops. The cellular proliferative response blunts the destructive phase and may enhance survival. Proliferation of type II pneumocytes occurs as alveolar remodeling takes place. In addition, an influx and proliferation of interstitial cells (fibroblasts, monocytes, and macrophages) appears to be mediated by both cytokine and autocrine factors; collagen deposition is seen as well. In baboons, lung histology and function have been shown to return to normal within 6 months of recovery from severe oxygen toxicity. However, in other settings, the end result may be, instead, varying degrees of fibrosis or emphysema. The complete complement of regulating factors remains to be defined.

In the aggregate, the pathophysiological and morphologic changes associated with hyperoxic stress are similar to other forms of diffuse alveolar damage. An initial inflammatory response (exudative phase) is followed by fibrosis and repair (proliferative phase), a sequence not dissimilar from other forms of ARDS.

Secondary Changes

The cellular changes that occur in response to toxic oxygen exposure also produce secondary changes in lung function. The increased capillary permeability that occurs with cellular damage results in decreased lung compliance, an increased alveolar-arterial oxygen gradient, and a decreased carbon monoxide diffusing capacity. Hyperoxia has also been reported to alter the pulmonary surfactant system. Alveolar surfactant material recovered from animals exposed to hyperoxic conditions exhibits markedly decreased surface tension–lowering capabilities. One potential explanation appears to be inactivation of the biophysical activity of surfactant by serum proteins which leak into the alveolar space.

CLINICAL SYNDROMES OF OXYGEN TOXICITY

The scenario of clinical events following exposure to hyperoxic environments is well-described as summarized in Table 149-8.

Table 149-8

Sequence of Pulmonary Changes during Hyperoxic Exposure in Humans

O_2 at 1 atm	Exposure Duration	Manifestions
100%	>12 h	Decreased tracheobronchial clearance; decreased forced vital capacity; cough; chest pain
	>24 h	Altered endothelial function
	>36 h	Increased alveolar-arterial oxygen gradient; decreased carbon monoxide diffusing capacity
	>48 h	Increasing alveolar permeability; pulmonary edema; surfactant inactivation
	>60 h	Acute respiratory distress syndrome
60%	7 days	Mild chest discomfort without changes in lung mechanics; possible changes in morphometry
24–28%	Months	Subclinical pathological changes; no clinical toxicity documented

Acute Toxicity: Tracheobronchitis and Acute Respiratory Distress Syndrome (ARDS)

Normal volunteers exposed to 100 percent O_2 experience symptoms within 12 to 24 h. The earliest manifestations represent effects on the tracheobronchial mucosa and include substernal chest pain and nonproductive cough. Measurements of tracheobronchial function show decreased particle clearance as early as 6 h after the start of exposure to 100 percent O_2. Systemic symptoms, including malaise, nausea, anorexia, and headache may be seen.

The onset of acute pulmonary oxygen toxicity usually follows an asymptomatic period during which no physiological changes are seen. In normal volunteer subjects given 100 percent O_2 for 6 to 12 h, no abnormalities were noted in the alveolar-arterial oxygen gradient, pulmonary artery pressure, vascular resistance, cardiac output, pulmonary extravascular lung water, or chest radiograph. By 24 h, significant decreases in their vital capacities were found, and at 48 h of exposure to 98 percent oxygen, decrements in static compliance and carbon monoxide diffusing capacity were seen. In patients with irreversible brain damage given 100 percent O_2, the

alveolar-arterial gradient increased precipitously after 40 to 60 h. The longest voluntary exposure to 100 percent O_2 reported is 110 h; the subject developed severe dyspnea, a marked decrease in pulmonary function, and acute respiratory failure.

Chronic Pulmonary Syndromes

Although not well understood in humans, the subacute and chronic phases of oxygen toxicity are well documented in animals and appear to be related to dose and duration of exposure. The best-known clinical syndrome of chronic pulmonary oxygen toxicity occurs in newborns receiving oxygen for treatment of neonatal respiratory distress syndrome. Persistent morphologic changes with healing may produce the chronic disorder bronchopulmonary dysplasia. The effects of long-term exposure of adults to inspired oxygen concentrations of 60 to 100 percent are less clear, although morphometric changes after 13 days of exposure in brain-dead patients have been described. Data on longer exposures, including exposure to lower levels of inspired oxygen, are unavailable.

Diagnosis

Pulmonary oxygen toxicity develops insidiously after a variable lag period, during which the biochemical and cellular changes described previously occur. Early clinical detection of oxygen toxicity during this lag period is impossible; tests to identify biochemical changes (e.g., lipid peroxidation) would improve diagnostic accuracy. However, such tests are currently unavailable for clinical use. Although reversible (early) physiological, anatomic, and biochemical changes can be detected following short exposure to hyperoxia, humans can tolerate 100 percent oxygen at sea level for 24 h without serious pulmonary injury. Currently, the diagnosis of hyperoxic lung injury depends on a nonspecific symptom complex or abnormal pulmonary function in the proper clinical setting.

Symptoms and Signs

Development of chest pain, tachypnea, or cough in a patient breathing elevated concentrations of oxygen should alert the clinician to the possibility of oxygen toxicity. The best index of oxygen toxicity may be the individual's subjective symptom of retrosternal chest pain. Unfortunately, in a critically ill patient who requires mechanical ventilation or who has an altered mental status, detection of subjective complaints is difficult or impossible. On physical examination, the presence of crackles suggestive of interstitial or alveolar edema may be noted as a nonspecific finding.

Pulmonary Function Tests

Decreases in vital capacity, pulmonary compliance, or carbon monoxide diffusing capacity, as well as a widening of the alveolar-arterial oxygen gradient, have been observed during hyperoxic exposures. Monitoring serial changes in vital capacity has been proposed as a means of detecting and following injury from oxygen exposure. However, the practicality and cost-effectiveness of such testing remains unsubstantiated.

Radiographic Changes

The chest radiographic findings of increased interstitial markings or alveolar filling are similar to those found in other causes of diffuse alveolar damage; the findings are nonspecific and are insensitive as early markers.

Potentiation of Oxygen Toxicity

Susceptibility of cells or organisms to oxygen toxicity can be modified by factors other than intrinsic cellular antioxidant mechanisms. Many therapeutic drugs act synergistically with hyperoxia, accelerating free radical production and worsening oxygen toxicity. Bleomycin has been shown to increase lung injury and fibrosis through enhanced production of $O_2.^-$. Potentiation of oxygen toxicity by disulfiram occurs through inhibition of cytosolic superoxide dismutase by diethyldithiocarbamate, which is produced in vivo from the conversion (reduction) of disulfiram. The metabolism of nitrofurantoin and paraquat results in production of superoxide or hydroxyl radicals, and O_2 has been shown to increase their cytotoxicity. Variability of dietary intake can also modify oxygen tolerance. Protein malnutrition, as well as dietary deficiency of any of the antioxidant quenchers, may alter the response to hyperoxia. Protein deficiency is thought to potentiate toxicity from hyperoxia due to a lack of sulfur-containing amino acids which are crucial for GSH synthesis. The adverse effects of vitamin A and vitamin E deficiencies are also well described.

Prevention and Therapy

As with other drugs, oxygen should be administered judiciously, in doses designed to achieve therapeutic efficacy with limited toxicity. Because early detection of oxygen toxicity has remained elusive and specific therapy is lacking, avoidance of pulmonary toxicity during oxygen therapy remains the cornerstone of management. The best approach is to monitor the efficacy of the inspired oxygen concentration and to adhere to guidelines to use doses that have not been found to be associated with major side effects.

The primary therapeutic goal associated with use of supplemental oxygen is assurance of adequate tissue oxygenation without use of toxic levels of F_{IO_2}. A significant obstacle in achieving this goal centers around monitoring the efficacy of oxygen therapy and assessing the adequacy of tissue oxygenation. As noted previously, the clinical approach entails correction of arterial hypoxemia as the cause of tissue hypoxia and assessment of the response to supplemental oxygen administration through measurement of Pa_{O_2} or use of continuous, cutaneous, infrared pulse oximetry.

Extrapolations about the state of tissue oxygenation from measurement of $\bar{v}_{O_2}$ using an indwelling pulmonary artery catheter can be used in the critical care setting. Transcutaneous estimations of tissue P_{O_2} and, hence, intracellular oxygen sufficiency, remain experimental. Based upon general consensus, the following guidelines can be offered regarding oxygen administration at 1 atmosphere.

Oxygen in concentrations up to 100 percent can be administered in the transport and initial management of critically ill patients. In patients who are not on mechanical ventilation, evidence of respiratory depression should be monitored. If needed, an F_{IO_2} of 1.0 can be used for up to 24 h without significant lung injury. During this period, management should be directed toward improving pulmonary gas exchange, optimizing oxygen delivery, and limiting tissue metabolic demands so that inspired O_2 concentration can be decreased to the lowest possible levels.

Oxygen at an F_{IO_2} of 0.5 or less can be administered safely to most patients for weeks, although factors specific to individual patients (e.g., prior bleomycin use) may dictate a lower tolerance. The maximal safe duration for oxygen exposures between an F_{IO_2} of 0.5 and 1.0 is less certain, although these concentrations probably can be tolerated longer than 24 h. The safe upper limit of F_{IO_2} for chronic oxygen therapy in the ambulatory setting is largely undefined.

SUMMARY

Use of supplemental oxygen is a powerful tool in the management of critically ill patients as well as those with chronic cardiopulmonary disease, but it represents a double-edged sword. Concomitant with initiation of its use in management of hypoxemia, careful assessment for the underlying etiology of the hypoxemia and implementation of therapeutic measures aimed at its reversal should be undertaken. The proper prescription of oxygen is based upon general principles that are applied to the administration of any other drug. Knowledge of the various techniques of oxygen administration, establishment of clear therapeutic end points, monitoring of the efficacy of treatment, and awareness of the potential toxicity of oxygen are required.

Pulmonary Pharmacotherapy

Karen J. Tietze • Scott Manaker

A wide spectrum of therapeutic agents are currently employed in the treatment of respiratory disorders, including obstructive lung diseases. This chapter reviews the rationale for, and clinical use of, these agents in current clinical practice. A brief discussion of potentially useful therapeutic drug strategies for the future is also provided.

BRONCHODILATORS

Pharmacologic management of obstructive airway diseases is based heavily upon bronchodilation produced by β-adrenergic agonists, muscarinic antagonists, and methylxanthines. In addition, magnesium and inhaled diuretics may ultimately prove to be effective bronchodilators suitable for clinical use.

β-Adrenergic Agonists

The β-adrenergic agonists mimic the actions of norepinephrine at neuroeffector and synaptic junctions. Norepinephrine is the major neurotransmitter in the sympathetic nervous system; therefore, this class of drugs is referred to as *adrenergic agonists* or *sympathomimetics.* Adrenergic receptor stimulation catalyzes the conversion of adenosine triphosphate (ATP) to cyclic-3′5′-adenosine monophosphate (cAMP) by activating adenyl cyclase, a cofactor in the production of cAMP. The increase in cAMP triggers the intracellular events that mediate pulmonary and extrapulmonary responses. The two major types of adrenergic receptors are the alpha and beta receptors; at least two alpha and two beta receptor subtypes have been identified. The β-adrenergic agonists (Table 150-1) are indicated in the treatment of bronchospasm associated with acute and chronic asthma, bronchitis, emphysema, exercise, and other obstructive pulmonary diseases. Selection of a specific agent and route of administration depends on underlying patient risk factors and the receptor specificity of the drug.

Pharmacology

Adrenergic receptor stimulation produces a wide range of responses, depending on the effector organ and the specific

receptor. Although bronchial smooth-muscle relaxation results from β_2-adrenergic receptor stimulation, none of the currently marketed agonists are completely specific for β_2-adrenergic receptors.

The α-adrenergic receptor is generally associated with constrictor/contractor responses, including constriction of arteries and veins and contraction of the uterus, radial and sphincter muscles of the iris, urinary bladder, and stomach sphincters. β_1-Adrenergic receptor stimulation increases heart rate, atrial and ventricular contractility, and cardiac conduction velocity. Effects from β_2-adrenergic receptor stimulation include relaxation of bronchial and uterine smooth muscle, dilatation of arteries and veins, and several metabolic effects, including glycogenolysis, gluconeogenesis, and induction of hepatic pancreatic beta cell secretion.

Structure-Activity Relationships

The parent compound for the adrenergic agonists, phenylethylamine (Fig. 150-1), consists of a benzene ring and an ethylamine side chain. Substituents can be added to the alpha or beta carbons of the ethylamine side chain, the terminal amine group, or one or more of the carbons in the aromatic ring.

The basic chemical structures of the adrenergic agonists include the catecholamines, resorcinols, and saligenins (Fig. 150-1). The catecholamines were the first adrenergic agonists to be marketed. The resorcinols (metaproterenol and terbutaline) have hydroxyls at positions 3 and 5 of the aromatic ring. This promotes oral bioavailablity and prolongs the duration of effect by protecting the molecules from catechol-o-methyl transferase degradation. Terbutaline, with a large substituent on the terminal amine, is selective for β_2-adrenergic receptors. The saligenins (albuterol and salmeterol) have a hydroxyl at position 4, various carbon moieties on position 3 of the aromatic ring, and large substituents on the terminal amine. These large substituents confer a longer duration of action and β_2-adrenergic receptor specificity, particularly for salmeterol. Salmeterol's long side chain results in increased lipophilicity, protecting the structure from

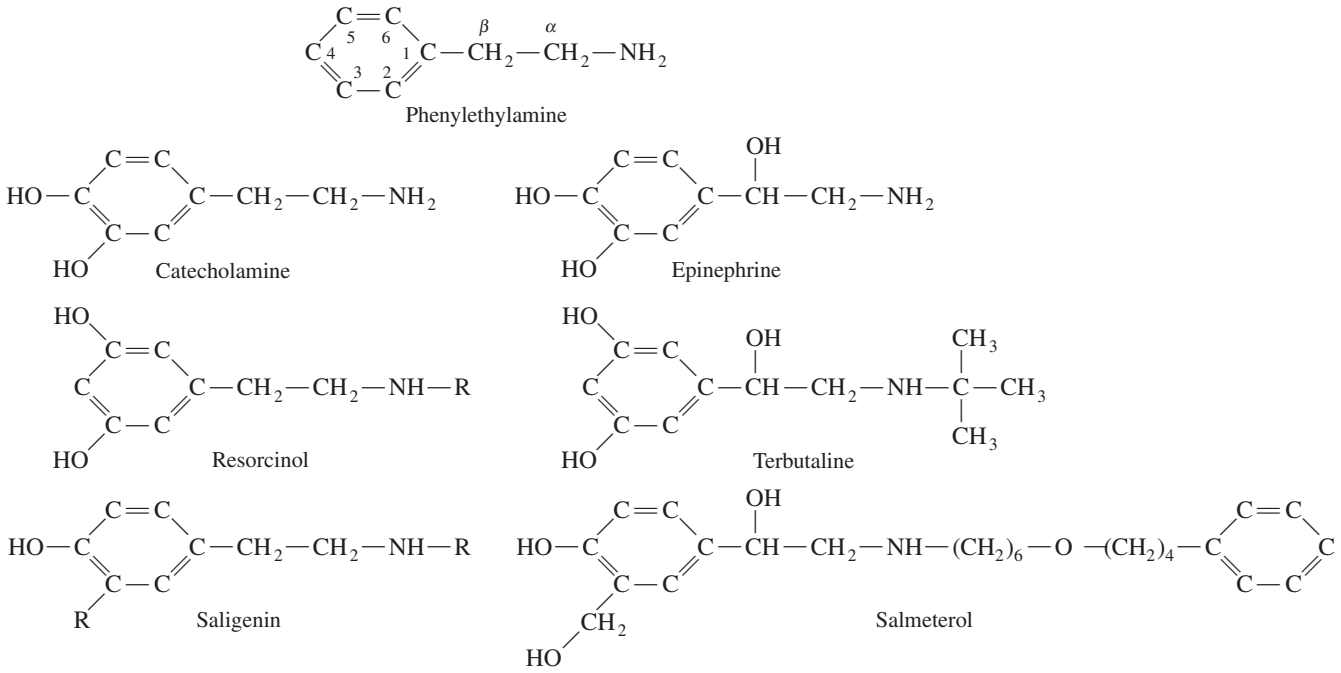

Figure 150-1 Structures of adrenergic agonists.

metabolism by catechol-o-methyl transferase and allowing the compound to bind both to the beta receptor and to an adjacent exoreceptor site. In theory, the exoreceptor binding site anchors the drug close to the beta receptor, further prolonging its action. Albuterol is a 1:1 mixture of the R- and S-enantiomers. The R-albuterol enantiomer is the active moiety; the S-albuterol enantiomer is inactive. Although early animal and clinical studies suggested that the S-albuterol enantiomer might antagonize the effects of the R-albuterol enantiomer, a clear clinical advantage of levalbuterol, the first pure enantiomer (R-albuterol) has not been demonstrated. Formoterol is a phenylethanolamine derivative with a phenyl-isopropyl group attached to the terminal amine. Physicochemical properties account for formoterol's long duration of action. Pirbuterol differs from all other adrenergic agonists in that the aromatic ring is a pyridine, instead of a benzene.

Drug Delivery

The β-adrenergic agonists may be administered systemically or by inhalation; however, not all drugs are marketed in every dosage form. Systemic dosage forms include oral, subcutaneous, and intravenous preparations. Systemic administration decreases the β_2-adrenergic receptor selectivity of the drug due to exposure to various metabolic enzymes, including catechol-o-methyl transferase, monoamine oxidase, and sulfatase. These enzymes change the chemical structure of the drug, decreasing the β_2-adrenergic receptor selectivity. The oral route of administration is generally reserved for patients who cannot successfully use metered-dose inhalers (e.g., children or the elderly). Sustained-release, oral dosage forms may be useful in controlling nocturnal symptoms of asthma, although not as effectively as the long-acting, inhaled adrenergic agonists. The subcutaneous route is generally reserved for patients too dyspneic to inhale the drug, and parenteral drug administration is generally employed for pediatric patients.

The preferred route of β-adrenergic agonist administration is by inhalation. Local application of small amounts of drug directly to the airways decreases the amount available for systemic absorption, minimizing systemic side effects. Inhaled β-adrenergic agonists are available in several dosage forms, including wet aerosols, aerosols from metered-dose inhalers, and dry powder forms. Most commonly, wet aerosols are delivered by jet or ultrasonic nebulizer, whereas metered-dose inhalers are primarily marketed as "press and breathe" devices. Historically, nebulized drug delivery was standard practice for children, emergency treatment of asthma exacerbations, hospitalized patients, and severely obstructed patients. However, nebulized drug delivery is labor intensive; significant cost savings can be realized, without sacrificing efficacy, by using metered-dose inhalers coupled with spacer devices.

Drug delivery by metered-dose inhaler is highly dependent on administration technique. Less than 10 percent of the dose is delivered to the lung using optimal inhalation technique; the rest of the drug is deposited in the mouth. Spacer devices eliminate the split-second timing necessary with proper metered-dose inhaler technique and decrease the amount of drug deposited in the oropharynx (an important factor with inhaled corticosteroids); however, they do not provide a therapeutic advantage over correct use of a metered-dose inhaler alone.

Metered-dose inhalers initially contained chlorofluorocarbon (CFC) propellants. In 1978, international concerns regarding the ozone-depeleting properties of CFCs led to a generalized ban on CFC-containing products. In 2005, the Food and Drug Administration (FDA) announced that CFC-containing MDIs, previously exempt from the ban on CFC production and importation, will not be produced, marketed, or sold in the United States after December 31, 2008. CFC-containing MDIs are being replaced by hydrofluoroalkane (HFA)-containing MDIs and a variety of dry powder inhalers (DPIs).

Clinical Use

The β_2-adrenergic agonists are considered first-line drugs in the treatment of both asthma and chronic obstructive pulmonary disease (COPD). In asthma, the short-acting inhaled β_2-adrenergic agonists are preferred for treating acute symptoms and for preventing exercise-induced bronchospasm. The subcutaneous route of administration is generally reserved for patients unresponsive to frequent, high-dose, inhaled β_2-adrenergic agonists; uncooperative patients; or patients too severely dyspneic to inhale the dose. Subcutaneous or parenteral administration should not be used in patients with angina or a recent history of myocardial infarction. Oral adrenergic agonists may be appropriate for children too young to cooperate with inhaled drug administration; sustained-release, oral adrenergic agonists decrease nocturnal symptoms, but they are less effective than long-acting β_2-adrenergic agonists.

In COPD, β_2-adrenergic agonists provide modest symptomatic relief and improvement in pulmonary function. Long-acting inhaled β_2-adrenergic agonists are standard bronchodilator therapy for patients with moderate and severe COPD. Standard doses of inhaled β_2-adrenergic agonists appear as effective as inhaled anticholinergic drugs for relief of acute exacerbations of COPD. The value of subcutaneous drugs and high-dose short-acting bronchodilators in the management of COPD has not been determined.

The intensity and duration of response to β_2-adrenergic agonists is dose- and frequency dependent. For patients with asthma, higher doses result in incrementally greater bronchodilation. The dose-response relationships are less well defined for COPD. The dose-response curve in asthma led to the development of intensive inhaled β_2-adrenergic agonist drug regimens for the treatment of severe, acute exacerbations. Typically, the nebulized drug is administered every 20 min for three to six doses; some patients respond better to continuous nebulized drug delivery. These regimens are generally well tolerated, although cardiac stimulation is common.

The long-acting β_2-adrenergic agonists are add-on agents for patients with moderate or severe asthma when usual doses of inhaled corticosteroids are inadequate and for patients with moderate to severe COPD. The long-acting β_2-adrenergic agonists are also alternate add-on agents for patients with symptoms of nocturnal asthma. The long-acting β_2-adrenergic agonists have no role in the treatment of acute asthma or an acute exacerbation of COPD; all patients should have a short-acting inhaler and should be instructed on how and when to use each type of β_2-adrenergic agonist.

Tolerance

Tolerance, or receptor subsensitivity, is defined as a decreased response to receptor stimulation. Although tolerance to the nonbronchodilator effects of β-adrenergic agonists, including tremor, tachycardia, prolongation of the QT_c interval on the electrocardiogram, hypoglycemia, hypokalemia, and vasodilator response, has been demonstrated, data on tolerance to the bronchodilator effects of β-adrenergic agonists are limited and conflicting.

Tolerance to the long-acting drugs may make patients less responsive to short-acting β_2-adrenergic agonists during an acute attack or may mask inadequate control of inflammation. Although the mechanism for tolerance to the long-acting drugs has not been precisely identified, one hypothesis is that prolonged drug-receptor interaction may induce receptor down-regulation. Concomitant disease-modifying drug therapy (e.g., corticosteroids) may also modify the development of tolerance by modulating adrenoceptor function.

Safety

The β_2-selective adrenergic agonists produce less cardiovascular toxicity than do the nonselective agents, but β_2-selectivity does not protect from all adverse events. Biochemical abnormalities associated with the β_2-adrenergic agonists include hyperglycemia, hyperinsulinemia, lipolysis, hypokalemia, hypomagnesemia, and lactic acidosis. These side effects are most pronounced with parenteral and oral drug administration; they are minimal with usual doses of inhaled agents. Furthermore, the biochemical abnormalities are more pronounced in drug-naïve normal volunteers than in asthmatic patients, suggesting that tolerance develops following chronic drug administration.

β_2-adrenergic agonists cause dose- and route-dependent hyperglycemia by stimulating glycogenolysis and gluconeogenesis. This effect may be clinically most important in asthmatic patients with diabetes mellitus or during pregnancy. β_2-adrenergic agonists increase plasma insulin by directly stimulating pancreatic islet cells; indirect increases occur secondary to the hyperglycemic response. β_2-adrenergic agonists induce the release of free fatty acids from adipose tissue. Although hyperinsulinemia and high concentrations of free fatty acids have been linked with cardiovascular morbidity and mortality, tolerance minimizes these effects. β_2-adrenergic receptor stimulation also induces muscle glycogenolysis, increasing lactate production.

The β_2-adrenergic agonists induce hypokalemia by directly stimulating the uptake of potassium into skeletal muscle cells. β_2-adrenergic receptor stimulation induces the cellular uptake of magnesium; hypomagnesemia may induce arrhythmias or worsen symptoms of coronary artery disease. Other

adverse β_2-adrenergic agonist effects include: (a) an increased baseline tremor by creating an imbalance in fast- and slow-twitch muscle groups; (b) tachycardia by direct chronotropy and through reflex peripheral vasodilatation and decreased venous return; and (c) central nervous symptoms, such as appetite suppression, headache, nausea, and sleep disturbances. The nervousness reported by many patients is probably a response to the peripheral tremors rather than a result of direct stimulation of the central nervous system.

β-adrenergic agonist use has increased coincident with the increase in asthma morbidity and mortality in the United States and other countries. This observation has promoted interest in the possible relationship between asthma mortality and use of these agents. The first link was made during the 1960s when the newly marketed nonselective β-adrenergic agonist isoproterenol was associated with an increase in asthma morbidity and mortality in the United Kingdom. Although never conclusively proved, the increase in asthma morbidity and mortality was blamed partly on the lipolytic effect of the drug, which increases the potential for myocardial ischemia, and partly on the high-dose formulation. In the 1970s, when fenoterol was linked to an increased death rate in New Zealand, part of the increased mortality was attributed to the hypokalemic effect of fenoterol.

Interest in the association between regular use of short- and long-acting β-adrenergic agonists and asthma morbidity and mortality was heightened by several reports that use of multiple fenoterol or albuterol inhalers per month was associated with an increased risk of death. A subsequent meta-analysis of case-control studies reported only a very weak, although statistically significant, relationship between the use of nebulized β agonists and death from asthma. Although this weak relationship was more likely in adults than adolescents, data from large, well-designed trials are needed to assess accurately the risk of death associated with long-acting β-adrenergic agonists.

Anticholinergics

Atropine and other anticholinergic alkaloids from plant extracts have been used for thousands of years to relieve respiratory symptoms in humans with airway diseases. Historically, clinical use of atropine and atropinelike agents has been limited by anticholinergic side effects, including dry mouth and skin, tachycardia, and meiosis; higher doses produce difficulties in speaking, swallowing, urinating, and mentating, as well as other neurologic side effects.

Pharmacology

Muscarinic receptors control airway smooth muscle function. Activation of airway M_1 and M_3 muscarinic receptors results in bronchial smooth muscle contraction and mucus secretion. M_2 "autoreceptor" activation results in decreased acetylcholine (Ach) release; blockade of M_2 receptors increases airway Ach. The ideal anticholinergic drug would selectively block M_1 and M_3 receptors and have no effect on M_2 receptors.

Quaternary ammonium atropine derivatives were developed to avoid the systemic side effects associated with tertiary derivatives, such as atropine. The quaternary ammonium compounds do not penetrate the blood-brain barrier, are minimally absorbed systemically, and have longer durations of action than atropine. Ipratropium bromide (FDA approved in 1998) and tiotropium bromide (FDA approved in 2004) are closely related quaternary ammonium drugs that differ in terms of muscarinic receptor binding affinities and receptor-drug complex half-lives. Ipratropium bromide nonselectively blocks M_1, M_2, and M_3 receptors. Tiotropium bromide has a greater affinity for muscarinic receptors than ipratropium bromide, but it dissociates rapidly from M_2 receptors, resulting in prolonged M_1- and M_3-drug complex half-lives compared to ipratropium bromide. Inhalation of ipratropium bromide produces bronchodilation in seconds to minutes, with a peak effect after 1 to 2 h. Inhalation of a single dose of tiotropium bromide produces a peak FEV_1 in 1 to 3 h; the duration of effect is about 32 h. The trough FEV_1 increases after multiple doses, reflecting carryover bronchodilation from the prolonged half-life.

Clinical Use

Ipratropium bromide and tiotropium bromide are most efficacious in patients with COPD, including emphysema and chronic bronchitis. In such patients, ipratropium bromide and tiotropium bromide are equally or more effective than β-adrenergic agonists in increasing FEV_1 and reducing airway resistance. Limited data suggest that tiotropium bromide may be superior to ipratropium bromide and the long-acting β_2-adrenergic agonist, salmeterol, in long-term management of moderate to severe COPD. The increased cost of tiotropium bromide may be offset by reduced overall health care expenditures. Chronic inhalation of ipratropium bromide or tiotropium bromide does not lead to development of tolerance or tachyphylaxis.

The combination of inhaled anticholinergic and β-adrenergic agonist produces greater improvement in FEV_1 and specific conductance than does administration of either agent alone. Most large-scale studies of patients with COPD demonstrate that the addition of oral corticosteroids does not increase maximal flow over that achieved by the administration of a β-adrenergic agonist with inhaled ipratropium bromide.

In contrast, ipratropium bromide is less effective than β-adrenergic agonists in the treatment of chronic asthma, and the role of tiotropium is not established. Some asthmatics may gain more relief of bronchospasm from inhalation of ipratropium bromide than β-adrenergic agonists. However, this unusual response requires initial evaluation with an empiric trial of ipratropium bromide and should be reserved only for patients whose moderate to severe asthma is difficult to control. A recent meta-analysis of 32 randomized controlled trials of anticholinergics in treatment of children

and adults with acute asthma found that compared with use of inhaled β_2-adrenergic agonists alone, addition of inhaled anticholinergics significantly reduced hospitalizations and increased spirometric parameters 1 to 2 h after treatment.

Safety

Consistent with their very low systemic bioavailability, both ipratropium bromide and tiotropium bromide are remarkably free of side effects. Transient dry mouth of mild intensity has been reported in 16 percent of patients inhaling tiotropium bromide and in up to 10 percent of patients inhaling ipratropium bromide. Side effects of tiotropium bromide typically appear after 3 to 5 wk of continued use, reflecting the slow linear tissue accumulation of the drug. Neither ipratropium bromide nor tiotropium bromide change pulmonary hemodynamics, ventilation-perfusion matching, oxyhemoglobin saturation, heart rate, or urinary flow; however, blurred vision and pupillary dilation may occur if either drug inadvertently contacts the eye. Both drugs should be used with caution in patients with myasthenia gravis, narrow-angle glaucoma, prostatic hyperplasia, or bladder neck obstruction. Tiotropium bromide should be used with caution in patients with moderate to severe renal insufficiency (Cl_{cr} less than 30 to 50 ml/min).

Although systemic administration of muscarinic anticholinergics decreases mucus formation, neither ipratropium bromide nor tiotropium bromide have much effect on respiratory secretions. Ipratropium bromide inhalation produces a clinically insignificant decrease in mucus viscosity and does not change mucus transport or ciliary beat frequency. Tiotropium bromide does not appear to adversely affect mucus transport.

Concomitant use of drugs with anticholinergic properties may increase the risk of side effects with either ipratropium bromide and tiotropium bromide.

Methylxanthines

Theophylline and aminophylline, the ethylenediamine salt of theophylline, are used to treat asthma and the obstructive component of COPD. Other pulmonary diseases for which theophylline may have a role include obstructive sleep apnea, apnea of prematurity, and airway obstruction secondary to pulmonary edema.

Potentially beneficial therapeutic effects of theophylline include bronchial smooth-muscle relaxation, enhanced mucociliary transport, inhibition of mediator release, suppression of permeability edema, decreased pulmonary hypertension, increased right ventricular ejection fraction, improved diaphragmatic contractility, and central stimulation of ventilation. Although bronchial smooth-muscle relaxation is most likely responsible for the majority of theophylline's beneficial therapeutic effects in the treatment of obstructive lung disease, the anti-inflammatory and diaphragmatic effects may contribute to the overall efficacy of the drug.

Pharmacology

Despite having been marketed and studied for several decades, the precise cellular mechanism of theophylline's bronchodilating action is unknown. It is unlikely that theophylline bronchodilates via adenosine antagonism. However, many of the extrapulmonary effects associated with theophylline, including cardiac stimulation, anxiety, tremors, seizures, diuresis, gastric secretion, and free fatty acid release have been attributed to adenosine antagonism.

Anti-inflammatory Effects

Anti-inflammatory actions attributed to theophylline include inhibition of neutrophil and mononuclear cell migration, leukotriene B_4 generation, T-cell proliferation, and lymphokine production; increased activity and number of suppressor T cells; and stabilization or inactivation of macrophages and platelets. The anti-inflammatory effect of theophylline appears to be qualitatively different than that of corticosteroids, resulting from the selective inhibition of phosphodiesterase IV at low serum theophylline concentrations. Although there has been a great deal of interest in the immunomodulatory effect of the methylxanthines, the clinical relevance of this effect remains unknown.

Diaphragmatic Effects

Theophylline increases diaphragmatic strength and contractility, actions potentially mediated by transmembrane calcium movement. Most data are from in vitro studies or from normal volunteers; results from controlled clinical trials in patients with COPD are limited and conflicting. Theophylline may be potentially most beneficial in patients with hypoxic and hypercapnic COPD when dosed to midtherapeutic plasma concentrations.

Structure-Activity Relationships

Theophylline and aminophylline are 1,3-dimethylxanthines. Other methylxanthines, including theobromine (3,7-dimethylxanthine) and caffeine (1,3,7-trimethylxanthine), differ in the positions of the methyl substituents on the xanthine molecule. N-1 substituents are important for adenosine antagonism, whereas N-3 substituents augment bronchodilator activity. Substituents at N-7 decrease bronchodilator potency; substituents at N-9 decrease the potency of the xanthine.

Clinical Use

For bronchodilation, the target theophylline serum concentration is generally accepted as 10 to 20 mg/L. The therapeutic range for other effects (e.g., anti-inflammatory properties, enhanced diaphragm capability, respiratory stimulation) may be different, prompting interest in a lower (5 to 15 mg/L) target range. Approximately 50 percent of maximal bronchodilation is achieved at a serum level of 10 mg/L; only an additional 17 percent increase is observed at 20 mg/L.

The precise clinical role of theophylline is unclear. Relatively noncontroversial indications include severe

bronchodilator-dependent COPD; severe, systemic, corticosteroid-dependent asthma; nocturnal asthma uncontrolled with adrenergic agonists; and acute, severe asthma progressing to respiratory failure.

Safety

Adverse effects associated with theophylline include nausea, vomiting, diarrhea, irritability, insomnia, supraventricular tachycardia, ventricular arrhythmias, and seizures. Although the risk of adverse effects increases at serum concentrations greater than 20 mg/L, patients also may experience serious adverse effects within the usual therapeutic range. Because of this narrow therapeutic index, emphasis should be placed on achieving the midtherapeutic range for serum theophylline levels (10 to 15 mg/L), while accepting a broader range (5 to 20 mg/L) as appropriate.

Magnesium Sulfate

Magnesium blocks calcium entry into smooth-muscle cells, thereby relaxing muscle fibers. Several small trials randomized patients upon presentation to the emergency room to receive either 2 g of magnesium sulfate intravenously over 20 min or placebo, in addition to standard therapy. Intravenous magnesium administration demonstrated no overall beneficial effect, although in retrospective analysis, the degree of airflow obstruction and rate of hospital admission were reduced for patients with severe asthma.

Subsequent case reports and small series suggested similar results could be obtained with inhalation of various doses of inhaled magnesium. The few randomized clinical trials reported to date seem to demonstrate similar small reductions in the degree of airflow obstruction and rate of hospital admission following magnesium sulfate inhalation in patients with severe asthma presenting to the emergency room setting.

Despite these limited clinical data demonstrating efficacy of magnesium sulfate, the recommendation from the Global Initiative for Asthma is that intravenous magnesium sulfate be considered in therapy of acute severe asthma. Recent survey data reveal that 21 percent of children receiving intensive care for asthma in the United States between 2000 and 2003 received parenteral or inhaled magnesium sulfate therapy during their hospitalization.

Inhaled Diuretics

While inhaled magnesium may act as a direct bronchodilator, inhaled diuretics may act upon the airways through a variety of mechanisms to achieve bronchodilation, reduce mucosal inflammation, or interrupt sensory nerve reflex responses to irritants. Inhaled furosemide has no role in the treatment of exacerbations of acute asthma, and additional information is needed before use of inhaled diuretics can be recommended for prevention of exercise- or irritant-induced asthma.

ANTI-INFLAMMATORY AGENTS

Corticosteroids are the mainstay of current anti-inflammatory regimens; other agents in clinical use include mast cell stabilizers, leukotriene receptor antagonists, and synthetic inhibitors of leukotrienes.

Corticosteroids

Corticosteroids are cortisollike drugs that influence metabolic pathways and have an anti-inflammatory effect. By reducing airway inflammation, corticosteroids are clearly useful in the management of asthma, but they have a more limited and targeted role in the management of COPD.

Pharmacology

Glucocorticoids (i.e., cortisol) are produced by the adrenal cortex via the hypothalamic-pituitary axis in response to physical and emotional distress. Although the usual daily secretion of cortisol is approximately 10 to 20 mg, as much as 400 to 500 mg per day can be secreted during periods of severe stress. Although the cellular mechanisms are incompletely understood, corticosteroids stimulate the transcription and creation of certain proteins, such as lipocortin-1, and inhibit DNA transcription, resulting in decreased cytokine production. The clinical effects of corticosteroids are delayed for several hours following administration, reflecting the time needed to create new proteins or inhibit cytokine production. Leukocytes, mucous glands, and blood vessels are glucocorticoid targets.

The inhaled glucocorticoids differ in potency, lipophilicity, relative receptor binding affinity, and pharmacokinetics. Since glucocorticoid preparations are marketed and prescribed in relatively equipotent doses, potency may be the least important differentiating characteristic. However, lipophilicity and relative glucocorticoid receptor binding and dissociation affinities are important discriminants among the inhaled corticosteroids. These characteristics determine the rate of receptor association and dissociation and the amount of drug absorbed systemically following inhalation. All corticosteroids undergo hepatic metabolism. Orally administered drugs, including drug swallowed after inhalation, undergo significant first-pass metabolism.

Mometasone furoate and fluticasone propionate, with an esterified lipophilic group at the 17-α positon, are the most lipophilic of the marketed inhaled corticosteroids; beclomethasone dipropionate, budesonide, triamcinolone acetonide, and flunisolide follow in descending order of lipophilicity. The relative receptor binding affinity and receptor association follow the same order as lipophilicity. Mometasone furoate differs from other inhaled corticosteroids in that it is less specific for glucocorticoid receptors; in addition, the drug demonstrates agonist activity at progesterone receptors and partial agonist activity at mineralocorticoid receptors.

Clinical Use

Corticosteroids are the cornerstone of therapy in the treatment of asthma; the role of glucocorticoid therapy in COPD is more limited.

Asthma

The role of airway inflammation in asthma is well established, and high-dose systemic (parenteral or oral) corticosteroids are standard therapy for patients experiencing severe acute exacerbations of asthma. Parenteral administration of corticosteroids is often used preferentially due to the inability of some patients to swallow medications while in respiratory distress or because of lack of oral access after intubation. Dose-ranging studies of intravenous corticosteroids have not established a minimum effective dose, although as little as 120 mg/d of methylprednisolone (in divided doses administered every 6 h) is effective in asthmatic adults having an acute exacerbation. The time to initial response, as evidenced by augmentation of FEV_1 with bronchodilator administration, begins as early as 1 h after corticosteroid administration; maximal response is achieved in 8 to 12 h. Parenteral corticosteroid therapy is usually maintained for 24 to 72 h, with subsequent conversion to oral prednisone at 60 mg daily when the FEV_1 reaches a threshold of 50 percent of predicted normal. This dose may be maintained for 2 to 7 d, followed by gradual tapering of the dose over 1 to 3 wk. Parenteral methylprednisolone is emerging as the corticosteroid of choice, due to its lower mineralocorticoid and greater glucocorticoid effects than hydrocortisone.

Oral corticosteroid therapy is seldom indicated for chronic stable asthma. Oral therapy is maintained at the lowest dose possible to sustain control of symptoms and optimize peak expiratory flow in conjunction with inhaled β_2-adrenergic agonists. Hydrocortisone, methylprednisolone, or prednisone are most commonly used. Unlike prednisone, the first two agents do not require hepatic metabolism for therapeutic activity and are preferred in patients with significant liver disease.

Inhaled corticosteroids offer direct delivery to the lung and reduced risk of systemic effects. To achieve the same effect as higher potency agents, the lower potency agents are given in higher doses; adverse effects are more likely to occur.

The combination of an inhaled corticosteroid and a long-acting bronchodilator is better than either agent alone in terms of improving lung function and preventing asthma exacerbations; in patients with moderate-to-severe asthma, the combination of low-dose inhaled corticosteroid appears to be as effective as high-dose inhaled corticosteroid alone.

Poor adherence with inhaled corticosteroid regimens is an ongoing issue. Inhaled corticosteroids initially required four-times-a-day dosing schedules, but they are now usually prescribed twice daily. Mometasone furoate, the newest inhaled corticosteroid, is FDA approved for once daily administration. Although data are limited, patients with stable mild to moderate asthma might benefit from a trial of once-daily inhaled corticosteroids. Twice-daily dosage regimens may be more effective for patients with severe or difficult-to-control asthma.

Chronic Obstructive Pulmonary Disease

The mechanism underlying the beneficial effects of corticosteroids in COPD is not fully known, but changes in inflammatory gene transcription and modulation of β_2-adrenergic receptor function appear to play a role.

No evidence exists that systemic corticosteroids prevent exacerbations in patients with stable COPD or that steroid responsiveness can be predicted. A common clinical practice has been to test steroid response by measuring the change in FEV_1 following a trial of systemic corticosteroids and then limiting subsequent corticosteroid therapy to steroid responders. However, in a 3-y, large, randomized, double-blind, placebo-controlled prospective trial, no significant relationship between initial steroid response and subsequent FEV_1 decline was found.

Short courses (10 to 15 d) of moderate doses (40 mg/d of prednisone) of systemic corticosteroids in combination with standard bronchodilator therapies are effective for treating acute exacerbations of COPD in outpatients, inpatients, and patients in the emergency room who have moderate or severe COPD. However, the role of systemic corticosteroids in the treatment of patients with COPD who are receiving mechanical ventilation is unknown. Chronic maintenance therapy with inhaled corticosteroids reduces the incidence of acute exacerbations by 20 to 30 percent and improves health status in patients with stage III or IV COPD and a history of frequent exacerbations.

Definitive data regarding the clinical usefulness of combining inhaled corticosteroids and long-acting bronchodilators are lacking. Guidelines published in 2004 recommend the combination of inhaled corticosteroid and long-acting bronchodilator for patients with severe or very severe disease and frequent exacerbations.

Safety

Short-term use (less than 14 d) of systemic corticosteroids is associated with mild glucose intolerance, fluid retention that may progress to edema and hypertension, proximal muscle weakness (especially with large parenteral doses), and mood alteration. Long-term systemic corticosteroids prolong the short-term effects; in addition, peptic ulcer disease, cataracts, increased risk of infection, and impaired wound healing occur. Truncal obesity, hirsutism, acne, moon-shaped facies, striae, and ecchymoses contribute to a cushingoid appearance. Disruption of bone metabolism predisposes patients to osteoporosis and resultant vertebral and long-bone fractures; inhibition of long-bone growth is the major complication in children who receive systemic corticosteroids. Suppression of the hypothalamic-pituitary-adrenal axis diminishes body cortisol stores, which, in turn, reduces the capacity of the body to confront stress, such as trauma, surgery, or infection.

Inhaled corticosteroids are less systemically bioavailable due to poor absorption from the tracheobronchial tree. The most common adverse effect is local irritation of the oropharynx, cough, and bronchospasm. Dysphonia may arise from vocal cord myopathy induced by the presence of corticosteroid in the oropharynx. Thrush is easily avoided by rinsing the mouth after each use of a corticosteroid inhaler, using a spacer device to decrease deposition of drug particles in the mouth, and keeping the inhaler mouthpiece clean. Newer inhaled corticosteroids, such as fluticasone, undergo extensive first-pass metabolism to inactive substances, thereby decreasing concentrations of active drug and the potential for systemic adverse effects. Long-term studies of inhaled corticosteroids have not documented significant adrenal suppression.

Steroid Resistance

Patients with asthma who are unresponsive to usually sufficient doses of corticosteroids are described as *steroid resistant.* Steroid resistance has been formally defined by a smaller than 15 percent increase in FEV_1 after 7 d of oral prednisolone administered at a dose of 20 mg daily in bronchodilator-responsive asthmatics. Steroid resistance must be distinguished from steroid dependency, which is usually defined as the need for systemic corticosteroids for maintaining control of asthma.

Steroid resistance may involve reduced metabolism of oral corticosteroids to the active compound or accelerated drug clearance. An impaired cellular response to corticosteroids has been observed in steroid-resistant asthmatics, and altered receptor binding or the presence of antilipocortin antibodies may contribute to the phenomenon.

Corticosteroid-Sparing Agents

Chronic systemic corticosteroid therapy required for the treatment of severe airflow obstruction often results in numerous side effects. Therefore, many anti-inflammatory agents have been evaluated in an effort to identify alternatives to systemic corticosteroid therapy.

Troleandomycin

Since the 1960s, anecdotal clinical observations suggested that the macrolide antibiotic, troleandomycin, might reduce corticosteroid requirements in patients with severe asthma by decreasing steroid metabolism. However, results from double-blind, randomized trials are mixed. To date, the weight of evidence suggests that troleandomycin has little or no clinical effect at relieving airway obstruction or inflammation independent of its effects on corticosteroid metabolism. Troleandomycin has little role in the current therapy of severe, steroid-dependent asthma.

Methotrexate

From initial observations in patients with rheumatoid arthritis and coexistent asthma, methotrexate therapy appeared to ameliorate both asthmatic and arthritic symptoms. Currently, no clear documentation exists of the clinical efficacy of methotrexate administration in severe, steroid-dependent asthma. Due to significant side effects, potentially fatal complications and long-term toxicity concerns, prudency argues for limiting methotrexate administration in severe, steroid-dependent asthmatics to empiric trials in individual patients or investigations in large-scale, controlled clinical trials.

Cyclosporine

Used widely in organ transplantation, cyclosporine inhibits lymphokine synthesis, thereby blocking the activation of T cells. The absence of significant drug interactions with β-adrenergic agonists, corticosteroids, or theophylline makes cyclosporine particularly attractive as an anti-inflammatory agent for use in asthma. However, only one of three small, double-blind, placebo-controlled studies suggested that cyclosporine increased peak expiratory flow and FEV_1, reduced exacerbations of airway obstruction, or reduced oral prednisolone dosage by over 60 percent. Hypertrichosis, hypertension, reversible nephrotoxicity, and a large number of nonspecific side effects limit widespread use of cyclosporine in the management of asthma.

Other Agents

The search continues for anti-inflammatory agents with potential efficacy in asthma. A broad spectrum of agents have been touted, including gold salts, pooled immunoglobulins, azathioprine, colchicine, dapsone, hydroxychloroquine, ketotifen, nonsteroidal anti-inflammatory agents, and inhaled heparin. The original studies purporting the efficacy of these various agents comprise mainly anecdotal reports or small case series. Use of these drugs in obstructive airway disease should be restricted to well-designed, controlled clinical trials.

Mast Cell Stabilizers

Cromolyn sodium and nedocromil exert anti-inflammatory actions by stabilizing mast cells. This blockade of mast cell degranulation prevents inflammatory mediator release, which is partially responsible for the bronchoconstriction and epithelial injury that are characteristic of asthma.

Cromolyn Sodium

Cromolyn sodium was the first mast cell stabilizer to be approved for clinical use in asthma and is widely employed in pediatric asthmatics.

Pharmacology

Cromolyn sodium is a potent inhibitor of inflammatory responses. Cromolyn sodium diminishes early phase reactions in asthma by blocking the release of intracellular calcium and inhibiting enzymes responsible for mast cell degranulation; cromolyn reduces late phase reactions in asthma by inhibiting production of the enzymes necessary for superoxide

generation. Cromolyn sodium may also exhibit tachykinin antagonism, accounting for some of its anti-inflammatory properties. In vitro, cromolyn sodium potentially inhibits the activation of inflammatory cells, antibody-induced granulocyte cytotoxicity, IgE production by atopic cells, and monocyte IgG production.

Clinical Use

Cromolyn sodium is indicated for the management of asthma in children and atopic young adults. Cromolyn sodium, alone or in combination with β_2-adrenergic agonists, improves exercise tolerance, enhances sleep quality, reduces asthma exacerbations, and facilitates patient acceptance of therapy. Patients diagnosed with asthma prior to the age of 4 years, patients less than 17 years of age, and patients with long-term asthma (more than 5 y) may experience maximal benefit from cromolyn sodium therapy. Cromolyn sodium significantly improves seasonal allergic asthma symptoms. Long-term use of cromolyn sodium (at least 12 wk) four times daily is recommended for effective control of chronic bronchial hyperresponsiveness, while a shorter treatment duration (up to 6 wk) usually suffices for control of seasonal allergic attacks.

Cromolyn sodium prophylaxes against exercise-induced asthma in children as efficaciously as do beta$_2$ agonists. Premedication with cromolyn sodium, inhaled β_2-adrenergic agonist, or both, 15 to 30 min prior to vigorous exercise is recommended for children and adults. Cromolyn sodium is a useful adjunct to bronchodilators in adults with atopic asthma; it may provide added benefit when administered in conjunction with inhaled corticosteroids.

Safety

Cromolyn sodium causes few adverse effects, even after long-term use. Its efficacy in preventing childhood asthma symptoms and safety record make cromolyn sodium a first-line agent, in conjunction with β_2-adrenergic agonists, in management of asthma in children.

Nedocromil

Nedocromil also stabilizes mast cells in the bronchial mucosa, but it has a broader anti-inflammatory spectrum than cromolyn sodium. Nedocromil blocks activation of eosinophils and neutrophils, further reducing inflammation. Dose-dependent inhibition of IL-4-induced IgE and IgG production has been demonstrated in vitro. Nedocromil is useful prophylactically against asthma exacerbations, but not therapeutically for acute bronchospasm.

The similar pharmacology of cromolyn sodium and nedocromil have prompted direct comparisons of the two agents in asthmatics. Nedocromil appears to be more effective as a bronchodilator-sparing agent than cromolyn sodium in adults, but it provides a similar level of protection against exercise-induced asthma in children. Lack of long-term experience with nedocromil relegates it to second-line status as an adjunct to bronchodilators in the management of asthma.

Leukotriene Antagonists and Inhibitors

The leukotriene antagonists and inhibitors are the first new class of asthma drugs to be developed in several decades. Advances in our understanding of the inflammatory pathogenesis of asthma and the role of leukotrienes as inflammatory mediators have generated great interest in the development of and therapeutic potential for these drugs.

Leukotrienes are synthesized from arachidonic acid, a fatty acid stored in phospholipids of cell walls. Numerous stimuli, including IgE receptor activation, antigen-antibody interactions, and activation of phospholipase A_2 induce release of arachidonic acid from phospholipids. Arachidonic acid is converted to a variety of products via several unrelated pathways; the 5-lipoxygenase pathway is the pathway of importance in asthma. Leukotriene A_4 (LTA_4) is metabolized by two different pathways to either the nonpeptide LTB_4 or the cysteinyl leukotrienes (LTC_4, LTD_4, and LTE_4). LTB_4 recruits and activates inflammatory cells but has no effect on bronchial tone or reactivity. The cysteinyl leukotrienes stimulate smooth-muscle contraction, increase vascular permeability, and enhance bronchial hyperresponsiveness; thus, they have a major role in the pathogenesis of asthma.

Leukotriene action may be inhibited by either selective receptor blockade or interference with synthesis. Most clinical experience has been with the LTD_4 receptor antagonists, since LTC_4, LTD_4, and LTE_4 interact with a common LTD_4 receptor. Inhibition of 5-lipoxygenase (5-LO) reduces the generation of all leukotrienes.

Clinical Use

Two LTD4 receptor antagonists (montelukast and zafirlukast) and one 5-LO inhibitor are FDA-approved and marketed in the United States. The leukotriene receptor antagonists are alternate anti-inflammatory medications for long-term use in children and adults with mild to moderate asthma, including aspirin- or exercise-induced asthma and asthma associated with concomitant allergic rhinitis. To date, data are insufficient to assess the role of antileukotriene receptor antagonists in the management of acute exacerbations of asthma or COPD. Inhaled glucocorticosteroids in doses of 400 μg/d of beclomethasone equivalent are more effective than the leukotriene receptor antagonists in adults with mild or moderate asthma. However, addition of a leukotriene receptor antagonist to therapy that includes an inhaled corticosteroid results in some further improvement in lung function.

Safety

Montelukast and zafirlukast are well tolerated. Montelukast chewable tablets contain phenylalanine and therefore are contraindicated in patients with phenylketonuria. Hepatotoxicity has been reported with zileuton. Zileuton is contraindicated in patients with active liver disease and in patients with serum transaminase levels exceeding three times the upper limit of normal. Baseline liver function tests should be obtained prior to initiating therapy with zileuton, and patients should be monitored closely for the duration of therapy. Zileuton must

be discontinued if serum transaminase levels exceed five times the upper limit of normal.

The leukotriene receptor antagonists have numerous drug interactions.

Immunoglobulin E Antibody

Pharmacology

Omalizumab is a recombinant humanized antibody developed for therapy of allergic diseases that has significant efficacy in severe atopic asthmatics. By specifically binding with high affinity to immunoglobulin E (IgE), but not to other immunoglobulins, omalizumab does not activate mast cells or basophils. Clinical efficacy depends upon almost total elimination of circulating IgE; therefore, the role of omalizumab is limited to those asthmatics with elevated IgE levels. Parenteral administration of omalizumab produces rapid binding of circulating IgE, with serum levels slowly rebounding over the subsequent 4 to 6 wk.

Several randomized, double-blind placebo controlled studies of omalizumab have been completed in patients more than 12 years of age with moderate to severe atopic asthma refractory to high-dose inhaled corticosteroids; patients also received inhaled, long-acting β agonists and oral leukotriene antagonists. Use of omalizumab resulted in reproducible decreases in asthmatic flares, reduced inhaled and oral steroid dosage, and improved quality of life.

Clinical Use

Omalizumab therapy is indicated for moderate to severe asthmatics who have serum IgE levels exceeding 30 IU/ml (75 ng/ml) and an allergic basis for their asthma, as demonstrated by positive skin testing or radioallergosorbent tests (RAST) to common antigens. As a chronic therapy, omalizumab treatment should not be initiated in the setting of an acute asthma flare. Subcutaneous administration of omalizumab every 2 to 4 wk is required to maintain reductions in circulating IgE, with required dose and frequency dependent upon body weight and initial serum IgE level. Up to three separate subcutaneous injections, each not exceeding 150 mg at a single site, may be required at each administration. Subsequent serum IgE measurements are unnecessary, as levels are expected to plummet to negligible levels and slowly rebound after each administration of the drug.

The total duration of necessary therapy is unclear, although a review every 6 to 12 mo is commonly employed to assess whether improved asthma control has been achieved (as indicated by reduced inhaled and oral steroid usage, fewer emergency medical encounters and hospitalizations, and decreased overall medical costs).

Safety

Minor local skin reactions at the injection sites occur in almost one-half of patients. A diffuse urticarial rash has been reported, but it is extremely uncommon. Severe hypersensitivity reactions, including anaphylaxis, are rarely observed. Nonetheless, close observation, including frequent assessment of vital signs, is recommended for at least 2 h following initial drug administration; similar monitoring is warranted for at least 1 h following each subsequent administration.

MUCOKINETIC AGENTS

Chronic sputum production or inspissated airway secretions plague most patients with obstructive lung disease. Some mucokinetic agents are effective in promoting the clearance of obstructed airways.

Dornase Alpha

Purulent, viscous secretions contribute to airway obstruction and chronic pulmonary infections in patients with cystic fibrosis, chronic bronchitis, and bronchiectasis. High concentrations of mucus contribute to the increased viscosity of bronchial secretions in these conditions. Polymorphonuclear leukocytes recruited to ward off chronic pulmonary infections eventually degenerate, releasing DNA into the extracellular environment. Although recombinant human deoxyribonuclease I (DNAse) metabolizes DNA liberated from airway leukocytes, the high concentration of DNA released in these chronic conditions overwhelms the endogenous ability of the lungs to clear the DNA. Exogenous administration of DNAse promots clearance of airway DNA by reducing mucus viscosity, increasing mucus clearance, diminishing airway obstruction, and preventing recurrent pulmonary infections.

Results of randomized clinical trials of nebulized DNAse as short-term adjunctive therapy in patients with cystic fibrosis demonstrate modest dose-dependent improvement in pulmonary function and reduction in symptoms. Placebo-controlled investigations of DNAse in adults with chronic bronchitis or bronchiectasias not due to cystic fibrosis reveal prolonged antibiotic therapy requirements, no enhancement of pulmonary function, and no improvement in quality of life.

N-Acetylcysteine

N-acetylcysteine (NAC) lyses disulfide bonds in mucus proteins, reducing airway mucus viscosity. Increased mobilization of mucus and decreased inspissation with use of inhaled NAC has been reported in patients with asthma or COPD. However, randomized placebo-controlled trials in COPD have demonstrated no objective benefit of treatment with NAC.

Due to the in vivo conversion of NAC to the potent antioxidants, glutathione and cysteine, recent investigations have focused on NAC as an immunomodulator. Since antioxidant formation is distinct from the local mucolytic effect, oral NAC has been investigated in most studies. Unfortunately, intravenous NAC in patients with acute lung injury

or the acute respiratory distress syndrome (ARDS) offers no significant reduction in mortality or disease progression.

Iodinated Agents

Some iodinated compounds have mucolytic-expectorant properties. When ingested, iodide is liberated and stored in secretory glands of the tracheobronchial tree. Upon stimulation by coughing or inhalation of irritant substances, iodide promotes secretion of respiratory tract fluid and mucoproteins and augments ciliary activity. Increased mucus mobilization and decreased mucus viscosity result.

Adverse events appear to be infrequent, although thyroid dysfunction may be induced by the iodine load and has been reported after long-term use in elderly patients with COPD. Clinicians should use iodinated compounds with caution in elderly patients or those with preexisting thyroid dysfunction.

Sodium Bicarbonate

Sodium bicarbonate solutions (2 to 7.5 percent) are frequently used as vehicles for bronchodilators and N-acetylcysteine. By raising the pH of the respiratory tract fluids, aerosolized sodium bicarbonate weakens the saccharide structure of airway mucus, increasing its susceptibility to proteases and promoting its removal through enhanced ciliary activity. These effects are additive when used with N-acetylcysteine and cause reduction in mucus viscosity. Local irritation from hypertonic sodium bicarbonate solutions may occur; cough and bronchospasm have been observed in some patients. Therefore, bronchodilators should be given prior to sodium bicarbonate aerosols.

Guaifenesin

Guaifenesin remains the only agent approved by the FDA as an expectorant, based upon a single placebo-controlled trial in patients with chronic bronchitis in whom guaifenesin significantly reduced sputum volume and improved sputum quality. These patients also experienced subjective relief of respiratory congestion, and no adverse effects were reported. However, the purported expectorant properties of guaifenesin have not been substantiated in well-controlled studies.

PHYSIOLOGICAL REPLACEMENTS

Replacement therapy comprises a novel class of agents to replace deficient, or augment existing, endogenous substances. To date, replacement therapy has been employed only in adults with α_1-antitrypsin deficiency or neonates with respiratory distress syndrome. However, clinical studies of replacement therapy are underway in patients with a wide spectrum of obstructive and other lung diseases.

α_1-Antitrypsin

α_1-Antitrypsin is a glycoprotein synthesized and secreted by hepatocytes. A protease inhibitor, α_1-antitrypsin, blocks the actions of neutrophil-derived elastase in the lung. Inherited deficiency of α_1-antitrypsin promotes development of emphysema in adulthood; tobacco smoking rapidly accelerates the clinical presentation and severity of the emphysema. Since 1988, α_1-antitrypsin replacement therapy has been available for intravenous administration as a purified product derived from pooled human plasma.

Clinical Use

Weekly or monthly intravenous infusion of α_1-antitrypsin to deficient patients increases α_1-antitrypsin levels in serum and bronchoalveolar lavage specimens and restores antielastase activity in serum and alveolar lining fluid. Numerous case reports and small series dispute whether α_1-antitrypsin replacement reduces the accelerated rate of decline in pulmonary function associated with α_1-antitrypsin deficiency. Currently, α_1-antitrypsin replacement therapy is recommended for patients with α_1-antitrypsin deficiency who are older than 18 years of age and have both abnormal pulmonary function tests and a serum α_1-antitrypsin level less than 11 mM. Replacement therapy for α_1-antitrypsin deficient patients is not recommended after lung transplantation.

Side Effects

α_1-Antitrypsin replacement therapy is remarkably nontoxic, and current preparations have few side effects other than mild fever. Repeated administration of α_1-antitrypsin does not shorten the serum half-life, suggesting that α_1-antitrypsin antibodies do not develop, even in patients with complete deficiency.

Pulmonary Surfactant

The administration of pulmonary surfactant to premature infants with, or at risk for, respiratory distress syndrome has become the standard of care. Surfactant administration decreases mortality from respiratory distress syndrome by 30 to 40 percent and reduces morbidity due to pneumothoraces, interstitial emphysema, bronchopulmonary dysplasia, and intraventricular hemorrhage.

Endogenous pulmonary surfactant is an emulsion of phospholipids, cholesterol, and apoproteins that reduces surface tension within alveoli. Natural surfactant is commercially available and is prepared from lung tissue or lavages from a variety of species. Synthetic surfactant is available from a number of commercial sources, although the optimal composition of the material remains to be determined.

Pulmonary surfactants reduce oxygen toxicity by scavenging free radicals, and the surfactants may be cytoprotective for alveolar cell surfaces. Pulmonary surfactants suppress mediator release by inflammatory cells and may deactivate inflammatory mediators upon release. In vitro studies indicate that surfactant suppresses lymphocyte mitogenic

responses, leading to a decrease in inflammatory cell influx. Pulmonary surfactant has both antibacterial and antiviral properties which are mediated by an increase in alveolar macrophage phagocytosis. Surfactant may promote airway clearance by changing the physical properties of mucus, as well as by increasing ciliary beat frequency. Finally, pulmonary surfactant may directly relax airway smooth muscle. This spectrum of putative biologic activities may directly interrupt the pathogensis of airway inflammation, chronic infection, and bronchoconstriction seen in most obstructive lung diseases.

Limited clinical data are available to document the effects of pulmonary surfactant in adults. In anecdotal case reports and small patient series, surfactant administration to patients with respiratory failure has produced occasional increases in Pa_{O_2}, although usually no change in radiographic, physiological, or respiratory findings were reported. However, in two large, double-blind, randomized, placebo-controlled trials, administration of synthetic surfactant for 5 days yielded no demonstrable physiological benefit and no significant decrease in mortality rate measured at 30 days.

RESPIRATORY STIMULANTS

Respiratory stimulants are a group of pharmacologically unrelated agents used to treat diverse pathophysiological conditions, including obstructive or central sleep apnea, COPD, postanesthesia respiratory depression, and acute mountain sickness.

Acetazolamide

Acetazolamide is a noncompetitive inhibitor of carbonic anhydrase that induces a weak diuresis and mild metabolic acidosis. Currently, acetazolamide is approved for the prophylaxis of acute mountain sickness and has been proposed as an alternative therapy for chronic mountain sickness. Sometimes used to treat patients with chronic hypercapnia and drug-induced or compensatory metabolic alkalosis, acetazolamide may have both indirect and direct respiratory stimulant properties. The increased hydrogen concentration indirectly stimulates respiration via peripheral and medullary chemoreceptor stimulation. Acetazolamide may also directly stimulate respiration by increasing cerebral blood flow through mechanisms unrelated to the metabolic acidosis.

Recently, a small, double-blind, placebo-controlled study demonstrated acetazolamide improves nocturnal oxyhemoglobin saturations and reduces hematocrit in patients with chronic mountain sickness. However, further large scale studies will be required before acetazolamide can be recommended over standard therapies, including phlebotomy or relocation to lower altitude.

Limited data from short-term trials of acetazolamide in hypercapnic patients are available. In small numbers of patients with hypercapnic obstructive lung disease, acetazolamide produces modest reductions in Pa_{CO_2} and pH, while improving $P_{A_{O_2}}$. Long-term safety and efficacy data are unavailable, and larger studies will be required before acetazolamide therapy can be recommended for hypoventilation associated with either sleep-disordered breathing or hypercapnic obstructive lung disease.

Almitrine

Almitrine bismesylate stimulates peripheral chemoreceptors in the carotid body and has no central respiratory stimulant effect. Also a pulmonary vasoconstrictor, almitrine improves ventilation-perfusion matching and, therefore, has received attention in small case series as adjunctive therapy for hypoxemic respiratory failure from ARDS. Although marketed in Europe, almitrine bismesylate is not available in the United States. Toxicities and side effects include right ventricular strain from pulmonary arterial vasoconstriction, peripheral neuropathy, weight loss during long-term therapy, and diuretic activity.

Methylxanthines

Aminophylline and theophylline are methylxanthine bronchodilators that augment the central ventilatory response to hypoxia, likely through adenosine receptor activation in the carotid body and or brain stem ventilatory control centers. Limited data suggest theophylline reduces periodic breathing at high altitude. Used to treat apnea of prematurity and infants with periodic breathing, methylxanthines are less useful in the treatment of obstructive sleep apnea or in stimulating adult respiration in normobaric environments.

Doxapram

Doxapram is a short-acting, parenterally administered, peripheral chemoreceptor agonist and central respiratory stimulant. Doxapram has been approved for postanesthesia respiratory depression or apnea, drug-induced central nervous system respiratory depression, and short-term use as a respiratory stimulant in acute respiratory insufficiency superimposed on chronic pulmonary disease. Limited case reports and small studies describe doxapram as a respiratory stimulant in COPD complicated by acute respiratory failure.

Medroxyprogesterone

Medroxyprogesterone is a gestational respiratory stimulant. Although its mechanism of action is unclear, medroxyprogesterone increases minute ventilation and produces hypocapnia in normal subjects. However, it does not improve breathing disturbances during sleep in normocapnic patients with obstructive sleep apnea. Limited data reveal medroxyprogesterone stimulates minute ventilation in patients with hypercapnic obstructive lung disease, without improving nocturnal oxygenation.

Protriptyline

Protriptyline is a tricyclic antidepressant that is cited frequently as an effective respiratory stimulant in patients with obstructive sleep apnea. The mechanism of action may include suppression of rapid eye movement (REM) sleep and increased tone in the upper airway muscles. Protriptyline is contraindicated in patients with glaucoma or prostatic hypertrophy, and anticholinergic side effects limit its usefulness.

Intubation and Upper Airway Management

C. William Hanson III • Erica R. Thaler

The first known use of positive pressure ventilation (PPV) as a medical intervention dates back to the sixteenth century, as described in Vesalius' *de Humani Corporis Fabrica*:

> But that life may in a manner of speaking be restored to the animal, an opening must be attempted in the trunk of the trachea, into which a tube of reed or cane should be put; you will then blow into this, so that the lung may rise again and the animal take in air. Indeed with the slight breath in the case of the living animal, the lung will swell to the full extent of the thoracic cavity, and the heart become strong . . . for when the lung, long flaccid, has collapsed, the beat of the heart and arteries appears wavy, creepy, twisting; but when the lung is inflated at intervals, the motion of the heart and arteries does not stop. . . .

Vesalius subsequently resuscitated a Spanish nobleman by inflating his lungs through the trachea, resulting in resumption of cardiac activity and nearly in Vesalius' death at the hands of the Inquisitors. Vesalius, an excellent anatomist who disproved many of the cherished teachings of Galen that had been accepted as absolute truth for 13 centuries, was viewed as a heretic by his peers. In fact, one described him as "an impious madman who is poisoning all of Europe with his vaporings."

Because of lack of enthusiasm in response to Vesalius' findings, a 100-year hiatus attended the next attempt at endotracheal ventilation. In 1667, Robert Hooke, a prominent mathematician, geologist, and paleontologist kept a dog alive by intermittently insufflating air into its trachea using a set of bellows. One century later, in 1744, John Fothergill, one of the founders of the British Humane Society, described successful mouth-to-mouth resuscitation.

Because of concerns over development of emphysema and tension pneumothorax as complications of PPV (recognized as early as 1827), research on artificial ventilation in the nineteenth and early twentieth centuries focused on negative-pressure ventilation (NPV). Iron lungs, tank ventilators, cuirass ventilators, and a variety of strange and remarkable differential pressure chambers and boxes were developed in the United States and Europe. The devices were powered by hand, water, steam, or electricity, and, in some cases, by the patient himself. However, PPV became incorporated into the resuscitation strategy of the Dutch Humane Society, which advocated mouth-to-mouth ventilation in conjunction with external thoracic and abdominal compression. In 1776, John Hunter described an apparatus that blew fresh air into the lungs with one set of bellows and sucked "bad" air out with a second set.

By the end of the nineteenth century, a surge in the evolution of thoracic surgery led to the use of tracheal intubation and PPV through cuffed tubes as acceptable components of medical care. An American surgeon, Joseph O'Dwyer,

designed a series of metal tubes that were inserted between the vocal cords of children afflicted with diphtheria. Rudolph Matas referred to O'Dwyer's devices in describing "intralaryngeal intubation" and "insufflation" and noted that, "the procedure that promises the most benefit in preventing pulmonary collapse in operations is . . . the rhythmic maintenance of artificial respiration by a tube in the glottis." In the early part of the twentieth century, Franz Kuhn, a German surgeon, described techniques for oral and nasal intubation using flexible metal tubes introduced into the trachea with the assistance of the operator's index finger; the procedure was preceded by application of topical anesthesia using cocaine. The airway was then sealed with a supralaryngeal flange and gauze packing.

Among the further advances that followed was the first laryngoscope created by Alfred Kirstein in Berlin. However, his model was never widely accepted. Chevalier Jackson developed a U-shaped laryngoscope that otorhinolaryngologists still use for endoscopy but was never adopted by anesthesiologists. In 1913, Janeway described an endotracheal tube with a removable cuff, an anesthesia ventilator, and a battery-powered laryngoscope. From 1900 to 1920, Dorrance, Elsberg, Löwen, and Sievers published methods for tracheal intubation and PPV.

The most influential figure in the history of endotracheal intubation is Sir Ivan Magill. Along with Stanley Rowbotham, he used anesthetics on Royal Army casualties during World War I (in particular, on patients with disfiguring facial injuries). Their patients were often intubated nasally to allow freer access to the face by the surgeon. Magill's inventions include the Magill forceps, which is still used to facilitate nasal intubation, semirigid endotracheal tubes fashioned from mineralized rubber, and the Magill circuit, an L-shaped laryngoscope. He is also credited with describing the "sniffing position."

Arthur Guedel, an American contemporary of Magill, refined the cuffed endotracheal tube and, by extensive experimentation on animal tracheas, determined that the best position for the cuff was just below the vocal cords. He popularized use of the cuffed endotracheal tube by publicly anesthetizing his pet dog, "Airway," and immersing the animal in a tank of water. Upon awakening, the dog shook itself off and departed the arena.

In current practice, access to the trachea through the nasopharynx or oropharynx takes advantage of laryngoscope blades invented in the 1940s by Robert Miller, a Texas clinician, and Robert Macintosh, an Oxford professor. The Miller blade was an advance over similar straight blades; it was designed to pick up the epiglottis and expose the vocal cords. The curved Macintosh blade differed from previous models and was designed for insertion between the epiglottis and tongue. Although many variants of the two blades are available today, including those with different angulations, prisms, and fiberoptic bundles, the Miller and the Macintosh blades remain the mainstays of the anesthesiologist's armamentarium.

The first departments of anesthesiology were founded in the early 1940s. Thereafter, the skills required for management of the upper airway and endotracheal intubation became widely disseminated in the United States and the United Kingdom.

UPPER AIRWAY ANATOMY AND CLINICAL RELEVANCE

The two functional conduits between the trachea and atmosphere—the oropharynx and the nasopharynx (Fig. 151-1)—join at the level of the base of the skull to form the hypopharynx. The oropharynx includes the base of the tongue,

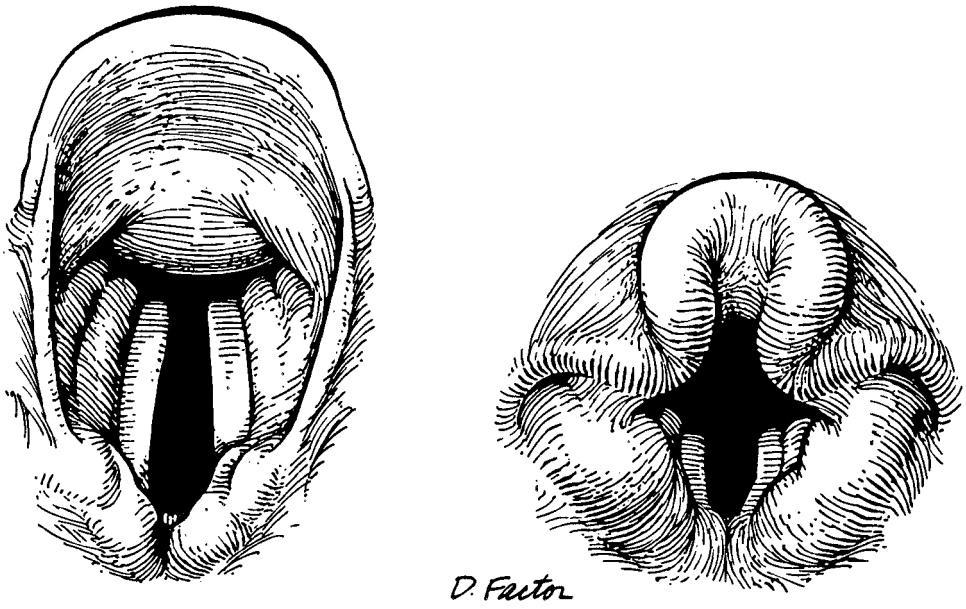

Figure 151-1 Comparative anatomy of adult and infant airways. *(Courtesy of Barash P, et al (eds.):* Clinical Anesthesia, *Philadelphia, Lippincott, 1989, p 544, D. Factor, illustrator.)*

uvula, and tonsils. The nasopharynx is separated from the oropharynx by the mobile soft palate. The hypopharynx includes the vallecula, which is the space posterior to the tongue and anterior to the cervical esophageal inlet. Typically, the adult epiglottis is crescentic, moderately stiff, and thin. Because of its ligamentous attachments, the adult epiglottis can be lifted indirectly using a curved laryngoscope blade applied to the base of the tongue. The U-shaped infant epiglottis is longer and floppier than the epiglottis of the adult. Therefore, a straight blade is typically required to lift the infant epiglottis directly during endotracheal intubation.

The adult and infant airways differ in several other respects. The narrowest portion of the adult airway is the rima glottidis, the area between the vocal cords; in contradistinction, the cricoid is the narrowest portion of the infant's airway. The infant larynx is also situated relatively more cephalad than the larynx of the adult; in addition, the vocal cords of the infant are angled, whereas the vocal cords of the adult are perpendicular to the airway.

In an awake patient, with the head in the neutral position (i.e., neither flexed nor extended), air moves freely through both the oropharynx and nasopharynx. In most normal subjects, the same is true during sleep. Abnormalities of any of the component parts of the upper airway can impede airflow during respiration while awake; alternatively, impeded airflow may only become evident during sleep (e.g., as snoring or obstructive apnea). Consequently, a directed history and physical examination should be performed prior to any procedure on the airway.

A history of nasal polyps or nasal septal deviation mandates caution prior to nasotracheal intubation, transnasal passage of a fiberoptic scope, or insertion of a nasal airway. The patient's sleeping partner is often the best source of information about snoring and apnea, manifestations that may result from a variety of upper airway abnormalities, including soft tissue redundancy, masses, polyps, stenosis, or lymphoid hypertrophy from the nose to the hypopharynx and larynx. Vocal changes or abnormalities may suggest abnormalities of the vocal cords and warrant preintubation evaluation.

The physical examination of the airway is preceded by a conversation with the patient. Hoarseness, stridor, tachypnea, and coughing suggest potential upper airway problems. The examination then can be pursued systematically beginning with the nasopharynx. The patient's ability to breathe through a single nostril (when the mouth is closed and the other nostril occluded) indicates that the passage is relatively patent. Asymmetry often exists between the two sides and, whenever possible, instrumentation should be performed on the more patent side.

The ability to open the mouth is limited in patients with temporomandibular joint disease. The temporalis muscle may be scarred or fibrotic (e.g., secondary to prior radiation) resulting in restricted mandibular mobility. Fractures to the mandible produce limited ability to open the mouth that, when the limitation is caused by muscle spasm, disappears with anesthesia. Some fractures functionally affect the mobility of the jaw, irrespective of anesthetic state. Inability to open the mouth more than 40 mm is considered to be clinically significant.

The patient's dentition should also be assessed prior to elective management of the airway. Protruding maxillary incisors ("buck teeth") interfere with direct laryngoscopy by restricting the extent to which the laryngoscope blade can be aligned with the trachea. Dental caps and other prostheses are fragile and easily damaged during laryngoscopy. The laryngoscope may become lodged in gaps between the maxillary teeth during instrumentation and interfere with intubation. Severe dental caries or periodontal diseases make it easier to dislodge teeth during airway instrumentation. The edentulous patient often has an atrophic mandible and large tongue and may be difficult to ventilate by mask because of poor fit of the mask. Intubation of the trachea in such a patient becomes difficult because the tongue, no longer constrained by the teeth, interferes with visualization of the larynx.

Abnormalities of the tongue, hard palate, tonsillar pillars, and hypopharyngeal structures can impede or prevent intubation. Normally the tongue is small and sufficiently flexible to be displaced by a laryngoscope blade during visualization of the vocal cords. However, the tongue is enlarged in obese patients, those with angioedema or impaired lymphatic drainage (e.g., after cervical surgical procedures or trauma), or in the setting of certain neoplasms. Burns, scars, or radiation of the submandibular soft tissue prevent lateral displacement of the tongue into the oropharynx during laryngoscopy. Similarly, in patients with small jaws ("receding chins"), displacement or flattening of the tongue during laryngoscopy is difficult, making intubation a challenge. A hyomental distance (the distance from the hyoid bone to tip of the mandible) of less than 6 cm should raise awareness of potential difficulty with intubation.

A cleft or high, arched palate is seen in a variety of congenital abnormalities of the facial bones, including the Treacher-Collins, Pierre Robin, Klippel-Feil, Goldenhar, Beckwith-Wiedemann, and Crouzon's syndromes, as well as the mucopolysaccharidoses. Affected patients are difficult or impossible to intubate using standard approaches.

Intraoral, oropharyngeal, hypopharyngeal, and laryngeal lesions, as well as tonsillar hypertrophy, can interfere with both laryngoscopy and ventilation by mask. The epiglottis can be infiltrated, inflamed, floppy, or enlarged by fat. The retropharyngeal and lateral pharyngeal spaces are continuous with and therefore subject to expansion by processes that involve the mediastinum (e.g., the presence of edema, blood, pus, or soft-tissue emphysema). Patients with epiglottitis and parapharyngeal swelling often exhibit a characteristic posture, sitting upright in the sniffing position and drooling.

The preferred position for visualization of the vocal cords is the sniffing position (Fig. 151-2). However, this position may be unsuitable in some patients or impossible to achieve in others.

The normal range for flexion and extension of the neck ranges from 90 to 165 degrees. A variety of disorders limit this range. Patients with cervical osteophytes or ankylosing spondylitis, who are often fixed in an anteroflexed head

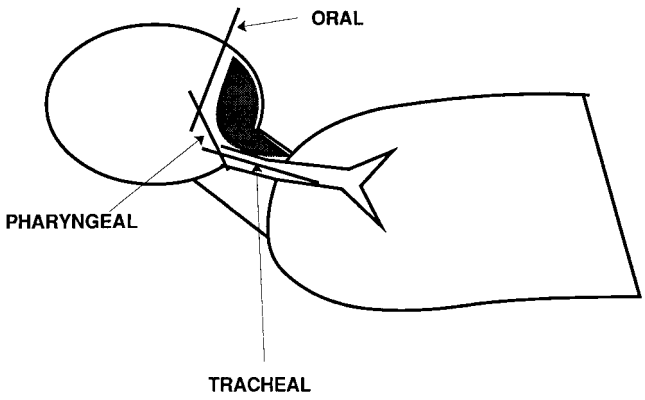

Figure 151-2 The sniffing position with the oral, pharyngeal, and tracheal axes.

position, may be difficult to intubate. Halo fixation imposes similar constraints. Rheumatoid arthritis, which may affect the cervical spine even in asymptomatic patients, may be problematic. By the age of 75 years, the normal aging process results in as much as a 20 percent reduction in cervical spine mobility. Injury to the cervical spine or the presence of a cervical collar also impairs the ability of the laryngoscopist to position the head. Finally, patients with short, muscular necks have limited neck mobility and redundant soft tissue in the mouth and submandibular space, making airway visualization a challenge.

A variety of other anatomic features, including large breasts or a barrel chest, can complicate airway management by interfering with the excursion of the butt of the laryngoscope blade. During pregnancy, the oral and pharyngeal mucosae are swollen and bleed easily. When associated with a diminished functional residual capacity and increased volume of acidic gastric contents, intubation becomes quite hazardous.

Based upon anatomical considerations, clinicians commonly employ the Mallampati scale (Table 151-1) to evaluate objectively the airway's suitability for placement of the endotracheal tube. The ability to visualize the soft palate, fauces, tonsillar pillars, and uvula is used to predict the degree of difficulty in exposing the larynx. A careful examination of the airway, coupled with attention to difficulties during prior procedures and the physical features described above, permit adequate preparation for instrumentation of the difficult airway.

Table 151-1

Mallampati Scale for Characterizing the Airway

Class II Soft palate, fauces, and uvula visible
Class III Soft palate and base of uvula visible
Class IV Soft palate only visible

UPPER AIRWAY MANAGEMENT

Airway management is well suited to the use of algorithms. The American Society of Anesthesiologists has a "difficult airway" algorithm for use in the operating room. In addition, algorithms for the critical care unit and trauma setting have been developed. In using an algorithm-based approach, the first decision branch point typically addresses the need for endotracheal intubation, since short-term respiratory insufficiency often can be managed noninvasively.

Factors that must be considered in the care of patients with respiratory compromise include the level of consciousness, clinical context (e.g., the perioperative setting, emergency circumstances, etc.), anticipated duration of respiratory problem, risk of gastric aspiration, airway patency, concurrent medical problems, and anticipated relative ease of noninvasive (i.e., spontaneous or mask ventilation) vs. invasive (i.e., endotracheal intubation) management of the airway.

In the patient with neurological depression due to injury of the central nervous system, noninvasive management is usually inappropriate due to the potential for developing hypercarbia or hypoxia and exacerbation of the primary injury. Conversely, in the patient sedated or obtunded by drugs or seizures, the clinical state is often brief in duration, so temporizing measures may be appropriate.

Several factors differentiate elective perioperative airway management from emergency care. During surgery, an anesthesiologist or anesthetist is constantly present; the patient is properly prepared (i.e., the stomach is empty and a drying agent has been administered) and the environment is designed to facilitate airway management (i.e., there is ready access to suction, a ventilator, etc.). Under these circumstances, caregivers may choose to sedate the patient to the point of semiobtundation. Conversely, in an emergency, the setting is usually less than optimal. Airway management is usually only one component of the care rendered during cardiac or trauma resuscitation, and definitive airway intervention is essential in order to allow care providers to concentrate on other problems.

Potentially quickly reversible processes (e.g., some attacks of asthma or episodes of pulmonary edema) may be appropriately managed without intubation. In other instances (e.g., blunt chest injury), the initial problem can be expected to worsen, and early intubation is warranted.

The volume and acidity of the patient's gastric contents must be factored into any decision about management of the airway. Aspiration of solid food can be catastrophic, as can large volumes of acidic, enzymatically active gastric fluid. Most studies have indicated that aspirated stomach contents with a pH lower than 2.5 or volume greater than 0.5 to 1.0 cc/kg are likely to cause lung damage. The lung damage is manifested by loss of ciliated and nonciliated epithelial cells in the trachea, destruction of type I and II pneumocytes, depletion of surfactant, and increased vascular permeability (see Chapter 144). Pain and narcotics may alter gastric emptying or change gastric pH, as can a number of disease states, such as intestinal obstruction, diabetic gastroparesis, and obesity. Unless the patient has fasted for more than 8 h and is not subject to the confounding factors noted above, a full stomach should be presumed, and airway management handled accordingly.

The patient's coexisting medical problems and expected course must also be considered in management of the airway. For example, endotracheal intubation can be a dangerous stress to a patient with coronary artery disease and can be performed more safely after suitable preparation than under emergency circumstances. As another example, a patient with Fournier's gangrene and normal lungs is appropriately managed by maintaining intubation and sedation between trips to the operating room for debridement, rather than by performing multiple extubations and reintubations. Similarly, elective intubation and mechanical ventilation can prevent aspiration or atelectasis in a patient with hepatic encephalopathy who is awaiting liver transplantation, thereby improving the likelihood of a successful outcome.

Some degree of airway obstruction can be managed without intubation by proper positioning of the head, use of an oral or nasal airway, or application of positive airway pressure (PAP) by mask. A rolled towel or small pillow placed behind the neck or occiput reproduces the sniffing position. Oral and nasal airways can alleviate airway obstruction due to redundant airway soft tissue or muscle relaxation. The application of positive pressure to the mouth and nose (mask continuous positive airway pressure or mask CPAP) distends the soft tissue of the airway. For this reason, nasal mask CPAP is frequently used in the management of obstructive sleep apnea (see Chapter 97). These measures can be used as short-term, temporizing alternatives to intubation in the patient who is ventilating spontaneously in the intensive care unit or operative setting.

Although a growing literature exists on the use of noninvasive ventilation in a variety of settings that previously would have mandated endotracheal intubation, anesthesia is frequently administered in the operating room by mask using positive pressure. True mask ventilation is readily accomplished in the anatomically normal patient. However, some anatomic features, such as a beard, flat or sharp nose, or sunken cheeks (in the edentulous patient) can make mask-assisted ventilation difficult or impossible.

Indications for tracheal intubation (Table 151-2) fall broadly under several categories: respiratory failure, airway protection, hemodynamic instability, and perioperative management. If intubation is indicated, the clinician must decide upon the route and technique.

Table 151-2

Indications for Intubation of the Trachea

Ventilatory failure Cardiac arrest, primary lung disease, neuromuscular disease or weakness
Airway obstruction Primary airway process, neurogenic obstruction
Airway protection Upper airway bleeding or injury (burn), central nervous system depression
Pulmonary toilet Inability to manage secretions

TECHNIQUES AND EQUIPMENT

Although expertise is a function of experience, several principles are generally applicable in any approach to airway management. The first applies to correct head positioning, which facilitates mask management, oral or nasotracheal intubation, and fiberoptic examination of the airway. Incorrect positioning impedes each procedure.

The previously noted sniffing position refers to extension of the head on the neck while the neck is flexed on the thorax (Fig. 151-3). The hypopharynx is at its maximal circumference in this position, and the tongue is farthest from the posterior pharyngeal wall. Anterior displacement of the jaw can be accomplished by pulling it forward or applying pressure on the angle of the mandible (the "jaw thrust" maneuver).

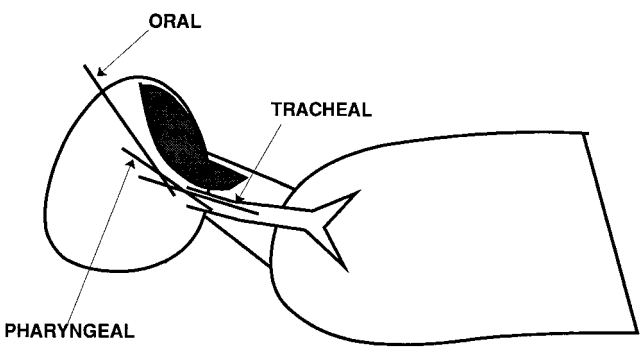

Figure 151-3 The sniffing position modified by additional head extension for oral intubation, with alignment of the oral, pharyngeal, and tracheal axes.

This serves to open further the retrolingual space. Pulling the tongue forward while grasping it with gauze or an instrument accomplishes the same goal. The position is appropriate for spontaneous respiration because it limits soft-tissue obstruction to airflow.

Nasotracheal intubation is easiest in the sniffing position, because the tip of the endotracheal tube is best aligned with the larynx and least likely to be deflected by the walls of the pharynx. Nasal and oral fiberoptic procedures are also easier in this position in which the oral, pharyngeal, and tracheal axes are well aligned (Fig. 151-3). The sniffing position may be modified by further head extension and flattening of the back of the tongue by the laryngoscope blade during oral intubation.

A second general principle underlining airway management is that saliva and blood interfere with mask ventilation, direct visualization of the airway, and fiberoptic procedures. When circumstances permit, pretreatment with an antisialogogue, such as atropine, glycopyrrolate, or scopolamine, significantly diminishes saliva production. Suction must be available prior to initiation of any elective procedure (as well as on the emergency cart) to clear secretions or deal with regurgitation of gastric contents. A suction tip with a large bore, such as the Yankauer tonsil suction tip, is commonly used; suction should be maximized in order to clear thick, viscous oral secretions.

A third general principle of airway management refers to preparation of the patient and airway. Small, titrated doses of sedatives, topical anesthesia, and vasoconstrictor agents markedly enhance the ease with which procedures, such as fiberoptic, nasotracheal, or oral intubation, are performed while the patient is awake. Narcotics are more likely to suppress the cough reflex than are other agents. Topical cocaine has anesthetic and vasoconstrictor properties, but because of its classification as a controlled agent, the combination of lidocaine and phenylephrine is often used as an alternative. The light source of a laryngoscope or fiberoptic scope should be checked prior to instrumentation, and, with the latter, the focus adjusted. Finally, a backup plan for airway management is essential in case the primary plan should go awry.

Finally, perhaps the most important principle of airway management is that a source of oxygen and means of ventilation should be available. This implies that the pressure in nearby oxygen tanks should be checked, as should the proximity of a source of wall oxygen. In the absence of an oxygen source, a self-inflating resuscitation bag can provide a method for ventilation, obviously using only room air (see below). Bags used for most anesthesia circuits require a gas source for inflation.

AIRWAYS

A large variety of nasal and oral airways, designed for children and adults of different sizes (Fig. 151-4), are available. Nasal airways are generally made of flexible rubber and have a beveled tip, permitting insertion through narrow nasal passages. Oral airways are curved, designed to lie over and behind the tongue. Some are fashioned with slots for ready passage of a suction catheter, whereas others have a central channel designed to accommodate a fiberoptic scope. Binasal airways are designed to be fitted to a ventilation circuit, permitting ventilation in anesthetized patients without endotracheal intubation.

Figure 151-4 Oral and nasal airways and face masks.

RESUSCITATION BAGS

Resuscitation bags are available in many styles (Fig. 151-5) and are designed with several common features. They are self-inflating, and can, therefore, be used in the absence of a gas source. An internal flap valve system directs inflowing gas to the patient or reservoir, permitting application of positive pressure by mask or endotracheal tube and venting exhaled gas to the atmosphere. Inspired oxygen concentration is ordinarily limited to 40 to 60 percent when oxygen inflow is 10 L/min; bag reinflation is rapid, since room air is entrained with each breath. Addition of an oxygen reservoir, usually in the form of a sleeve or tail at the back of the bag, permits administration of oxygen concentrations of 75 to 90 percent at 10 to 15 L/min. Some bags are equipped with adjustable valves for application of positive end-expiratory pressure.

MASKS

Although a large variety of masks are available (Fig. 151-4), all have three features in common: the body, seal, and

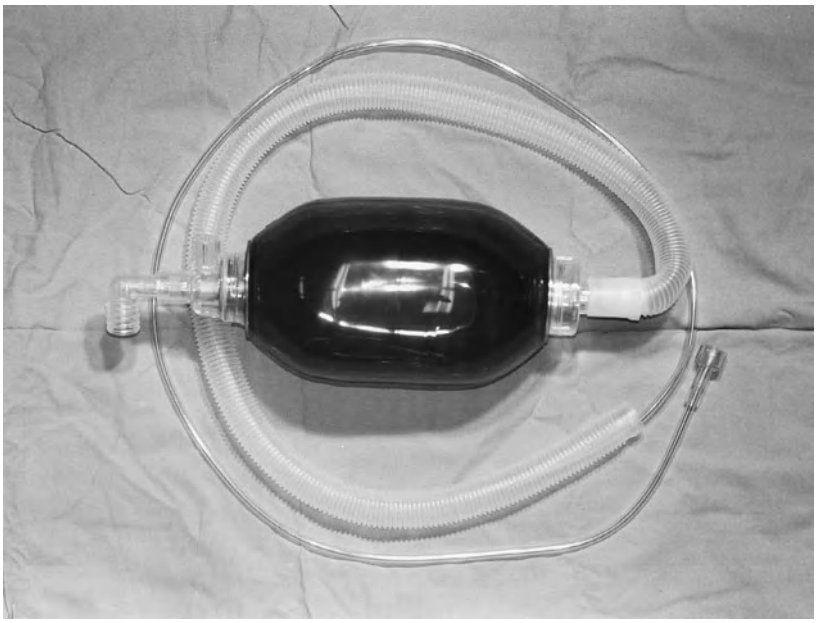

Figure 151-5 Self-inflating resuscitation bag.

connector. The body is usually made of malleable or moldable material and adjustable to individual facial anatomy. The body of some masks is made of clear plastic to allow diagnosis of regurgitation of gastric contents. The seal is usually a cushioned rim (which can be inflated or deflated) attached to the body, although some are detachable. Some seals are flanged and not cushioned. The connector is designed with a universal fitting (22-mm internal diameter) for attachment to any ventilating circuit. Many are equipped with retaining straps for attachment to mask straps (which pass behind the patient's head, freeing the hand of the operator).

EXTRAGLOTTIC AIRWAY DEVICES

A number of extraglottic or supraglottic airway devices exist, and new ones are described every year. Some are cuffed, while others are uncuffed; some are nasally inserted, while others are orally inserted. A few devices are based on cannulation of the esophagus. The most familiar devices are cuffed, orally inserted, hypopharyngeal airways, such as the laryngeal mask airway (LMA) and the laryngeal tube airway (LTA).

The LMA (Fig. 151-6) is analogous to the facial mask: It has a compliant cuff that is applied to the dorsal surface of the larynx, isolating the airway from the mouth and esophagus. The LMA came into common intraoperative usage in the early 1990s. While used most extensively in surgical patients, the LMA has also been used for awake, fiberoptic bronchoscopy, in the intensive care unit, and in emergency resuscitation. Variants are specifically designed to be flexible, disposable, or to permit passage of an endotracheal tube through the device's lumen. The LMA is inserted through the mouth into the hypopharynx; its correct positioning is verified by assessment of breath sounds.

The LTA is similar to the LMA. The device has two cuffs, one of which is designed to seal the lower pharynx and esophagus and the other the upper pharynx. A lumen exists between the two.

The esophageal obturator airway (EOA) is similar to the LTA in that it also has two cuffs and a single lumen. However, the distal end of the device is designed to lie in the esophagus. A newer device, the Combitube (Armstrong Medical Industries), addresses a concern that the tip of the EOA may inadvertently enter the trachea, making ventilation impossible. The Combitube is designed to permit ventilation and airway isolation regardless of whether its tip lies in the esophagus or trachea.

TRACHEAL INTUBATION

Four approaches are commonly employed in tracheal cannulation: nasal, oral, laryngeal, and tracheal. The first two are noninvasive, whereas the latter two require surgical incisions.

Nasotracheal intubation can be done "blindly" (i.e., without tracheal lumen visualization) or using a laryngoscope and forceps. A blind nasotracheal intubation, when performed by a skilled operator, allows rapid control of the airway in an awake patient and minimal suppression of protective airway reflexes. The technique is used widely by paramedics in prehospital patient care, as a component of many difficult airway algorithms, and as an integral part of Advanced Trauma Life Support algorithms.

In performing blind nasotracheal intubation in a nonemergency setting, the operator examines the nasal passages for patency, septal deviation, or the presence of polyps.

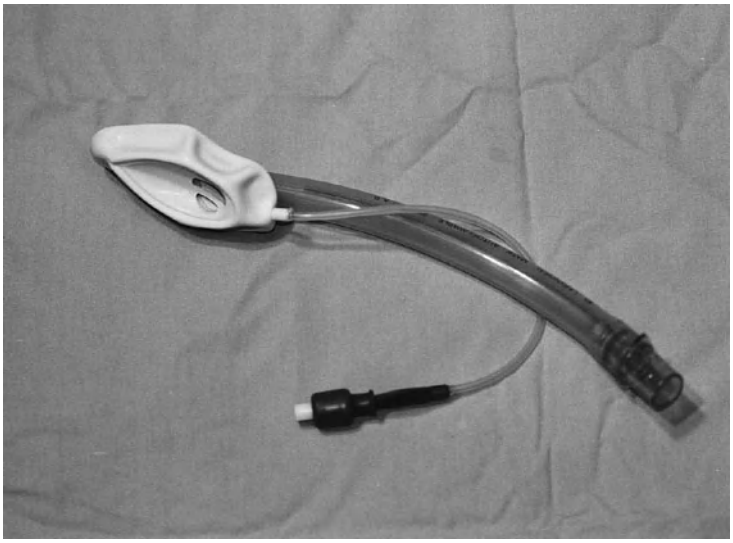

Figure 151-6 The laryngeal mask airway.

If the patient is able to cooperate, the larger nasal passage is selected by alternately occluding each nostril and choosing the one with better airflow. A topical anesthetic and vasoconstrictor agent are sprayed in the nostril or applied with cotton pledgets. Anesthetic is also sprayed into the back of the mouth in order to anesthetize the hypopharynx.

An appropriately sized tube (6 to 7 mm for women, 7 to 8 mm for men) is selected and lubricated. Lubrication eases passage of the tube and minimizes abrasion of the nasal mucosa, making bleeding less likely. The patient is placed in the sniffing position and the tube inserted and advanced using slow, firm pressure. The natural slope of the tube is oriented so that the tip initially points toward the occiput and curves in a caudad direction as it is advanced.

During the procedure in an awake patient, the operator listens for breath sounds as the tip approaches the vocal cords. A commercially available whistle attachment (Bamm, Great Plains Ballistics, Inc., Lubbock, TX) enhances the operator's ability to hear breath sounds (Fig. 151-7). The tube is

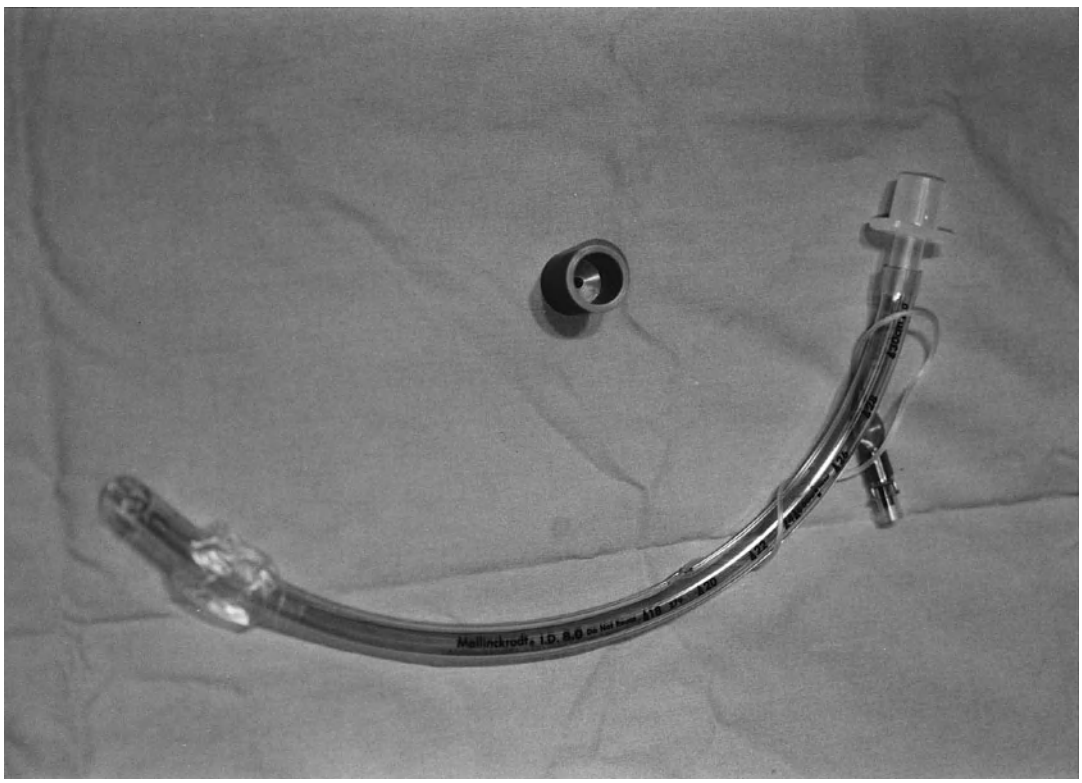

Figure 151-7 Standard endotracheal tube with whistle tip attachment to amplify breath sounds during blind nasal intubation.

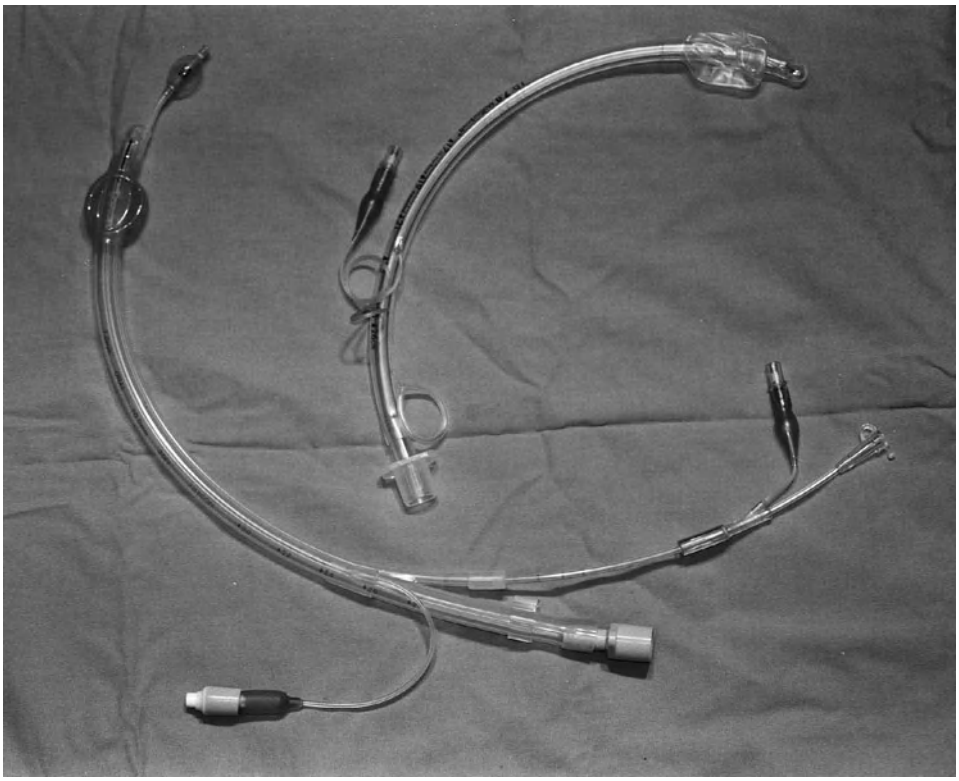

Figure 151-8 Endotracheal tube modified with a "trigger" permitting anteroflexion of the tip of the tube during blind nasal intubation. Univent tube for lung isolation (see text).

advanced into the airway during *inspiration*. Slight clockwise or counterclockwise rotation of the tube at the nose can be used to correct for lateral misalignment. A commercially available endotracheal tube (Endotrol, Mallinckrodt, Athlone, Ireland) allows the operator to anteroflex the tip of the tube with a "trigger" at the connector (Fig. 151-8). This is especially effective in patients with anteriorly positioned vocal cords or those who cannot assume the sniffing position (e.g., due to the presence of a cervical collar).

When nasotracheal intubation is performed in an anesthetized patient, the endotracheal tube tip is advanced into the hypopharynx above the vocal cords, laryngoscopy is performed, and the tube is then advanced into the trachea under direct visualization. Magill forceps (Fig. 151-9) are often used to grasp the tube and direct its tip between the vocal cords. Care must be taken to avoid grasping the tube by the cuff, which is easily perforated.

Correct position of the tube can be verified using a number of methods. Audible or palpable air passage (in the spontaneously breathing patient), a visible vapor trail within the tube, or auscultatory evidence of breath sounds over the lung fields are standard approaches. End-tidal capnometry showing phasic variation in carbon dioxide levels is the gold standard and has become more feasible in nonoperative settings because of the development of portable and disposable devices.

Extensive literature exists on the pros and cons of nasal versus oral intubation in the intensive care environment. Nasal intubation is associated with a higher incidence of bleeding, nasal discomfort, and hemodynamic alterations during tube placement. A minimal increase in the dead space of the equipment (less than 10 cc) without significant difference in airflow resistance occurs with nasotracheal intubation compared with the orotracheal route. Literature regarding the incidence of sinusitis and pneumonia as a result of each of the two methods is conflicting; one prospective, randomized trial showed no differences. In general, early tracheostomy is increasingly preferred in critically ill patients who are likely to be intubated for prolonged periods.

By far, direct laryngoscopy with orotracheal intubation is the most common approach that is applied to secure the airway. With the patient's head in the sniffing position, the operator inserts a Macintosh or Miller blade (Fig. 151-10) into the right side of the mouth using the left hand (regardless of the handedness of the operator). While some anatomic situations make it advantageous to use one blade rather than the other (e.g., the Miller blade in the setting of an anatomically anterior larynx), most operators become familiar with one blade and use it preferentially.

The blades of both instruments are flanged to keep the tongue to the left and out of the visual field. Larger adult blades (Macintosh no. 4 or Miller no. 3) are used for patients with long mandibles, whereas shorter blades (Macintosh no. 3 or Miller no. 2) are used in normal patients. Smaller blades are used for children.

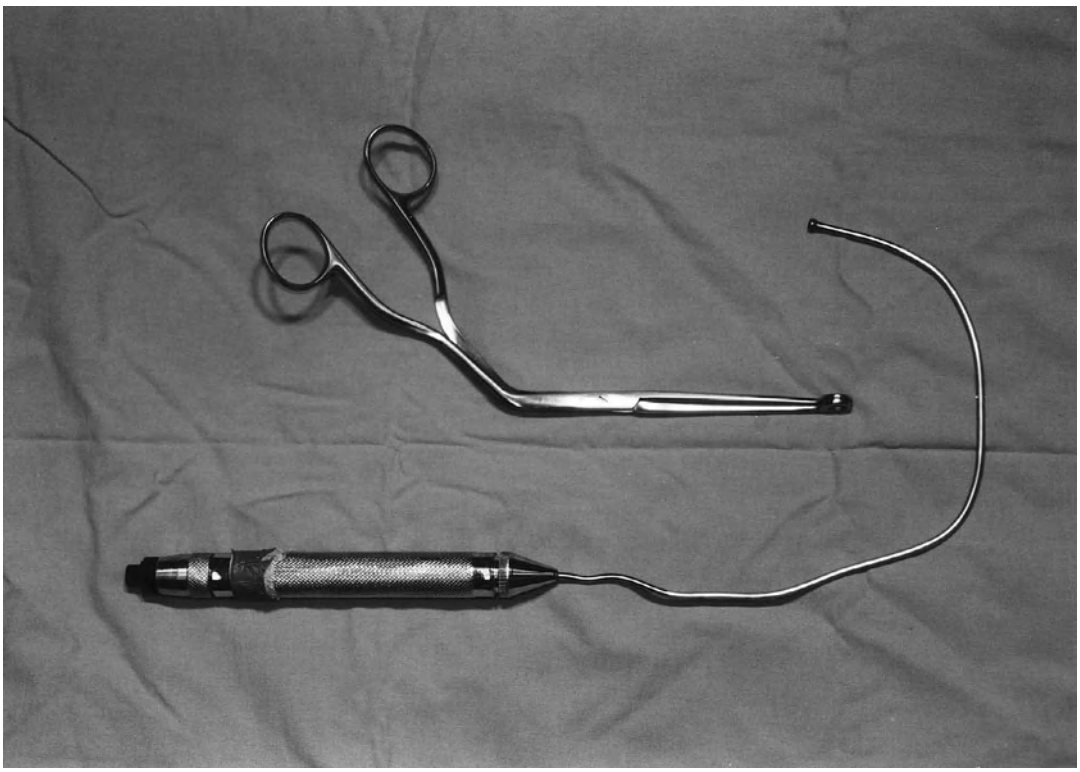

Figure 151-9 Magill forceps (see text) and light wand for transillumination of the trachea during blind oral intubation.

Figure 151-10 Macintosh and Miller blades.

During the procedure, the operator's right hand pulls the upper and lower lips out of the way, so that they are not caught and injured between the blade and teeth. The tip of the laryngoscope blade is advanced along the tongue until the epiglottis is visible. If the Macintosh blade is used, it is advanced between the tongue and epiglottis; when the Miller blade is used, the epiglottis is elevated directly. The cords should be visible immediately below the epiglottis. Most infants are intubated using a Miller blade. The shape, length, and pliancy of the infant epiglottis are such that it must be "picked up" by the tip of the Miller laryngoscope so that the cords can be seen.

Because some patients are difficult to intubate due to anatomic considerations, a number of alternate approaches have evolved. These include fiberoptic laryngoscopy, by which the trachea is entered using a bronchoscope and an endotracheal tube advanced into the airway over the device. A flexible light wand (see Fig. 151-9) can be used to transilluminate and identify the airway; an endotracheal tube is then advanced into the airway using the wand as a stylet. Retrograde techniques involve percutaneous cannulation of the trachea in the neck and retrograde passage of a wire or catheter into the oropharynx. The wire is grasped and secured to an endotracheal tube and used to guide its passage back into the trachea.

Percutaneous cricothyrotomy kits are available for emergency access to the airway, as are percutaneous tracheostomy kits. Percutaneous ventilation has been taught in airway management portions of Advanced Cardiac Life Support (ACLS), Advanced Trauma Life Support (ATLS), and

Pediatric Advanced Life Support (PALS) courses. The technique requires insertion of a needle or intravenous catheter through the cricothyroid membrane in order to insufflate oxygen during emergency airway management.

Anatomic features indicative of the difficult airway are listed in Table 151-3. While a full discussion of the management of the potentially problematic airway is beyond the scope of this chapter, adequate preparation by the operator can prevent a catastrophe.

Early assessment of the anatomy to determine whether difficulty with intubation alone or intubation and ventilation should be anticipated is important. An anteriorly placed larynx is usually associated with difficulty in intubation alone, whereas an obese patient is more likely to present a challenge with regard to both intubation and ventilation.

An additional important determination is whether interventional airway management is actually necessary. Can the procedure be performed under regional, rather than general, anesthesia? If regional anesthesia cannot be employed, awake intubation using sedation and topical airway anesthesia may be an excellent alternative. Direct laryngoscopy and fiberoptic bronchoscopy are equally appropriate adjuncts in intubating cooperative patients.

If difficulty in airway management is unexpectedly encountered in an already anesthetized patient, ensuring adequate ventilation and oxygenation is critical. A mask or, if necessary, one of the invasive approaches described above, may be used. Establishment of reliable ventilation allows time for alternate approaches, including abandonment of the procedure (allowing the patient to awaken) or tracheostomy.

A large number of endotracheal tubes are commonly employed in a variety of clinical settings.

Single-lumen, reusable, red rubber tubes with separate cuffs were used as recently as the mid-1970s, and red rubber double-lumen tubes were in common use 5 to 10 years ago. Disposable tubes are now widely available, and a host of different design modifications have been made to make the tubes safer and accommodate different surgical procedures.

The cuff of the adult tube has been changed from a low-volume, noncompliant cuff to a higher volume, very compliant cuff; a corresponding decrease in the incidence of tracheal stenosis has been observed. Pediatric tubes are generally uncuffed because children are more vulnerable to development of subglottic stenosis due to tube contact with the trachea. Uncuffed tubes also maximize the cross-sectional area of the airway. Oral and nasal RAE tubes (Fig. 151-11) are preconfigured to permit facial and oral surgery without interference from the proximal portion of the endotracheal tube.

A variety of special tubes are used for laser surgery. These tubes are less likely to burn when contacted by the laser beam. Reinforced or anode tubes have an embedded wire or nylon filament spiral in the wall of the tube that prevents kinking or collapse due to external pressure (see Fig. 151-11). The Hi-Lo Jet endotracheal tube (Mallinckrodt) has four

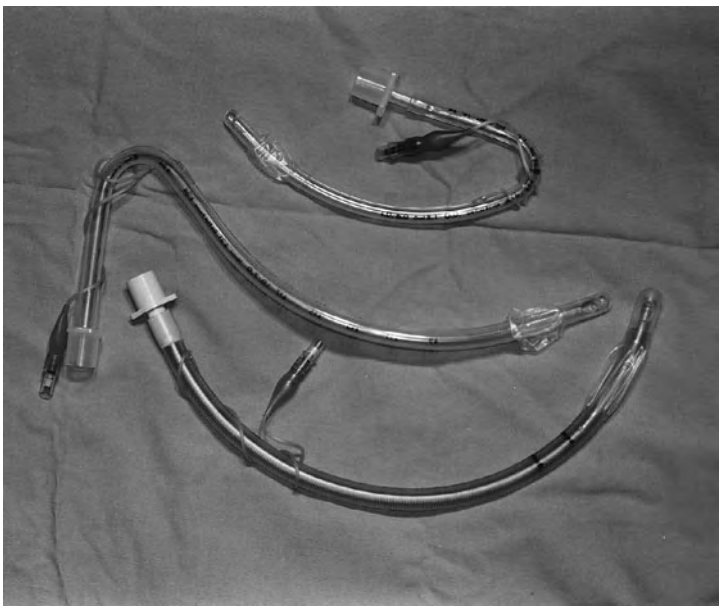

Figure 151-11 Oral and nasal preshaped tubes (RAE tubes). Anode, wire-wrapped tubes to prevent kinking.

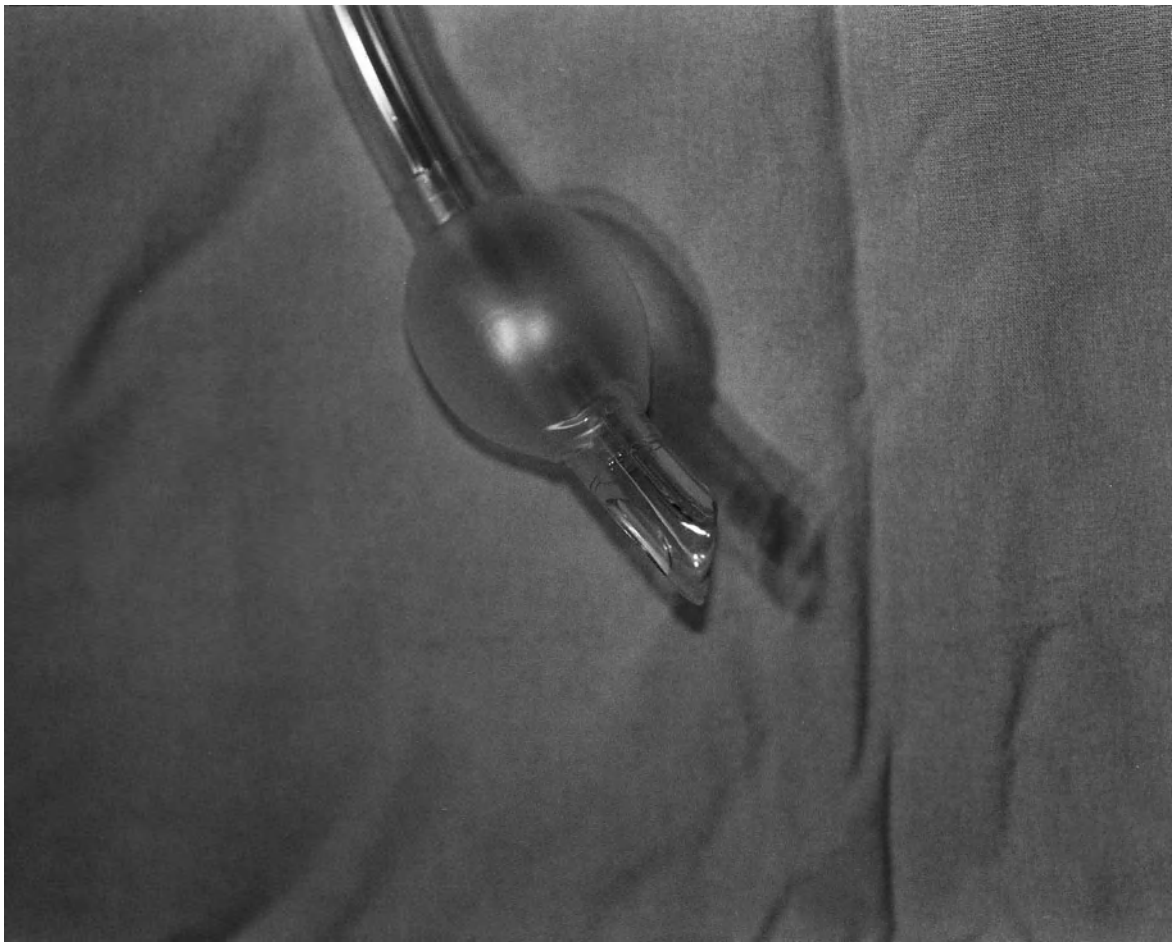

Figure 151-12 Endotracheal tube tip with Murphy eye and bevel (see text).

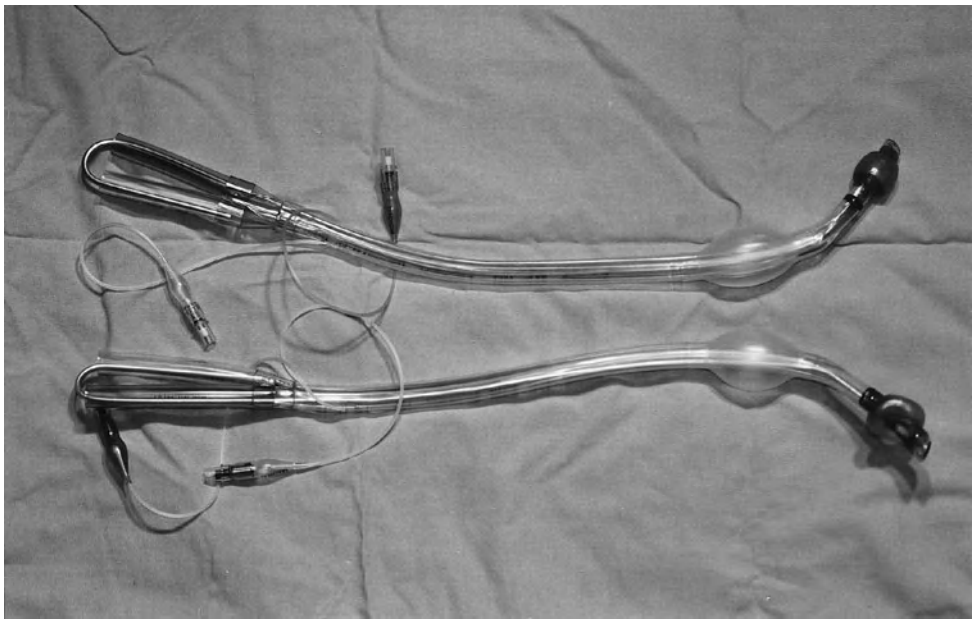

Figure 151-13 Right- and left-sided double-lumen endotracheal tubes. Note oblique bronchial cuff on the right-sided tube to accommodate right upper-lobe bronchial orifice.

lumens: one for entrained gas, a second for jet ventilation, a third for cuff inflation, and a fourth for pressure monitoring.

All single lumen tubes have a 15 mm outer diameter and connect to any standard ventilation device. Most also have a radioopaque stripe that permits tube localization on chest roentgenograms. The tip of the tube is beveled (Fig. 151-12); the bevel faces to the left because endotracheal tubes are generally inserted from the right by right-handed operators. An extra hole (Murphy eye) lies opposite to the bevel on many tubes and is designed to permit suctioning or antegrade gas flow if the bevel becomes occluded.

Finally, disposable double-lumen endotracheal tubes are now available. The Carlens and White tubes that were used in the past were equipped with a carinal hook for correct tube placement. These tubes have largely been abandoned in favor of the Robertshaw design, which has tracheal and bronchial cuffs and no hook. The tube is available in four adult sizes (35, 37, 39, and 41 French) in both right- and left-sided designs (Fig. 151-13). The right-sided tube has an oblique bronchial cuff to accommodate the takeoff of the right upper lobe orifice. Correct placement of a double-lumen tube has become easier with development of bronchoscopes small enough to pass through the narrow tube lumens.

An alternative to the double-lumen tube (the Univent tube, introduced in 1982) has a self-contained endobronchial blocker. The tube is inserted in the standard fashion, and the endobronchial blocker is then advanced (blindly or under direct vision) into the right or left main bronchus. A central lumen in the endobronchial blocker allows for inflation or deflation. While the bronchial blocker is integrated into the Univent tube construction, the same functionality can be achieved by using the Arndt wire-guided endobronchial blocker (Cook Critical Care, Bloomington, IN). The device is a multiport airway adapter, which can be used without a tube change (unlike the Univent tube) and can be "swapped" for a standard Y-piece connector, when desired.

CONCLUSION

While some of the skills developed by the early pioneers may be lost to current practitioners (Fig. 151-14), advances in pharmacology, equipment, and equipment manufacturing

Figure 151-14 Earlier diagnostic airway intervention. *(From Kirstein:* Archiv Laryngol Rhinol *3:156–164, 1895. Courtesy of Cushing/ Whitney Medical Library.)*

standards have greatly facilitated airway management and have made new surgical procedures possible.

Hemodynamic and Respiratory Monitoring in Acute Respiratory Failure

Barry D. Fuchs • Patrick Neligan

GENERAL PRINCIPLES

Patients with acute respiratory failure (ARF) sustain significant morbidity and mortality, with adverse outcomes resulting from both the primary insult responsible for the ARF and secondary complications, many of which are preventable. Admission of these patients to the intensive care unit (ICU) allows more for intensive monitoring in an attempt to diminish risks and guide therapeutic interventions. This chapter reviews methods currently available for monitoring hemodynamics and respiratory function in patients with ARF.

A number of important goals of ICU monitoring can be identified. One is to ensure adequacy of respiratory and circulatory functions in patients who appear clinically stable. Another is to provide close surveillance for early signs of respiratory and circulatory instability, with the presumption that early detection improves outcome. In addition, measurement of the response to therapeutic interventions, including application of supportive devices, such as endotracheal tubes and mechanical ventilators, is routinely performed in the ICU. Although life-saving, these devices, like all therapeutic interventions, are associated with risks that must be monitored. Finally, monitoring respiratory and hemodynamic derangements over hours to days provides valuable insight about prognosis, since the trend in physiological derangements over time predicts outcomes far better than does the severity of abnormalities on admission. Consequently, failure to improve over days, despite full support and appropriate treatment, suggests the need for alternative therapeutic strategies, including patient comfort as the primary goal of care.

Physiological parameters normally vary in critically ill patients. Furthermore, the devices used to measure these parameters are often imprecise and, at times, inaccurate. Therefore, clinical assessment and decision making should not be based, in general, on single data points. Rather, *trends* in data add reliability to interpretation of measurements.

INDICATIONS FOR MONITORING HEMODYNAMICS

When managing patients with ARF, intensivists are regularly required to make judgments about circulatory function

that can often be made confidently using routine monitoring equipment. However, several clinical questions become more challenging without application of more invasive or sophisticated measuring devices. These questions include:

1. For the patient with pulmonary edema, is the edema cardiogenic or noncardiogenic in origin?
2. Is hypoperfusion causing, or contributing to, the patient's end-organ dysfunction?
3. Recognizing the risk of worsening hypoxemia in ARF following administration of intravenous fluids, should the patient with ARF who presents with or develops shock be given fluids? If so, how much?
4. For those patients with volume overload, given the risk of causing or exacerbating organ dysfunction, how much fluid should be removed by using diuretics or dialysis to reduce lung water and improve respiratory function?

The first question requires an estimate of ventricular preload, the second an estimate of cardiac output, and the third and fourth an assessment of the inter-relationship of both preload and cardiac output.

Varieties of both noninvasive and invasive techniques are available to monitor hemodynamics and are discussed below.

METHODS FOR MONITORING HEMODYNAMICS

Assessment and monitoring of hemodynamics are based on a spectrum of clinical tools, ranging from a detailed history and physical examination to a variety of noninvasive and invasive techniques.

History and Physical Examination

While patients with ARF may require heavy sedation, some do not, and the clinician should routinely attempt to obtain a focused history from all intubated patients.

The physical examination is equally important, providing valuable visual, auditory, and tactile information. Alterations in the general appearance of the patient, including restlessness, agitation, delirium or ventilator dyssynchrony, may be readily apparent and should be investigated as a potential first sign of a serious underlying circulatory problem, particularly in the heavily sedated patient. Alterations in heart rate and blood pressure often accompany significant pathophysiological changes (e.g., severe hypoxemia), but they may also be seen as a side effect of medications or cardiac ischemia. A reduction in blood pressure, while attributable to many potential causes, may be a late manifestation of shock and always requires emergent evaluation. Unfortunately, changes in vital signs have limited sensitivity and specificity. In one study of normal subjects, a 25 percent reduction in blood volume resulted in no change in vital signs. In addition, a variety of nonhemodynamic conditions (e.g., pain or anxiety) may cause significant changes in vital signs.

The remainder of the physical examination may provide information about the adequacy of perfusion and help to establish the type and cause of shock. The adequacy of cardiac output is assessed by evaluating heart rate, mean arterial pressure, pulse pressure, urine output, mental status, and extremity and skin perfusion (as reflected by peripheral temperature, capillary refill, and absence of mottling or livedo reticularis). Estimates of right and left ventricular filling pressure based on assessment of jugular venous distention or the presence or absence of lung crackles provides a presumptive diagnosis of the type of shock and helps guide initial resuscitation. When coupled with other physical findings (e.g. unequal breath sounds) the specific etiology of shock may be determined.

Despite the potential usefulness of a careful physical examination, several studies have shown that clinical assessment correlates poorly with objective measurements of central hemodynamics, including cardiac filling pressures and cardiac output. Thus, if accurate hemodynamic measurements are needed to make safe clinical decisions, use of more sophisticated monitoring devices or diagnostic evaluation is required.

Arterial Blood Pressure

Mean arterial pressure (MAP) is the primary determinant of cerebral and myocardial blood flow. In the setting of hypotension, cardiovascular homeostatic mechanisms maintain MAP in a narrow range, in part through compensatory vasoconstriction in other, less vital, organs. However, MAP is not a useful measure of the adequacy of cardiac output. A low MAP may accompany shock, but it is a late manifestation, occurring when cardiovascular reserves are exhausted. Conversely, acute elevations in MAP may also be associated with injury to vital organs.

Patients with chronic hypertension should be maintained at a higher MAP, given the likelihood of vascular wall thickening which may limit vasodilator capacity for autoregulation. A general rule is that the MAP should be maintained within 25 percent of the patient's baseline value in order to minimize the likelihood of myocardial or cerebral ischemia. In contrast, patients with chronic liver disease may have adequate organ perfusion despite a low MAP. Nevertheless, normalizing the MAP is a primary goal in circulatory resuscitation. In patients with a normal baseline MAP, resuscitation to a goal greater than or equal to 65 mmHg has been recommended, since higher resuscitation targets fail to improve organ perfusion. Once the MAP resuscitation goal is met, other parameters more sensitive to organ perfusion are used to guide the adequacy of resuscitation.

Measurement of arterial blood pressure may be accomplished using invasive or noninvasive methods. Although in healthy patients noninvasive measurements of blood pressure

correlate well with invasive measurements, invasive methods are preferred in patients with ARF. Noninvasive methods are unreliable in shock states, which are not uncommon in patients with ARF. Continuous monitoring of arterial blood pressure during resuscitation or titration of vasoactive agents minimizes the chance of missing a critically low or high recording between measurements. Furthermore, an indwelling arterial catheter is often required for monitoring arterial blood gases.

In contrast to MAP, the pulse pressure provides information about cardiac output that is useful in the assessment of shock. Pulse pressure is determined primarily by stroke volume and aortic compliance. Since the latter doesn't change beat-to-beat and is assumed to be normal in most patients (except the elderly), pulse pressure changes in proportion to stroke volume. Thus, in a patient with tachycardia, a normal or stable pulse pressure suggests normal or high cardiac output, while a reduced pulse pressure indicates a low cardiac output.

In animals subjected to graded hemorrhage, the magnitude of respiratory phase-related changes in systolic arterial pressure and pulse pressure correlate with the degree of hypovolemia. Numerous studies have corroborated these findings, establishing a potential role for use of systolic and pulse pressure variation in determining fluid responsiveness in critically ill patients. Indeed, in the hypovolemic patient, central veins collapse more easily following a positive pressure breath, and ventilator-induced changes in right atrial pressure are greatest when the right atrium is underfilled and most compliant. Furthermore, hypovolemia increases the likelihood that mechanical insufflation will collapse pulmonary capillaries, increasing pulmonary vascular resistance and decreasing left ventricular filling. Finally, when the left ventricle is underfilled and operating on the steep (linear) portion of its Starling curve, it is more sensitive to changes in right ventricular output. Hence, the greater the variation in systolic and pulse pressure during a single cycle of mechanical ventilation, the more underfilled the ventricles and the more likely the response to a fluid challenge ("preload responsiveness").

These principles may also be used to monitor the titration of positive end-expiratory pressure (PEEP) by assessing variation in systolic or pulse pressure as PEEP is applied. PEEP can reduce cardiac output, thereby limiting or negating any improvement in arterial oxygenation on oxygen delivery. When systolic or pulse pressure begins to vary with each mechanical breath, the level of PEEP has likely decreased cardiac preload, suggesting the need for a fluid challenge.

Respiratory variations in systolic and pulse pressure have been shown to accurately predict fluid responsiveness in critically ill patients with respiratory failure, with or without septic shock. Once validated, these findings may be more useful in predicting fluid responsiveness than other, more traditional, estimates of cardiac preload, including central venous pressure, pulmonary artery occlusion pressure, or left ventricular end-diastolic volume (LVEDV).

Laboratory Tests

Two laboratory tests deserve special mention for their potential role in hemodynamic monitoring: B-type natriuretic peptide (BNP) and lactic acid.

Serum levels of BNP (either B-type or N-terminal pro-B-type) correlate with the degree of cardiac dysfunction and have shown promise as a tool to diagnose, monitor, and predict outcome of patients with congestive heart failure (CHF) in outpatient and emergency department settings. Accordingly, interest has arisen in using BNP as a noninvasive test to monitor volume status in critically ill patients.

Unfortunately, in patients with ARF, BNP levels do not correlate with pulmonary artery occlusion pressure. BNP increases with right heart dysfunction, sepsis (with or without cardiac dysfunction), and ARF, reflecting low test specificity. Furthermore, hypotensive patients who are in a non–steady-state condition may present acutely with an elevated BNP, despite hypovolemia, because of preexisting cardiac disease. On the other hand, a *low* BNP level may be useful in ruling out cardiac dysfunction.

In assessing the net "result" of cardiac performance, namely, end-organ perfusion, an absolute value for cardiac output or index cannot be used to diagnose shock. In addition to the physical examination and assessment of selected parameters, including urine output and central or mixed venous oxygen saturation (see below), measurement of venous lactate levels represents a useful screening tool for determining the adequacy of global and regional hemodynamics.

Elevated lactate levels have also been shown to correlate with patient outcome in the ICU, although in individual patients, lactate clearance (change in level over time) is a more accurate predictor of outcome. With newer assays and sampling techniques (e.g., by finger stick) lactate levels are readily available.

In patients with ARF, lactic acidosis is most commonly caused by cellular hypoxia due to hypoperfusion or hypoxemia. Although cellular hypoxia may contribute to lactic acidosis associated with sepsis, particularly early in its course, endotoxin and other mediators may also cause lactate release due to cytopathic hypoxia via direct inhibition of the mitochondrial enzyme that metabolizes pyruvate. When a patient has an elevated lactate not explained by hypoxemia, global and regional hypoperfusion must be excluded immediately. If the physical examination and central or mixed venous oxygen saturations (see below) are normal (suggesting normal cardiac output), ischemic bowel or extremity compartment syndrome must be considered, as should "occult sepsis," certain drugs, or liver disease.

Central Venous Catheterization

Since most patients with ARF require a central venous catheter (CVC) for administration of medications, no additional rationale or risk-benefit considerations are required to justify insertion of the line. However, the type of catheter inserted determines the extent of monitoring permitted. All

CVCs, regardless of lumen diameter or length, can be used to transduce central venous pressure (CVP) and measure central venous blood oxygen saturation (Scv_{O_2}), a surrogate for true mixed venous oxygen saturation (Sc_{O_2}). However, in order to monitor Scv_{O_2} continuously, a special oximetric catheter (Pre-SEP, Edwards Scientific) is required.

The internal jugular (IJ) or subclavian vein (SV) is the preferred access site, since femoral lines are associated with increased rates of infection and deep venous thrombosis. The choice between SV and IJ sites is dependent on many factors, but, in general, the IJ is safer because the vein is compressible, amenable to ultrasound localization, and associated with a reduced rate of pneumothorax. However, the Centers for Disease Control and Prevention (CDC) recommends the SV site over the IJ because of a presumed lower risk of infection. Both sites are reasonable, and the decision is a function of specific patient issues and operator experience and preference.

Central Venous Pressure

CVP is the downstream pressure that governs the rate of venous return to the right heart; it represents a good approximation of mean right atrial (RA) pressure. CVP can be measured accurately through a variety of catheter types, including triple lumen, tunneled, and percutaneously placed varieties. Commonly employed CVP catheter sites include the IJ, subclavian, and femoral veins.

CVP has been used to assess volume status in the diagnosis and management of shock and to infer the etiology of pulmonary edema. However, numerous studies have demonstrated flaws in this approach. Although, in some cases, a very low (less than 5 mmHg) or a very high (greater than 20 mmHg) CVP may be helpful in guiding decisions about volume status, in most patients, a single CVP value is rarely helpful.

The central venous or RA pressure is the pressure within the RA relative to atmospheric pressure. However, right ventricular preload, which is best defined as right ventricular end-diastolic volume (RVEDV), is equally dependent on the extracardiac (i.e., intrathoracic) pressure and right ventricular compliance, neither of which can be determined reliably at the bedside. Applied or intrinsic PEEP and intra-abdominal hypertension, among other conditions, may also increase extracardiac pressure.

Even if CVP correlated with RVEDV, the latter correlates poorly with LVEDV in patients with ARF because of discordance in ventricular afterload and contractility. Indeed, lung disease and the PEEP used to treat it increase pulmonary vascular resistance and may produce right ventricular failure. Furthermore, since the pericardium limits ventricular dilatation, ventricular interdependence further increases the disparity in LVEDVs and RVEDVs when differential contractility or loading conditions are present. This occurs because ventricular dilatation displaces the septum laterally and compresses the adjacent ventricle. Use of CVP in lieu of measurement of pulmonary artery occlusion pressure (PAOP) in determining whether pulmonary edema is of cardiogenic or noncardiogenic origin is equally tenuous.

In contrast, measurement of dynamic changes in CVP and the diameters of the superior and inferior vena cavae in response to changes in intrathoracic pressure provides more clinically useful information about cardiac preload. The basis for these dynamic responses is similar to that discussed previously. Unfortunately, lack of standardization, rigorous validation of the techniques, or outcome studies preclude recommending routine clinical use.

Mixed Venous Oxygen Saturation

Normally, the circulation delivers oxygen to tissues at a rate sufficient to maintain an intracellular (mitochondrial) oxygen tension above a critical threshold. If oxygen delivery (D_{O_2}) fails to meet tissue oxygen requirements (V_{O_2}), shock exists and anaerobic metabolism ensues; if prolonged, cell death occurs.

If D_{O_2} decreases and tissue V_{O_2} remains constant, a reduction in the oxygen content in mixed venous blood (Sv_{O_2}) is observed, reflecting an increase in oxygen extraction which occurs as a result of increased diffusion. The reduced D_{O_2} causes mitochondrial and tissue P_{O_2} to fall, which, in turn, increases the gradient for oxygen diffusion from capillary blood to tissue. The result is a reduction in end-capillary and, hence, venous P_{O_2}.

Since blood flow to organs is not equally distributed, and since rates of oxygen utilization are heterogeneous among organs, the venous oxygen content of blood draining from organs varies. The mixed venous oxygen content measured in the pulmonary artery (Sv_{O_2}), which reflects "global" oxygen delivery, represents a weighted average of the product of blood flow and oxygen content from all organs. Thus, Sv_{O_2} is not sensitive to localized tissue ischemia (e.g., bowel ischemia)—an important limitation of this monitoring tool.

Based on an understanding of the determinants of Sv_{O_2}, the clinician can use the Fick equation (Eq. 1, below) to elucidate the mechanism of shock and, perhaps, to target therapy:

$$V_{O_2} = CO \times (\text{arterial } O_2 \text{ content} - \text{venous } O_2 \text{ content}) \quad (1)$$

where CO is cardiac output. Recalling that O_2 content of either arterial or venous blood is the sum of hemoglobin (Hgb)-bound oxygen (1.34 ml O_2/g Hgb × [Hgb]/100 ml blood × % hemoglobin saturation) and dissolved oxygen (0.003 ml O_2/mm Hg), the following expression (Eq. 2) for mixed venous O_2 is derived:

$$Sv_{O_2} \sim (\text{arterial } O_2 \text{ content} \times [\text{Hgb}] \times CO)/V_{O_2} \quad (2)$$

Thus, if Sa_{O_2} is stable, Sv_{O_2} decreases if either CO or [Hgb] decreases or V_{O_2} increases. Since Sa_{O_2} and [Hgb] are readily measured and changes in V_{O_2} can be grossly estimated, the cause of a decrease in Sv_{O_2} can usually be determined quickly. Compared with alternative methods of monitoring CO, Sv_{O_2} reflects the adequacy of CO relative to oxygen requirements, which is a more valuable measurement than is

the absolute CO. In this regard, Sv_{O_2} is also more sensitive than measurement of blood lactate (see below) as a measure of the adequacy of CO.

Goal-Directed Therapy

Recent studies indicate that when a central venous oxygen saturation (Scv_{O_2}) of greater than or equal to 70 percent is achieved early in the resuscitation of patients with severe sepsis, survival increases significantly. Indeed, achievement of this target as part of "goal-directed therapy" has been embraced by the critical care community, and a consensus guideline for treatment of sepsis has been published. The guideline, developed by experts from 11 multidisciplinary, international critical care societies, recommends routine monitoring of central venous oxygen saturation to guide initial resuscitation of patients with severe sepsis.

Pulmonary Artery Catheterization

The pulmonary artery catheter (PAC) was first introduced into clinical practice in 1970. Since that time, the PAC has been the most commonly used device for monitoring hemodynamics in critically ill patients. It is also the most controversial. The PAC represents a reference standard for testing the accuracy and precision of noninvasive methods of assessing volume status and hemodynamic parameters. Indeed, the breadth of directly measured and derived parameters obtained using a PAC is unparalleled. However, more recently, use of the catheter has been curtailed because of data suggesting increased complications with its use and no evidence of any benefit to patient outcome.

Pulmonary Artery Occlusion Pressure

The PAC is used to estimate right and left ventricular filling pressures, PAOP or "wedge" pressure, and cardiac output.

When the balloon of the catheter, "wedged" into a branch of the pulmonary artery, is inflated, a static column of blood is created downstream from the catheter tip, which extends to the point of confluence with other, unoccluded pulmonary veins. Without blood flow, a pressure drop across the static column of blood is absent, making the column a direct extension of the fluid column between the tip of the PAC and the pressure transducer. In the absence of disease in the pulmonary veins, left atrium, or mitral valve, the mean end-expiratory PAOP approximates left ventricular end-diastolic pressure (LVEDP). If "a" and "v" waves are visible in the transduced pressure recording, the mean value of the "a" wave (halfway between the top of the "a" wave and the bottom of x descent) is used to indicate the PAOP.

PAOP is also used to estimate pulmonary capillary pressure in determining whether pulmonary edema is due to increased capillary permeability or hydrostatic pressure. In contrast to measuring PAOP as an estimate of LVEDP, the mean of the end-expiratory tracing is always used, even when large "v" waves are present, since the systolic pressure spike ('v" wave) is transmitted with an equal contribution to the capillary hydrostatic pressure. If PAOP never exceeds 18 mmHg, hydrostatic pulmonary edema can be excluded; however, transient spikes in left atrial pressure occurring between normal PAOP measurements can be missed. A PAOP greater than 18 mmHg is consistent with a hydrostatic cause of pulmonary edema, but high-permeability edema cannot be excluded.

Cardiac Output

Cardiac output (CO) is measured routinely in the ICU using the thermodilution (TD) technique. The principle of TD is that by lowering the temperature of blood flowing through the right heart by injecting a bolus of saline at room temperature, the resultant change in blood temperature over time, as recorded by a thermistor at the distal port of the PAC (i.e., the area under the curve of a plot of temperature versus time), will provide an approximation of CO.

With TD, CO can be measured intermittently using manual methods, or continuously using automated techniques. The manual method is based on the average value determined from 4 to 6 successive 10-ml boluses of saline injected into the proximal right atrial port of the PAC. For continuous measurements a specialized catheter with a proximal thermal filament, which heats the blood repeatedly using a brief thermal pulse, is used. Although limitations of TD methods are recognized—most notably, errors in measurement in the setting of tricuspid regurgitation—the technique provides a reasonably accurate measurement of CO. Measurement of CO using TD and a PAC is considered the gold standard to which other CO technologies are compared.

CO can also be measured indirectly with the PAC using the Fick method, based on the fact that CO is equal to oxygen consumption (V_{O_2}) divided by the difference in O_2 content across the circulation (i.e., the arteriovenous O_2 difference). Since V_{O_2} is usually not measured directly, the method is limited by inaccuracies in estimating V_{O_2} using body surface area alone in a critically ill patient. Hence, in patients with ARF, CO should be measured using TD unless significant tricuspid regurgitation is present. Application of the Fick method may be reasonable when values obtained by TD are unexpected.

Oxygen consumption varies significantly over time in any given patient and among patients with ARF. Furthermore, since CO normally increases directly in proportion to V_{O_2} and inversely with hemoglobin concentration and O_2 saturation, no normal or range of normal for CO has been established in patients with ARF. Normalizing CO to body surface area for comparison with reference values is also tenuous. From a management perspective, the most important questions in these patients are whether CO is adequate for the patient's needs, whether CO can be improved with intravenous fluids, and whether fluid can be removed by diuresis or dialysis without significant compromise of CO.

Outcome Studies

In the mid-1990s, a study addressing the effectiveness of the PAC purported to show that use of the PAC increased

mortality. The report stimulated a great deal of concern about the safety and use of the PAC and promoted significant efforts at improving education about use of the catheter. Use of the PAC fell dramatically following publication of the study.

Subsequently, several randomized controlled trials were conducted to assess the value of the PAC in a variety of critically ill patients. The findings can be summarized as follows: use of the PAC does not alter patient outcome in patients undergoing high-risk surgery, those with septic shock, acute respiratory distress syndrome (ARDS) or CHF, or in patients deemed critically ill enough to require the PAC.

Cautions in Using Pulmonary Artery Catheters

Based on the outcome studies summarized previously, one can legitimately question whether the PAC should be used at all in patients with ARF. Proponents of PAC use cite several observations as the basis for their argument. The studies only evaluated whether use of the PAC improved overall outcome. None included explicit, standardized treatment protocols to direct patient management using the catheter. In addition, no systematic effort was made to minimize errors in measurement and interpretation of data, particularly errors due to respiratory variation (see below). In all but one of the studies inclusion criteria were based on disease or condition, rather than a specific clinical question, thus making it difficult to rule out a potential benefit with more selective application of the catheter.

Given all of the information provided by use of the PAC, why have studies failed to show improved patient outcomes? Several hypotheses have been proposed, including an adverse physical effect of the PAC, inaccurate data, and misinterpretation of data, promoting misguided therapeutic interventions. Although physical complications from use of the PAC are well recognized, most are related to insertion of the central venous catheter through which the PAC is inserted. The few physical complications attributable to PAC, itself, are rare. In contrast, studies do support the notion that inaccuracies in pressure measurements or misinterpretation of data may lead to misguided treatment decisions and adverse outcomes.

Studies using standardized tests demonstrate that clinicians from a variety of countries, disciplines, and levels of experience have inadequate knowledge about the PAC and difficulty reading pressure measurements accurately. In one study, the difficulty in reading tracings was due primarily to misidentification of end-expiration; interobserver variability in PAOP measurements was greatest when recordings showed marked phasic respiratory variation.

Traditionally, clinicians have been taught to record all vascular pressures at end-expiration in order to minimize the effect of intrathoracic (i.e., juxtacardiac) pressure. Unfortunately, widely available resources for PAC education have misleading instructions on identification of end-expiration; in particular, these resources suggest that end-expiration in patients on mechanical ventilation is defined by the lowest point on the vascular pressure waveform. However, it is well known that patients may actively inspire during assist-control

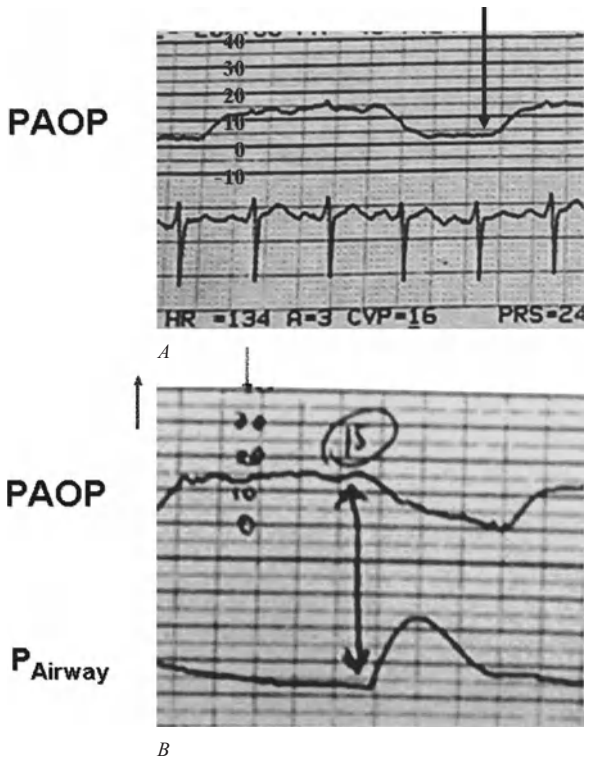

Figure 152-1 *A*. In this patient on mechanical ventilation in the AC-mode, pulmonary artery occlusion pressure (PAOP) is read conventionally at the lowest vascular pressure (arrow), which is 3 mmHg. *B*. With airway pressure (P_{AW}) displayed concurrently, in place of the electrocardiogram tracing, it becomes obvious that vascular pressure falls throughout inspiration due to inspiratory effort. The true end-expiratory time point is shown by the arrow, which is a PAOP of 15 mmHg.

mechanical ventilation, causing intrathoracic (and, hence, vascular) pressure to fall, rather than rise. Consequently, in such patients the lowest point on the vascular pressure waveform corresponds to end-inspiration, while end-expiration coincides with the highest point on the tracing (Fig. 152-1 *A*). Erroneous selection of the nadir pressure results in vascular pressure readings (including CVP and PAOP) that may markedly underestimate the true values; the magnitude of the error is proportional to patient inspiratory effort. The significance of this potential error has likely increased in the last 5 years because of a trend toward use of minimal sedation and reduced tidal volumes in patients with ARF, each of which may increase respiratory effort and further lower pleural pressure during inspiration.

Attempts to visually quantify and coordinate patient ventilatory efforts with the waveform displayed on a bedside monitor can be problematic, especially with higher respiratory frequencies observed in patients ventilated with lower tidal volumes. Addition of a simultaneous airway pressure (P_{AW}) signal to strip chart recordings of CVP and PAOP may provide a reliable signal for accurately timing end-expiration and significantly reduce interobserver variability (Fig. 152-1 *B*). Intensivists who use the PAC should consider concurrent

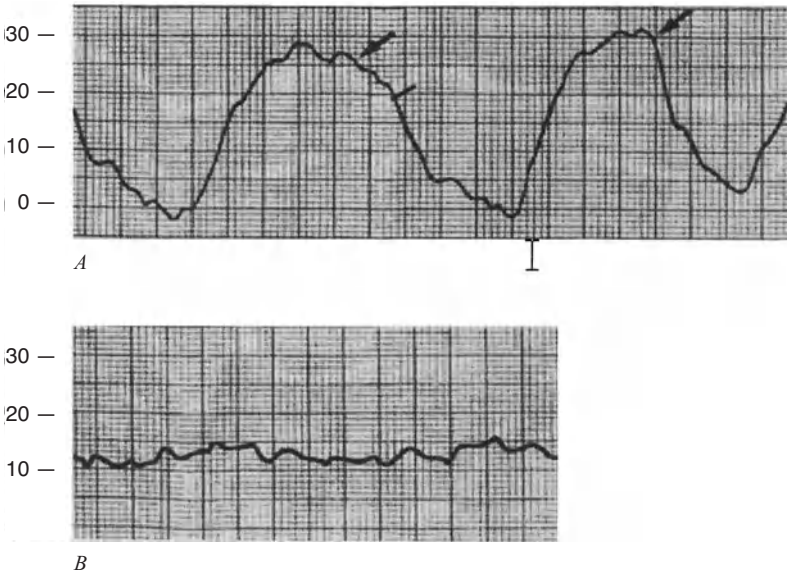

Figure 152-2 *A*. In this patient on mechanical ventilation in AC-mode, an airway pressure (P_{AW}) tracing (not shown) confirms that end-expiratory pulmonary artery occlusion pressure (PAOP) is 25 mmHg (arrows) with respiratory variation of greater than 20 mmHg. *B*. Immediately after paralysis with succinylcholine repeat PAOP is 12 mmHg with minimal respiratory variation.

monitor display of P_{AW} and vascular pressures when recordings show significant (greater than 8 mmHg) respiratory variation in CVP or PAOP.

Patients with significant phasic respiratory variation may also *exhale* forcefully, and significant errors in interpretation of hemodynamic data may occur despite measurement of P_{AW}. Expiratory muscle use during exhalation increases abdominal pressure, which is transmitted directly across the relaxed diaphragm, resulting in increased end-expiratory pleural pressure. This, in turn, increases all vascular pressures in the thorax. Since transmural filling pressures of the right and left ventricles are unchanged, if unrecognized, forced expiration causes CVP and PAOP to be overestimated by an amount directly proportional to expiratory muscle effort (Fig. 152-2).

The significance of forced expiration raises two important questions:

1. How does one account for the effect of forced expiration when interpreting CVP or PAOP?
2. How does one recognize when forced expiration is present?

With regard to the first question, studies performed in patients with significant respiratory variation in PAOP demonstrated that the PAOP before and after muscular paralysis was similar to the PAOP measured as the midpoint between values recorded at end-expiration (peak) and end-inspiration (nadir) prior to paralysis—a value more closely approximated by the mean PAOP (Figs. 152-2 and 152-3).

Recognition of forced expiration is necessary to determine when to apply this "midpoint" rule in the measurement of PAOP. In the absence of significant (greater than 8 mmHg) respiratory variation in PAOP, one can rule out forced expiration. Abdominal inspection and palpation usually confirm forced expiration if inward movement of the lateral and anterior abdominal walls occurs during expiration. Of note, if significant respiratory variation occurs in the absence of forced expiration (from isolated inspiratory muscle effort alone), the pressures read at end-expiration are accurate. If it is not clear from the physical examination whether forced expiration is present, simultaneous measurement of CVP or PAOP and intra-abdominal pressure can be performed. Forced expiration is easily identified if PAOP and intra-abdominal pressure increase concordantly during expiration (Fig. 152-4), and is ruled out if the phasic changes in the two pressure recordings are discordant.

Additional factors may result in misinterpretation of PAOP as an estimate of left ventricular preload. For example, PAOP may correlate poorly with LVEDV because of alterations in juxtacardiac pressure (e.g., from increases from set or occult PEEP or intra-abdominal hypertension) or ventricular compliance (e.g., due to ischemia or hypoxia). Finally,

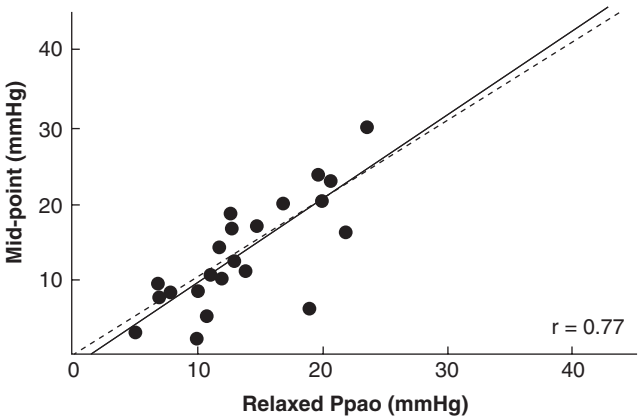

Figure 152-3 Relationship between the relaxed pulmonary artery occlusion pressure (PAOP) (post-paralysis) and the midpoint PAOP (obtained during active respiratory effort). (*From Hoyt JD, Leatherman JW: Interpretation of the pulmonary artery occlusion pressure in mechanically ventilated patients with large respiratory excursions in intrathoracic pressure.* Intensive Care Med *23:1125, 1997.) (Reproduced with permission.)*

Figure 152-4 Arrows indicate end-exhalation. *A*. In this strip chart recording from a patient on AC-mechanical ventilation, there is minimal respiratory variation in pulmonary artery occlusion pressure (PAOP). Note, intra-abdominal blood pressure (IABP) rises during inhalation and falls during exhalation, paralleling the change in PAOP. *B*. On the same ventilator settings with less sedation, there is marked respiratory variation (~30 mmHg) in PAOP. PAOP falls during inspiration consistent with active respiratory effort. Forced exhalation is confirmed by seeing a rise in IABP during exhalation (~20 mmHg), in parallel with the PAOP. If IABP falls during exhalation in this setting, forced exhalation can be ruled out (not shown).

because of pericardial constraint of ventricular enlargement, right ventricular overload may cause PAOP and LVEDV to change reciprocally (increases in PAOP associated with decreases in LVEDV).

Given the limitations of using pressure measurements to estimate cardiac preload (end-diastolic volume), a modified PAC was developed to allow continuous measurements of RVEDV using TD. The catheter contains a proximally located thermal filament which emits thermal pulses to heat the blood, while a sensitive and rapidly responsive thermistor located at the distal end of the catheter records temperature in the pulmonary artery. Input from the electrocardiogram allows timing of ventricular systole and a beat-to-beat analysis of the temperature decay curve. Right ventricular ejection fraction is computed from the exponential slope of the temperature decay curve and mean heart rate; RVEDV is calculated as stroke volume divided by ejection fraction. Studies have shown that RVEDV correlates well with CO, and specified thresholds of RVEDV may distinguish patients with hypovolemia who are fluid-responsive. However, other studies have not corroborated these thresholds and have failed to show that RVEDV can reliably predict preload responsiveness. Thus, routine use of these catheters cannot be recommended.

Even if the problems with measuring, recording, and interpreting PAOP and CO could be eliminated, PAC-guided care will likely be limited by lack of standardized guidelines for treatment based on the hemodynamic data obtained.

Noninvasive Alternatives to the Pulmonary Artery Catheter

A variety of noninvasive techniques, including echocardiography, have been used as alternatives to PACs. They are described briefly below.

Echocardiography

Echocardiography is the most commonly used technique for cardiac imaging in critically ill patients, providing unique and important diagnostic information for the evaluation of shock, including assessment of biventricular volumes, contractility, valvular function, and pericardial anatomy.

In patients who are adequately resuscitated, but who continue to have low output shock, early use of echocardiography to assess biventricular volumes and function is important. In the setting of an elevated PAOP and low CO, systolic dysfunction cannot be differentiated from any of the many states of ventricular compression, including cardiac

tamponade, massive pleural effusion, mediastinal fluid collections, auto-PEEP, pneumothorax, or ventricular interdependence. When right ventricular dysfunction is suspected as the primary cause of shock, echocardiographic findings may assist in establishing the etiology.

The presence of pulmonary arterial hypertension, which can be estimated in most critically ill patients, suggests pulmonary embolism, nonthrombotic pulmonary embolism, ARDS, or severe lung hyperinflation; right ventricular infarction is unlikely. Furthermore, in the setting of pulmonary hypertension, the echocardiogram may point to an acute process (e.g., pulmonary emboli, rather than chronic pulmonary hypertension), if regional akinesia of the right ventricular free wall and normal apical wall motion is found ("McConnell sign"). The diagnosis of acute pulmonary embolism is highly likely if a free floating clot is seen in the right atrium or ventricle, and the diagnosis is confirmed if a clot is visualized in the proximal pulmonary arteries.

Both volumetric and Doppler-based techniques have been developed to allow echocardiographic estimates of cardiac preload and CO. Volumetric measurements using two-dimensional imaging of ventricular size during diastole and systole provide the basis for estimates of preload, stroke volume, and contractility. Signs of hypovolemia on the two-dimensional echocardiogram include a hyperdynamic ventricle and appearance of "kissing walls" at end-systole. CO can be determined using volumetric estimates of stroke volume, calculated as the difference in end-systolic and end-diastolic volumes. However, Doppler-based measurements of CO are more accurate.

The Doppler method relies on the principle that flow in a cylinder (e.g., the aorta) is equal to cross-sectional area of the aorta times the blood-flow velocity. Velocity, in turn, is determined according to the principle that when ultrasonic waves are emitted perpendicular to flowing blood, the change in frequency of the sound waves reflected back is proportional to the blood-flow velocity. Stroke volume is derived from these two measurements; when multiplied by heart rate, CO is determined. Doppler-based estimates of CO have been shown to correlate reasonably well with those obtained by TD.

Doppler techniques can also be used to estimate PAOP by assessing the relative velocity of blood flow through the mitral valve during early and late diastole. However, estimates of PAOP using this technique do not correlate well with direct measurements using a PAC. In any event, given the limitations of PAOP as a measure of preload, there is little utility in estimating PAOP using this technique, except to provide a rough estimate about whether or not pulmonary edema is on a cardiogenic basis.

Echocardiography is performed at the bedside using either the transthoracic esophageal (TTE) or transesophageal (TEE) routes. Since rapidity of diagnosis is important, TTE is the initial study of choice in the ICU, given the technique's widespread availability. TTE provides adequate assessment in the vast majority of mechanically ventilated patients; morbid obesity and emphysema may necessitate TEE. TEE is also recommended as the initial study to rule out aortic dissection. Although considered a very low-risk procedure, TEE is not risk free. TTE is associated with trauma to the upper gastrointestinal tract and is contraindicated in patients with known or suspected pathology of the esophagus or cervical spine.

One of the major limitations of both TTE and TEE is that neither allows for continuous hemodynamic monitoring. To fill this need, an esophageal catheter with a distal Doppler probe that allows measurement of CO continuously has been developed. The device is easy to use and eliminates the need for a specialist in Doppler signal acquisition, although some operator experience is required to ensure proficiency. Numerous studies have evaluated the accuracy of these devices relative to TD-based assessment of CO. A recent review concluded that esophageal Doppler does not provide accurate assessment of absolute CO, but its validity is high for monitoring changes in CO in critically ill patients.

Finally, imaging dynamic changes in the diameter of the central veins and assessment of the velocity of aortic blood flow may predict preload responsiveness. Using portable echocardiography in completely sedated patients in septic shock respiratory collapse of the inferior or superior vena cavae in response to a large (8 to 10 ml/kg) mechanically delivered breath suggests hypovolemia and potential fluid responsiveness.

In conclusion, bedside echocardiography is the diagnostic study of choice for unexplained or persistent circulatory shock. For patients who require continuous monitoring of CO, esophageal Doppler is a reasonable alternative to a PAC. The technique can be used to guide fluid resuscitation for optimization of CO in acute shock and guide a diuresis strategy to minimize pulmonary edema without adversely affecting peripheral perfusion. Although esophageal Doppler monitoring has been increasingly used as a substitute for a PAC, we still favor use of the PAC over esophageal Doppler for monitoring hemodynamics continuously in selected patients.

Other Methods

Several other noninvasive methods have been developed for determining CO, including expired carbon dioxide (CO_2) analysis (indirect Fick method), lithium dilution method, measurement of thoracic impedance, and pulse contour analysis. The techniques are approved by the Food & Drug Administration (FDA) and are currently available, but none have been validated sufficiently to justify their routine use in critically ill patients.

Indirect Fick Method

By imposing a brief period of partial rebreathing through the addition of dead space to the breathing circuit, changes in CO_2 elimination and end-tidal CO_2 concentration can be effected. Comparison of the new resultant steady-state values compared to baseline allows calculation of CO using the Fick principle. The technique has serious limitations in patients

with ARF. Spontaneous breathing and hypocapnea limit its accuracy. Steady-state conditions must be achieved to assure accuracy, and intrapulmonary shunt affects the sensitivity of the measurement.

Thoracic Electrical Bioimpedance

Thoracic electrical bioimpedance is based on the principle that the chest is an electrical conductor whose impedance is altered by changes in blood volume and blood-flow velocity with each heartbeat. By placing electrical current-transmitting and voltage-sensing electrodes on the chest, stroke volume may be calculated based on an equation incorporating values for the baseline and maximum rate of change in chest impedance. Unfortunately, although noninvasive, measurement of thoracic electrical bioimpedance is confounded by too many factors in patients with ARF to support its routine clinical use.

Transpulmonary Indicator Dilution Techniques: Thermodilution and Lithium Dilution

Transpulmonary indicator dilution techniques are based on intravenous injection of an indicator solution (e.g., cold saline or lithium chloride) and measurement of the change in temperature or lithium concentration, respectively, over time using a special arterial catheter. For the TD technique, the catheter is equipped with a thermistor at its tip; for the lithium-based technique, blood samples must be drawn successively for external measurement using a lithium-sensitive electrode. The greater the degree of indicator dilution (i.e., the *less* the change in temperature or lithium concentration) over time, the greater the CO. Values derived from each of these techniques correlate well with PAC-determined values. However, more data are needed to determine the accuracy of these techniques under a wide variety of clinical conditions.

Pulse Contour Analysis

This method is based on the concept that changes in the contour of the arterial pressure waveform are proportional to stroke volume and are dependent on the mechanical properties of the aorta. Since the latter is relatively constant from beat to beat, changes in the pulse pressure correlate with changes in stroke volume. The technique requires calibration with an independent measurement of CO—currently accomplished by combining the indicator dilution technique (to determine mean CO) with assessment of beat-to-beat variability in the arterial pressure waveform (as a measure of stroke volume). Most studies have shown fair to good agreement of the technique with that of PAC-based measurements. Major limitations include the requirements for a femoral or axillary arterial catheter and frequent recalibration in patients who are hemodynamically unstable. Although the technique is promising, more studies are required to validate its usefulness and applicability in critically ill patients with ARF.

METHODS FOR MONITORING RESPIRATORY FUNCTION

A number of respiratory parameters are routinely monitored in patients with ARF and are discussed briefly below.

Oxygenation

In the ICU, oxygenation is generally monitored using pulse oximetry, arterial blood gas analysis, or transcutaneous methods.

Pulse Oximetry

Pulse oximeters are universally deployed in the monitoring of perioperative and critically ill patients. Unique as monitoring devices, they provide useful data regarding oxyhemoglobin saturation (Sp_{O_2}), heart rate, pulse volume, and tissue perfusion.

Pulse oximeters use the spectrophotometric characteristics of pulsatile arterial blood to determine oxygen saturation and heart rate. Oxygenated blood absorbs light at 660 nm (red light), while deoxygenated blood absorbs light preferentially at 940 nm (infrared light). The oximeter consists of two light-emitting diodes (wavelengths, 600 nm and 940 nm) and two light-collecting sensors that measure the amount of red and infrared light emerging from tissues traversed by the light rays. The relative light absorption by oxyhemoglobin and deoxyhemoglobin is analyzed by the device and an oxygen saturation is calculated. The sensing function of the device is directed at pulsatile arterial blood, while local "noise" arising from the tissues is ignored. The result is a continuous qualitative measurement of oxyhemoglobin saturation.

Use of pulse oximetry has not been shown to improve clinical outcomes, but epidemiological data have demonstrated a significant reduction in anesthesia-related morbidity. Although the technique accurately predicts arterial oxygen tension, the relationship between Pa_{O_2} and Sp_{O_2} is nonlinear, as dictated by the oxyhemoglobin dissociation curve. Accuracy falls off substantially at low-oxygen tensions, and saturation readings of less than 80 percent cannot be used reliably to guide oxygen therapy.

The use of pulse oximeters is limited by a number of factors. The devices are designed to measure levels of oxygenated and deoxygenated hemoglobin, but no provision is made for measurement error in the presence of dyshemoglobinemias, including carboxyhemoglobinemia and methemoglobinemia. Since carboxyhemoglobin absorbs red light, conventional oximeters cannot distinguish oxy- from carboxyhemoglobin. In clinical situations where carbon monoxide poisoning is suspected, co-oximetry is essential. Co-oximeters measure reduced hemoglobin, oxyhemoglobin, carboxyhemoglobin, and methemoglobin.

An additional source of error in using oximeters is abnormal patient movement (e.g., due to agitation). Low blood flow, hypotension, vasoconstriction, or hypothermia reduce pulsatility of capillary blood, resulting in underreading or

no reading of oxygen saturation. Conversely, increased venous pulsation, such as occurs with tricuspid regurgitation, may result in an erroneously low reading by the device. Finally, oximetry-determined saturation is inaccurate on the steep part of the oxyhemoglobin dissociation curve. While the *trend* between directly measured arterial saturation and Sp_{O_2} appears accurate, the correlation between the two is not; a drop in Sp_{O_2} below 90 percent must be considered a potentially significant clinical event.

Arterial Blood Gases

Blood gas analyzers have been available for 40 years and provide accurate measurement of Pa_{O_2}, Pa_{CO_2}, and pH. From these primary determinations, a number of parameters are calculated, including serum bicarbonate, base deficit or base excess, and oxyhemoglobin saturation.

Through application of the alveolar gas equation (see Chapters 11 and 34) arterial blood gas analysis is used commonly in calculating the alveolar-arterial oxygen gradient, a number that reflects the severity of ventilation-perfusion abnormalities. A significant limitation of the alveolar-arterial oxygen gradient is that it varies directly with FI_{O_2}; consequently, changes in the value may not reflect changes in the underlying disease process. An alternative calculation—the ratio of Pa_{O_2} to FI_{O_2}, ("PF ratio"), which does not vary with FI_{O_2}—has been used as a measure permitting comparisons of gas exchange at differing levels of FI_{O_2}.

The PF ratio has been incorporated into consensus definitions of ARDS and acute lung injury (ALI). A PF ratio less than or equal to 300 defines ALI; a ratio less than or equal to 200 defines ARDS. Neither the alveolar-arterial oxygen gradient nor the PF ratio takes into account differences in mean airway pressure. Although comparisons using the PF ratio would be more accurate if arterial blood was sampled uniformly at end-expiration and in the absence of PEEP, clinical constraints may preclude such sampling conditions.

Transcutaneous Oxygen Monitoring

The commonly employed oxygen electrode is based on a modification of the electrode developed in 1956. The device is constructed of a platinum wire tip surrounded by glass. Covered by a polyurethane membrane which is permeable to oxygen, the electrode responds in a linear fashion to oxygen in the gaseous or liquid phase over a concentration range of 1 to 100 percent. The margin of error is less than 1 percent.

Although the oxygen electrode has been employed predominantly for blood gas measurements, it can be modified for use in the continuous, noninvasive measurement of transcutaneous oxygen tension (Ptc_{O_2}). Electrode heating of the skin changes the structure of lipoproteins in the stratum corneum from the gel to the sol state, allowing rapid diffusion of oxygen from subcutaneous tissues through the skin. In addition, electrode heating prevents local vasoconstriction, ensuring that Ptc_{O_2} closely reflects Pa_{O_2}. In hemodynamically stable patients who have good tissue perfusion, Ptc_{O_2} accurately represents P_{O_2}; however, the values are not identical, with Ptc_{O_2} approximately equal to 80 percent of Pa_{O_2}. Under conditions of hypoperfusion, the relationship may vary dramatically. In addition, various tissues have different values for Ptc_{O_2}, depending on local perfusion, skin thickness, and anatomic location (e.g., trunk versus limb). In order to prevent burns, the electrodes must be changed every 4 to 6 h, and the membrane must be changed and calibrated before each use. Despite these limitations and lack of widespread use, transcutaneous oxygen monitoring remains a useful device in multicomponent oxygen monitoring systems.

Ventilation

Clinical assessment of CO_2 metabolism is usually considered with regard to the amount of gas that is dissolved in plasma (Pa_{CO_2}), the amount present in the exhaled tidal volume (end-tidal CO_2), and the total extracellular content (total CO_2 or bicarbonate concentration). In the setting of respiratory failure, these measurements provide information on adequacy of ventilation, percentage of physiological dead space, acid-base balance, and nutritional status.

In progressive chronic respiratory failure, as the ability to eliminate CO_2 declines, total body CO_2 stores (bicarbonate) increase. The ratio of total CO_2 to bicarbonate concentration provides an indication of the acuity of the respiratory failure. Changes in Pa_{CO_2} may also be related to changes in base deficit or excess.

Assessment of CO_2 elimination forms the basis of calculating the ratio of dead space to tidal volume—a useful physiological construct in gauging the severity of underlying lung disease in respiratory failure. Through application of the modified Bohr equation (see Chapter 34), the ratio of dead space to tidal volume (V_D/V_T) is calculated in Eq. (3) as follows:

$$V_D/V_T = (Pa_{CO_2} - PE_{CO_2})/Pa_{CO_2} \qquad (3)$$

where PE_{CO_2} is mean expired CO_2. PE_{CO_2} can be measured using a metabolic monitor that collects expired gas over 5 min. Alternatively, main stream or side stream capnometry can be used to measure PE_{CO_2}.

In the normal lung, alveolar P_{CO_2} is equivalent to Pa_{CO_2} and can be estimated by sampling expired end-tidal gas. However, in the presence of significant physiological dead space (as in ARF), end-tidal CO_2 grossly underestimates Pa_{CO_2}. Given this limitation, aside from confirming endotracheal tube placement, end-tidal CO_2 measurements are not used routinely in managing patients with ARF.

Endotracheal Tube Placement

Monitoring endotracheal tube (ETT) position is an important aspect of critical care. An extremely common complication of intubation is misplacement of the ETT, with passage into the right main bronchus. Ideally, the ETT tip should be located 4 to 5 cm above the carina. In the case of a tracheotomy,

the tube tip should be located about halfway between the tracheotomy stoma and the carina.

ETT placement can be confirmed in several ways: (1) by assessing for the presence of bilateral breath sounds during breath delivery, (2) by palpation of the ETT cuff in the jugular notch, (3) with chest radiography, or (4) using fiberoptic bronchoscopy.

In addition to tube placement, pressure within the ETT cuff should be measured regularly. The cuff is inflated to create a seal between the side wall of the ETT and the tracheal wall. Since capillary perfusion pressure of the tracheal mucosa is approximately 25 cm H_2O, cuff pressure should be kept below this level to prevent ischemia, which may lead to ulceration, inflammation, and, if severe, tracheal dilatation. In addition, the injured tracheal segment may develop fibrosis and, ultimately, stenosis. On the other hand, evidence exists that low cuff pressures may increase the risk of pneumonia, presumably by promoting microaspiration. Thus, the current recommendation for optimal tracheal cuff pressure is 20 to 25 cm H_2O.

Following intubation and ETT positioning, the tube cuff should be slowly and progressively inflated just to the point of loss of gas leak occurring with ventilation—the so-called "minimal occluding pressure" technique (some experts advocate use of the "minimal leak" technique). To measure cuff pressure, an aneroid manometer is connected to the cuff's pilot tube (the tube from which the balloon is inflated). If excessive cuff pressure is required to maintain an adequate tracheal seal, the ETT is likely too narrow for the patient's trachea. If cuff pressure increases over time, tracheomalacia should be suspected and the tube changed to one with a foam cuff.

The presence of a cuff leak may be problematic, particularly in patients who are critically ill. Signs of leak include an audible noise during inspiration, audible patient phonation, frothy mouth secretions with each breath, a difference between set and exhaled tidal volumes, inadequate ventilatory volumes, hypoxemia, and the presence of a thrill over the trachea. Cuff leaks may be caused by rupture or herniation of the cuff, proximal displacement of the ETT, pilot tube valve malfunction, or inadvertent cuff deflation.

Respiratory System Mechanics

Assessment of respiratory system mechanics may be useful in differentiating the etiology of ARF (e.g., restrictive versus obstructive disease or upper versus lower airway obstruction), troubleshooting the cause of new episodes of clinical instability, assessing the effectiveness of therapeutic interventions (e.g., use of bronchodilators or application of PEEP), or minimizing the risk of ventilator-induced lung injury.

Airway Pressure

Airway pressure is an important variable which is routinely monitored during mechanical ventilation. Respiratory pressures are usually referenced to atmospheric pressure ("single-ended" pressures). Electromechanical transducers (or aneroid manometers), which convert pressure to electrical current, may be located in the patient's ventilator circuit or esophagus. The most common site of pressure transduction is the wye connector (the connector that joins the inspiratory and expiratory limbs of the ventilator circuit), although the distal ETT can also be used. Pressure measured within the ventilator or ventilator circuit is referred to as "airway pressure," P_{AW} (or, more correctly, airway opening pressure, P_{AO}), while that measured at the tip of the ETT is referred to as "tracheal pressure," P_{TR}. Pressure measured within the esophagus is referred to as "esophageal pressure," P_{ES}.

Five different pressure measurements are commonly made during the respiratory cycle: (1) peak airway pressure (P_{PEAK}), (2) plateau pressure (P_{PLAT}), (3) mean airway pressure (P_{MEAN}), (4) positive end-expiratory pressure (PEEP), and (5) auto-PEEP (also called intrinsic PEEP). Measurement of tracheal pressure at the tip of the distal ETT provides an assessment of pressure in the native airway, as the effect of flow through the ETT is eliminated. Esophageal pressure provides an estimate of pleural pressure. Although not used routinely in clinical practice, esophageal pressure can be used to estimate transpulmonary pressure, which is a more accurate measure of alveolar distending pressure than is plateau pressure.

Accurate measurement of airway resistance requires that airway pressures be determined using constant flow conditions (i.e., a square flow-wave profile) (Fig. 152-5). Most modern ventilators make the flow-wave profile adjustment automatically when the "mechanics function" of the device is selected. In addition, since airway pressures are altered by respiratory muscle contraction, patients must be fully relaxed and exert minimal breathing effort. These conditions may be accomplished by using ventilator settings designed to fully support the patient (e.g., by providing a level of ventilatory support that exceeds patient demand, or administration of sedation). For quality control, ventilator waveforms should

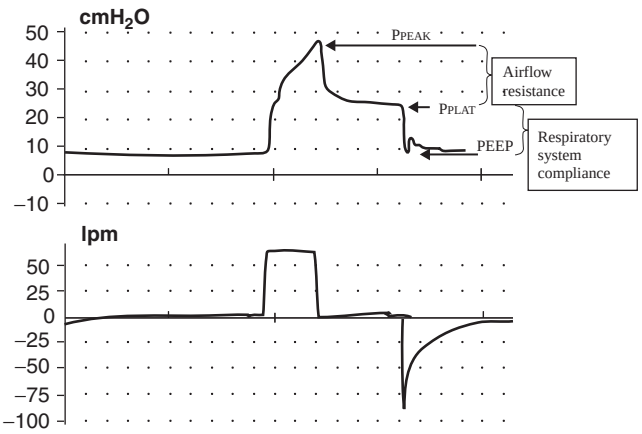

Figure 152-5 Inspiratory hold maneuver during constant flow in a volume-controlled breath. Note the significant difference between the patient's peak airway pressure (48 cm H_2O) and plateau pressure (26 cm H_2O), indicative of increased airways resistance.

be assessed during the mechanics maneuver to ensure the conditions have been met.

P_{PEAK} represents the total pressure the ventilator must generate in order to overcome the impedance of the respiratory system, including airflow resistance, elastic load (lung and chest wall distention), and any threshold load due to dynamic hyperinflation (from auto-PEEP). When interpreting P_{PEAK}, in addition to impedance, several other factors must be considered, including peak flow rate, waveform profile (square or decelerating), and tidal volume. This is a very important point in clinical practice, since P_{PEAK} may erroneously be considered as the primary determinant of barotrauma. When a high P_{PEAK} is observed (as commonly seen in obstructive lung diseases), an attempt to lower P_{PEAK} by reducing inspiratory flow rate may achieve the opposite effect. The risk of barotrauma may be increased by the resulting increment in plateau pressure that occurs as a consequence of reduced expiratory time and increased auto-PEEP.

P_{PLAT} reflects the pressure within the alveoli at end-inhalation and is the most important pressure to monitor in preventing barotrauma. The goal is less than or equal to 30 mmHg in all cases of ARF, including those due to obstructive airway disease. P_{PLAT} is measured at end-inspiration during a period of zero flow, which is achieved by applying an inspiratory "hold" during volume-controlled ventilation (see Fig. 152-5). P_{PLAT} is always lower than P_{PEAK} by an amount equal to the pressure required to drive inspiratory flow through the ventilator circuit, ETT, and airways.

For the patient with a high P_{AW}, the clinician can determine rapidly whether the problem is resistive (airway) or elastic (lung or chest wall) in nature by assessing the pressure gradient between P_{PEAK} and P_{PLAT} and between P_{PLAT} and total PEEP (set PEEP plus auto-PEEP) (see Fig. 152-5). For instance, if the differential between P_{PEAK} and P_{PLAT} increases, airflow resistance must have increased; potential causes include bronchospasm, a kink in the ETT, and increased airway secretions. In contrast, if the rise in P_{AW} is unaccompanied by an increase in the P_{PEAK}–P_{PLAT} pressure gradient (i.e., both P_{PEAK} and P_{PLAT} increase relative to total PEEP), the elastic load must have increased; causes include loss of lung volume (e.g., right main bronchus intubation; lobar atelectasis; or an alveolar filling process, such as pneumonia or CHF) or a stiffer chest wall apparatus (e.g., pleural effusion or intra-abdominal hypertension).

These routinely measured airway pressures are also used to calculate additional important measures of respiratory mechanics, including airway resistance and respiratory compliance.

Dividing the P_{PEAK}–P_{PLAT} pressure gradient by inspiratory flow rate yields *airway resistance*. The normal value depends on the size of the ETT, but it is typically about 5 to 15 cm H_2O/L/s.

Respiratory system compliance, expressed as ml/cm H_2O, is calculated as tidal volume divided by the difference between P_{PLAT} and total PEEP. Failure to consider auto-PEEP in the calculation results in overestimation of compliance. Normal respiratory system compliance is greater than 60 ml/cm H_2O.

Auto-PEEP

Auto-PEEP (also known as "intrinsic" PEEP) refers to the positive pressure within alveoli at end-expiration that has not been generated by a ventilator. A form of naturally occurring auto-PEEP may be observed with forced exhalation that occurs during heavy exercise. In this case, lung mechanics may be normal, and expiratory muscle force maintains positive intrathoracic and airway pressures throughout expiration; functional residual capacity (FRC) may be normal or decreased.

In contrast, two other types of auto-PEEP are associated with dynamic hyperinflation. In one, auto-PEEP results from a high minute ventilatory requirement, as occurs in ARDS, where insufficient expiratory time promotes incomplete expiration before delivery of the next breath. In the other, more common variety, auto-PEEP results primarily from delayed emptying of alveoli due to airflow obstruction, as most commonly seen in status asthmaticus or an acute exacerbation of chronic obstructive pulmonary disease.

The development of auto-PEEP is determined by three factors: tidal volume, expiratory time, and the respiratory system expiratory time constant (the product of resistance and compliance). Auto-PEEP poses significant problems in pressure-targeted mechanical ventilation, where the additional PEEP reduces ventilator driving pressure, and consequently, tidal volume. In contrast, in volume-targeted ventilation, auto-PEEP causes P_{AW} and P_{PLAT} to increase, which, in turn, increase end-inspiratory lung volumes and alveolar "stretch."

In a mechanically ventilated patient, auto-PEEP is most easily identified by examining the ventilator flow waveform and observing that expiratory flow does not return to zero before initiation of the next breath (Fig. 152-6). Quantification of the magnitude of auto-PEEP is achieved by implementing a prolonged "expiratory hold" maneuver, during which equilibration of pressure throughout the ventilatory circuit is achieved (Fig. 152-7). A mechanically ventilated patient who is generating spontaneous breaths presents a challenge for measurement of auto-PEEP, as airway occlusion usually incites increased respiratory drive. Under these circumstances, an esophageal balloon catheter may be used to estimate pleural pressure, and auto-PEEP calculated by measuring the magnitude of the negative deflection in esophageal pressure from the start of inspiratory effort to onset of inspiratory flow. This method underestimates auto-PEEP in patients with significant airway obstruction.

If auto-PEEP arises as a result of hyperinflation due to expiratory flow limitation in a spontaneously breathing, ventilated patient, external PEEP upto, but not exceeding, the level of auto-PEEP can be applied to offset the increased work of breathing associated with the additional inspiratory threshold load. The applied PEEP does not impact expiratory flow or lung volume. The applied PEEP should be no greater than 85 percent of the measured auto-PEEP.

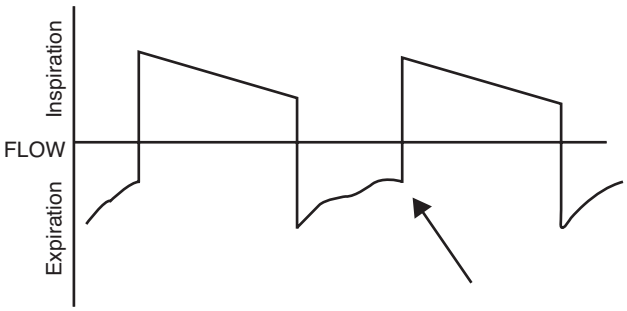

Figure 152-6 The presence of auto-PEEP is identified from the flow waveform. The next breath commences before expiratory flow returns to zero.

Pressure-Volume Curves

In the normal lung, compliance is greatest at FRC, decreasing progressively as lung volume increases (Fig. 152-8). In patients with diffuse parenchymal lung disease (e.g., ARDS) FRC declines, and pressure application at low lung volume yields little increase in volume. With increasing levels of inflation pressure, a point is reached (the lower inflection point, or LIP) beyond which compliance improves dramatically. With further increments in inflation pressure, another point is reached beyond which the pressure-volume curve flattens, defining the upper inflection point (UIP).

A significant reduction in mortality has been demonstrated in patients with ARF using PEEP levels greater than LIP as part of a ventilator protocol based on pressure-control, inverse-ratio, and pressure-limited techniques. The findings may relate to a reduction in the lung injury thought to be related to phasic opening and closing of lung units ("atelectrauma") and resulting epithelial disruption, local inflammation, cytokine release, and tissue destruction. Therefore, some have advocated as an optimal ventilation strategy for minimizing ventilator-induced lung injury (VILI) application of

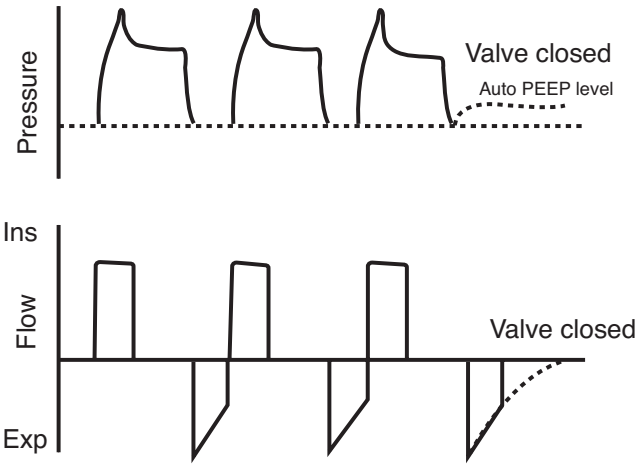

Figure 152-7 Expiratory hold technique to quantify auto-PEEP. The expiratory valve is closed during an expiratory "hold" at the end of a set expiratory time. When flow equals zero, airway pressure rises to the auto-PEEP level.

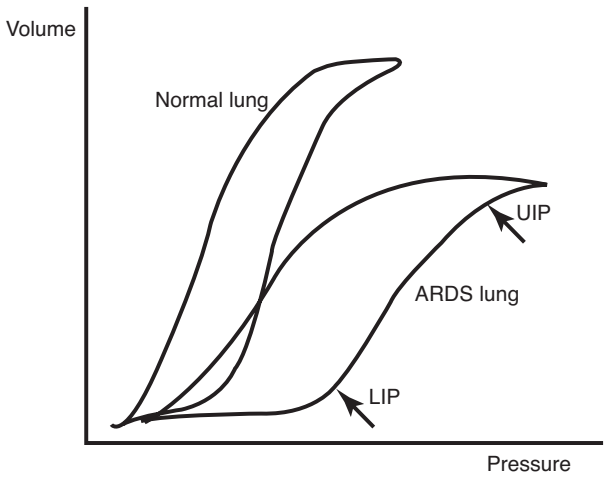

Figure 152-8 Pressure-volume curves of normal and diseased lungs. In the curve in acute respiratory distress syndrome (ARDS), two inflection points have been identified: a lower inflection point (LIP) and an upper inflection point (UIP).

a PEEP level 2 cm H_2O above the LIP and maintenance of P_{PLAT} just below the UIP. However, although many believe that the LIP represents the critical opening pressure of the majority of atelectatic alveoli, alveolar recruitment has been shown to continue for the duration of inspiration. In addition, investigators have found no such inflection point in patients with obvious alveolar recruitment demonstrated by computed tomography (CT).

Esophageal Pressure

Measurement of respiratory system compliance includes the mechanical properties of the lung *and* chest wall. By measuring pleural pressure, the transmural distending pressure of the lung can be calculated. Although regional variation in pleural pressure exists, measurement of lung compliance is based on the *change* in pleural pressure, rather than its absolute value.

Pleural pressure is usually estimated from esophageal pressure, which is recorded using an esophageal catheter. The typical device consists of a latex balloon which is 10 cm long and has several holes. The catheter is inserted into the lower esophagus (usually to a depth of about 40 cm). At this level, artifact from the beating heart is minimized. The adequacy of esophageal balloon positioning is confirmed by having the patient perform inspiratory attempts against an occluded airway. The esophageal pressure changes should be equal (±10 percent) to airway pressure changes. In the paralyzed patient, external chest compressions are used to create pressure fluctuations.

Ventilator Waveforms

Most modern ventilators include a spirometer or flow monitor to measure the volume and flow of gas passing through the ventilator circuit with each breath. Data are analyzed by a microprocessor in the ventilator and are graphically represented

as waveforms. The most commonly displayed waveforms include volume, pressure, and flow. Plots of flow versus volume (flow-volume loops) and pressure versus volume can be constructed electronically from the measurements. Monitoring of ventilator waveforms provides useful information about patient-ventilator synchrony, circuit leaks, patient-ventilator disconnection, development of auto-PEEP, and airway obstruction.

Inspiratory Muscle Strength

Respiratory muscle strength may be assessed by measuring maximum inspiratory and expiratory pressures generated against an occluded airway. This is most easily measured using an aneroid manometer. Inspiratory strength is measured at FRC, where the length-tension relationship of the inspiratory muscles is optimal. The pressure determined by this maneuver is known as the negative inspiratory force (NIF) or maximal inspiratory pressure (MIP). Clearly, the measurement is dependent on the intensity of the inspiratory effort, which may be suboptimal in uncooperative or unconscious patients. The problem can be circumvented by performing the maneuver off the ventilator, using a one-way valve; the NIF is measured over 10 sequential breaths or 30 s. By measuring over time, progressively lower lung volumes are reached and the inspiratory drive increases progressively, promoting a maximal effort. Although the utility of the NIF as a predictor of weaning outcome has fallen out of favor, it remains a useful measurement in troubleshooting reasons for ventilator dependence.

Maximal expiratory pressure (MEP) is measured at total lung capacity, where the expiratory muscle length-tension relationship is optimal. Although not routinely employed in clinical practice, MEP may have use in predicting extubation outcome in selected patient populations.

Imaging in Acute Lung Injury

A variety of imaging techniques may be useful in monitoring patients with ARF, including diaphragm ultrasound, electrical impedance activity (EIT), and CT.

The thickness of the diaphragm changes dynamically between the relaxed phase and maximum inspiration. Ultrasound can be used to evaluate changes in diaphragm thickness in the so-called "zone of apposition," where the lateral portions of the diaphragm lie adjacent and parallel to the lateral chest walls. The technique is noninvasive, inexpensive, and free of ionizing radiation. Diaphragm ultrasound has proved useful in the diagnosis of diaphragm paralysis in the context of ARF.

EIT is a relatively new bedside imaging technique in which an image of gas distribution within the chest is constructed during different phases of respiration. Although the technique's spatial resolution is limited in comparison with CT, its temporal resolution is better. With EIT, a series of eight pairs of electrodes are placed around the chest circumference and a current applied between electrode pairs. The resulting electrical potential is measured, and the process is repeated for numerous configurations of applied current. Potential applications for the technique include titration of PEEP, evaluation of alveolar recruitment maneuvers, and investigation of phasic atelectasis. At present, EIT remains a research tool.

The use of CT has dramatically changed the way in which clinicians view ARDS. Because of the diffuse, widespread distribution of abnormalities seen on conventional radiographs, ARDS was traditionally considered a homogeneous pathological process. However, application of CT imaging in ARDS has demonstrated that the disorder is quite heterogeneous. Furthermore, the advent of high-resolution, multidetector scanners will expand the number of applications of this technology—for example, in the diagnosis of the etiology of the lung injury (pulmonary versus extrapulmonary), nature of the injury (pneumonia versus lung contusion), or progression of injury from inflammation to fibrosis. In addition, the presence of complications (e.g., occult barotrauma or pleuropulmonary infection) and the response to interventions (e.g., adjustment of PEEP, implementation of alveolar recruitment maneuvers, incorporation of spontaneous breathing during mechanical ventilation, or determination of the need for insertion of chest drains) will be more readily discerned.

Principles of Mechanical Ventilation

Martin J. Tobin

The historical evolution of mechanical ventilation is rich and built on advances in many fields, including endeavors by anatomists, chemists, explorers, physiologists, and clinicians. In 1543, Vesalius demonstrated that positive-pressure ventilation could be used to resuscitate a dying animal. Bellows ventilation was advocated by various lay bodies in the resuscitation of near-drowning victims late in the eighteenth century. In 1827, however, Leroy demonstrated that overzealous bellows inflation could result in pneumothoraces. Official bodies condemned the technique, and, thus, early in its infancy, positive-pressure ventilation was banned from use. Around this time, negative-pressure ventilators were developed and later popularized as a panacea for a wide variety of ailments.

The modern era of mechanical ventilation was ushered in by Bjorn Ibsen in response to epidemic of bulbar poliomyelitis in Copenhagen in 1952. In the first 3 weeks of the epidemic, 31 patients had been treated with negative-pressure respirators, and 27 had died. Ibsen advised immediate tracheostomy and the use of positive-pressure ventilation with manual positive pressure from a rubber bag, as was then customary in the operating room. Hundreds of medical students worked in relays, delivering bag ventilation during the epidemic; shortly thereafter, machines were introduced to deliver positive-pressure ventilation. Over the following 40 years, ventilators changed enormously in appearance, becoming more sophisticated and versatile and having enhanced capabilities for monitoring and alarming.

OBJECTIVES AND INDICATIONS FOR MECHANICAL VENTILATION

The objectives of mechanical ventilation are listed in Table 153-1. In isolation, hypoxemia of mild to moderate severity can be managed by administration of oxygen (O_2) through a face mask. With more severe hypoxemia secondary to shunt or ventilation-perfusion ($\dot{V}_A/\dot{Q}$) mismatching, it is difficult to guarantee the delivery of a high fractional inspired oxygen concentration ($F_{I_{O_2}}$) through a face mask. Moreover, these patients are commonly in considerable distress. Thus, intubation helps by ensuring delivery of the required $F_{I_{O_2}}$, and positive-pressure ventilation helps by recruiting collapsed lung units, leading to improved matching of ventilation and perfusion.

Table 153-1

Objectives of Mechanical Ventilation

Improve pulmonary gas exchange
Reverse hypoxemia
Relieve acute respiratory acidosis
Relieve respiratory distress
Decrease oxygen cost of breathing
Reverse respiratory muscle fatigue
Alter pressure-volume relationships
Prevent or reverse atelectasis
Improve lung compliance
Prevent further lung injury
Permit lung and airway healing
Avoid complications

SOURCE: *From: Tobin MJ: Mechanical ventilation.* N Engl J Med *330:1056–1061, 1994, with permission.*

Acute progressive respiratory acidosis is a major indication for mechanical ventilation, although simpler measures can sometimes reverse the process. For example, among patients with acute severe asthma and hypercapnia, hypercapnia resolves with standard bronchodilator therapy, without the need for mechanical ventilation, in more than 90 percent of patients. If a patient has severe respiratory depression that is expected to be slow in resolving (e.g., certain drug overdoses), intubation and mechanical ventilation should be instituted without delay.

A substantial proportion of patients who require (and benefit from) mechanical ventilation have relatively normal arterial blood gases but have clinical signs of increased work of breathing: nasal flaring; vigorous activity of the sternomastoid muscles; tracheal tug; recession of the suprasternal, supraclavicular, and intercostal spaces; paradoxical motion of the abdomen; and pulsus paradoxus. This picture of a patient "tiring out" is the most common reason for instituting mechanical ventilation. The increase in work of breathing may be the result of increased airway resistance, increased stiffness of the lungs or chest wall, or the presence of a threshold inspiratory load secondary to auto- or intrinsic positive end-expiratory pressure ($PEEP_i$).

Increased respiratory work increases the O_2 cost of breathing to as much as 50 percent of total O_2 consumption. By decreasing respiratory work, mechanical ventilation allows precious O_2 stores to be rerouted to other vulnerable tissue beds. To substantially reduce patient effort, the ventilator must cycle in unison with the patient's central respiratory rhythm (Fig. 153-1). For perfect synchronization, the period of mechanical inflation must match the period of neural inspiratory time (the duration of inspiratory effort), and the period of mechanical inactivity must match the neural expiratory time. Work of breathing is increased in patients with atelectasis or acute lung injury because breathing occurs on the low, flat portion of the pressure-volume curve. By shifting tidal ventilation to the steep, compliant portion of the curve, mechanical ventilation can decrease respiratory work.

Commonly listed indications for mechanical ventilation include acute respiratory failure, exacerbation of chronic respiratory failure (e.g., secondary to infection, bronchoconstriction, or heart failure), coma, and neuromuscular disease. Many patients with these same conditions, however, do not require ventilator assistance. Indeed, the most common, and honest, reason that mechanical ventilation is instituted is a tautology: A physician thinks that "the patient looks like he (or she) needs to be placed on the ventilator." Mechanical ventilation is most commonly instituted based on a physician's clinical gestalt, formed through assessing a patient's signs and symptoms, rather than because a patient satisfies a certain set of criteria on a checklist. It is important to ground this decision on solid knowledge of pulmonary pathophysiology.

MODES OF MECHANICAL VENTILATION

The term *mode* refers to the relationship among various breath types (mandatory, assisted, supported, and spontaneous), as well as inspiratory phase variables.

Controlled Mechanical Ventilation

In controlled mechanical ventilation, the ventilator delivers all breaths at a preset rate, and the patient cannot trigger the machine. In the volume-targeted mode, the breaths have a preset volume—so-called volume-controlled ventilation. When the breaths are pressure limited and time cycled, the mode is termed *pressure-controlled* ventilation. Use of volume-controlled ventilation is largely restricted to patients who are apneic as a result of brain damage, sedation, or paralysis.

Assist-Control Ventilation

In the assist-control mode, the ventilator delivers a breath either when triggered by the patient's inspiratory effort (pressure- or flow-triggered) or, independently, if such an effort does not occur within a preselected time period. All breaths are delivered under positive pressure by the machine, but unlike controlled mechanical ventilation, the patient's triggering effort can exceed the preset rate. If the patient's spontaneous rate drops below the preset back-up rate, controlled ventilation is provided. The pressure to achieve the set tidal volume may be provided solely by the machine or, in part, by the patient. By design, delivered tidal volume is not influenced by patient effort. The more the patient contributes, the less pressure is provided by the machine, and ventilator-generated pressure bears an inverse relationship to patient-generated pressure.

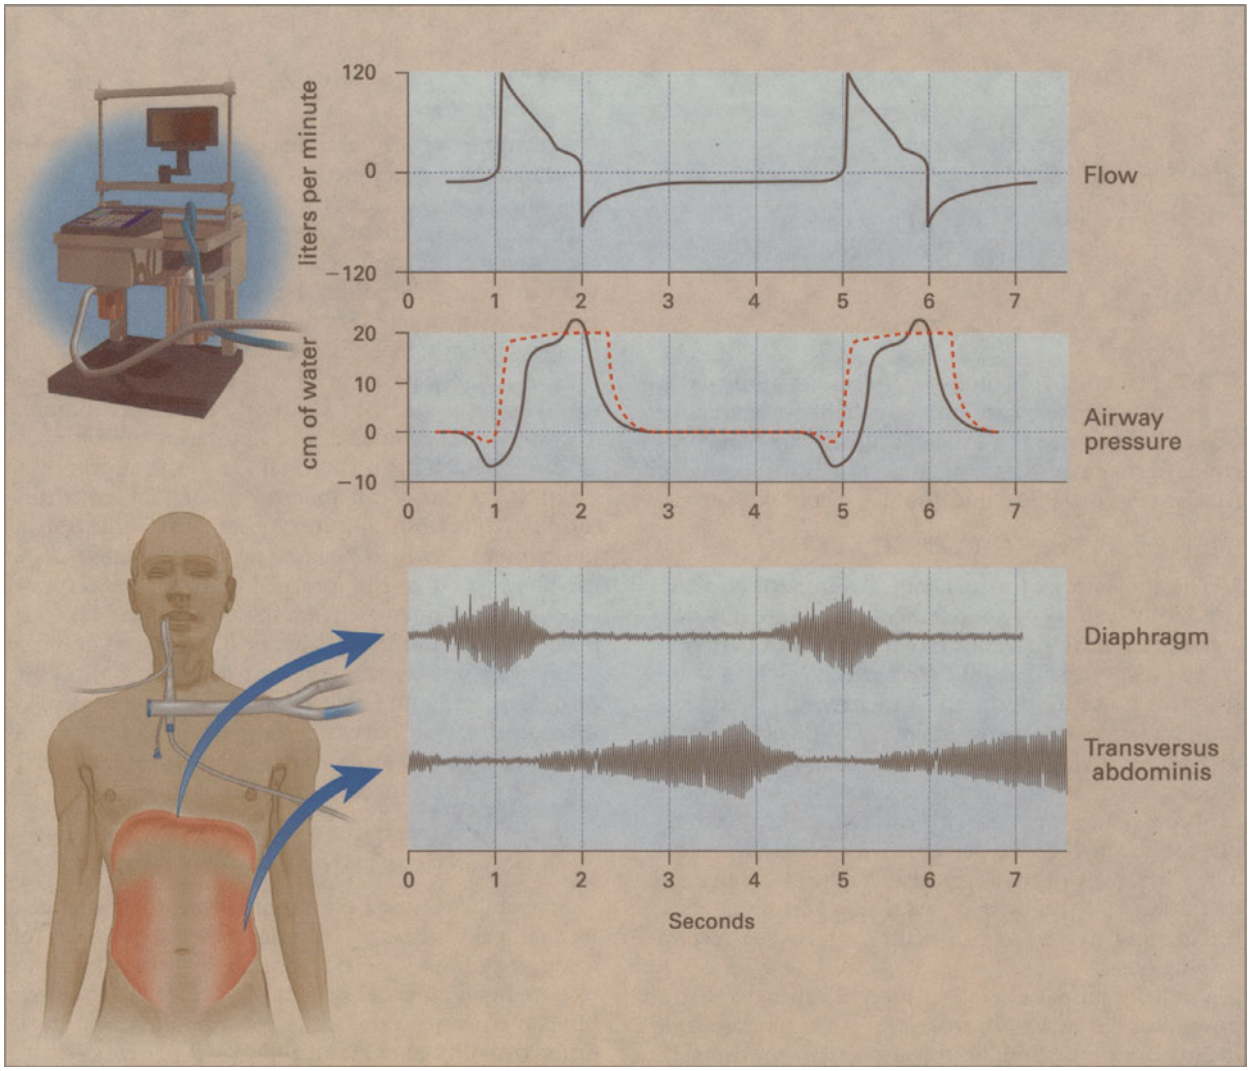

Figure 153-1 Flow, airway pressure, and inspiratory and expiratory muscle activity in a patient with chronic obstructive pulmonary disease who received pressure-support ventilation at an airway pressure of 20 cm H_2O. The electromyograms in the lower portion of the figure show inspiratory muscle activity in the patient's diaphragm and expiratory muscle activity in the transversus abdominis. The patient's increased inspiratory effort caused the airway pressure to fall below the set sensitivity (−2 cm H_2O), and inadequate delivery of flow by the ventilator resulted in a scooped contour on the airway-pressure curve during inspiration. While the ventilator was still pumping gas into the patient, his expiratory muscles were recruited, causing a bump in the airway-pressure curve. That the flow never returned to zero throughout expiration reflected the presence of $PEEP_i$. The broken red line shows airway pressure in another patient, who generated just enough effort to trigger the ventilator and in whom there was adequate delivery of gas by the ventilator. *(Data are from Jubran A, Van de Graaff WB, Tobin MJ: Variability of patient-ventilator interaction with pressure support ventilation in patients with chronic obstructive pulmonary disease.* Am J Respir Crit Care Med *152:129–136, 1995; Parthasarathy S, Jubran A, Tobin MJ: Cycling of inspiratory and expiratory muscle groups with the ventilator in airflow limitation.* Am J Respir Crit Care Med *158:1471–1478, 1998. Reproduced with permission from Tobin MJ: Advances in mechanical ventilation.* N Engl J Med *344:1986–1996, 2001.)*

The ventilator cycles off when the preset tidal volume is reached, and machine inspiratory time may be shorter or longer than the patient's intrinsic (neural) inspiratory time. If the set tidal volume is reached before the end of neural inspiratory time, the machine cycles off while the patient's inspiratory effort continues. If the patient's inspiratory effort ceases before the set tidal volume is reached, the machine increases pressure to provide continued inspiratory flow. The amount of active work performed by a patient ventilated in the assist-control mode is critically dependent on the trigger sensitivity and inspiratory flow settings. Even when these settings are selected appropriately, patients actively perform about one-third of the work performed by the ventilator during passive conditions.

Intermittent Mandatory Ventilation

With intermittent mandatory ventilation (IMV), the patient receives periodic positive-pressure breaths from the ventilator at a preset volume and rate, but the patient can also breathe

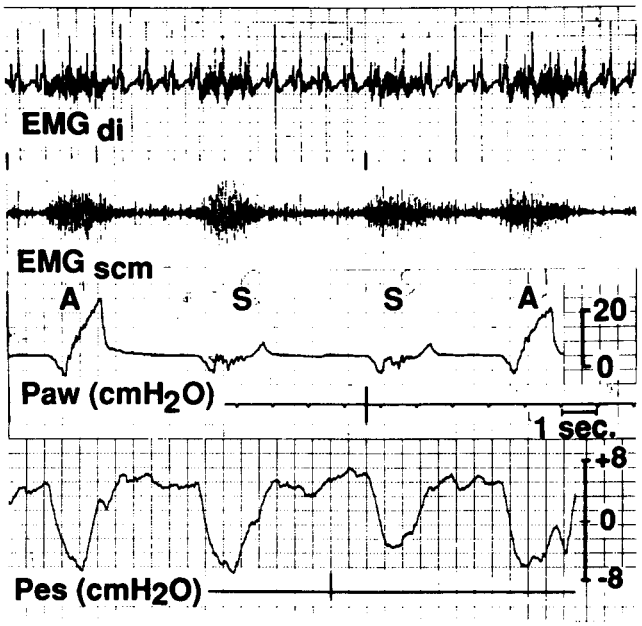

Figure 153-2 Electromyograms of the diaphragm (EMGdi) and sternocleidomastoid muscles (EMGscm) in a patient receiving synchronized intermittent mandatory ventilation. Similar intensity and duration of electrical activity during assisted (A) and spontaneous (S) cycles are demonstrated. P_{aw} = airway pressure; P_{es} = esophageal pressure. *(From Imsand C, Feihl F, Perret C, et al: Regulation of inspiratory neuromuscular output during synchronized intermittent mechanical ventilation.* Anesthesiology *80:13–22, 1994, with permission.)*

spontaneously between these mandatory breaths. A problem unforeseen at the time IMV was introduced is the difficulty that patients encounter in trying to adapt to the intermittent nature of ventilator assistance. It had been assumed that the degree of respiratory muscle rest achieved by IMV would be proportional to the number of mandatory breaths delivered. Studies, however, have demonstrated that inspiratory effort is equivalent for spontaneous and assisted breaths during IMV (Fig. 153-2). Indeed, the tension-time index for both spontaneous and assisted breaths is above the threshold associated with respiratory muscle fatigue at IMV rates of 14 breaths per minute or less. At a moderate level of machine assistance (at which the ventilator accounts for 20 to 50 percent of total ventilation), electromyographic activity of the diaphragm and sternocleidomastoid muscles is equivalent for assisted and spontaneous breaths. These findings suggest that respiratory center output is preprogrammed and does not adjust to breath-to-breath changes in load, as occur during IMV. As a result, IMV may contribute to development of respiratory muscle fatigue or prevent its recovery.

Pressure-Support Ventilation

Pressure-support ventilation is patient triggered, like assist-control ventilation and IMV, but differs in that it is pressure targeted and flow cycled. The physician sets a level of pressure that augments every spontaneous effort, and the patient can alter respiratory frequency, inspiratory time, and tidal volume. Tidal volume is determined by the pressure setting, the patient's effort, and pulmonary mechanics, in contrast to assist-control ventilation and IMV, in which a guaranteed volume is delivered. With volume-targeted ventilation, the inspiratory flow setting is a crucial determinant of patient work. There is no flow setting with pressure-support ventilation, although the initial peak flow determines the speed of pressurization and the initial pressure ramp profile.

The level of pressure delivered by the ventilator is usually adjusted in accordance with changes in the patient's respiratory frequency. However, the frequency that signals a satisfactory level of respiratory muscle rest has never been well defined, and recommendations range from 16 to 30 breaths per minute.

Several investigators have shown that pressure support is very effective in decreasing the work of inspiration. The degree of inspiratory muscle unloading, however, is variable, with a coefficient of variation of up to 96 percent among patients. Pressure-support does not decrease $PEEP_i$ in patients with chronic obstructive pulmonary disease (COPD). Thus, at a pressure support of 20 cm H_2O, $PEEP_i$ may account for two-thirds of total inspiratory effort.

Cycling to exhalation is triggered by a decrease in inspiratory flow to a preset level, such as 5 L/min or 25 percent of peak inspiratory flow, depending on the manufacturer's algorithm (Fig. 153-3). The algorithm for "cycling-off" of mechanical inflation causes problems in patients with COPD, because increases in resistance and compliance produce a slow time constant (of the respiratory system). The longer time needed for flow to fall to the threshold value can cause mechanical inflation to persist into neural expiration.

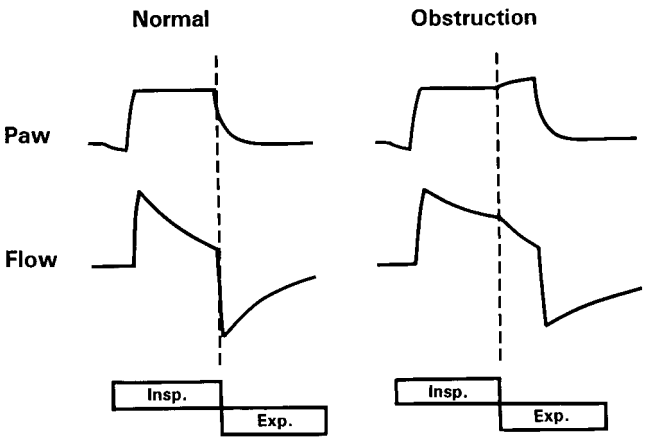

Figure 153-3 Airway pressure (P_{aw}) and inspiratory (Insp) and expiratory (Exp) flow during pressure support ventilation in patients with normal and obstructed airways. Patient effort triggers the ventilator to deliver a preset pressure, and inspiratory assistance continues until the flow rate falls to 25 percent of the peak inspiratory flow. In patients with airway obstruction who have a prolonged time constant, more time is required for flow to decrease to this threshold value, so that neural expiration commences before the termination of mechanical inflation. The resulting activation of the expiratory muscles hastens the fall in flow, but it also results in dyssynchrony between the patient's neuromuscular activity and the mechanical phase of the ventilator—so-called "fighting the ventilator."

In 12 patients with COPD receiving pressure support of 20 cm H_2O, investigators found that five recruited their expiratory muscles while the machine was still inflating the thorax. Interestingly, the patients who recruited their expiratory muscles during mechanical inflation had an average time constant of 0.54 seconds, as compared with an average of 0.38 seconds in the patients who did not exhibit expiratory muscle activity. The persistence of mechanical inflation into neural expiration is very uncomfortable, as well recognized with use of inverse-ratio ventilation.

New Modes

New modes of mechanical ventilation are frequently introduced. Each has an acronym, and the jargon is inhibiting to those unfamiliar with it. Yet each new mode involves nothing more than a modification of the manner in which positive pressure is delivered to the airway and of the interplay between mechanical assistance and the patient's respiratory effort. The purpose of a new mode may be to enhance respiratory muscle rest, prevent deconditioning, improve gas exchange, prevent lung damage, enhance coordination between ventilator assistance and patient respiratory effort, and foster lung healing; the priority given to each goal varies.

VENTILATOR SETTINGS

Ventilator settings are based on the patient's size and clinical condition. Determination of the settings is a dynamic process, based on a patient's physiological response, rather than on a fixed set of numbers. The settings require repeated readjustment over the period of ventilator dependency. Such an iterative process requires careful respiratory monitoring.

Triggering

Many ventilators employ pressure triggering, whereby a decrease in circuit pressure is required to initiate ventilator assistance. Patients reach the set sensitivity by activating their inspiratory muscles. When the threshold is reached, however, inspiratory neurons do not simply switch off. Consequently, the patient may expend considerable inspiratory effort throughout a machine-cycled inflation. The level of patient effort during this post-trigger phase is closely related to a patient's respiratory drive at the point of triggering. As such, measures that decrease respiratory drive may enhance respiratory muscle rest during mechanical ventilation.

If respiratory drive at the point of triggering is important, one might expect that effort during the time of triggering would determine patient effort during the remainder of inspiration. To elucidate this issue, investigators applied graded levels of pressure support in eleven critically ill patients. They achieved a fourfold reduction in overall patient effort. Yet patient effort during the time of triggering did not change. The constancy of effort during the trigger phase was probably secondary to different factors becoming operational as the level of ventilator assistance was varied (Fig. 153-4). Thus, increases in the level of ventilator assistance do

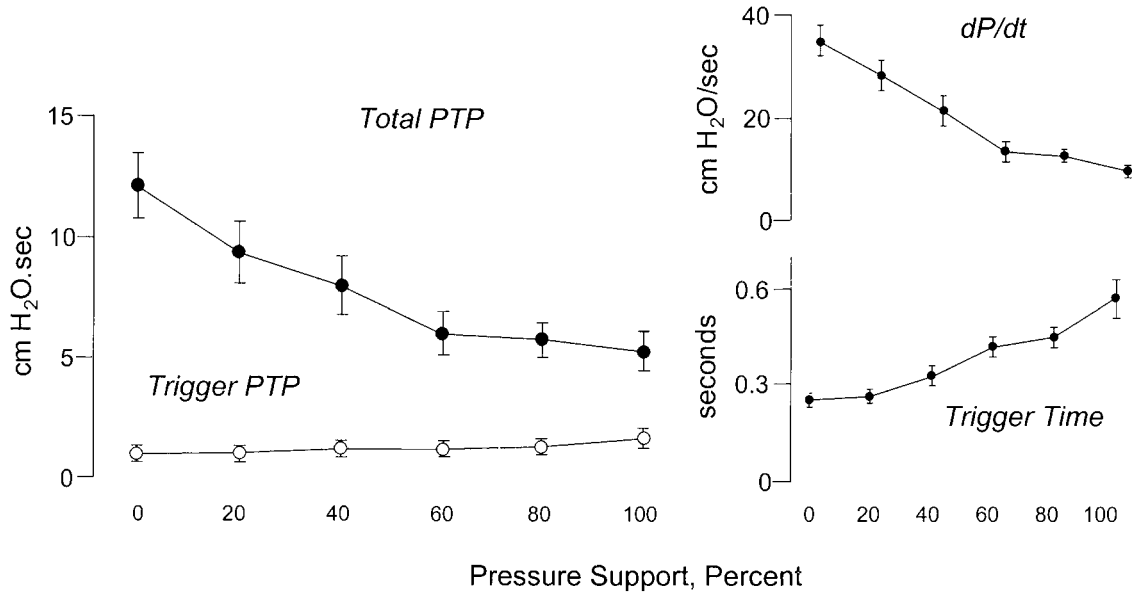

Figure 153-4 Graded increases in pressure support produced a decrease in total pressure-time product (PTP) per breath (closed symbols), although PTP during the trigger phase (open symbols) did not change (left panel). The constancy of PTP during triggering probably resulted from different factors becoming operational at different levels of assistance (right panel). At low levels of pressure support, respiratory drive (dP/dt) and $PEEP_i$ were high, but triggering time was short, resulting in a large change in pleural pressure over a brief interval. At high levels of pressure support, dP/dt and $PEEP_i$ were low, but triggering time was long, resulting in a smaller change in pleural pressure over a longer time. *(Based on data from Leung P, Jubran A, Tobin MJ: Comparison of assisted ventilator modes on triggering, patient effort, and dyspnea.* Am J Respir Crit Care Med *155:1940–1948, 1997; Tobin MJ, Jubran A, Laghi F: Patient-ventilator interaction.* Am J Respir Crit Care Med *163:1059–1063, 2001, with permission.)*

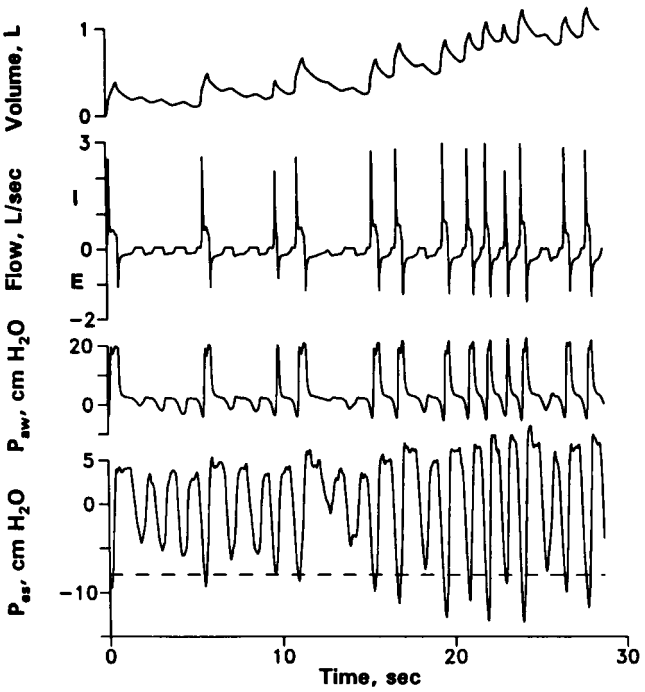

Figure 153-5 Recordings of tidal volume, inspiratory (I) and expiratory (E) flow, airway pressure (P_{aw}), and esophageal pressure (P_{es}) in a patient with COPD receiving pressure-support ventilation. Approximately half of the patient's inspiratory efforts do not succeed in triggering the ventilator. Triggering occurs only when the patient generates P_{es} more negative than −8 cm H_2O (indicated by the interrupted horizontal line), a pressure equal in magnitude to the opposing elastic recoil pressure. Expiratory flow exhibits a biphasic pattern, with momentary braking signaling ineffective inspiratory effort. Thus, monitoring of expiratory flow provides a more accurate measurement of the patient's intrinsic respiratory rate than does the number of machine cycles displayed on the bedside monitor. *(From Tobin MJ, Jubran A:* Pathophysiology of failure to wean from mechanical ventilation. *Schweiz Med Wochenschr 124:2138–2145, 1994, with permission.)*

not substantially decrease patient effort during the time of triggering.

The display of airway pressure and flow tracings on ventilator screens has increased awareness that inspiratory effort is frequently insufficient to trigger the ventilator. At high levels of mechanical assistance, up to one-third of a patient's inspiratory efforts may fail to trigger the machine (Fig. 153-5).The number of ineffective triggering attempts increases in direct proportion to the level of ventilator assistance. Surprisingly, unsuccessful triggering is not the result of poor inspiratory effort. In a study of factors contributing to ineffective triggering, effort was noted to be more than one-third greater when the threshold for triggering the ventilator was not reached than when it was. Breaths that do not reach the threshold for triggering the ventilator have higher tidal volumes and shorter expiratory times than do breaths that do trigger the ventilator. Consequently, elastic-recoil pressure builds up within the thorax in the form of $PEEP_i$. To trigger the ventilator, the patient's inspiratory effort has to first generate a negative intrathoracic pressure in order to counterbalance the elastic recoil; it then must reach the set sensitivity.

The time at which a patient initiates an expiratory effort (in relation to the cycling of the ventilator) partly determines the success of the ensuing inspiratory effort in triggering the machine. The relationship between the onset of expiratory muscle activity and termination of mechanical inflation by the ventilator has been quantified. At a pressure support of 20 cm H_2O, mechanical inflation continues for a longer time into neural expiration in the breaths preceding nontriggering attempts. Continuation of mechanical inflation into neural expiration counters expiratory flow, and also decreases the time available for unopposed exhalation. Consequently, elastic recoil increases. In turn, a greater inspiratory effort will be needed to achieve effective triggering. In this way, the time at which a patient commences an expiratory effort (in relation to cycling-off of mechanical inflation) partly determines the success of the ensuing inspiratory effort in triggering the ventilator.

Tidal Volume

In the past, use of a tidal volume setting of 10 to 15 ml/kg had been the standard recommendation. This setting is still used by many anesthesiologists for patients without lung disease who are undergoing surgery. Since the early 1990s, however, lower tidal volumes have been used when ventilating patients in medical intensive care units (ICUs). The change in practice was precipitated by research in experimental animals that provided convincing evidence of severe lung injury induced by alveolar overdistension. A 1990 retrospective study of patients with the acute respiratory distress syndrome (ARDS) revealed a 60 percent decrease in the expected mortality rate with use of lower tidal volumes. Subsequent randomized trials, including that conducted by the ARDS Network investigators, revealed a significantly lower mortality with a tidal volume of 6 ml/kg compared with a tidal volume of 12 ml/kg. Three other controlled trials, however, did not reveal a lower mortality using the lower tidal volume.

To understand the discrepant findings among the five randomized trials, a meta-analysis was undertaken. The analysis focused on plateau pressure, which is the airway pressure during an end-inspiratory pause. The low tidal volume arms of the three negative studies had plateau pressures that were at least as low as in the two positive studies. Thus, authors of the meta-analysis concluded that use of low tidal volumes did not lower mortality. The control arms of the three negative studies had plateau pressures that were comparable to those of usual practice (as reflected by plateau pressures before randomization). The control arms of the two positive studies, however, had plateau pressures higher than those used in usual practice (plateaus above 35 cm H_2O versus plateaus of 29 to 31 cm H_2O). Thus, the conclusion from the meta-analysis was that the control arms of the two positive studies were associated with increased mortality.

A subsequent analysis of the data from the ARDS Network study revealed that respiratory compliance had a major

influence on the response to the setting of tidal volume. If compliance was low before randomization, lowering of tidal volume decreased mortality from 42 to 29 percent. If compliance was high, however, lowering of tidal volume increased mortality from 21 to 37 percent. Thus, a low tidal volume is not appropriate for every patient with ARDS. Instead, it is essential to characterize each patient's pathophysiology and to customize the ventilator settings accordingly.

Respiratory Rate

Correct setting of the ventilator rate depends on the mode of ventilation employed. With assist-control ventilation, the ventilator supplies a breath in response to each patient effort. With this mode, physicians commonly pay little attention to the machine rate, which may be set much lower than the patient's spontaneous rate. This gap results in two problems: (a) If the patient has a sudden decrease in respiratory center output, a low machine rate results in serious hypoventilation. (b) A large discrepancy between the patient's spontaneous rate and the machine's back-up rate results in a respiratory cycle with an inverse inspiratory-to-expiratory time (I:E) ratio.

Development of an inverse I:E ratio arises because inspiratory time (T_I) on the machine remains fixed at the initial setting and does not change in response to increases in the patient's spontaneous rate (Fig. 153-6). For example, if the machine rate is initially set at 12 breaths per minute (T_{TOT} of 5 seconds) and T_I set at 1.65 seconds (either set directly or indirectly as a consequence of the volume and flow settings), then T_E will be 3.35 seconds. The I:E ratio will be 1:2. If the patient's spontaneous respiratory rate is increased to 25 breaths per minute, T_{TOT} will be 2.4 seconds. Because T_I remains fixed at 1.65 seconds, T_E will be 0.75 s, and the I:E ratio will be 2:1. Such inverse-ratio ventilation is very uncomfortable and may lead to increased sedative use, or even to use of neuromuscular blockade, simply because of inappropriate

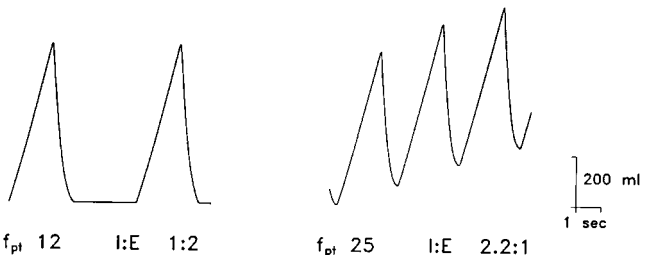

Figure 153-6 Effect of interaction between a patient's respiratory rate and the ventilator back-up rate on inspiratory time–expiratory time ratio (I:E) during assist-control ventilation. Ventilator back-up rate is 12 breaths per minute and inspiratory time (T_I) 1.65 seconds. *Left panel.* If the patient's intrinsic respiratory (f_{pt}) rate is also 12 breaths per minute, the total respiratory cycle time (T_{TOT}) is 5.0 seconds, the expiratory time (T_E) is 3.35 seconds, and the I:E ratio is 1:2. *Right panel.* If the patient's respiratory rate increases to 25 breaths per minute, the new T_{TOT} is 2.4 seconds, T_E is 0.75 seconds, and I:E is 1:0.45 (or, as more conventionally noted, 2.2:1).

setting of the back-up rate. Based on these considerations, the back-up rate during assist-control ventilation should be set at approximately four breaths less than the patient's spontaneous rate.

With IMV, the ventilator (or mandatory) rate is initially set high and then gradually reduced according to patient tolerance. Unfortunately, titration is often based on data from arterial blood gases, and even a small number of ventilator breaths can result in acceptable values for Pa_{O_2} and Pa_{CO_2} but achieve little or no respiratory muscle rest in patients with increased work of breathing. In ventilator-dependent patients, work of breathing at IMV rates of 14 breaths per minute or less may be sufficient to induce respiratory muscle fatigue.

With PS ventilation, the ventilator rate is not set.

Inspiratory Flow Rate

Clinicians initially set the inspiratory flow rate at a default value, such as 60 L/min. Many critically ill patients, however, have an elevated respiratory drive, and the initial flow setting may be insufficient to meet flow demands. As a result, patients will struggle against their own respiratory impedance and that of the ventilator. Consequently, work of breathing increases. Clinicians sometimes increase flow in order to shorten the inspiratory time and increase the expiratory time. However, an increase in flow causes immediate and persistent tachypnea; as a result, expiratory time may be shortened. In a study of healthy subjects, increases in inspiratory flow from 30 L/min to 60 and 90 L/min caused increases in respiratory rate of 20 and 41 percent, respectively.

One of the main reasons that clinicians increase inspiratory flow is to decrease inspiratory time, in hope of allowing more time for expiration and, thereby, decreasing $PEEP_i$, especially in patients with COPD. Because increased flow usually leads to an increase in respiratory rate, the expected shortening of expiratory time might actually increase $PEEP_i$.

An investigation of this phenomenon was conducted in 10 patients with COPD (Fig. 153-7). As with healthy subjects, an increase in flow from 30 to 90 L/min caused respiratory rate to increase from 16 to 21 breaths per minute. Despite the increase in rate, $PEEP_i$ fell from 7.0 to 6.4 cm H_2O. The decrease in $PEEP_i$ arose because of an increase in expiratory time (from 2.1 to 2.3 seconds), which allowed more time for lung deflation. Why did expiratory time increase? An increase in inspiratory flow is usually achieved by shortening of mechanical inspiratory time. The shortened inspiratory time combined with time-constant inhomogeneity of COPD causes overinflation of some lung units to persist into neural expiration. Continued inflation during neural expiration causes stimulation of the vagus nerve, which prolongs expiratory time.

When adjusting the flow rate and trigger sensitivity, examination of the contour of the airway pressure waveform is helpful (Fig. 153-8). Ideally, the waveform should show a smooth rise and convex appearance during inspiration. In

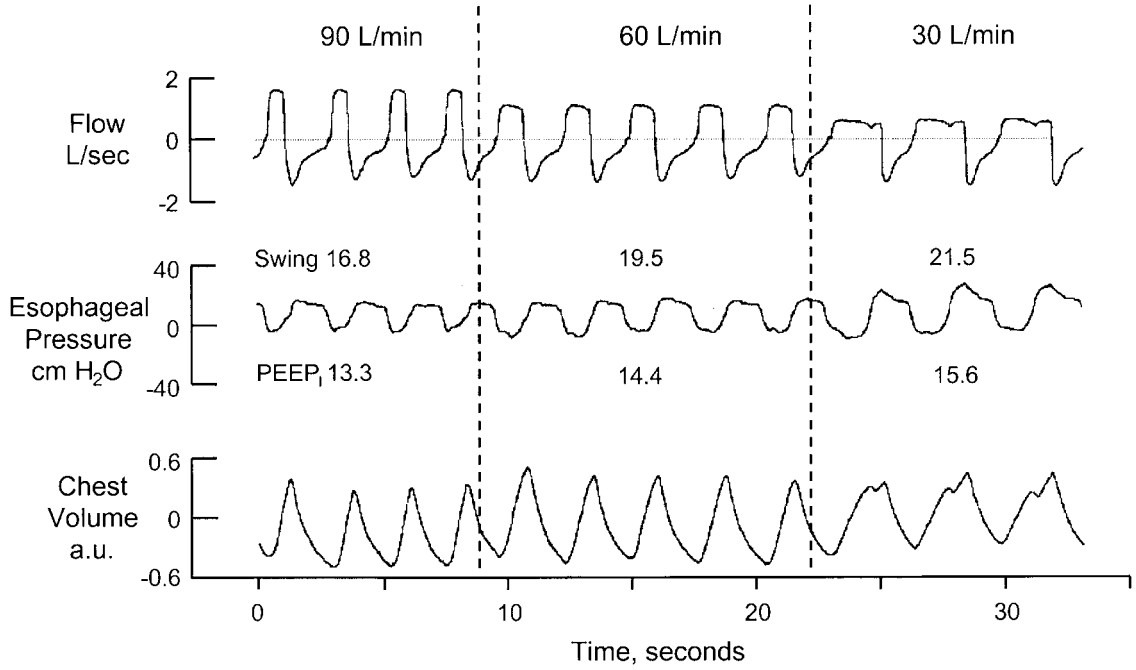

Figure 153-7 Continuous recordings of flow, esophageal pressure (Pes), and the sum of rib cage and abdominal motion, in a patient with chronic obstructive pulmonary disease receiving assist-control ventilation at a constant tidal volume. As flow increased from 30 to 60 and 90 L/min (from right to left), frequency increased (from 18 to 23 and 26 breaths/min, respectively), $PEEP_i$ decreased (from 15.6 to 14.4 and 13.3 cm H_2O, respectively), and end-expiratory lung volume also fell. Increases in flow from 30 L/min to 60 and 90 L/min also led to decreases in the swings in Pes from 21.5 to 19.5 and 16.8 cm H_2O, respectively. *(Reproduced from Laghi F, Segal J, Choe WK, et al: Effect of imposed inflation time on respiratory frequency and hyperinflation in patients with chronic obstructive pulmonary disease.* Am J Respir Crit Care Med *163:1365–1370, 2001.)*

contrast, a prolonged negative phase, with excessive scalloping of the tracing, indicates unsatisfactory settings of sensitivity or flow.

Fractional Inspired Oxygen Concentration

Correction of hypoxemia and its prevention are major goals in mechanically ventilated patients. Many predictive equations have been published to aid in selecting an appropriate

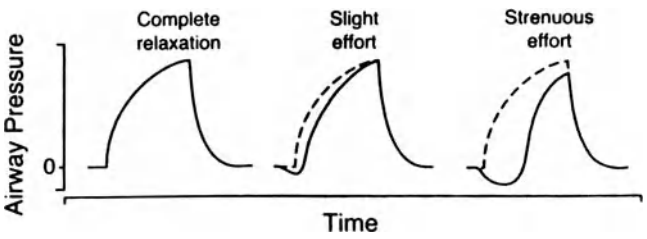

Figure 153-8 Airway-pressure waveforms recorded during assist-control ventilation. The tracings represent changes in airway pressure during inspiration in a completely relaxed patient, and in patients making slight (center tracing) and strenuous efforts (tracing on right) to breathe. The distance between the dashed line (representing controlled ventilation) and the solid line (representing spontaneous breathing) is proportional to the patient's work of breathing. *(From Tobin MJ: Mechanical ventilation.* N Engl J Med *330:1056–1061, 1994, with permission.)*

$F_{I_{O_2}}$, but none is sufficiently accurate to substitute for a trial-and-error approach. Initially, $F_{I_{O_2}}$ is set at a high value (often 1.0) to ensure adequate oxygenation. Thereafter, the lowest $F_{I_{O_2}}$ that achieves satisfactory arterial oxygenation should be selected. The usual target is a Pa_{O_2} of 60 mmHg or an arterial saturation (Sa_{O_2}) of 90 percent; higher values do not substantially enhance tissue oxygenation. Although it is customary to wait 30 min to assess the response to a change in $F_{I_{O_2}}$, the effect is usually well defined within 10 min. When using arterial blood samples to assess oxygenation, a target of 90 percent for Sa_{O_2} is appropriate. If pulse oximetry is employed, a Sp_{O_2} target may result in values for Pa_{O_2} as low as 41 mmHg. In white patients, a target of 92 percent for Sp_{O_2} indicates satisfactory oxygenation. In black patients, however, this target may still result in significant hypoxemia.

In experimental animals, hyperoxia produces diffuse alveolar damage, with histologic changes that are indistinguishable from ARDS resulting from any other cause. No diagnostic tests distinguish O_2-induced injury from progression of the underlying disease. Thus, the possibility of O_2 toxicity should be considered in any patient receiving an $F_{I_{O_2}}$ of more than 0.50 to 0.60 for 24 to 48 hours or longer. Healthy human subjects who inhale 100 percent O_2 develop acute tracheobronchitis, manifested as substernal discomfort, cough, sore throat, nasal congestion, eye and ear discomfort, paresthesias, and fatigue. Symptoms begin within 4 hours; bronchoscopic features of tracheal inflammation are evident after

6 hours. Retrosternal discomfort also occurs with an $F_{I_{O_2}}$ of 0.75 but not with an $F_{I_{O_2}}$ of 0.50. Hyperoxia causes absorption atelectasis in lung units with low $\dot{V}_A/\dot{Q}$ ratios, because the rate of absorption of O_2 from the alveoli into the bloodstream is faster than the rate of replenishment from inspired gas. Such atelectasis results in a small shunt (approximately 3 percent) in healthy elderly subjects and requires only about 6 minutes to develop.

A decrease in vital capacity is probably the best indicator of O_2 toxicity. In several studies of healthy volunteers breathing 50 percent O_2 over 7 to 28 days, little, if any, change in vital capacity was observed. When healthy subjects breathed 100 percent O_2, a decrease in static lung compliance was observed within 3 hours. This decrease resolved readily with deep breathing, suggesting that the decreased compliance was caused by absorption atelectasis, rather than direct toxicity. Exposure of healthy subjects to 100 percent O_2 for as long as 4 days resulted in only modest reductions in vital capacity, and gas exchange function returned to normal with air breathing.

Overall, studies in human subjects reveal much less parenchymal injury than has been observed in animals. It has been suggested the risk of O_2 toxicity might be greater in patients who have coexisting lung injury, but ironically, indirect data suggest that patients with ARDS have a reduced risk of O_2 toxicity. Exuded plasma proteins and intra-alveolar hemorrhage provide a medium that is rich in antioxidant enzyme capacity and helps to protect against O_2 toxicity. Death in experimental animals exposed to prolonged hyperoxia is usually attributed to acute lung injury. Several investigators, however, have reported a terminal course characterized by severe cardiac embarrassment associated with focal areas of myocardial necrosis on microscopy.

In the face of potential O_2 toxicity, the only possible strategy is to reduce the $F_{I_{O_2}}$ to the lowest level compatible with adequate systemic oxygenation. Thus, excess O_2 demand should be minimized, and measures to enhance systemic oxygenation optimized. Although excessive O_2 administration should be avoided, there is more to fear from severe hypoxemia than from the potential damage that might result from hyperoxia.

Positive End-Expiratory Pressure

The beneficial effects of positive end-expiratory pressure (PEEP) include improvement in arterial oxygenation, improvement in lung compliance, alleviation of excessive respiratory work secondary to $PEEP_i$ in patients with airflow limitation, and, possibly, a decrease in lung injury resulting from repeated alveolar collapse and reopening. The principal beneficial effect of PEEP is an increase in Pa_{O_2}, which permits a decrease in $F_{I_{O_2}}$ and a reduction in the risk of O_2 toxicity. The major mechanism for the increase in Pa_{O_2} with PEEP is an increase in end-expiratory lung volume (Table 153-2).

Patients with ARDS develop alveolar instability and collapse (see Chapters 144 and 145). Consequently, functional residual capacity falls below closing volume, and small airways close during tidal breathing, leading to intrapulmonary shunt and hypoxemia. PEEP increases end-inspiratory lung volume by distending lung units that are already open, preventing collapse of unstable alveoli at end-expiration, recruiting collapsed lung units, and redistributing liquid within the lung. The decrease in venous admixture with PEEP is proportional to alveolar recruitment. It had been thought that the decrease in venous admixture with PEEP resulted largely from a decrease in cardiac output. This view has been shown to be erroneous.

Table 153-2

Mechanisms of Increased Pa_{O_2} with PEEP

Increase in end-expiratory lung volume
Distention of patent lung units
Recruitment of collapsed lung units
Redistribution of fluid within the lung
Decrease in shunt
Increase in end-expiratory lung volume
Decrease in cardiac output

At one time PEEP was thought to decrease extravascular lung water by "pushing" alveolar fluid back into the circulation. On the contrary, PEEP can actually increase lung water. As alveoli expand with application of PEEP, interstitial pressure in the extra-alveolar space decreases, leading to an increase in transmural pressure across the vessel wall. If intravascular pressures remain the same or increase, the filtration of fluid across the vessel wall increases, causing an increase in pulmonary edema; if PEEP causes a decrease in cardiac output and vascular pressures, lung water does not change. The beneficial action of PEEP in pulmonary edema is produced by redistribution of edema fluid from the alveolar space into the perivascular cuffs. This redistribution of lung water, in association with an increase in end-expiratory lung volume, is the major mechanism underlying the increase in Pa_{O_2} with PEEP.

In patients with acute respiratory distress syndrome, PEEP is often used for the purpose of recruiting previously nonfunctioning lung tissue (see Chapter 145). Selecting the right level of PEEP for a given patient is difficult, however, because the severity of injury varies throughout the lungs. PEEP can recruit atelectatic areas, but it may also overdistend normally aerated areas. In one study involving six patients with acute lung injury, the use of PEEP at 13 cm H_2O resulted in recruitment of nonaerated portions of lung, with a gain of 320 ml in lung volume; however, three patients had overdistention of already aerated portions of lung, with an excess volume of 238 ml.

Overall, about 30 percent of patients with acute lung injury either do not benefit from PEEP or experience a fall in Pa_{O_2}. With the patient in the supine posture, PEEP generally

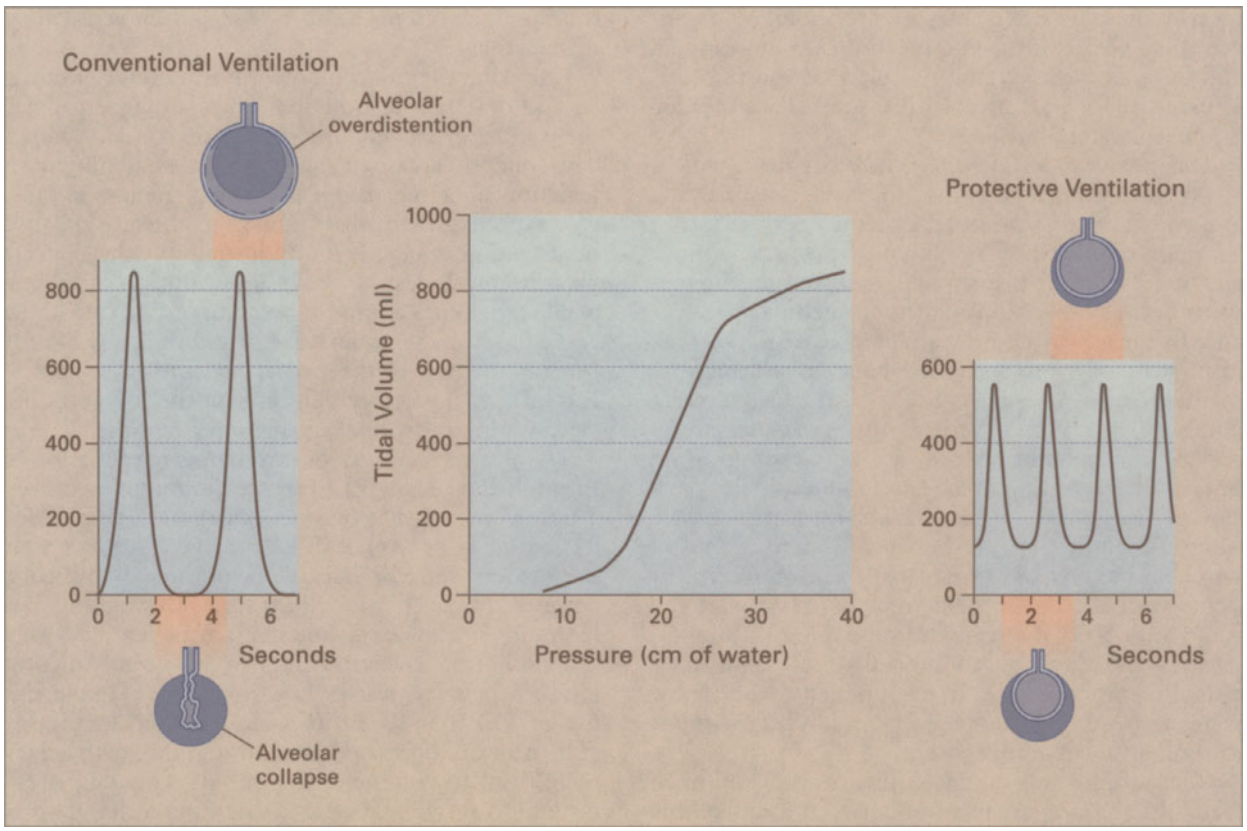

Figure 153-9 Respiratory pressure-volume curve and the effects of traditional versus protective ventilation in a 70-kg patient with acute respiratory distress syndrome. The lower and upper inflection points of the inspiratory pressure-volume curve (center panel) are at 14 and 26 cm H_2O, respectively. With conventional ventilation at a tidal volume of 12 ml/kg and zero end-expiratory pressure (left panel), alveoli collapse at the end of expiration. The generation of shear forces during the subsequent mechanical inflation may tear the alveolar lining, and attaining an end-inspiratory volume higher than the upper inflection point causes alveolar over-distention. With protective ventilation at a tidal volume of 6 ml/kg (right panel), the end-inspiratory volume remains below the upper inflection point; the addition of PEEP at 2 cm H_2O above the lower inflection point may prevent alveolar collapse at the end of expiration and provide protection against the development of shear forces during mechanical inflation. *(Reproduced Tobin MJ: Advances in mechanical ventilation.* N Engl J Med *344:1986–1996, 2001, with permission.)*

recruits the regions of the lung closest to the apex and sternum. Conversely, PEEP can increase the amount of nonaerated tissue in the regions close to the spine and diaphragm. Among patients in the early stages of ARDS, those with pulmonary causes, such as pneumonia, are less likely to benefit from PEEP than are patients with nonpulmonary causes, such as intra-abdominal sepsis or extrathoracic trauma. This distinction may be related to the type of morphologic involvement: Pulmonary causes of ARDS are characterized by alveolar filling, whereas nonpulmonary causes are characterized by interstitial edema and alveolar collapse. In the later stages of ARDS, remodeling and fibrosis may eliminate this distinction between pulmonary and nonpulmonary causes.

Even if a pressure-volume curve is not performed at the bedside, it is useful to select the PEEP level according to this conceptual framework (Fig. 153-9). A level above the lower bend in the pressure-volume curve is thought to keep alveoli open at the end of expiration, thereby preventing injury that can result from shear forces created by the opening and closing of alveoli. This level of PEEP may also prevent an increase in the amount of nonaerated tissue and, thus, atelectasis. However, the notion that the lower bend of the pressure-volume curve signals the level of PEEP necessary to prevent end-expiratory collapse, and that pressure above the upper bend signal alveolar overdistention, is a gross oversimplification. The relation between the shape of the pressure-volume curve and events at the alveolar level is confounded by numerous factors and is the subject of ongoing research and debate. An understanding of this relation is also impeded by the difficulty in distinguishing collapsed lung units from fluid-filled units on computed tomography scans.

BRONCHODILATOR THERAPY

Several obstacles are encountered when inhaled drugs are administered to ventilated patients. As a result, drug deposition to the lower respiratory tract is less than that in

ambulatory patients. Determinants of aerosol deposition include the configuration of the endotracheal tube and ventilator circuit, ventilator mode and settings, and patient-related factors.

Nebulizers have been used traditionally for the delivery of bronchodilators, but they have a number of disadvantages. Nebulizer contamination causes aerosolization of bacteria, and lack of attention to this matter by health care providers has led to epidemics of nosocomial pneumonia. Tidal volume and inspiratory flow must be adjusted to compensate for nebulizer flow. This factor is inconsequential in most adults, but instances of hypoventilation have occurred in patients who are unable to trigger the ventilator. Another shortcoming of nebulizers is the considerable variation in efficiency of different commercial brands, as well as among various batches of the same brand.

In contrast, metered-dose inhalers (MDIs) are easy to administer, involve less personnel time, and provide reliable dosing. Moreover, when MDIs are used with a collapsible cylindrical spacer, it is not necessary to disconnect the ventilator circuit for each treatment. Thus, risk of ventilator-associated pneumonia is decreased. Using MDIs instead of nebulizers results in substantial cost savings. The combination of an MDI and a chamber device achieves a four- to sixfold greater delivery of aerosol than MDI actuation into a connector attached directly to the endotracheal tube or into an in-line device that lacks a chamber. Aerosol delivery is increased with use of a higher tidal volume and longer fractional inspiratory time (T_I/T_{TOT}). Aerosol delivery is decreased by a high inspiratory flow rate; heating and humidification of inhaled gas reduce aerosol deposition by about 40 percent. When an aerosol is carried by a low-density gas, such as an 80:20 helium-oxygen mixture, aerosol delivery from a MDI is increased by more than 50 percent.

A dose-response study of four, eight, and 16 puffs of albuterol (administered with an MDI and cylindrical spacer) conducted in ventilated patients with COPD (Fig. 153-10) demonstrated a decrease in airway resistance after four puffs of albuterol; no additional effects were noted after cumulative doses of 12 and 28 puffs. In another study in ventilated patients with COPD, the bronchodilator effect of a single dose of four puffs of albuterol was sustained for at least 60 minutes. The bronchodilator effect obtained with four puffs of albuterol from an MDI was comparable to that obtained with six to 12 times the same dose given by a nebulizer.

Based on research conducted over the past decade, it is possible to formulate specific steps to achieve maximum bronchodilator effect with use of MDIs in ventilated patients (Table 153-3). Therapy can be given in combination with either controlled or assisted ventilation, provided aerosol administration is synchronized with inspiratory flow. Based on the recommended technique for use of an MDI in ambulatory patients, some authors recommend use of a postinspiratory breath hold; with optimal technique, however, this maneuver does not influence bronchodilator response in ventilated patients. Although humidification of the circuit reduces aerosol deposition, it is advisable not to bypass the humidifier. Even with a humidified circuit, significant bronchodilation can be achieved with as few as four puffs of a bronchodilator aerosol when the MDI technique is carefully executed.

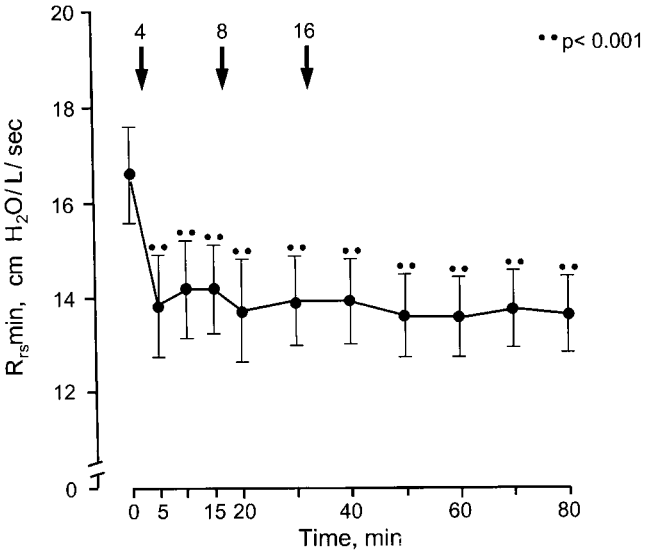

Figure 153-10 Effect of albuterol on minimal inspiratory resistance (Rrs_{min}) in 12 stable mechanically ventilated patients with chronic obstructive pulmonary disease. Significant decreases in resistance occurred within 5 minutes of administration of four puffs of albuterol. The addition of eight and 16 puffs (cumulative doses of 12 and 28 puffs, respectively) did not achieve a significantly greater effect than that with four puffs ($p > 0.05$). Bars represent SE. $^{**}p < 0.001$. *(Modified from Dhand R, Duarte AG, Jubran A, et al: Dose-response to bronchodilator delivered by metered-dose inhaler in ventilator-supported patients.* Am J Respir Crit Care Med *154:388–393, 1996, with permission)*

MONITORING AND COMPLICATIONS

Several devices can be used to monitor pulmonary gas exchange, respiratory neuromuscular function, respiratory mechanics, and patient-ventilator interaction. Use of the derived information permits the physician to better tailor ventilator settings to an individual patient's requirements, with the promise of enhancing patient comfort. Monitoring of key variables helps to minimize the risk of iatrogenic complications and alerts the physician to the likelihood of an impending catastrophe, allowing sufficient time for the institution of lifesaving measures. A detailed discussion of techniques used for monitoring of ventilator-supported patients can be found in Chapter 152 and in other textbooks.

Patients receiving mechanical ventilation are at risk for numerous complications, including O_2 toxicity, volutrauma and air leaks, decreased cardiac output, and endotracheal tube–related issues. These problems are discussed elsewhere in this volume.

Table 153-3

Technique for Using Metered-Dose Inhalers in Mechanically Ventilated Patients

1. Assure V_T > 500 ml (in adults) during assisted ventilation.
2. Aim for an inspiratory time (excluding the inspiratory pause) >0.30 of total breath duration.
3. Ensure that the ventilator breath is synchronized with the patient's inspiration.
4. Shake the metered-dose inhalers vigorously.
5. Place canister in actuator of a cylindrical spacer situated in inspiratory limb of ventilator circuit.*
6. Actuate metered-dose inhalers to synchronize with precise onset of inspiration by the ventilator.†
7. Allow a breath hold at end-inspiration for 3–5 s.
8. Allow passive exhalation.
9. Repeat actuations after 20–30 s until total dose is delivered.‡

** With metered-dose inhalers, it is preferable to use a spacer that remains in the ventilator circuit to avoid disconnecting the ventilator circuit for each bronchodilator treatment. Although bypassing the humidifier can increase aerosol delivery, it prolongs each treatment and requires disconnecting the ventilator circuit.*

† In ambulatory patients with metered-dose inhalers placed inside the mouth, actuation is recommended briefly after initiation of inspiratory airflow. In mechanically ventilated patients using a metered-dose inhaler and spacer combination, actuation should be synchronized with onset of inspiration.

‡ The manufacturer recommends repeating the dose after 1 min. Metered-dose inhalers' actuation within 20–30 s after the previous dose does not compromise drug delivery.

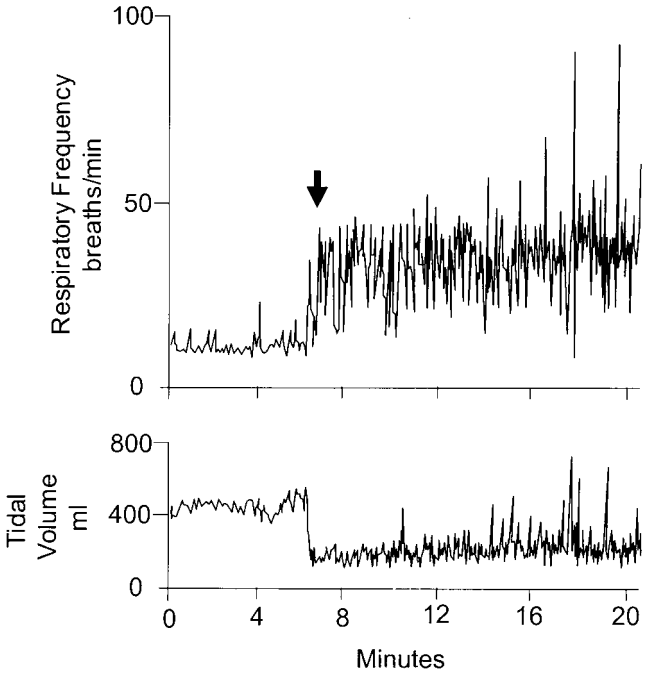

Figure 153-11 A time-series, breath-by-breath plot of respiratory frequency and tidal volume in a patient who failed a weaning trial. The arrow indicates the point of resuming spontaneous breathing. Rapid, shallow breathing developed almost immediately after discontinuation of the ventilator. *(From Tobin MJ, Perez W, Guenther SM, et al: The pattern of breathing during successful and unsuccessful trials of weaning from mechanical ventilation.* Am Rev Respir Dis *134:1111–1118, 1986, with permission.)*

WEANING

The term *weaning* literally means a slow, gradual decrease in the amount of ventilator support. However, the term is used more commonly to refer to all methods of discontinuing mechanical ventilation.

Causes of Weaning Failure

After discontinuation of mechanical ventilation, up to 25 percent of patients experience respiratory distress severe enough to necessitate the reinstitution of ventilator support. Our understanding of the basis for weaning failure in patients has advanced considerably in recent years. Among patients who cannot be weaned, disconnection from the ventilator is followed almost immediately by an increase in respiratory frequency and fall in tidal volume; that is, rapid, shallow breathing (Fig. 153-11). As a trial of spontaneous breathing is continued over the next 30 to 60 minutes, respiratory effort increases considerably, reaching more than four times the normal value at the end of this period (Fig. 153-12). The increased effort is caused mainly by worsening respiratory mechanics. Respiratory resistance increases progressively, reaching about seven times the normal value at the end of a failed weaning trial; lung stiffness also increases, reaching five times the normal value; and gas trapping, measured as $PEEP_i$, more than doubles over the course of the trial. Before weaning is started, however, respiratory mechanics in such patients are similar to patients in whom subsequent weaning is successful. Thus, unknown mechanisms associated with the act of spontaneous breathing cause the worsening of respiratory mechanics in patients who are weaning failures.

In addition to the increase in respiratory effort, an unsuccessful attempt at spontaneous breathing causes considerable cardiovascular stress. Patients can experience substantial increases in right- and left-ventricular afterload during a trial of spontaneous breathing, with increases of 39 and 27 percent in pulmonary and systemic arterial pressures, respectively. The changes are most likely attributable to the extreme negative swings in intrathoracic pressure. At the completion of a weaning trial, the level of O_2 consumption is equivalent in patients who can be weaned and in those who cannot. How the cardiovascular system meets the O_2 demand differs in the two groups of patients.

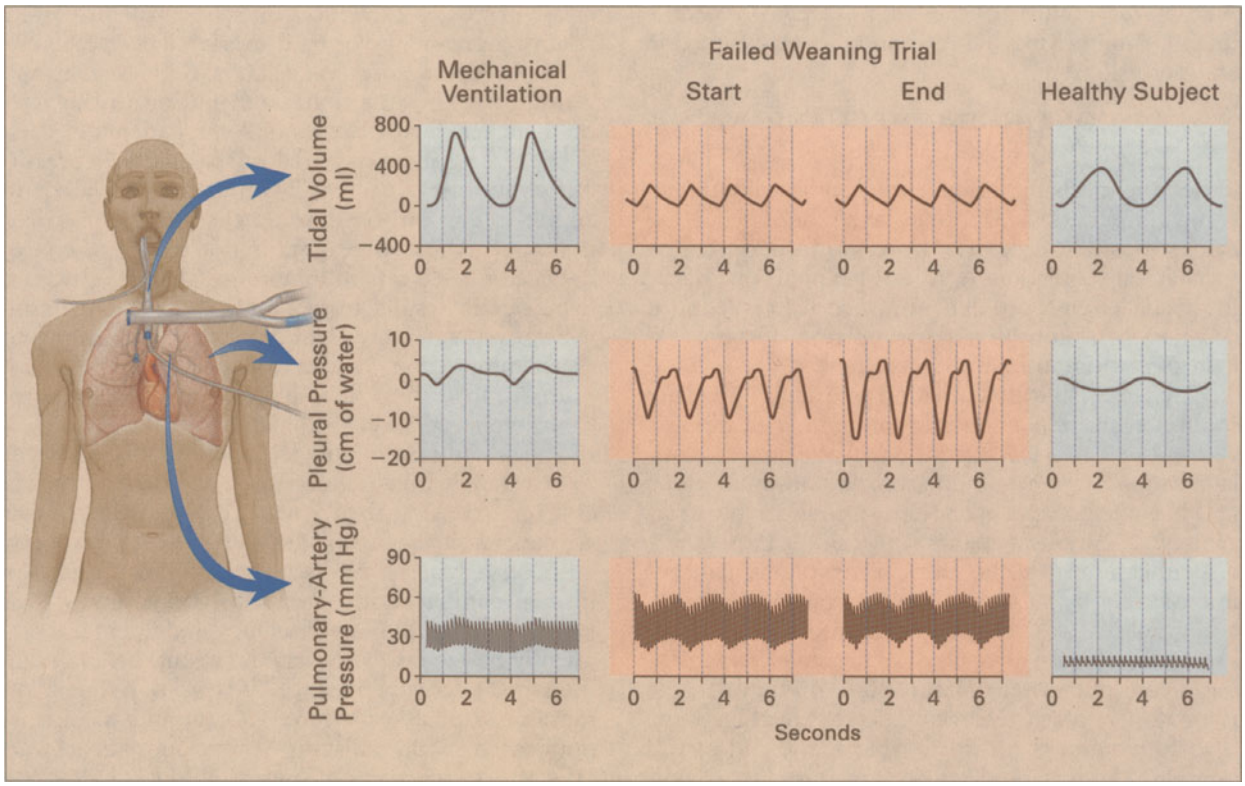

Figure 153-12 Tidal volume, pleural pressure, and pulmonary-artery pressure during assist-control ventilation and at the start and end of a failed weaning trial. During mechanical ventilation, the patient's inspiratory effort is in the normal range, and the pulmonary-artery pressure is 45/22 mmHg. At the start of the weaning trial, tidal volume falls to 200 ml, respiratory frequency increases to 33 breaths per minute, and a swing of 11 cm H_2O in pleural pressure is noted; the pulmonary-artery pressure at the end of expiration is 60/28 mmHg. At the end of the trial, 45 minutes later, the tidal volume and respiratory frequency are unchanged, a swing in pleural pressure of 19 cm H_2O is evident, and $PEEP_i$ is 4 cm H_2O; pulmonary artery pressure is 60/31 mmHg. The values in a healthy subject are tidal volume, 380 ml; respiratory frequency, 17 breaths per minute; pleural-pressure swing, 3 cm H_2O; and pulmonary artery pressure, 18/8 mmHg. *(Data are from Tobin MJ, Perez W, Guenther SM, et al: The pattern of breathing during successful and unsuccessful trials of weaning from mechanical ventilation.* Am Rev Respir Dis *134:1111–1118, 1986; Jubran A, Mathru M, Dries D, et al: Continuous recordings of mixed venous oxygen saturation during weaning from mechanical ventilation and the ramifications thereof.* Am J Respir Crit Care Med *158:1763–1769, 1998; Jubran A, Tobin MJ: Pathophysiologic basis of acute respiratory distress in patients who fail a trial of weaning from mechanical ventilation.* Am J Respir Crit Care Med *155:906–915, 1997. Reproduced from Tobin MJ: Advances in mechanical ventilation.* N Engl J Med *344:1986–1996, 2001, with permission.)*

In patients who are successfully weaned, O_2 demand is met through an increase in O_2 delivery, mediated by the expected increase in cardiac output on discontinuation of positive-pressure ventilation. In patients who cannot be weaned, O_2 demand is met through an increase in O_2 extraction; these patients have a relative decrease in O_2 delivery. The greater O_2 extraction causes a substantial decrease in mixed venous O_2 saturation, contributing to the arterial hypoxemia that occurs in some patients.

Over the course of a trial of spontaneous breathing, about half of patients in whom the trial fails have an increase in Pa_{CO_2} of 10 mm Hg or more. The hypercapnia is not usually a consequence of a decrease in minute ventilation. Instead, hypercapnia results from rapid, shallow breathing, which causes an increase in dead-space ventilation. In a small proportion of patients who cannot be weaned, primary depression of respiratory drive may be responsible for the hypercapnia.

Timing of the Weaning Process

One of the major challenges in the management of ventilator-supported patients is deciding on the right time to discontinue mechanical ventilation. If the physician is too conservative and postpones weaning onset, the patient is placed at an increased risk of life-threatening, ventilator-induced complications. Conversely, if weaning is begun prematurely, the patient may suffer cardiopulmonary or psychological decompensation of sufficient severity to set back a patient's clinical course.

In randomized trials of different weaning techniques, most patients who had received mechanical ventilation for a week or longer were able to tolerate ventilator discontinuation on the first day that weaning-predictor tests were measured. It is likely that many of these patients would have tolerated extubation a day or so earlier. As such, one of the main sources of weaning delay is the failure of the physician to *think* that the patient *just might* come off the ventilator. It is possible to speed up the weaning process by undertaking physiological assessment early in the patient's clinical course.

A cardinal precept of diagnostic testing is to begin with a screening test and follow with a confirmatory test. The characteristics of these test types differ. A single diagnostic test rarely fulfills both functions. The fundamental job of a weaning-predictor test is screening. Because the goal is to not miss anyone with the condition under consideration, a good screening test has a very low rate of false-negative results; to achieve this goal, a higher false-positive rate is acceptable. Thus, an ideal screening test has a very high sensitivity. The ratio of respiratory frequency to tidal volume (f/V_T) meets this requirement; numerous studies have documented that its sensitivity is 0.90 or higher.

The f/V_T ratio must be calculated during spontaneous breathing. Measurements of f/V_T in the presence of pressure support or CPAP will result in inaccurate predictions of weaning outcome. The higher is the f/V_T ratio, the more rapid and shallow the breathing and the greater the likelihood of unsuccessful weaning. A ratio of 100 discriminates between successful (less than 100) and unsuccessful (greater than 100) attempts at weaning.

Because the results of screening tests are often negative, an ideal screening test should be simple, expeditious, and safe. Measurement of f/V_T takes a minute or so to perform. In contrast, a trial of spontaneous breathing takes one-half to 2 hours to perform, during which time attendants commonly leave the patient's room. Accordingly, a spontaneous breathing trial does not satisfy the criteria for a desirable screening test, and commencing weaning with such a trial is likely to prolong the weaning process.

If clinicians obtain weaning-predictor tests at the earliest point that a patient might tolerate extubation, the results will be negative at least half the time. In studies of weaning-predictor tests, however, positive results have been obtained at least 75 percent of time. Such a high rate of positive test results indicates that clinicians were being too slow in initiating the weaning process.

When a screening test is positive, the diagnostician proceeds to a confirmatory test. A positive confirmatory test result essentially rules in a condition: The likelihood of a patient tolerating a trial of extubation is very high. An ideal confirmatory test has a very low rate of false-positive results, i.e., a high specificity. The specificity of a weaning trial is not known and will never be known, since its determination would require an unethical experiment—extubating all patients who fail a weaning trial and noting how many require reintubation.

Weaning Trials

Four methods can be used for conducting a weaning trial. The oldest is to perform trials of spontaneous breathing several times a day, using a T-tube circuit that contains an enriched supply of O_2. Initially 5 to 10 minutes in duration, T-tube trials are extended and repeated several times a day until the patient can sustain spontaneous ventilation for several hours. This approach has become unpopular because it requires considerable time on the part of ICU staff.

For many years, IMV was the most popular methods of weaning. With IMV, the mandatory rate from the ventilator is reduced in steps of one to three breaths per minute, and an arterial blood gas is obtained about 30 minutes after each rate change. Unfortunately, titrating the number of breaths from the ventilator in accordance with the results of arterial blood gases can produce a false sense of security. As few as two to three positive-pressure breaths per minute can achieve acceptable blood gases, but these values provide no information regarding the patient's work of breathing (which may be excessive). As noted previously, at IMV rates of 14 breaths per minute or less, patient inspiratory efforts are increased to a level likely to cause respiratory muscle fatigue. Moreover, this occurs not only with the intervening spontaneous breaths, but also with ventilator-assisted breaths. Consequently, use of IMV may actually contribute to the development of respiratory muscle fatigue or prevent its recovery.

When pressure support is used for weaning, the level of pressure is reduced gradually (decrements of 3 to 6 cm H_2O) and titrated on the basis of the patient's respiratory frequency. When the patient tolerates a minimal level of pressure support, he or she is extubated. What exactly constitutes a "minimal level of pressure support" has never been defined. For example, pressure support of 6 to 8 cm H_2O is widely used to compensate for the resistance imposed by the endotracheal tube and ventilator circuit. It is reasoned that a patient who can breathe comfortably at this level of pressure support will be able to tolerate extubation. However, if the upper airways are swollen because an endotracheal tube has been in place for several days, the work engendered by breathing through the swollen airways is about the same as that caused by breathing through an endotracheal tube. Accordingly, any amount of pressure support overcompensates and may give misleading information about the likelihood that a patient can tolerate extubation.

The fourth method of weaning is to perform a single daily T-tube trial, lasting for 30 to 120 minutes. If this trial is successful, the patient is extubated. If the trial is unsuccessful, the patient is given at least 24 hours of respiratory muscle rest with full ventilator support before another trial is performed.

Until the early 1990s, it was widely believed that all weaning methods were equally effective, and the physician's judgment was regarded as the critical determinant. However, the results of randomized, controlled trials clearly indicate that the period of weaning is as much as three times as long with IMV as with trials of spontaneous breathing. In a study involving patients with respiratory difficulties on weaning,

trials of spontaneous breathing halved the weaning time as compared with pressure support; in another study, the weaning time was similar with the two methods. Performing trials of spontaneous breathing once a day is as effective as performing such trials several times a day but is much simpler. In a recent study, half-hour trials of spontaneous breathing were as effective as 2-hour trials. This study, however, involved all patients being considered for weaning, not just those for whom there were difficulties with weaning.

In conclusion, to minimize the likelihood of either delayed weaning or premature extubation, a two-step diagnostic strategy is recommended: measurement of weaning predictors followed by a weaning trial. The critical step is for the physician to contemplate the possibility that a patient *just might* be able to tolerate weaning. Such diagnostic triggering is facilitated through use of a screening test, which is the rationale for measurement of weaning-predictor tests. It is important not to postpone this first step by waiting for a more complex diagnostic test, such as a T-tube trial.

Extubation

Decisions about weaning and extubation are commonly conflated. When a patient tolerates a weaning trial without distress, a clinician feels reasonably confident that the patient will be able to sustain spontaneous ventilation after extubation. Before removing the endotracheal tube, however, the clinician also has to judge whether or not the patient will be able to maintain a patent upper airway after extubation.

Of patients who are expected to tolerate extubation without difficulty, about 10 to 20 percent fail and require reintubation. Mortality among patients who require reintubation is more than six times as high as mortality among patients who can tolerate extubation. The reason for the higher mortality is unknown. It might be related to the development of new problems after extubation or complications associated with reinsertion of a new tube. A more likely explanation is that the need for reintubation reflects greater severity of the underlying illness.

Because of the high mortality associated with reintubation, clinicians are eager to avoid this problem. The major diagnostic test used to predict the success of an extubation attempt is a weaning trial. In contrast to the many studies that have evaluated the reliability of diagnostic tests that predict the outcome of a trial of weaning, the diagnostic accuracy of weaning trials in predicting the outcome of a trial of extubation is unknown. Moreover, the accuracy is impossible to determine, because the experiments necessary to measure the sensitivity and specificity of a weaning trial (for predicting extubation outcome) are unethical.

CONCLUSION

Since the previous edition of this textbook, we have gained a better understanding of the pathophysiology associated with unsuccessful weaning and have learned how to wean patients more efficiently. We have also learned how ventilator settings influence survival in patients with ARDS. Less progress has been made in determining how the ventilator can best be used to achieve maximal respiratory muscle rest, which is the most common reason for providing mechanical ventilation.

Nutrition in Acute Respiratory Failure

Lisa M. Bellini

OVERVIEW OF MALNUTRITION

Malnutrition is a disorder of body composition in which nutritional intake is less than required, resulting in reduced organ function, abnormalities in blood chemistry, reduced body mass, and worsened clinical outcomes. Malnutrition in the setting of acute respiratory failure (ARF) may be a preexisting condition due to underlying advanced lung disease, such as chronic obstructive pulmonary disease (COPD) (see Chapters 41 and 42); alternatively, it may develop during the course of acute illnesses that promote hypermetabolism, as occurs in acute respiratory distress syndrome (ARDS) (see Chapter 145). Regardless of the starting point, ARF results in alterations in substrate metabolism that are manifest as nutritional deficiencies and altered body composition. As the body tries to conserve protein, fat is metabolized as a principal source of energy. When fat stores are depleted, visceral and muscle protein catabolism and gluconeogenesis become the main processes for generating energy. Nutritional assessment in these settings is critical. Evaluation usually consists of determination of clinical, anthropometric, chemical, and immunologic parameters that reflect altered body composition. The assessment must be considered in light of the patient's underlying condition, as no single test is diagnostic of malnutrition.

Incidence of Malnutrition in the Intensive Care Unit

Physicians may contribute to malnutrition in the hospital setting by failing to recognize it as a complication of illness or injury and addressing it inadequately. Recognition of malnutrition does not insure that adequate nutrition repletion will

occur. When enteral feeding is undertaken in the intensive care unit (ICU), inadequate nutrition is frequently delivered because of underestimation of patients' nutritional needs and inappropriate cessation of feedings. A prospective study of patients requiring enteral feedings in an ICU found that physician prescriptions provided a mean of only 66 percent of goal caloric requirements; furthermore, a mean of only 78 percent of the ordered volume was actually infused. Cessation of enteral feeds was judged avoidable in 66 percent of cases, including circumstances when feeding was discontinued at midnight for a procedure on the following day, or was stopped for simple bedside tasks, such as bathing the patient or placement of intravenous lines. An additional study of patients with COPD presenting with ARF (with slightly over one-half requiring mechanical ventilation) revealed malnutrition in 60 percent. Malnutrition was more frequent in those that required mechanical ventilation (74 percent versus 43 percent).

In 1997, the American College of Chest Physicians (ACCP) published a consensus statement on nutrition in the ICU, aimed at guiding patient selection, timing and route of administration, nutrient use, and monitoring of nutrition support. In a study of over 1500 critically ill medical patients who had an ICU length of stay greater than 96 h, cumulative caloric intake reached only about 50 percent of ACCP-recommended guidelines. Notably, patients receiving 33 to 65 percent of recommended caloric targets were more likely to achieve spontaneous ventilation prior to discharge from the ICU, while those receiving more than 65 percent of targets were less likely to be weaned or to be discharged alive from the hospital. The findings suggest that current caloric targets may overestimate patient needs, since moderate caloric intake was associated with a better outcome.

Incidence of Malnutrition in Advanced Lung Disease

The finding that patients with advanced lung disease suffer from changes in body composition manifest by progressive weight loss has long been recognized. Thirty to seventy percent of patients with COPD have clinical evidence of malnutrition. Malnutrition associated with advanced lung disease, so-called "pulmonary cachexia syndrome," has been associated with increased mortality and decline in functional status. Although COPD has been best studied, current thinking is that all advanced lung diseases are characterized by progressive reduction in lean body mass, which is a function of many variables, including aging, exercise, metabolism, tissue hypoxia, inflammation, and use of certain medications. Importantly, basal metabolism in patients with advanced lung disease does not follow the expected normal age-related decline. Many patients are hypermetabolic, presumably secondary to an increased work of breathing. In fact, patients with COPD have a 10-fold increase in daily energy expenditure over the normal baseline of 36 to 72 calories per day.

EFFECTS OF MALNUTRITION

The effects of malnutrition may be considered with respect to the underlying pathophysiology, consequences of malnutrition during critical illness, and effects of nutritional supplementation.

Pathophysiology and Complications of Malnutrition

A reduction in food intake results in loss of fat, muscle, skin, and, ultimately, bone and viscera. Body mass declines and extracellular fluid volume increases. Nutritional requirements fall as an individual's body mass decreases, probably reflecting more efficient utilization of ingested food and a reduction in work capacity at the cellular level. However, the combination of decreased tissue mass and reduction in work capacity impedes homeostatic responses to stressors, such as acute respiratory failure.

Malnutrition causes a number of deleterious consequences, including increased susceptibility to infection, poor wound healing, increased frequency of decubitus ulcers, overgrowth of bacteria in the gastrointestinal tract, and abnormal nutrient losses in stool. These alterations result in increased morbidity and mortality in malnourished, hospitalized patients. One study of over 2000 hospitalized veterans found a 30-day mortality rate of 62 percent among those whose serum albumin concentrations fell below 2.0 g/dl. A study of over 4300 patients in ICUs revealed that those with a low body mass index (BMI) on admission (due to preexisting malnutrition) were at increased risk of death during hospitalization and at 6 mo following BMI measurement. A BMI on admission below the 15th percentile was associated with a 23 percent increase in 6-mo mortality.

Adequate nutrition is essential for reversing the physiological derangements described and for recovery from ARF. Supplemental nutrition has been demonstrated to improve morbidity and mortality in certain groups of patients, likely related to contraction of previously expanded extracellular fluid volume and repletion of protein reserves.

Protein Calorie Malnutrition and Critical Illness

Metabolic derangements are amplified during periods of critical illness, including ARF; protein calorie malnutrition is particularly detrimental in this situation. The stress of critical illness inhibits the body's natural conservation responses to malnutrition; aggressive nutritional support instituted early during a critical illness may be protective.

Hypermetabolism associated with critical illness causes a redistribution of macronutrients (fat, protein, and glycogen) from the labile reserves of adipose tissue and skeletal muscle to more metabolically active tissues, such as bone, liver, and other viscera. Within a few days, this response may lead to the onset of protein calorie malnutrition, defined as

a negative balance of 100 g of nitrogen and 10,000 kcal. The rate of development of malnutrition in critically ill patients is a function of preexisting nutritional status and degree of hypermetabolism.

In the 1940s, Cuthbertson described two phases of the metabolic response to shock: (a) an initial "ebb" phase, and (b) a later, hypercatabolic "flow" phase. The initial "ebb" phase lasts 12 to 24 h and is characterized by fever, increased oxygen consumption, decreased body temperature, and vasoconstriction. These adaptive changes reflect activation of the sympathetic nervous system and pituitary-adrenal axis, reflected in rapid rises in plasma concentrations of epinephrine, norepinephrine, adrenocorticotropic hormone, growth hormone, cortisol, and other corticosteroids. The "flow" phase, which lasts for the remainder of the acute illness, is marked by hypercatabolism and is mediated primarily by catecholamines. The hypercatabolism exceeds anabolism, resulting in net negative nitrogen balance and a shift to utilization of fat as the major fuel source. Subsequent to Cuthbertson's description, a third or "anabolic" phase was described, beginning with the onset of recovery and characterized by normalization of vital signs, improved appetite, and diuresis. The difference between the last two phases relates primarily to the level of energy expenditure.

Effects of Nutritional Supplementation in Acute Respiratory Failure

Supplemental nutrition may improve respiratory muscle strength and restore ventilatory drive and altered lung defenses. Patients with advanced lung disease often have increased ventilatory drive with a blunted response to hypoxemia. Supplemental nutrition in malnourished patients with advanced lung disease may help restore ventilatory drive, increasing the chances for successful weaning. Malnutrition in advanced lung disease may also increase the risk of infection through a detrimental effect on cell-mediated immunity and reduced cellular resistance of respiratory mucosa to bacterial infection. Introduction of an endotracheal tube may exacerbate the latter effect.

Several retrospective studies suggest that supplemental nutrition may facilitate weaning from mechanical ventilation. Although a randomized, prospective controlled trial on the effects of supplemental nutrition on weaning has yet to be done, current evidence supports the notion that nutritional support is an important determinant of weaning success.

ASSESSMENT OF NUTRITIONAL STATUS

Early detection of malnutrition in ARF enables prompt and aggressive intervention using supplemental nutrition. No single measurement or assessment tool can adequately characterize nutritional status, and the diagnosis of malnutrition remains somewhat subjective. However, both functional and biochemical parameters should be examined to identify patients at increased risk for developing malnutrition and its complications.

Functional Assessment

Functional nutritional assessment consists of a medical history, physical examination, and appraisal of muscle and organ function. Identification of preexisting malnutrition (i.e., malnutrition occurring prior to the onset of respiratory failure) is made by careful attention to the history of present illness and relevant past medical and surgical history, a focused dietary history, and review of the patient's medications and social habits. This information usually needs to be obtained from the patient's family. The degree to which the patient's usual weight deviates from estimated ideal body weight should be considered; the period of time over which the weight has changed is important in evaluating the severity of weight loss.

Historical data should be used to estimate the nutritional consequences of the current hospitalization. Prehospitalization weights should be documented, and any weight changes since hospitalization should be noted and evaluated in the context of concomitant diuresis or fluid supplementation.

Physical examination may suggest the presence of nutritional and metabolic deficiencies. Temporal muscle wasting, sunken supraclavicular fossae, and decreased adipose stores are easily recognized signs of starvation. Careful inspection of the hair, skin, eyes, mouth, and extremities may reveal additional stigmata of protein calorie malnutrition or vitamin and mineral deficiencies.

An assessment of muscle mass and function may yield information about a patient's protein reserves and overall nutritional status. Estimation of muscle mass and fat stores can be obtained from anthropometric measurements, such as arm circumference or triceps skin fold measurements. These methods are simple, safe, cost effective, and standardized; however, interpretation of results remains controversial, limiting their use in the intensive care setting.

Cardiovascular, respiratory, and gastrointestinal functions should be evaluated with regard to both evidence of malnutrition-related dysfunction and the ability of the patient to tolerate nutritional supplementation. Administration of large fluid volumes associated with parenteral nutrition may be limited by impaired cardiovascular function. Abdominal distention may make use of enteral supplementation difficult.

Newer methods of nutritional assessment that have not been well studied to date include magnetic resonance imaging (MRI), whole body conductance and impedance, and neutron activation.

Metabolic Assessment

Information from select laboratory tests may complement the functional assessment and should be evaluated in every patient during the standard nutritional evaluation.

Serum albumin concentration is the most frequently used laboratory measure of nutritional status; values less than 2.2 g/dl generally reflect severe malnutrition. Although serum albumin is used popularly as an indicator of nutritional status, its value as a surrogate for visceral protein status is limited. Because albumin has a long half-life of 14 to 20 d, its serum level does not accurately reflect acute changes in nutritional status. Furthermore, serum albumin concentration rises rapidly in response to exogenously administered albumin and fluctuates in conditions such as dehydration, sepsis, trauma, and liver disease, irrespective of nutritional status.

Prealbumin (transthyretin) is a more reliable indicator of nutritional status than is albumin because its half-life of 24 to 48 h makes its plasma concentration more reflective of current nutritional state. However, as is the case with albumin, the concentration of prealbumin is diminished in renal and liver disease. Transferrin, with a half-life of 9 d, makes it intermediate between prealbumin and albumin with regard to its sensitivity for identifying incipient malnutrition.

Although serum chemistry values are important in determining the specifics of nutritional support, they do not directly reflect nutritional status. Serum sodium, potassium, chloride, total carbon dioxide, blood urea nitrogen, glucose, iron, magnesium, calcium, and phosphate, as well as prothrombin and partial thromboplastin times, should be measured on admission and rechecked periodically.

Adequacy of cellular immunity may be estimated by measuring total lymphocyte count (TLC) and delayed-type hypersensitivity testing using a series of common antigens (e.g., *Candida, Trichophyton,* tuberculin, diphtheria, and a glycerin control). Compromise of cell-mediated immunity due to malnutrition is suggested by a TLC less than or equal to 1000/mm^3 or lack of skin test induration greater than 5 mm above the glycerin control at 48 h (unless another cause of lymphocyte dysfunction is present). Delayed-type hypersensitivity testing is least useful during an acute illness, because cell-mediated immunity may be depressed in this setting, even in the absence of malnutrition. Furthermore, technical application and interpretation are variable.

INDICATIONS FOR NUTRITIONAL SUPPORT

Adequate nutrition is essential for recovery from ARF. Indications for enteral or parenteral nutritional support include preexisting nutritional deprivation, anticipated or actual inadequate oral caloric intake, and significant multiorgan system disease (Table 154-1).

Although supplemental nutrition is a lower priority during the resuscitative phase of respiratory failure, it's use becomes increasingly important once a patient is stabilized and should be initiated as soon as feasible. Critically ill patients should not be allowed to remain in a state of unopposed starvation because this increases morbidity and mortality, particularly in the setting of multisystem organ failure. Several studies support early initiation of nutritional support in the ICU. A randomized multicenter trial of almost 500 critically ill patients found that early initiation of nutritional support reduced duration of hospitalization from 35 to 25 d; a trend toward reduced mortality was also noted. A related study of medical patients admitted to the ICU indicated that low caloric intake was independently associated with nosocomial blood stream infection.

Table 154-1

Indications for Nutritional Support

Preexisting malnutrition (i.e., BMI <19)
Anticipated inadequate oral intake
Significant multiorgan system disease

GOALS OF NUTRITIONAL SUPPORT

The goals of nutritional support are different in the different phases of critical illness, which are distinguished on the basis on energy expenditure. In the first several days of critical illness (the "ebb" and "flow" nutritional phases described previously), hypercatabolism exceeds anabolism, resulting in net negative nitrogen balance and a shift to utilization of fat as the major fuel source. During this time, the goal of metabolic support is to maintain vital organ structure and function and attenuate the complications of sepsis, shock, and multisystem organ failure. Metabolic support can blunt the negative nitrogen balance and minimize further protein wasting. However, such support cannot reverse the negative nitrogen balance entirely until patients enter the third, or anabolic, phase of critical illness. At this point, nutritional goals shift to achieving a positive nitrogen balance and repleting protein stores.

ROUTE OF ADMINISTRATION AND COMPLICATIONS

Nutritional support may be administered enterally or parenterally. Clinical circumstances dictate which method is employed.

Enteral

Enteral nutrition is preferred over parenteral nutrition because of its lower cost, fewer and less severe complications, lower rates of infection, better rates of wound healing, and association with lower gut mucosal permeability. Enteral feeding requires adequate gastric motility. Impaired gastric

Table 154-2

Complications of Nutritional Support

	Enteral	Parenteral
Mechanical	Aspiration Pharyngitis Otitis Sinusitis Airway occlusion	Bleeding Pneumothorax Infection Thromboembolism
Metabolic	Hyperglycemia Hyper-, hypophosphatemia Hyper-, hypokalamia Hyper-, hyponatremia Hyper-, hypocalcemia Hyper-, hypomagnesemia	Hyperglycemia Hyper-, hypophosphatemia Hyper-, hypokalemia Hyper-, hyponatremia Hyper-, hypocalcemia Hyper-, hypomagnesemia Metabolic acidosis Azotemia Elevated liver–associated enzymes
Gastrointestinal	Diarrhea Bowel/abdominal distention Vomiting Constipation	

emptying can be assessed by checking gastric residual volumes of the tube feedings. Volumes greater than 150 ml should prompt consideration of decreasing the infusion rate, alternative use of intravenous nutritional supplementation, or small bowel feeds. The efficacy of gastric motility agents has not been proved.

Complications of enteral feeding fall into three categories: mechanical, gastrointestinal and metabolic (Table 154-2). The most common complication of enteral feeding is diarrhea, the cause of which may be difficult to discern in the critical care setting, when patients are receiving multiple medications that may be responsible. Evaluation of enteral feeding as the cause of diarrhea begins with adjustment of a single parameter at a time, e.g., infusion volume, rate, or osmolality. Persistent diarrhea despite use of a low infusion volume infusion of a neutral formula should prompt investigation of other causes and, when appropriate and not contraindicated, use of antimotility agents.

Parenteral

Although parenteral nutrition is *presumed* to be preferable to no nutrition in patients who cannot tolerate enteral feedings, this hypothesis has not been rigorously tested. In fact, a meta-analysis of 26 studies that enrolled over 2200 patients did not demonstrate a decrease in mortality or complications in those receiving total parenteral nutrition (TPN) compared with those receiving standard care with intravenous dextrose until able to receive an oral diet. The parenteral route is recommended for those patients in whom enteral nutrition is not possible or is insufficient for meeting nutritional goals.

Complications of parental nutrition can be divided into mechanical and metabolic categories (Table 154-2). Most mechanical complications are related to establishing access for the infusion. Infection is a primary concern. Metabolic complications include the same as with enteral feeding, as well as metabolic acidosis, azotemia, and an increase in liver-associated enzymes.

BASIC NUTRITIONAL PRESCRIPTION

The initial parental nutrition regimen for patients with ARF, but without underlying lung disease, centers around administration of a concentrated, low-volume solution to replete electrolytes and address acid-base issues. Thereafter, caloric and protein content (and hence, volume) are increased over several days, progressing over a period of days (Table 154-3).

Enteral regimens typically begin with the agent at full concentration, delivered at a rate of 10 to 20 ml per h. The rate can be increased by 10 to 20 ml every 12 to 24 h until the goal rate is reached. This process should take no more than 4 d.

Table 154-3

Basic Nutrition Prescription

Calculate caloric need based on BEE:

BEE (men) = 66.5 + 13.7W + 5H − 6.8A

BEE (women) = 655.1 + 9.6W + 1.8H − 4.7A

where W = weight, kg
H = height, cm
A = age, years

Multiply total caloric need by stress factor, if applicable:

Stress	*Examples*	*Multiplier*
Mild	Stable postoperative state	1.0–1.25
Moderate	Pneumonia, peritonitis	1.25–1.5
Severe	Sepsis, burn, cancer, BMI <19	1.5–2.5

Administer total calories in a volume consistent with the total fluid needs of the patient. One ml of water is necessary for each kcal administered.

Consider recommended distribution of macronutrients:

Macronutrient	*% Total Calories*
Glucose	30–70%
Fat	15–30%
Protein	15–20%

Consider recommended micronutrients and electrolytes, as necessary:

Micronutrient	*Dose*	*Frequency of Administration*
Multivitamin	1 unit	Weekly
Vitamin K	10 mg	Weekly
Mineral aliquot	Premixed	Daily
Iron	2 mg	Daily
Zinc	5–10 mg	Daily

A patient's fluid and electrolyte status must not be compromised by use of nutritional supplementation. The initial volume of the supplement must be based upon careful assessment of the patient's volume. Electrolyte balance is restored and maintained through daily assessment of losses and requirements. Simultaneously, glycemic control is achieved by balancing glucose and insulin requirements. Once these metabolic parameters are stabilized, attention centers on insuring that protein and calorie needs are met (see below). Vitamins, trace elements, and lipids are added to complete the nutrition prescription. Despite the association of low albumin with severe malnutrition, administration of supplemental albumin does not improve morbidity or mortality.

Energy Requirements

Energy needs are calculated on the basis of *basal energy expenditure* (BEE). BEE is the amount of energy required to perform metabolic functions at rest; it is influenced by both body size and illness. BEE is estimated using the Harris-Benedict equations (1) and (2):

For men:

$$\text{BEE} = 66.5 + (13.7 \times \text{weight}) + (5 \times \text{height}) - (6.8 \times \text{age}) \quad (1)$$

For women:

$$\text{BEE} = 655.1 + (9.6 \times \text{weight}) + (1.8 \times \text{height}) - (4.7 \times \text{age}) \quad (2)$$

where weight is expressed in kg, height in cm, and age in years

In using these equations, weight is the usual or actual weight of the patient for those without significant weight loss; for those with significant weight loss, current weight is used; for obese patients, ideal body weight is used.

Traditionally, use of BEE measurements in critical illness has involved multiplication by a "stress factor" of 0.5 to 2.5. Application of the stress factor may result in overfeeding and may predispose the patient to liver steatosis, hyperglycemia, electrolyte imbalances, respiratory compromise due to increased CO_2 production, and macrophage

dysfunction. Use of the standard Harris-Benedict equation (without the stress factor) in determining the BEE of critically ill patients yields an average estimate of 25 kcal/kg body weight per day. Evidence suggests that total energy expenditure is maximal during the second week of critical illness, at which time it may reach 50 to 60 kcal/kg per day.

Glucose Requirements

Glucose administration may provide 30 to 70 percent of total daily calories. The amount is adjusted based on serum glucose measurements, aiming to keep levels less than 144 mg/dl. Administration of insulin may be required.

Protein Requirements

The patient's protein requirements depend upon the degree of metabolic stress to which he or she is exposed. Generally, 15 to 20 percent of daily calories may be administered as protein or amino acids. Importantly, mild or moderately stressed underweight patients have the protein requirements as severely stressed normal or obese patients (2 to 2.5 g/kg/day). Based upon periodic metabolic monitoring, formula protein content should be adjusted to promote positive nitrogen balance and support synthetic function.

Fat Requirements

Fat is added to the formula to prevent essential fatty acid deficiency. In general, 15 to 30 percent of calories should be administered as polyunsaturated fatty acids.

Micronutrients

Phosphate, magnesium, potassium and zinc should be administered in amounts necessary to keep serum levels normal. Consensus on the administration of vitamins, minerals, or trace elements is currently lacking.

Immunonutrition

Interest is growing in assessment of specific enteral formulations, particularly those with high concentrations of arginine, glutamine, nucleotides, or omega-3 fatty acids, to improve patient mortality and decrease infectious complications. In addition to providing nutritional support, these formulations appear to offer beneficial effects on immunologic and inflammatory responses to critical illness. However, results from randomized trials and systematic reviews have yielded equivocal results.

Glutamine

Glutamine is a precursor for nucleotide synthesis and an important fuel source for rapidly dividing cells, such as gastrointestinal epithelia. Animal experiments have shown that glutamine supplementation can prevent or ameliorate the gastrointestinal mucosal atrophy seen during prolonged parenteral nutrition. Glutamine may facilitate gastrointestinal mucosal healing after damage by radiotherapy or chemotherapy. Possible benefits of glutamine supplementation have been evaluated in more than 30 controlled trials, most of which, unfortunately, have significant methodologic problems or are too small to permit definitive conclusions. A meta-analysis of 14 randomized trials found that glutamine, especially when given parenterally and at high doses, may improve outcome in postoperative and critically ill patients. However, at present, identification of indications for glutamine supplementation awaits the results of larger clinical trials.

Arginine and Omega-3 Fatty Acids

Arginine is an amino acid with important roles in nitrogen and ammonia metabolism and in the generation of nitric oxide. Animals subjected to wounds or fractures demonstrate improved rates of wound healing, nitrogen retention, and growth when given supplemented dietary arginine. In addition, rats administered arginine-supplemented parenteral nutrition show increased ability to synthesize acute phase proteins when challenged with sepsis. Fatty acids of the omega-3 series have profound effects upon cell membrane fluidity and stability, receptor expression and function, and activation of intracellular signaling pathways.

Multiple randomized trials of "immunonutritional" formulations have been undertaken, primarily in the setting of critical medical illness or routine postoperative recovery. Results have been mixed: Immunostimulation may help counteract the immunosuppressive effects of surgery, but they also may aggravate the systemic inflammatory response in patients with critical illness.

MONITORING

The most important goal of monitoring nutrition supplementation is avoidance of overfeeding and metabolic derangements.

Nitrogen Balance

Monitoring of nitrogen balance is the best method of assessing effectiveness of supplemental nutritional therapy. Nitrogen balance is determined by measuring concurrent protein intake and urinary excretion of urea nitrogen (UUN) over 12 or 24 h. Urea nitrogen is a waste product of protein metabolism that is minimally resorbed by the kidney. Nitrogen balance is the difference between the intake and loss of nitrogen. A positive or negative protein balance is used to determine the adequacy of protein intake. Nitrogen balance is calculated using the following equation:

$$\text{Nitrogen balance} = (\text{protein intake}/6.25) - (\text{UUN} + 4) \quad (3)$$

where protein intake and UUN are each expressed in grams

The factor 6.25 is based on dietary protein containing 16 percent nitrogen. The factor 4 accounts for the obligatory, nonurea nitrogen losses in skin and feces. The current recommendation is to monitor nitrogen balance every 5 to 6 d.

In the initial stages of critical illness, the goal of nutritional therapy is to maintain a nitrogen balance of zero. A negative balance of 0 to 5 represents moderate stress, while a negative balance greater than 5 represents severe stress. Once the anabolic or recovery phase is entered, the goal is to maintain a positive nitrogen balance to allow for repletion of protein stores.

Glucose Control

Hyperglycemia and insulin resistance are common in critically ill patients, even in the absence of a history of diabetes mellitus. These problems are often compounded by initiation of parenteral or enteral feeding. The general approach to managing such patients traditionally has focused on keeping blood glucose levels under 200 mg/dl (11.1 mmol/L). A prospective, controlled trial of over 1500 mechanically ventilated patients in surgical ICUs suggested that tighter blood glucose control may have a profound effect on mortality.

Patients were assigned randomly to intensive insulin therapy (target blood glucose of 80 to 100 mg/dl [4.4 to 5.6 mmol/L]) or standard care (target blood glucose of 180 to 200 mg/dl [10 to 11.1 mmol/L]). Mortality while in the ICU and overall in-hospital mortality were lower in the more rigorously controlled group (4.6 versus 8 percent and 7.2 versus 10.9 percent, respectively). Over 97 percent of patients in the rigorously controlled group received intravenous insulin, compared with 33 percent in the control group. Episodes of hypoglycemia (glucose less than 40 mg/dl [2.2 mmol/L]) were more common in the rigorously controlled group (5 versus 0.7 percent); however, no episodes of hemodynamic instability or seizures were observed in association with hypoglycemia.

In addition, retrospective analysis of the data noted that glycemic control, rather than cumulative insulin dose, was more closely associated with improvements in outcome, including mortality, bacteremia, and development of critical illness, polyneuropathy. In-hospital mortality was significantly higher in patients whose mean blood glucose was 110 to 150 mg/dL (6.1 and 8.3 mmol/L) versus those with a mean level under 110 mg/dl (6.1 mmol/L).

In a subsequent, prospective, observational study of 523 adult critically ill patients, survival also correlated with glucose control, rather than cumulative insulin dose. The authors of this study suggested that a slightly higher target serum glucose (less than 144 mg/dl, rather than 110 mg/dl) might optimize survival and decrease the risk of iatrogenic hypoglycemia.

Other Monitoring

Daily monitoring of potassium, sodium, BUN, calcium, magnesium, phosphate, and zinc concentrations is usually recommended. Worsening prerenal azotemia may be related to protein administration and should prompt re-evaluation of the protein contribution to total calories. Triglyceride monitoring should be performed weekly. If triglyceride levels are greater than 500 mg/dl, total calories, percent of calories derived from fatty acids, or both, should be reduced. Visceral protein levels (serum prealbumin and transferrin) should be monitored weekly, recognizing that their levels may not represent a response to feeding. Liver-associated enzymes should be assessed weekly. Mild elevations should not prompt a change to liver-specific formulas (see Table 154-2).

SPECIAL CONSIDERATIONS IN PATIENTS WITH ADVANCED LUNG DISEASE

Several issues are unique in regard to nutritional support of patients with advanced lung disease who have ARF. Supplemental nutrition is associated with an obligate increase in basal metabolic rate and has a profound effect on gas exchange. Since the breakdown of nutrition products consumes oxygen and generates carbon dioxide, supplemental nutrition increases ventilatory demand. Patients with advanced lung disease have limited ability to respond to increases in ventilatory demand, making difficult ventilatory management and weaning. The desire to limit carbon dioxide production in mechanically ventilated patients has led to a number of studies exploring use of varying nutrient compositions on this metabolic parameter. Comparison of isocaloric formulas containing pure carbohydrates with those containing a mixture of carbohydrates and lipids has demonstrated that the mixtures generally produce lower rates of carbon dioxide production. In fact, excessive carbon dioxide production is well documented when carbohydrate intake is greater than energy demand (i.e., one and one-half times or more the resting energy expenditure). Utilization of exogenous protein as a substrate for anabolism requires nonprotein calories, such as carbohydrates or fat. Thus, increasing protein intake beyond what is appropriate for critical illness is unlikely to play a major role in regulating ventilatory demand.

Administration of lipids intravenously may adversely impact oxygenation in certain situations. Lipid infusions have been associated with transient reductions in diffusion capacity in noncritically ill patients. Although results of studies of lipid infusions in critically ill patients are conflicting, a mechanism for reduced oxygenation appears to be related to modulation of lung prostaglandins levels. Changes in gas exchange typically are clinically insignificant and are eliminated with infusions under 4 to 8 h in duration.

Current recommendations call for patients with advanced lung disease to receive mixed carbohydrate-fat diets in which the fat compromises 20 to 40 percent of total calories. The increase in carbon dioxide production using a mixed carbohydrate-fat diet is minimal; furthermore, if calories provided match energy expenditure, consequences

should be of little clinical significance. Use of very high fat (providing more than 40 percent of calories) or very low fat (providing fewer than 15 percent of calories) diets is not recommended. The former may reduce carbon dioxide production, but are usually poorly tolerated and result in diarrhea and abdominal discomfort. The latter do not deliver enough essential fatty acids in critically ill, stressed patients and usually increase carbon dioxide production.

Treatment of Agitation in the Intensive Care Unit

John P. Kress • Jesse B. Hall

Critically ill patients often require sedatives and analgesics, especially when mechanical ventilation is necessary. Most patients with respiratory failure experience a subjective sense of respiratory distress; furthermore, endotracheal intubation and positive pressure ventilation are uncomfortable for most patients in the intensive care unit (ICU). Patients in the ICU frequently experience pain. As a result, most receive analgesics along with sedatives while undergoing mechanical ventilation. Indeed, a recent multicenter international cohort study reported that 68 percent of mechanically ventilated patients received sedation for a median number of 3 days; 13 percent of mechanically ventilated patients received neuromuscular blocking agents at some point during mechanical ventilation.

Many sedative and analgesic drugs are available for managing agitation in the ICU. Recent studies reporting outcomes of critically ill patients have advanced our understanding of sedative and analgesic pharmacology in this setting. Drugs used for treatment of agitation in the ICU are extremely potent. A growing awareness of their enduring effects when the agents are used without discretion has dramatically impacted strategies for their administration.

SEDATION

Sedation is an important part of the management plan for many patients in critical care units. This section focuses on indications for use of sedative drugs, assessment of their efficacy, and clinical use of the most commonly employed agents.

Indications

Sedation requirements vary widely in mechanically ventilated patients. Although nonpharmacologic approaches, such as comfortable positioning in bed and verbal reassurance, are reasonable initial considerations, treatment using pharmacologic agents is frequently needed. Effective prescribing of sedatives in critically ill patients begins with an understanding of indications for their use.

Anxiety occurs frequently in patients undergoing mechanical ventilation and is one of the most common indications for sedation. Anxiety may result from uncomfortable experiences, such as the presence of an endotracheal tube; uncertainty of one's surroundings, diagnosis or prognosis; or isolation from family and friends. In addition, anxiety

frequently occurs in conjunction with pain, and analgesia should be considered concurrently with sedation; this topic is discussed in detail in a subsequent section.

Dyspnea is common in mechanically ventilated patients and may be a source of distress requiring sedation. Excessive coughing may contribute to patient-ventilator dyssynchrony in some patients. Many patients requiring mechanical ventilation suffer from cardiopulmonary instability and impaired gas exchange. Sedatives may be required to facilitate routine nursing care, particularly in mechanically ventilated patients. Procedures such as endotracheal suctioning, dressing changes, and repositioning often elicit distress requiring sedatives.

Autonomic instability and elevated endogenous catecholamine activity are common in mechanically ventilated patients and may lead to hemodynamic changes (e.g., tachycardia, hypertension) that may elicit myocardial ischemia, particularly in patients at risk for coronary artery disease. Sedatives may be administered to counter such autonomic hyperactivity. Elevations in oxygen consumption (V_{O_2}) and carbon dioxide production (V_{CO_2}) may compromise patients. Reduction of oxygen consumption can stabilize the balance between oxygen supply and demand by reducing V_{O_2}. The reduction may be critical in mechanically ventilated patients with shock or severe hypoxemic respiratory failure.

Amnesia is often cited as an indication for sedation of mechanically ventilated patients. For those mechanically ventilated during surgical procedures, the importance of amnesia is indisputable. In contrast, for patients mechanically ventilated during critical illness, the necessity of continuous amnesia is far less certain. Although amnesia for certain periods during the course of a critical illness requiring mechanical ventilation is logical (e.g., with performance of invasive procedures), complete amnesia for extended periods in the ICU does not appear to be beneficial. In fact, recent findings suggest that prolonged amnesia in the ICU may be detrimental to long-term neuropsychiatric recovery from critical illness. One circumstance in which amnesia is mandatory is during administration of neuromuscular blocking drugs.

The relationship between delirium and sedation is well established. Delirium—defined as an acutely changing or fluctuating mental status, inattention, disorganized thinking, and an altered level of consciousness that may or may not be accompanied by agitation—occurs in most critically ill patients. Hyperactive or agitated delirium may occur with anxiety, as well as sepsis, fever, encephalopathy (e.g., hepatic or renal), withdrawal syndromes (e.g., alcohol, tobacco, or illicit drugs) or use of certain medications. Hyperactive delirium is frequently treated with neuroleptic medications, such as haloperidol.

A much greater percentage of mechanically ventilated patients exhibit a hypoactive form of delirium. Whether hypoactive delirium responds to pharmacologic therapy is unclear. Available evidence suggests that sedative medications are more likely to exacerbate, rather than alleviate, hypoactive delirium.

Assessing Adequacy of Sedation

Assessment of the adequacy of sedation requires awareness and consideration of its indications. A reliable instrument for categorizing the level of sedation is necessary, and several sedation scales are currently available for use in the ICU.

The Ramsay scale is the most frequently utilized in clinical investigations of sedation. While it offers the benefit of simplicity, the Ramsay scale does not effectively measure quality or degree of sedation with regard to the indications outlined above. In addition, the scale has not been validated objectively.

More recently, other sedation scales, such as the Sedation Agitation Scale (SAS) and the Richmond Agitation-Sedation Scale (RASS) have been examined thoroughly for validity and reliability. The RASS is, perhaps, the most extensively evaluated scale. The scale's utility in detecting changes in sedation status over consecutive days of critical care and against constructs of level of consciousness and delirium have been validated. Furthermore, the RASS has been shown to correlate with doses of sedative and analgesic medications administered to critically ill patients. Because of their more rigorous scientific validation, the RASS and SAS are preferable to the Ramsay Scale.

Assessment of sedation adequacy is performed at the bedside. Guidance from nurses is useful, as changes in level of sedation are typically noticed first by the bedside nurse. In practice, protocols for sedative administration must take into account that, most often, drug administration is titrated by the nurse. Theoretically, optimal sedation results in a state in which all indications for sedation are addressed while the patient is fully communicative with caregivers. Although a communicative state of wakefulness during sedative administration is ideal and achievable, for many patients, the stresses of mechanical ventilation do not permit its attainment. Instead, many mechanically ventilated patients require sedation to a point at which constant communication is impossible.

An automated electronic device to monitor the sedation level would be useful in the care of mechanically ventilated patients. One such device, the bispectral index monitor, has been shown to track the level of consciousness under general anesthesia. The monitor is based on processing of raw EEG signals into a discrete, scaled number from 0 to 100, which reflects the level of cortical activity (0 indicating absence of cortical activity and 100 indicating full wakefulness). Preliminary data suggest a good correlation between the bispectral index and the SAS and RASS. However, the device has not been thoroughly evaluated in the ICU and awaits more extensive validation before its role in the critical care setting is established.

Selection of Agent

Once an indication for sedation is established, the clinician must choose one or more drugs. The use of commonly employed agents and their pharmacologic properties are outlined below.

Benzodiazepines

Benzodiazepines potentiate gamma-aminobutyric acid (GABA) receptor-mediated inhibition of the central nervous system (CNS). The GABA receptor complex regulates a cell membrane chloride channel by increasing intracellular flow of chloride ions. This activity causes hyperpolarization of neurons, raising their excitability threshold. The GABA receptor can be competitively antagonized using the synthetic agent, flumazenil, thereby reversing the pharmacologic effects of benzodiazepines. Midazolam, lorazepam, and diazepam are the three available parenteral benzodiazepines.

The onset of action of midazolam is rapid (0.5 to 5 min), and the duration of action following a single dose is short (approximately 2 h). All parenteral benzodiazepines are lipid soluble and have a large volume of distribution; therefore, they are widely distributed throughout body tissues. The duration of action following a single bolus of a parenterally administered benzodiazepine is dependent mainly on the rate of redistribution to peripheral tissues, especially adipose tissue. Midazolam undergoes hepatic metabolism and renal excretion. Alpha hydroxyl midazolam is a pharmacologically active metabolite that may accumulate in patients with impaired renal function. When midazolam is administered to critically ill patients by continuous infusion over extended periods, accumulation of the drug in peripheral tissues can occur, leading to prolonged clinical effects. Obese patients with larger volumes of distribution, and elderly patients with decreased hepatic and renal function, may be even more prone to prolonged effects.

Parenteral lorazepam has a somewhat slower onset of action (5 min) compared to midazolam due to lower lipid solubility and resultant reduced ability to cross the blood-brain barrier. The duration of action following a single dose is longer than that of midazolam (typically 6 to 10 h), depending on the dose given. Critically ill patients requiring mechanical ventilation may show a wide range of responses to the drug.

Parenteral diazepam has a rapid onset of action (1 to 3 min) and a limited duration of action (30 to 60 min) following a single dose, due to high lipid solubility. However, once peripheral tissues become saturated, recovery from the drug's effects can be prolonged for days. Diazepam has several active metabolites that may impair recovery time. Because of the tendency for drug accumulation with diazepam, it is rarely used in patients in the ICU.

Pharmacodynamic effects of all three of the benzodiazepines described are similar. All cause a dose-dependent suppression of awareness along a spectrum from mild reduction in responsiveness to obtundation. They are potent anxiolytic drugs and reliably produce amnesia. All benzodiazepines have anticonvulsant properties; lorazepam is the preferred agent for treatment of generalized seizures. Rarely, paradoxical agitation may occur in patients given benzodiazepines; the agitation may accelerate with additional doses and is more frequently observed in elderly patients.

All benzodiazepines induce a dose-dependent depression of respiratory drive. Benzodiazepine-induced depression of ventilation is less extreme than that seen with opiates; however, concurrent use of both agents may have a synergistic effect. Distinguishing benzodiazepine- from opiate-induced respiratory depression may be difficult. A pattern of reduced tidal volume and slightly increased respiratory rate is more characteristic of a benzodiazepine's effect, while opiates tend to produce slow, deep breathing.

Benzodiazepines have minimal cardiovascular effects in euvolemic patients; a slight decrease in blood pressure without a significant change in heart rate may be observed. Effects are potentiated in the presence of hypovolemia. For patients with elevated endogenous sympathetic drive, more profound decreases in blood pressure may be seen.

Table 155-1 summarizes the pharmacologic properties of the parenteral benzodiazepines. Dependence and withdrawal can be seen in patients receiving benzodiazepines for extended periods after the drugs are discontinued. Benzodiazepine withdrawal may be difficult to detect, since the signs (e.g., autonomic hyperactivity) are relatively nonspecific, particularly in critically ill patients. Accordingly, a high index of suspicion is necessary, especially for patients who have received these drugs for a protracted period.

Propofol

Propofol appears to act on the GABA receptor, although not at the same site as do the benzodiazepines. The drug is hydrophobic and must be prepared for administration as a lipid emulsion. The lipid solubility leads to rapid onset of sedation, since time required to cross the blood-brain barrier is short. High lipid solubility also permits rapid redistribution of propofol to peripheral tissues; therefore, the duration of effect is typically measured in minutes. With prolonged, continuous infusions, the duration of effect may be increased slightly, but rarely does it last beyond 60 min from the time the infusion is discontinued. When a propofol infusion is stopped, the drug is slowly redistributed back to the plasma from peripheral tissue stores; however, the redistribution is usually not clinically significant because of the drug's high lipid affinity. Propofol is ultimately metabolized primarily in the liver. The elimination half-life is 4 to 7 h and there are no active metabolites.

Propofol has predictable pharmacodynamic effects on the CNS, acting as a hypnotic agent and causing dose-dependent depression of responsiveness and awareness. The drug is also a potent anxiolytic and amnestic agent. Indeed, at high infusion rates, propofol is commonly used for general anesthesia. In addition, propofol is currently viewed by most authorities as an effective anticonvulsant, although preliminary reports of its impact on seizure threshold were conflicting. Propofol has no detectable analgesic activity and is not recommended as the sedative in management of mechanically ventilated patients, since pain control is important in this setting.

Table 155-1

Properties of Commonly Used Benzodiazepines

	Midazolam	Lorazepam	Diazepam
Typical starting dose	1–2 mg	0.5–1 mg	5–10 mg
Onset of action	0.5–2 min	3–5 min	1–3 min
Duration of action after single dose	2 h	6–10 h	1–6 h
Metabolism	Hepatic	Hepatic (less influenced by age and liver disease)	Hepatic
Elimination	Renal	Renal	Renal
Anxiolysis	4+	4+	4+
Analgesia	No effect	No effect	No effect
Hypnosis	4+	4+	4+
Amnesia	4+	4+	4+
Anticonvulsant activity	3+	4+	3+
Effectiveness in reducing dyspnea	1+	1+	1+
Cardiovascular effect	Venodilation	Venodilation	Venodilation
Respiratory effect	Hypcventilation	Hypoventilation	Hypoventilation
Common side effects	Paradoxical agitation	Paradoxical agitation	Paradoxical agitation

1+ = *minimal effect;* 2+ = *mild effect;* 3+ = *moderate effect;* 4+ = *large effect.*

Propofol causes ventilatory depression and even apnea in some patients. Because propofol-induced apnea is unpredictable and not always dose dependent, the drug should not be used in settings in which the airway can not be readily secured. Typically, the respiratory pattern seen with propofol is characterized by a decrease in tidal volume and slight increase in respiratory rate.

Propofol may cause significant decreases in blood pressure, especially in patients with hypovolemia. Venodilation and mild myocardial depression are observed. The hemodynamic effects of propofol generally are more pronounced than those of the benzodiazepines. The drug should be administered cautiously in patients with cardiac disease.

Development of hyperlipidemia is a well described complication of propofol. As described previously, the drug is delivered in an intralipid carrier. A 1 percent solution of propofol provides 1.1 kcal/ml; consequently, parenteral lipid feedings must be adjusted accordingly when a propofol infusion is given. Serum triglyceride levels should be checked frequently and the propofol stopped if hypertriglyceridemia is noted.

Propofol can support growth of bacteria and fungi; therefore, strict aseptic technique and frequent replacement of infusion tubing are essential to prevent blood stream infection.

Finally, the "propofol infusion syndrome," which manifests as dysrhythmias, heart failure, metabolic acidosis, hyperkalemia, and rhabdomyolysis is a rare complication of propofol use. The syndrome appears more likely to occur when high doses (greater than 80 μg/kg/min) and or high concentrations (2 versus 1 percent) of the drug are used. An unpublished, randomized, controlled trial of propofol in pediatric patients reported a drug concentration-dependent increase in 28-d mortality in propofol-treated patients (8 percent with 1 percent propofol; 11 percent with 2 percent propofol) compared with those given other sedatives (4 percent).

Butyrophenones

Butyrophenones, such as haloperidol, are sometimes used for sedation of mechanically ventilated patients. These drugs induce a state of tranquility, and patients often demonstrate

a detached affect. Butyrophenones appear to antagonize dopamine, especially in the basal ganglia, although their exact site of action is not known.

The time of onset of the effect of intravenously administered haloperidol is 2 to 5 min; the half-life is 2 h. Starting doses of 1 to 10 mg are used typically, and the dose is titrated depending on desired endpoint. Haloperidol is metabolized in the liver.

As noted, patients receiving haloperidol appear calm and detached. Consequently, the butyrophenones are typically reserved for acutely agitated or hyperactive patients. Patients may appear indifferent to their surroundings; occasionally, a state of cataleptic immobility is seen.

Haloperidol provides no amnesia, has no effect on seizure activity, and has minimal analgesic properties. Haloperidol and other butyrophenones are the drugs of choice for agitated delirium.

Recent data suggest reduced mortality in mechanically ventilated patients treated with haloperidol. However, the findings are preliminary and retrospective in nature. Nevertheless, such reports have created an interest in use of the drug as a sedative in the ICU. More studies are needed to validate these preliminary findings.

When used as a single agent, haloperidol has no significant respiratory depressant activity; there is little attenuation of respiratory depression when used in conjunction with opiates. Hypoxic pulmonary drive is maintained. Reliable maintenance of respiratory function is an attractive feature of haloperidol, since most sedative or analgesic drugs cause respiratory depression.

Concern over adverse cardiovascular effects has limited use of haloperidol as a sedative in critically ill patients. Haloperidol is known to prolong the QT interval in some patients; although rare, torsade de pointes has been noted in patients receiving the drug. The drug also mildly antagonizes the α_1 receptor and may decrease the neurotransmitter function of dopamine, resulting in mild hypotension.

Extrapyramidal effects are occasionally seen with haloperidol, but they are much less common with intravenous, than oral, butyrophenones. When these complications occur, treatment with diphenhydramine or benztropine may be necessary. The neuroleptic malignant syndrome (NMS) is another extremely rare problem thought to result from central dopaminergic blockade, leading to extrapyramidal side effects, muscle rigidity, and excess heat generation. NMS is a life-threatening complication manifested by "lead pipe" muscle rigidity, fever, and mental status changes. Bromocriptine, dantrolene, and pancuronium have all been used to successfully treat NMS.

Dexmedetomidine

Dexmedetomidine is a selective α_2 agonist with both sedative and analgesic properties. Patients receiving this drug appear to be sedated when undisturbed, but they are easily aroused with minimal stimulation. Dexmedetomidine is unique in that patients treated with the agent may transition between sedate and awake states quickly and easily without discontinuing the infusion. Consequently, frequent neurological examinations can be performed. The drug is approved for short-term use (less than 24 h) in patients initially receiving mechanical ventilation.

Dexmedetomidine has been shown to be analgesic-sparing in postoperative patients. The drug causes no respiratory depression; therefore, it can be continued after discontinuation of mechanical ventilation and extubation. Side effects include bradycardia and hypotension, especially with hypovolemia or high endogenous sympathetic tone. Vasoconstriction and hypertension with increasing doses of dexmedetomidine also have been described. To date, the majority of studies of dexmedetomidine have evaluated postoperative patients in the ICU. Unfortunately, dexmedetomidine has not been extensively studied as an agent for long-term administration in critically ill, mechanically ventilated patients. Table 155-2 summarizes the pharmacologic properties of propofol, haloperidol, and dexmedetomidine.

Ketamine

Ketamine is a so-called "dissociative" anesthetic with a molecular structure similar to phencyclidine. Patients receiving the drug experience a state of mind in which perception is separated from sensation; i.e., patients feel detached from their surroundings ("dissociative state"). While patients appear unaware of their environment, they keep their eyes open and are able to maintain a protective cough reflex. In addition, they may demonstrate coordinated movements that appear without purpose.

Ketamine has profound analgesic properties, but it does not produce respiratory depression. Hypertension and tachycardia may be observed and reflect increased activity of the sympathetic nervous system. Some, but not all, patients experience amnesia. The common side effects of emergence delirium and severe hallucinations greatly limit use of the drug in mechanically ventilated patients. As a phencyclidine derivative, ketamine recently has gained popularity as an illicit drug. Benzodiazepines may reduce the incidence and severity of ketamine-related hallucinations.

Barbiturates

Barbiturates, such as thiopental and pentobarbital, are potent agents that cause amnesia and unconsciousness. They have no role as sedatives in mechanically ventilated patients because of their propensity to cause hemodynamic instability and exert prolonged effects due to accumulation in peripheral tissues because of high lipid solubility. Thiopental is sometimes used to induce anesthesia in facilitating endotracheal intubation. These drugs may be used to induce a pharmacologic coma in patients with severe brain injury.

Inhalational Anesthetics

Inhalational anesthetics are used widely in the operating room to maintain general anesthesia in mechanically ventilated patients. The exhaled anesthetics must be effectively scavenged to prevent pollution of the ICU environment, since the agents

Table 155-2

Properties of Other Sedative Agents

	Propofol	Haloperidol	Dexmedetomidine
Typical starting dose	1–2 mg/kg	0.5–1 mg	0.5–1.0 μg/kg over 10 min; 0.2–0.7 μg/kg/h infusion
Onset of action	0.5–1 min	2–5 min	5–10 min
Duration of action after single dose	2–8 min	2 h	30–60 min
Metabolism	Hepatic, renal, pulmonary?	Hepatic	Hepatic
Elimination	Renal	Renal	Renal
Anxiolysis	4+	3+	3+

Respiratory effect	Hypoventilation	No effect	No effect
Common side effects	Increased triglycerides	Neuroleptic malignant syndrome (rare), extrapyramidal effects (rare)	Hypotension, bradycardia

1+ = *minimal effect;* 2+ = *mild effect;* 3+ = *moderate effect;* 4+ = *large effect*

are not metabolized to any significant degree. Delivery and scavenging of inhalational anesthetics is technically challenging and has limited use of these agents outside the operating room. However, some studies have reported successful use of these drugs in mechanically ventilated, critically ill patients. For example, isoflurane, which has analgesic, amnestic, and hypnotic properties, has been described as an effective single agent for mechanically ventilated patients in the ICU.

ANALGESIA

The observations that most mechanically ventilated patients experience some level of discomfort and have limited ability to communicate fully mandates an aggressive, pre-emptive strategy for use of analgesia. Failure to achieve adequate analgesia may result in a mechanically ventilated patient developing agitation that is inadequately treated with sedatives alone. As a result, inappropriate escalation of sedative doses may result in excessive administration of the drug.

Indications

Pain from surgical incisions or trauma is usually obvious, but other indications for pain control in the ICU are often covert. These include endotracheal suctioning or placement of invasive catheters, such as arterial or venous lines. For many patients, the mere presence of an endotracheal tube is painful. Preexisting problems, such as skeletal fractures from

metastatic cancer or prolonged immobility during bed rest, may also be sources of pain. If all potential causes of pain are not recognized and addressed, discomfort and agitation often persist.

Pain in critically ill, mechanically ventilated patients can increase endogenous catecholamine activity and cause myocardial ischemia, hypercoagulability, a hypermetabolic state, sleep deprivation, anxiety, or delirium. These problems are diminished by adequate treatment.

Because failure to recognize pain as a cause of agitation may lead to inappropriate administration of nonanalgesic sedatives, an aggressive approach to managing pain in mechanically ventilated patients has been strongly recommended by consensus groups. Clinicians should actively search for sources of pain. Ability to discern its presence may be difficult because of impaired communication with mechanically ventilated patients. Furthermore, clinical parameters, such as changes in vital signs, are often not reliable indicators. Therefore, a high level of vigilance toward a need for analgesia is essential in critically ill patients, especially those undergoing mechanical ventilation.

Despite consensus recommendations, management of pain in the ICU is often inadequate. Ineffective communication and delirium may contribute to the problem. Concern over addiction to opiates is not a valid reason for inadequate analgesia in critically ill patients. In addition, an arbitrary limit should not be placed on drug doses.

For most patients, intravenous administration of opiate analgesics is preferred. Intramuscular injections are not recommended because of injection-related pain and unpredictable drug absorption in critically ill patients. Dosing strategies for intravenous administration of opiates include continuous infusions and intermittent dosing.

Intermittent opiate dosing regimens can be divided into scheduled administration, administration on an as-needed (prn) basis, and patient-controlled analgesia (PCA). Strategies employing an as-needed basis may lead to fluctuations between inadequate and excessive analgesia. Patients alert enough to respond to their own pain needs may benefit from a PCA-based regimen, although the majority of mechanically ventilated patients are not alert enough to utilize a PCA device.

Transdermal opiates may be continued in patients who are treated chronically with these medications; however, transcutaneous absorption is unpredictable during critical illness. Certainly, this route should not be used for treating acute pain in mechanically ventilated patients.

Use of clinical tools to categorize pain, such as scales or scoring systems, may be helpful. In general, simpler scales are more effective, since communication for many mechanically ventilated patients is limited. Although it has not been evaluated in critically ill, mechanically ventilated patients, the visual analogue scale (VAS) has excellent reliability and validity.

The VAS uses a self-reported measure of pain intensity that consists of a 10 cm line inscribed on paper; verbal anchors—"no pain" and "severe pain"—define the ends of the scale. The scale may provide useful information in patients alert enough to respond. A similar scale is the numeric rating scale. This scale also consists of a horizontal line with numeric markings: 1 and 10 anchoring the extremes of the pain intensity scale. The numeric rating scale may be preferred because it can be completed by writing, speaking, or using hand gestures. In addition, it may demonstrate better performance across various age groups.

Selection of Agent

Nonpharmacologic analgesic strategies are occasionally helpful and should be considered. For example, malpositioning of invasive catheters (e.g., an endotracheal tube impinging on the main carina) is a problem that may be easily remedied. Likewise, optimal patient positioning in the bed may at least partially relieve low back pain, pain from chest tubes and surgical incisions, etc. However, in spite of attention to these issues, most patients require administration of pharmacologic agents. Opiates are the most commonly used analgesic agents for critically ill patients.

Opiates

Opiate receptors are found in both the central nervous system and peripheral tissues. The two most clinically important opiate receptors are the mu and kappa types. Mu receptors include two subtypes: μ_1, which mediate analgesia, and μ_2, which mediate respiratory depression, nausea, vomiting, constipation, and euphoria. Kappa receptors mediate other effects, including sedation, miosis, and spinal analgesia. Opiates may have some anxiolytic properties, but they do not provide reliable amnesia. Commonly utilized opiates are discussed in detail below.

Morphine is the most commonly used opiate and is the standard against which all other opiates are compared. When given intravenously, morphine has a relatively slow onset of action (typically, 5 to 10 min) due to its low lipid solubility. As a result, movement of the drug across the blood-brain barrier is delayed. The duration of action after a single dose is approximately 4 h. However, when the drug is given repeatedly, drug accumulation and a prolonged effect are the rule.

Morphine is metabolized in the liver through glucuronide conjugation; an active metabolite (morphine-6-glucuronide) is generated that may accumulate, especially in renal failure. Drug elimination occurs in the kidney.

Fentanyl is a highly lipid-soluble, synthetic opiate. Its lipid solubility allows rapid movement across the blood-brain barrier and a quick onset of action. Redistribution of fentanyl into peripheral tissues leads to a short duration of action after a single dose (0.5 to 1 h). However, when fentanyl is given repeatedly, tissue stores become saturated and the clinical effect can be prolonged. Fentanyl has no active metabolites and does not release histamine.

Hydromorphone is similar to morphine with regard to its onset of action. However, since hydromorphone has

no active metabolites, the drug's duration of action following long periods of administration may be less than that of morphine.

Meperidine is a lipid-soluble opiate that moves rapidly across the blood-brain barrier and has a rapid onset of action (3 to 5 min). The higher lipid solubility leads to peripheral redistribution, so that duration of action after a single dose may be shorter than that of morphine (1 to 4 h). Meperidine undergoes hepatic metabolism and renal elimination. Metabolites of meperidine may accumulate and lead to neurotoxic effects, including seizures. Because many other opiates with better safety profiles are available, this drug probably should not be used in the ICU.

Remifentanil is another synthetic, lipid-soluble drug with a rapid onset of action. The drug is unique because of its rapid metabolism via hydrolysis by nonspecific blood and tissue esterases. Consequently, the pharmacokinetic profile of remifentanil is not affected by hepatic or renal insufficiency. The drug must be given by continuous infusion because of its rapid metabolism and quick recovery time.

To date, remifentanil has not been studied extensively for long-term use in the critical care setting. Most studies report experiences with short-term use in neurosurgical and cardiothoracic surgical units. Some studies suggest that when remifentanil is used during general anesthesia, the incidence of postoperative respiratory failure may be reduced, presumably because patients wake up more rapidly. As a result, extubation in the operating room may reduce the need for routine postoperative care in the ICU.

Opiate Toxicities

All opiates cause centrally mediated, dose-dependent respiratory depression mediated by μ_2 receptors in the medulla. The typical breathing pattern seen with opiates is a reduced respiratory rate with preservation of tidal volume. The response to hypercapnia is decreased and the ventilatory response to hypoxia is obliterated. The respiratory depressive properties of opiates are frequently exploited in mechanically ventilated patients suffering from dyspnea or coughing.

The hemodynamic effects of opiates are less profound than are the respiratory effects. Hypovolemic patients whose blood pressure is sustained by sympathetic hyperactivity may become hypotensive following administration of opiates. Most opiates cause a decrease in heart rate because of decreased sympathetic activity. The histamine release caused by morphine rarely leads to hemodynamic compromise. Meperidine is unique in that it may cause tachycardia, perhaps through an anticholinergic mechanism. Remifentanil may cause bradycardia and hypotension, particularly when administered concurrently with drugs having vasodilating properties, such as propofol. Hypertension after remifentanil dosing, although described, is uncommon.

Gastrointestinal dysfunction, including drug-related ileus, is seen frequently in mechanically ventilated patients receiving opiates. Methylnaltrexone, a specific antagonist of μ_2 receptors in the gut, has been reported to attenuate opiate-induced ileus in humans. However, use of methylnaltrexone in critically ill, mechanically ventilated patients has not been studied.

The neurotoxic effects of meperidine, including seizures, have been discussed previously.

Muscle rigidity occasionally occurs with use of synthetic opiates, such as fentanyl and remifentanil; however, it is not observed with naturally occurring opiates like morphine. The finding may be seen when high doses of the drugs are injected rapidly. The mechanism of opiate-induced skeletal muscle rigidity, although not fully understood, is thought to involve supraspinal activity of the drugs in the striata and substantia nigra. In the most extreme cases, chest wall muscle rigidity may make ventilation impossible. Neuromuscular blockade (e.g., using succinylcholine) is necessary to reverse the rigidity. Fortunately, the problem is extremely rare with the doses of opiates used in management of mechanically ventilated patients.

Findings of drug dependence and withdrawal may be seen in patients receiving opiates for extended periods. Patients who abuse opiates are at risk when hospitalized for a critical illness. Signs and symptoms are nonspecific and include: pupillary dilation, sweating, lacrimation, rhinorrhea, piloerection, tachycardia, vomiting, diarrhea, hypertension, yawning, fever, tachypnea, restlessness, irritability, increased sensitivity to pain, nausea, cramps, muscle aches, dysphoria, insomnia, symptoms of opioid craving, and anxiety. Patients without prior illicit drug use may also experience opiate withdrawal when pharmacologically administered opiates are stopped suddenly. Whether any pre-emptive strategies, such as downward dose titration or regular interruption of dosing, can attenuate or prevent opiate withdrawal is not known.

In one study of trauma patients in a surgical ICU, a high incidence of withdrawal was noted in those receiving opiates or sedatives for more than 1 week. Patients manifesting withdrawal findings received higher doses of opiates and benzodiazepines than did those not experiencing withdrawal. A potential role for long-acting opiates, such as methadone, in overcoming this problem is logical, although it has not been studied. Table 155-3 summarizes the pharmacologic properties of commonly used opiates.

STRATEGIES FOR USE OF SEDATIVES AND ANALGESICS IN THE INTENSIVE CARE UNIT

Since no single drug can achieve all of the indications for sedation and pain control in the ICU, a combination of drugs, each titrated to specific end points, may be a more effective strategy. The strategy may permit use of lower doses of individual drugs, thereby reducing problems of drug accumulation.

In the ICU, sedatives and analgesics are almost always administered intravenously. Administration by continuous infusion or intermittent boluses has been advocated. Intermittent administration may lead to fluctuations in level of

Table 155-3

Properties of Commonly Used Opiates

	Morphine	Meperidine	Fentanyl	Methadone
Usual starting dose	2–5 mg	20–50 mg	25–50 μg	5–10 mg
Onset of action	10 min	3–5 min	0.5–1 min	10–20 min
Duration of action after single dose	4 h	1–4 h	0.5–1 h	6–24 h
Metabolism	Hepatic	Hepatic	Hepatic	Hepatic
Elimination	Renal	Renal	Renal	Renal

N/V = nausea and vomiting.

sedation and increase demands on nursing time, potentially diverting attention from other aspects of patient care. The perceived benefits of continuous infusions include a more consistent level of sedation and better patient comfort. The convenience of the continuous infusion strategy for both patients and caregivers is likely the greatest reason for its popularity.

Ideally, strategies for sedation and analgesia in critically ill patients should be based upon pharmacokinetic and pharmacodynamic principles. Unfortunately, patients in the ICU frequently exhibit unpredictable alterations in pharmacodynamics, making establishment of precise guidelines for drug administration impossible. For instance, when "short-acting" benzodiazepines, such as midazolam and lorazepam, are administered in the ICU, the drugs accumulate in tissue stores and produce prolonged clinical effects. Other circumstances that confound prediction of pharmacologic behavior of sedatives and analgesics include altered hepatic or renal function, complex drug-drug interactions, altered protein binding, and circulatory instability. The multicompartmental pharmacokinetics typical of critically ill patients defy simple bedside pharmacokinetic profiling. Consequently, clinicians must titrate sedatives and analgesics against discernible clinical end points. Indeed, some critically ill patients require extraordinarily high doses of sedatives; such doses may be much greater than those described in the literature or recommended by the drug manufacturer.

Since oversedated patients are easier to manage than undersedated patients, clinicians are usually very aggressive in using sedation in the ICU. This is appropriate during the state of agitation that is often seen early during critical illness. However, maintenance of deep sedation after agitation resolves may lead to the problems described previously.

Recent clinical studies in critical care have led to evidence-based treatment strategies for many common conditions. For example, over the last decade improved outcomes

for critically ill patients with ARDS, sepsis, acute renal failure, status asthmaticus, and cancer have been reported. As sicker patients survive the acute phases of critical illness, more aggressive levels of sedation and analgesia may be necessary. This is especially true for those managed using unconventional ventilator strategies (e.g., permissive hypercapnia, low stretch, prone positioning, and pressure-controlled ventilation), since these modalities may be inherently distressing to many patients.

Although it is not without problems, deep sedation may be the only realistic option for some patients. Ideally, a head-to-toe daily assessment for the presence of organ failure should be routine for every critically ill patient. This is particularly true during the resuscitative phases of ICU care, when assessment of the adequacy of end-organ perfusion and organ function is vital, including neurological assessment.

The mental status examination is an important gauge of brain perfusion. Since brain injury is a devastating complication of critical illness, acute cerebral dysfunction must be detected quickly and corrected, if possible, before permanent injury arises. A thorough neurological examination, including assessment of mental status, may detect problems early and obviate the need for urgent diagnostic studies or therapeutic interventions. However, use of sedatives may limit a clinician's ability to serially follow a patient's neurological status.

A protocol-driven approach to sedation has been shown to alleviate many of the problems noted previously. A protocol directed by bedside nurses can shorten the duration of mechanical ventilation, ICU and hospital lengths of stay, and need for tracheostomy. Protocols may help assure adequate analgesia and sedation, based on frequent patient assessment and goal-directed titration of drugs.

A daily respite from sedatives may eliminate the tendency of clinicians to "lock in" to a high sedative infusion rate, which—while appropriate early in ICU care—may be unnecessary on subsequent days. Recently, the practice of routine daily interruption of continuous sedative infusions has been shown to reduce sedation-related complications, duration of mechanical ventilation, and ICU length of stay. The strategy allows patients to remain awake and interactive, thereby potentially reducing the amount of sedatives and opiates given and need for diagnostic studies to evaluate unexplained alterations in mental status. Although interruption of sedative infusions may lead to abrupt awakening and agitation, anticipation of these developments by the ICU team can reduce the incidence of complications, such as self-extubation.

Literature evaluating long-term consequences of recovery from respiratory failure and sedation is limited. Available data suggest that post-ICU depression is common in those who require mechanical ventilation during critical illness. Posttraumatic stress disorder (PTSD) following recovery has been reported, as well. As noted previously, studies suggest that lack of awareness related to sedation or underlying illness is associated with development of PTSD and that preservation of awareness during mechanical ventilation may reduce the risk.

CONCLUSIONS

Critically ill patients frequently exhibit agitated behavior. Sedation and pain control are important components of treatment, especially in those requiring mechanical ventilation. Treatment of agitation should be directed to specific, individualized goals.

All currently available drugs used to treat agitation have limitations. Complications related to use of these agents are common. Rather than seeking an ideal drug, clinicians should employ strategies of drug administration that are based upon principles of sedative pharmacology in critical illness. When sedative drugs are administered, recognition of specific goals allows rational management strategies to be implemented, leading to improved short- and long-term outcomes.

Decision Making in the Intensive Care Unit

Bruno DiGiovine • Mark A. Kelley

Care of the critically ill patient is a complex interplay of science, health care economics, ethics, and the art of medicine. In the intensive care unit (ICU), the health care team utilizes costly technology to rescue patients from the extremes of illness. This struggle places emotional strain on patients, their families, and health care professionals as they balance the desire for cure with concerns for dignity, comfort, and patient autonomy. In this difficult scenario, the physician must provide facts to patients and their families about the severity of illness and prognosis. The prognostic information should include not only predictions about risk of death, but also likely outcomes in terms of quality of life if the patient survives. A description of the objective information available on the outcome of critically ill patients is provided later in this chapter.

Critical care in the United States utilizes expensive health care technology. Recently, general health costs have escalated to approximately 15 percent of the U.S. gross national product, and critical care accounts for as much as 10 percent of the health-related costs. Whether this investment in critical care results in improved health for the nation has been questioned, as has whether most patients even desire this type of treatment. Consequently, considerable research has been performed in defining the prognosis of critically ill patients, through both historical case series and objectively derived predictive instruments.

This chapter focuses on three specific areas. First is a description of the prognosis of patients with the most common conditions found in the medical ICU, such as respiratory failure and sepsis. A discussion of what is known about quality of life after recovery from these conditions is included. The second area is an overview of the outcome instruments that have been developed to predict mortality in the ICU, while the third covers social issues in critical care, such as expectations of patients and their families, advanced directives, and stratification of critically ill patients by resource utilization. The last section also addresses the ways in which access to prognostic information affects practitioners.

OUTCOMES OF MEDICAL CONDITIONS COMMONLY SEEN IN THE INTENSIVE CARE UNIT

Much has been written about the prognosis of certain syndromes and diagnoses prompting admission to the ICU. In general, diagnoses can be divided into two categories. The first is the group of disorders that result in critical illness in the course of chronic illnesses, such as chronic obstructive pulmonary disease (COPD) or cancer. In these disorders, the prognosis depends on the status of the underlying disease. The second category is an acute illness, such as acute respiratory distress syndrome (ARDS) or severe sepsis. Although the mortality for patients with these diagnoses is certainly affected by underlying disease, many of the prognostic factors measured in the ICU have a direct impact on the prognosis.

Consideration of quality of life after surviving these illnesses is important, since families often make decisions based mainly upon issues surrounding quality of life. This is most obvious if one considers a patient in a coma in whom the prognosis of eventual neurological recovery impacts decision making much more than the likelihood of the patient surviving into the immediate future.

Respiratory Failure

Acute respiratory failure (ARF) has been one of the most widely studied critical conditions. Studies have focused on three disorders: COPD, status asthmaticus, and ARDS.

Chronic Obstructive Pulmonary Disease

Acute hypercapnic respiratory failure in COPD is usually defined as the presence of an arterial CO_2 tension (Pa_{CO_2}) that exceeds 50 mmHg, or an increase of 10 mmHg or more from baseline. Recently, a reduction in the hospital mortality of this condition has been improved through use of noninvasive positive pressure ventilation (NPPV). In controlled trials of NPPV (as reviewed by the Cochrane Airways group), the overall hospital mortality in the treatment group was half of that in the usual care group (11 versus 22 percent). However, little evidence exists for an improved prognosis in the era of of NPPV for patients who are intubated. This has been confirmed by recent studies showing that patients who require critical care have hospital mortalities of 20 to 25 percent.

Nevertheless, the long-term prognosis of patients with COPD who are hospitalized remains quite guarded. A prospective study of 17,440 patients admitted to the ICU for acute respiratory failure from COPD demonstrated a 1-year mortality of 59 percent. Long-term mortality was similar for patients who received mechanical ventilation as for those who did not. Indeed, this observation recently has been reinforced by a study addressing the long-term outcomes of patients who received NPPV for COPD-related acute respiratory failure in which the 1-year mortality was 49 percent.

These studies point out that long-term survival in COPD is a function of the underlying severity of the patient's disease, rather than the severity of the exacerbation. Indeed, a recently published metric that incorporates measures of body mass index, airflow obstruction, dyspnea, and exercise capacity (as determined using the 6-minute walk test)—the so-called "BODE index"—is an accurate predictor of long-term mortality. This, or other validated prognostic metrics, may prove useful in determining prognosis in the ICU.

Based on these observations, a reasonable conclusion is that patients with COPD admitted to the ICU for acute respiratory failure have a hospital survival rate that exceeds 70 percent. Hospital survival for these patients is influenced by the overall severity of illness, rather than degree of respiratory failure, whether acute or chronic. However, survival at 2 years is less than 50 percent and is influenced by severity of the lung disease.

Status Asthmaticus

Previously reported hospital mortality rates for patients with status asthmaticus requiring mechanical ventilation ranged from 10 to 38 percent. Subsequent studies report fatality rates of 3 to 8 percent. Possible explanations for the improved outcome are the conservative use of mechanical ventilation to avoid barotrauma and the aggressive use of bronchodilators. Women have a higher risk than men of fatal asthma.

Patients with near-fatal asthma, when followed prospectively, have an alarming mortality. The mortality rate of near-fatal asthma is 10 percent at 1 year of follow-up, 14 percent at 3 years, and up to 25 perecent at 6 years. Anoxia and prehospital asphyxiation are typical presentations. The statistics emphasize that the critically ill patient with asthma may require special follow-up after discharge in order to prevent recurrence of near-fatal asthma.

Acute Rsepiratory Distress Syndrome

ARDS is a common cause of hypoxic respiratory failure that frequently accompanies such conditions as sepsis, shock, and transfusion of blood products (see Chapter 145). Mortality in ARDS is often analyzed by dividing deaths into early (less than 72 hours after ARDS onset) and late groups. Early deaths are thought to be related to the presenting illness or injury, while late deaths are presumably due to complications arising after onset of ARDS. Prognosis and mortality late in the illness appear more dependent on the presence of infection and failure of other organs, particularly the liver, kidney, and central nervous system.

In recent years, survival has improved for patients with ARDS. Two NIH-sponsored trials of controlled ventilation in ARDS have demonstrated that, in specialized centers, hospital mortality ranges from 25 to 31 percent. Reasons for the improvement are unclear, but a study at one referral center showed that the improved mortality appears limited to certain underlying diagnoses. In particular, investigators have found that the case-fatality for sepsis-related ARDS has remained at about 55 percent since 1981, while that related to trauma and other risk factors has dropped from approximately 65 to 25 percent.

Multiple organ failure is a strong prognostic factor in the outcome of ARDS. Mortality approaches 80 percent with failure of two or more organs (brain, liver, lung, heart, kidney) and reaches 90 percent with failure of three or more. In a report examining prognostic factors among patients with ARDS, the initial ratio of Pa_{O_2} to inspired oxygen fraction (Pa_{O_2}/FI_{O_2}) had only a modest influence on mortality. More important were the presence of multiorgan failure, primary ICU diagnosis, and treatment location before ICU admission. Hence, although the magnitude of initial hypoxemia reflects the severity of ARDS, outcome is determined by the interplay of mutliple organ systems.

For patients with ARDS, considerable information exists regarding quality of life in survivors. In many, quality of life, as measured by the SF-36 and other tools, appears to be reduced for up to 2 years. At 2 years, almost a quarter of survivors report moderate to severe depression, and a similar fraction report moderate to severe anxiety; almost half (47 percent) demonstrate neurocognitive impairment.

Recent studies have demonstrated that an important factor affecting quality of life after ARDS is decreased pulmonary function. Pulmonary function testing reveals diminished function in a large number of survivors. As many as 80 percent of patients have decreased diffusion, although impairment is mild in the majority. In addition, 20 to 50 percent have a restrictive pattern, while 20 percent also have an obstructive component. Notably, one study found that over 30 percent of ARDS survivors were less than fully ambulatory at 1 year.

Persistent symptoms one year after recovery correlate with the duration of mechanical ventilation, the lowest recorded lung compliance, and the requirement of an Fi_{O_2} greater than 0.6 for more than 24 hours. No link between choice of ventilatory strategy and long-term outcome has as yet been demonstrated.

Sepsis and the Systemic Inflammatory Response Syndrome

Based on a consensus conference held jointly in 1992 by the American College of Chest Physicians and the Society of Critical Care Medicine, *sepsis* is defined as a combination of the *systemic inflammatory response syndrome* (SIRS) and confirmed or suspected infection. SIRS is defined clinically as the presence of two or more of the following: (a) body temperature greater than 38°C or less than 36°C; (b) heart rate greater than 90 beats/min; (c) respiratory rate greater than 20 breaths/min or Pa_{CO_2} less than 32 mmHg; (d) WBC greater than 12,000 cells/mm^3 or less than 4000 cells/mm^3 or greater than10 percent immature (band) forms. *Severe sepsis* is defined as sepsis that occurs in association with organ failure. When hypotension is present also, the patient is said to have *septic shock*.

The epidemiology of sepsis has been elucidated in recent years using ICD-9 codes to evaluate the disorder's national impact and outcome. Studies have pointed to a reduction in hospital mortality from sepsis over the last two decades. Average mortality from sepsis was 27.8 percent from 1979 though 1984 and 17.9 percent from 1995 through 2000. Despite the decrease, overall sepsis-related mortality in the population has increased because of an increased incidence of sepsis in elderly persons. Studies have highlighted the importance of organ failure in predicting mortality; patients with three or more failing organs have a mortality rate of approximately 70 percent.

Nontraumatic Coma

The prognosis of patients with nontraumatic coma has been the subject of several prospective studies. In such patients, neurologic observations must be made in the absence of central nervous system (CNS) depressant drugs or status epilepticus. Patients without brain stem function (e.g., as indicated by the absence of corneal reflexes) within the first 12 hours, or without pupillary reflexes within the first 72 hours after the onset of coma, have little chance of meaningful neurological recovery. Although nontraumatic coma is frequently encountered in patients in whom cerebral hypoxia has resulted from cardiopulmonary resuscitation, the prognosis of nontraumatic coma is independent of etiology.

Prognostic information exists not only for neurological recovery, but also for mortality. When patients are assessed on day 3 of coma, five independent risk factors for death at 2 months can be identified: (a) age greater than or equal to 70 years; (b) abnormal brain stem response; (c) absent verbal response; (d) absent withdrawal to pain; and (e) level of creatinine in blood greater than or equal to 1.5 mg/dl. When none of these factors are present, mortality is 20 percent; with one factor, 33 percent; with two factors, 60 percent; with three factors, 94 percent; with four factors, 96 percent; and with all five factors, 100 percent. For patients with three or more risk factors, aggressive care beyond 3 days does not improve outcome and comes at a very high economic cost.

Malignancy

Continuous improvements in oncologic treatment make mortality predictions for care in the ICU difficult. For example, studies published prior to 2000 cited a 50 percent in-hospital mortality for cancer patients entering the ICU for nonoperative care; if mechanical ventilation was required, mortality exceeded 70 percent. However, in a study published in 2005, patients with cancer who underwent mechanical ventilation had a mortality rate of 50 percent. Predictors of a poor outcome included older age, poor performance status, recurrent or progressive cancer, or presence of organ failure.

Similar improved outcomes appear to be the case for bone marrow transplant (BMT) recipients. Previous studies showed a very poor prognosis, with in-hospital mortality exceeding 70 percent; patients who required ventilatory support had an in-hospital mortality in excess of 95 percent. However, recent reports of patients who have undergone stem cell BMT have been more optimistic: when admitted to the ICU for any cause, patients had a 50 percent in-hospital mortality.

Cardiopulmonary Resuscitation

The outcome of cardiopulmonary resuscitation (CPR) is influenced by the setting in which it is performed (in hospital versus out of hospital), age of the patient, and underlying diseases. When discussing goals for patient care in the ICU, physicians may attempt to offer a prognosis on outcome if the patient should experience a cardiopulmonary arrest. Recent data from the Cleveland Clinic demonstrated a 23 percent survival to hospital discharge in patients experiencing cardiopulmonary arrest—a rate that compares favorably to pooled analyses of worldwide data, in which survival rate to hospital discharge was 15 percent. Long-term outcome of discharged patients appears favorable, with nearly three-quarters surviving for 1 year.

Finally, cardiopulmonary arrests due to ventricular tachycardia or ventricular fibrillation are associated with better survival rates than those caused by asystole or pulseless electrical activity. Similarly, witnessed arrest, arrest in an ICU, respiratory arrest, short duration of CPR, and absence of comorbidities are associated with better chances of survival.

Age

Controversy exists over whether age is an independent predictor of mortality in critically ill patients. Approximately half of all patients in the United States admitted to the ICU are over 65 years of age. The percentages are much lower in other western countries. Past reports suggested a correlation between increasing age and hospital mortality. However, more recent investigations using prognostic scoring systems have found that age is a weak variable in portending the likelihood of death. More predictive power rests with such factors as underlying disease, previous functional status, and number of failing organs. Nonetheless, older age is associated with a greater likelihood of disease and poor functional status; no large studies have compared patients in different age groups who have similar severity of disease.

Two other elements that have been examined in relation to patient age and critical care include utilization of ICU resources and the cost and quality of life. About 10 percent of critically ill patients consume about 50 percent of ICU costs. Although one might envision that the elderly compose a large fraction of these high-resource patients, this is not the case. Functional assessment of quality of life in the elderly following critical care has yielded mixed results. Some studies find no differences in functional outcome between elderly and young patients; others suggest that the elderly are more impaired after critical care. The studies have not been stratified for severity of illness, making comparisons between the two age groups difficult.

Acquired Immunodeficiency Syndrome

The natural history of HIV infection changed dramatically after the introduction of highly active antiretroviral therapy (HAART). The change has also affected the prognosis of HIV-infected patients in the ICU.

Two studies have shown improvement in prognosis for patients with AIDS treated in the ICU in the era of HAART compared with prior times, with survival rates increasing from 50 to 60 percent to 70 to 75 percent. The improvement is related to a change in the general epidemiology of critical care for affected patients; in particular, fewer admissions to the ICU during the HAART era are for respiratory failure. HIV-infected patients entering the ICU are more likely to be black, less likely to be homosexual, and more likely to be users of injection drugs.

SEVERITY OF ILLNESS SCORING SYSTEMS AND MORTALITY PREDICTION

The complexity of critically ill patients has exposed the limitations of historical methods of prognostication, such as case studies and clinical judgment. From the time of Socrates, physicians have accurately predicted outcome in patients at the extreme ends of the spectrum of disease severity. For example, even inexperienced clinicians can predict the high likelihood of death in a patient with multiple organ failure and shock. Similarly, clinicians can correctly judge that patients admitted to the ICU only for monitoring of an arrhythmia have an excellent prognosis.

The challenge in formulating a prognosis is that most patients entering the ICU fall somewhere between the two ends of the spectrum, and the outcome of most patients cannot be accurately assessed by simple application of clinical judgment. A patient presenting with sepsis and hypotension might have a predicted mortality ranging from 15 to 40 percent, depending on underlying diseases, source of the infection, and other organ system dysfunction.

A number of compelling reasons exist for defining the severity of disease and prognosis in all patients in the ICU. Furthermore, assessment of quality of ICU care is difficult without a means to compare severity of disease among different ICUs. In an era of public accountability, critical care physicians must ensure that patients are provided the best possible care. Objectively measuring the severity and prognosis of the disease enables a rational description of patients in the ICU and lays the foundation for quality assessment. In addition, utilization of severity scoring systems provides a stable platform for research in critical care therapeutics and economics. An objective scoring system stratifies patients by disease severity, thereby permitting measurement of therapeutic effects and economic consequences. Finally, scoring systems of severity may be useful in clinical decision making, especially in mapping the trajectory of the patient's critical illness.

Methods Employed in Developing Severity-Scoring Systems

Severity-scoring systems utilized in critical care settings assign numeric values to various degrees of illness. The scores

are then applied in a mathematical formula to calculate predicted mortality. To a great extent, the ultimate importance of the severity score is its power to predict mortality. Two characteristics are essential in judging predictive instruments: discrimination and calibration.

Discrimination is the ability of a predictive model or scoring system to discriminate between patients who ultimately die and those who ultimately live. Typically, predictive models are based upon sensitivies and specificities for various levels of probability of death. A graphed compilation of sensitivities and specificities across different probability cutoffs results in generation of a receiver operating characteristic (ROC) curve, the area under which is a measure of the discriminative ability of the model. In effect, the curve provides a measure of how well the scoring system works over a range of predictions, but it does not assess how well the model works at any specific probability.

Calibration describes how well the prediction model performs at each specific probability cutoff. For example, a group of patients may have a predicted probability of death of 0.1. Data analysis would include determination of whether 10 percent of this group actually died. Similar analyses could be performed for other probabilities (e.g., 0.2, 0.3, etc.). For all groups, a determination can then be made with regard to how well the resultant curve predicts actual mortality. Overall assessment of the relationship of observed to predicted mortality is a measure of calibration. As noted previously, although the time-honored method of outcome prediction using clinical judgment tends to be highly discriminatory at extremes of probability, the method tends to be poorly calibrated.

Characteristics of discrimination and calibration are depicted in Fig. 156-1. A predictive instrument with perfect calibration and discrimination has predicted mortalities identical to observed mortalities over the complete range of mortality prediction. This corresponds to the line of identity seen on the graph. A poorly calibrated instrument has wide variability around the line of identity and a well calibrated instrument less variability. Therefore, the ideal prediction instrument has minimal variability and comes as close as possible to the line of identity.

Several steps are used in developing ICU severity-scoring systems. The first is to assess a representative patient population from a variety of ICUs. The key clinical characteristics of the patients are then analyzed statistically using methods of multivariate analysis and logistic regression. Variables with the most discriminatory power for predicting mortality are then tested and validated in another patient population. Based on this process, severity-scoring system and mortality prediction algorithms are derived.

A number of important features characterize currently available instruments for assessing outcome: (a) They measure an outcome of clinical significance. Most critical care–based severity-scoring systems have focused on in-hospital mortality but interest is increasing in tools to assess post-discharge mortality and functional status. (b) The instruments are easy to use. Data collection on critically ill patients

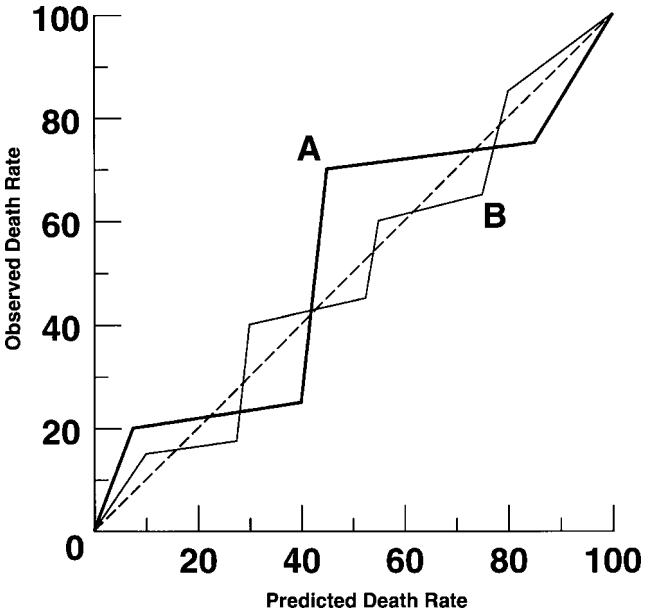

Figure 156-1 Calibration curves for two hypothetical scoring instruments. Perfect calibration is described by the line of identity. Instrument (*A*) has a wide variation around the identity line. Instrument (*B*) has less variability and therefore is better calibrated across the range of death rates. *(Data from Cowen J, Kelley M: Predicting intensive care unit outcome: Errors and bias in using predictive scoring systems.* Crit Care Clin *1053-1072, 1994.)*

can be time consuming and costly. Therefore, outcome instruments focus on data that are simple to record and reproduce. (c) The instruments have limitations in their application. Notably, they do not accurately predict outcome for populations that are not included in their sets of derivation data. For example, ICU severity-scoring systems are not applicable to all hospitalized patients. Understanding these limitations is important in preventing misuse of the instruments.

Acute Physiology, Age, and Chronic Health Evaluation Scoring System

The Acute Physiology, Age, and Chronic Health Evaluation (APACHE) scoring system has two versions (II and III) that are widely used in the United States. APACHE II was derived from studies in 13 hospitals, based on approximately 6000 patients. The instrument assigns points for age, underlying disease, and several other elements of chronic health status; it adds points for physiological variables measured in the first 24 h of ICU admission. The total severity score is entered into a logistic regression equation, which provides a predicted mortality.

APACHE II has excellent calibration and discrimination, but it has several flaws. The first is that the instrument is not as accurate when applied to patients in the ICU who are transferred from other inpatient facilities. The mortality of these patients is generally underestimated by APACHE II as a result of an effect known as "lead time bias." A similar phenomenon has been recognized to affect prediction using the updated version of APACHE, i.e. the APACHE III. The

second flaw is that the derivation database is not powerful enough to allow stratification of patients by certain disease categories, such as liver failure, respiratory failure, etc. Therefore, APACHE II cannot accurately predict outcome for any specific patient subgroup. Nevertheless, some have suggested that it can be used to decide whether to use certain medical therapies in patients with severe sepsis.

The updated version of APACHE II, called APACHE III, addresses these problems. APACHE III was derived from 40 representative hospitals and more than 17,000 patients. This instrument includes many of the variables in APACHE II but adds the location of prior treatment and the disease that required admission to the ICU. APACHE III also updates prognosis daily, based on newly measured physiological variables.

The APACHE instruments have been published widely and studied internationally. Their discrimination and calibration have been well validated; flaws in older versions have been corrected. However, the APACHE scores require a great deal of data collection and an investment in expensive proprietary computer technology. In addition, whether specific disease subgroups can be assessed, even using the expanded APACHE III database, remains unclear.

Simplified Acute Physiological Score

The simplified acute physiological score (SAPS) was developed as an alternative tool to the data-intensive APACHE instrument. SAPS provides a summary score after 24 h of ICU admission. It concentrates on physiological variables, as well as such elements as type of admission and underlying diseases. SAPS II uses 17 variables: 12 physiological variables, age, type of admission, and three underlying disease variables (AIDS, metastatic cancer, hematologic malignancy). The scoring system was derived from 8500 patients and validated on a sample of 4500 patients. The model provides a score that is entered into a mathematical formula the solution of which provides a prediction of in-hospital mortality. SAPS II does not require a principal ICU diagnosis, which is mandated with APACHE III. Based on published data, SAPS II has excellent discrimination and calibration.

Mortality Prediction Model

Like SAPS, the mortality prediction model (MPM) was developed to simplify the scoring of severity in critically ill patients. MPM was originally developed in one hospital, but its second version (MPM II) had a derivation database of 12,610 patients from many hospitals. MPM requires that patients be placed in categories that correspond to certain scores. The categories are based on several physiological assessments, chronic diagnoses, acute diagnoses, and other characteristics, such as type of admission, age, and use of CPR or mechanical ventilation. The total score is derived from 15 easily obtainable variables.

The MPM score is determined immediately upon ICU admission (MPM 0) but can be updated after 24 h (MPM 24). The update contains five of the admission variables and eight additional variables, such as arterial blood gases, creatinine, prothrombin time, urine output, etc. Like SAPS II, MPM II has excellent calibration and discrimination. Since MPM 0 utilizes measurements that are made immediately upon ICU admission, the measurement time may define a patient population that is different from that assessed 24 h after treatment and after the evolution of other diagnoses. Only the MPM 24 can be compared to SAPS and APACHE, since all three instruments use measurements performed within the first 24 h of admission.

USE OF SEVERITY SCORES IN THE INTENSIVE CARE UNIT

Development of reliable severity scoring systems in critical care has opened the field to a wide range of opportunities in health care management and research. Severity-scoring systems can be considered with regard to their potential uses in resource allocation, quality management, and clinical decision making.

Allocation of Resources

Allocation of ICU resources is grounded in the fundamental principle of *fairness*, which itself has several potential interpretations. The first is the concept of *equality,* which implies that all patients are entitled to the same access and level of ICU care. The second principle is the principle of *equity,* according to which a patient's level of care does not jeopardize that of others. A third concept, *utilitarianism,* places the overall benefit to society above that of the individual. The final application of fairness is *distribution according to medical need,* regardless of social issues (see Chapter 157).

In the United States, medical need has traditionally dictated allocation of critical care resources. Recently, outcomes and outcome prediction in critical care have raised the issue of medical suitability. This concept dictates that outcome of care, as well as medical need, should be used to assess application of ICU resources. The critical care community has summarized these issues in a consensus statement on the triage of critically ill patients. The guiding principles in this statement are patient advocacy, equitable distribution of care, and provision of care on the basis of expected benefit.

Outcome instruments have been useful in management of hospital resources. Severity scores have been used to identify patients who no longer need intensive nursing and who can be placed in lower-cost settings. Physician and nursing staffs can be queried with respect to the patient's need for the ICU and appropriate adjustments made. These analyses may extend beyond the hospital walls to include a regional approach to critical care. Like trauma patients, critically ill patients may be triaged by severity of illness, so that the most complex cases are treated in larger ICUs.

Quality Management

Because of the rising costs of health care, patients and insurers have sought methods to compare the value of choosing certain providers. This "health care value" has been defined conceptually as quality divided by cost. While the economic side of this equation is straightforward to measure, quantifying the quality of care is more elusive.

In critical care, severity-scoring instruments have been useful in assessing quality of ICU care. Some uncontrolled studies using predictive scoring instruments suggest that patient outcome is better in ICUs staffed by trained intensivists. Interhospital comparisons of hospital mortality have been widely published, since several states have mandated outcome measurements in all hospitals.

Institutional comparisons using predictive instruments may be misleading. Two studies using APACHE II demonstrated that previous site of treatment can influence the accuracy of APACHE II. In the first report, APACHE II underestimated mortality in an ICU that accepted transfers from other institutions. In the second, APACHE II underestimated mortality for patients previously treated in the hospital but overestimated mortality for patients admitted from the emergency room. As previously described, this phenomenon, called "lead-time bias," has been adjusted in APACHE III. Nevertheless, investigators have shown that patients accepted in transfer have a worse prognosis than expected based upon their APACHE III score. These examples demonstrate that even well-designed instruments, such as APACHE II and III, can have unanticipated problems, making institutional comparisons challenging.

Controversies abound concerning the accuracy and relevance of measuring quality of care. The critical care arena offers several advantages over the general health care setting in assessing quality of care: (a) The patient population in ICUs is well defined, and the provision of care is well circumscribed; (b) substantial evidence exists that the degree of illness in the ICU is the major determinant of patients' hospital mortality; (c) the predictive instruments described have considerable power to risk-adjust ICU populations and to permit evaluation of ICU effectiveness and efficiency. Therefore, severity-scoring systems provide a foundation for assessing quality of critical care.

Clinical Decision Making

Severity-scoring systems can be helpful in predicting outcome across the entire range of prognosis. However, in assessing an individual patient in the ICU, only the extremes of probability are of practical importance. For purpose of triage, patients who are clearly terminal, or who do not require intensive care, should be identified. For such assessment, clinical judgment, often based on historical case series, is as accurate as any outcome instrument. Patients in between the extremes of prognosis are usually eligible for critical care.

A concept of continuous prognostication has been introduced into the APACHE III instrument. Using this technology, disease severity and prognosis can be updated continuously to plot the trajectory of the patient's illness. The updated severity score may have more predictive power than that obtained in the first 24 h of ICU admission. The implication is that continuous monitoring of disease severity may assist in critical decisions, such as limiting or withdrawing therapy. This idea has evolved into the concept of "potentially ineffective care" that categorizes patients with a poor prognosis who consume an inordinate amount of resources.

The challenge is that there may be a substantial disparity between how health care workers use prognostic information and how patients and their families use this information. In Canada, a survey demonstrated that health care workers could not even agree among themselves on criteria for withdrawing life support. Two studies have documented that do-not-resuscitate orders are increasingly common in ICUs. However, one of these reports indicated that patients and their families did not always participate in this process.

Given these considerations, one might ask whether having reliable prognostic information actually influences physician behavior. The question was answered by The Study to Understand Prognoses and Preferences for Outcomes and Risks of Treatment (SUPPORT).

SUPPORT consisted of an observational period that, in addition to measuring prognosis, demonstrated significant differences in the outcome expectations of health care workers, patients, and families. The intervention component of the study attempted to bridge the communication gap by sharing updated prognoses and establishing better methods of communication among the health care providers, patients, and families. Surprisingly, the study showed that this intervention had no measurable effect on clinical decision making. The ICU teams continued to emphasize the technological quest for cure, rather than concentrating on the patients' desires to avoid suffering and prolonged, painful dying. The investigators concluded that, at least in the five tertiary academic centers that were part of the study, critical care providers appear to be insensitive to the needs and expectations of patients.

SUPPORT pointed out that simply providing prognostic information will not, by itself, change decision making in the ICU. The reasons for this are likely multiple, but all revolve around the need for better communication among physicians, patients, and their families. Studies have shown that even when physicians are confident about prognosis, they share their assessment with the patient only 37 percent of the time, perhaps, stemming from a belief that physicians must not extinguish patient hope.

However, methods exist for providing honest prognosis while allowing patients to continue to hope for the best outcome. In fact, SUPPORT suggests that patients may have more limited and realistic expectations of high technology than do critical care physicians. Further training on how to best to negotiate issues of trust, uncertainty, and affect in dealing with end-of-life are of benefit to all health care professionals. With such training, physicians will be able to use prognostic information from severity-scoring systems to facilitate

doctor-patient communication and support rationale decision making about the level of care.

Ethics in the Intensive Care Unit

Paul N. Lanken

Patient care in a modern intensive care unit (ICU) presents a striking contrast. On the one hand, by definition, the ICU is the health care setting in which depersonalized, "high-tech" medicine is practiced and in which the "technological imperative" is often played out. On the other hand, the ICU also is a health care delivery site in which the deeply humanistic concerns of bioethics are evident on a day-to-day basis. *Ethics,* in simple terms, is the discipline that concerns itself with defining the right action for the right reasons. *Bioethics* generically refers to the ethics encompassing health care and health care professionals as well as basic biological and physical scientific research relevant to human health and disease.

Many ethical dilemmas in the ICU share common themes. For example, advanced technology and a high level of professional intervention in the ICU can keep patients alive for prolonged periods. However, this same capacity for delivering life-sustaining care often fails to achieve what patients really want and what also has been the traditional goal of critical care medicine: restoring patients to sufficiently good health to permit them to leave the ICU with a good quality of life. Ethical dilemmas that characterize critical care medicine often arise from this interface between the ability to prolong life by expensive and sometimes scarce technology and an inability to cure patients or even restore them to their

baseline. The relevant ethical question often is whether this technology is being used wisely, i.e., whether the patient's life *should* be prolonged. The question becomes even more complex for practitioners and patients' families when different ethical principles suggest conflicting answers.

Although the practice of critical care medicine encompasses a broad range of bioethical issues, several are particularly common, including end-of-life decision making, medical futility, resource allocation, and "do not attempt resuscitation" (DNAR) orders. These issues are some of the most challenging for ICU practitioners and constitute the focus of this chapter.

FUNDAMENTAL PRINCIPLES OF BIOETHICS

Overview

These fundamental principles of bioethics are particularly relevant in the ICU: (a) beneficence and nonmaleficence; (b) respect for patient autonomy; and (c) justice. *Ethical dilemmas* in the ICU arise when two or more of these principles are in conflict (Fig. 157-1) and when health care providers must violate one or more ethical principles to resolve the conflict. Determining which principle is the overriding one is the goal of ethical analysis applied to such conflicts.

Each of these principles also relates to certain moral entities (Fig. 157-1). The principle of beneficence primarily involves physicians, nurses, other health care providers, and health care institutions, all of which are moral agents, i.e., entities with inherent values and moral responsibilities that arise from their established roles and positions in society. Respect for patient autonomy relates to patients, their families, and surrogate decision makers or proxies—i.e., individuals who speak on behalf of those patients who lack the capacity to make medical care decisions.

Justice refers to fairness in the distribution of limited resources, i.e., *distributive justice.* This principle is usually discussed in terms of two levels of applicability. First, on the level of *macroallocation* of resources, distributive justice entails governmental and institutional decisions on the relative importance of funding health care among a number of social goods and services, e.g., education and defense. Macroallocation also refers to the distribution of health care resources among various regions and communities, e.g., funding for Medicare, Medicaid, and the Veterans Administration health care system. Second, on the level of *microallocation* of resources, *distributive justice* refers to decision making about an individual patient or resource allocation within an individual ICU, hospital, or local health care system.

Beneficence and Nonmaleficence

The principle of *beneficence* refers to the traditional aim of medicine and nursing to provide services that benefit the patient. Beneficence may be broadly interpreted to include the principle of *nonmaleficence*, i.e., doing no harm to the patient. The Hippocratic maxim *primum non nocere,* which can be translated as "First of all do no harm," reflects the fundamental importance of this principle for physicians. These two principles—beneficence and

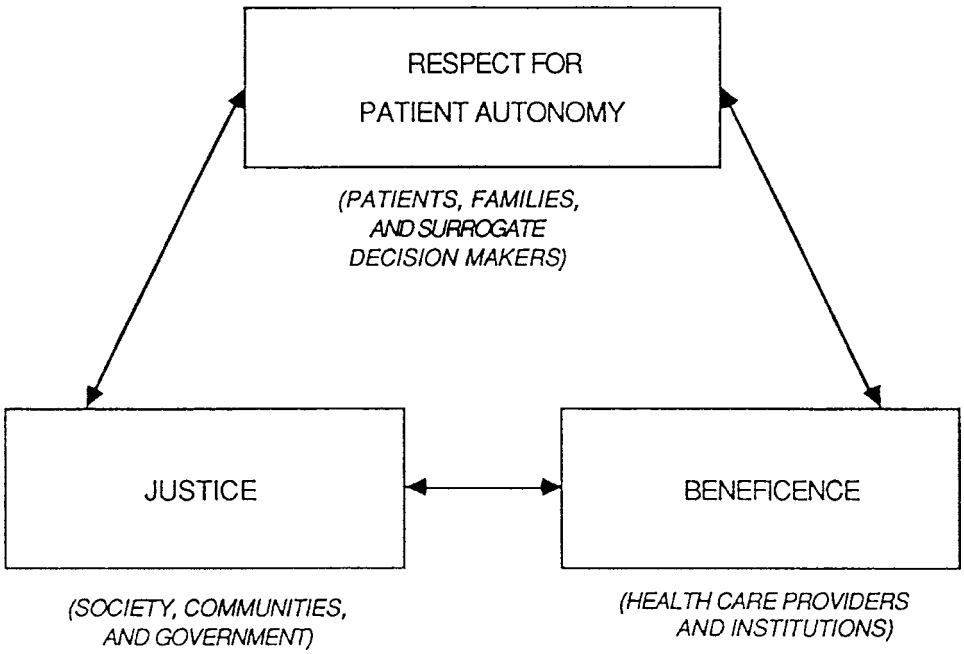

Figure 157-1 Basic ethical principles and related moral agents commonly involved in intensive care unit ethical dilemmas: respect for patient autonomy, beneficence (which includes the principle of nonmaleficence), and justice. Opposing arrows represent potential conflicts between principles.

nonmaleficence—commonly conflict when the patient suffers pain as a consequence of receiving beneficial care, e.g., the discomfort of suctioning while intubated. The bioethical conflict is resolved when it reasonably can be concluded that the discomfort of suctioning is more than balanced by its beneficial effects and that the actions are in accord with the patient's preferences.

In the Hippocratic tradition of beneficence and nonmaleficence, physicians had not only the responsibility, but also the authority to determine what was best for their patients. This has evolved to the more contemporary notion, especially prominent in the United States, that the patient, rather than the physician, determines what is best for the patient. The U.S. physician's role has evolved from the traditional authoritarian or paternalistic model to that of someone whose role is to share decision-making responsibility with the patient through educating and making recommendations. In this interpretation, the principles of beneficence and nonmaleficence are congruent with the principle of respect for patient autonomy.

Respect for Patient Autonomy

The principle of *respect for patient autonomy* is embodied by the legal concept of *self-determination:* A competent adult has a right to determine what will be done to his or her body. This principle also relates closely to the legal principle of an individual's right to privacy. According to these principles, the patient has the right to decide whether or not to undergo interventions that are available and medically appropriate. It is important to recognize that autonomy is a right to choose, not a right to demand and receive any desired treatment. The principle of respect for autonomy is also the basis for informed consent. Except in emergency circumstances, a competent adult must give informed consent prior to receiving medical care, especially that which involves potentially hazardous interventions. Under emergency conditions, i.e., when the patient's life, limb, or other vital functions are at risk without the intervention, consent is presumed. In the United States, there is a widespread societal and professional consensus that health care providers should not only respect a patient's autonomy but also enhance it through shared medical decision making. Outside of the United States, ICU physicians are much more likely to follow the paternalistic tradition of decision making, i.e., make decisions, including decisions to withhold or withdraw life support, on behalf of their patients.

Distributive Justice

In the ICU setting, the principle of justice refers to the principle of *distributive justice.* As alluded to previously, this principle pertains to defining fairness in allocating resources among individuals when not all can receive the resources. Aristotle stated the concept of distributive justice as the "principle of formal justice," according to which equals should be treated equally and unequals unequally. Although it appears rather straightforward, this formulation cannot be applied easily, because specific criteria need to be identified and agreed upon when judging if two individuals are equal or unequal. When applied to distributive justice, various ethical theories define different values as the most relevant criterion for making such judgments, as described below.

Egalitarian Theory

The *egalitarian theory* of justice holds that all individuals have equal intrinsic worth and therefore distributions should not be made based on perceptions of individuals' different social worth. One egalitarian strategy for fair allocation of health care resources is that patients having the same medical need should have the same medical resources. An example of this is health care funding in the United States for patients with end-stage renal disease (ESRD), all of whose medical expenses are covered by Medicare. Another egalitarian approach holds that each person should have an equal chance of receiving a scarce resource. Examples include dialysis centers that, prior to Medicare funding, held lotteries to determine who would receive chronic dialysis, and centers that took applicants on a "first come, first served" basis. Although the latter practice resembles a "natural lottery," it is biased due to unequal access to the health care system by poor (uninsured) and wealthy patients due to financial constraints and timeliness of referrals.

Utilitarian Theory

Other theories of ethics are based on different criteria. The *utilitarian* theory of justice is centered on the principle of utility and contends that a fair decision should maximize utility as its consequence. For example, the maxim "The greatest good for the greatest number" reflects utilitarianism. According to this theory, a country with limited health care resources could justify disproportionate spending on public health interventions benefiting many citizens, rather than on critical care beds that benefit relatively few. In the United States, prior to universal Medicare coverage for chronic dialysis, some centers based treatment access on perceived social worth—a utilitarian schema. Patients were prioritized according to whether they were employed, their type of employment, family status, and other measures of perceived social worth. Not unexpectedly, successful dialysis candidates resembled the white, male, middle-class constituents of the anonymous selection committees (so-called "God Committees" because they made life-and-death decisions). When this approach was publicized, it was criticized as unfair and discriminatory, and ensuing public outcry was the impetus for universal Medicare funding for patients with ESRD.

Libertarian Theory

The *libertarian* point of view holds that health care resources should be allocated according to one's own resources and ability to pay for them. Private health insurance in the United States is an example of the libertarian view.

Deontological Theories

Deontological, or duty-based, theories of justice are based on rules that define ethical behavior. One influential deontological theory developed by the philosopher John Rawls relates to social institutions in general. From Rawls' theory were derived the concepts of provision of fair, decent, minimum health care benefits for all, and fair, equal opportunity. The latter concept supports provision of *more than an equal share* of resources to those who are disadvantaged in order to promote a basic level of societal functioning. On this basis, health care resources should be allocated according to need of the individual patient in order to preserve or restore a basic level of functioning.

Another deontological principle that affects the distribution of limited resources is the so-called rule of rescue. This principle refers to the duty of society to expend resources to save an identified individual's life if society has the means to do so. The rule underlies well-publicized rescue efforts for *individuals* whose lives are in danger. Equally predictable but unidentifiable (i.e., anonymous) statistical deaths are not accorded the same moral obligation. Emphasis on the practice of "rescue-type" medicine in the United States, including the burgeoning of ICUs, has been heavily influenced by the rule of rescue.

RELATIONSHIP BETWEEN HEALTH CARE LAW AND ETHICS

Ethical behavior and legal requirements are generally not completely congruous. For example, some argue that the traditional application of the law to health care providers is a type of "minimal morality." For example, states *require* that practitioners providing medical or nursing care be licensed. In contrast, the professional ethics of these practitioners represents ideal professional behavior: Care *should* always be provided in accord with the principle of beneficence. For many clinical issues, the relationship between ethical and legal viewpoints is even more complex.

The legality of what health care professionals do may change, depending on external circumstances. For example, health care law may vary considerably over time between two different jurisdictions. Similarly, what is regarded as ethical or unethical behavior for physicians may change. As an example, consider active euthanasia by physicians. Although controversial, all major U.S. professional medical societies consider the practice of euthanasia as unethical. Furthermore, according to state law, it is illegal in the United States. However, over the past 10 years, euthanasia administered by physicians with certain safeguards has become both legal and professionally accepted in the Netherlands and Belgium.

As these considerations highlight, health care providers should view bioethics not as a fixed body of knowledge, but rather as a continually evolving field similar to clinical medicine.

PRINCIPLES REGARDING END-OF-LIFE CARE IN THE INTENSIVE CARE UNIT

During the last three decades a broad societal consensus has developed regarding the ethics of withholding or withdrawing life-sustaining therapies or life support. This consensus was catalyzed, for the most part, by a bioethical foundation developed by the President's Commission in the early 1980s and a series of precedent-setting judicial decisions, including the 1972 Spence decision in the District of Columbia on informed consent, the 1976 New Jersey Supreme Court decision regarding Karen Ann Quinlan, the 1984 California Supreme Court decision regarding Bartling, and culminating with the 1990 U.S. Supreme Court decision regarding Nancy Cruzan. Based this consensus, one can derive a number of principles that can guide health care professionals in making decisions related to withholding and withdrawing life-sustaining therapy. These principles are discussed in this and subsequent sections.

Principle 1

Informed adults with adequate decision-making capacity can forgo any life-sustaining medical therapy, even if the action results in their death.

The key words and phrases in Principle 1 are *adult, informed,* and *adequate decision-making capacity.* The principle applies only to adults, since children generally lack the personal autonomy required by legal or ethical standards. An adult must have appropriate information, provided in an understandable manner, in order to arrive at an informed decision. In addition, he or she must have sufficient mental capacity to evaluate the specific decision being considered. Assessment of adequacy of decision-making capacity is described below.

Principle 2

Forgoing life-sustaining therapy includes not only the withholding *of therapy, such as cardiopulmonary resuscitation, but also the* withdrawal of *interventions, such as mechanical ventilation, artificial nutrition, and hydration. There is no substantive ethical or legal difference between withholding and withdrawing life-sustaining therapy.*

Controversy over the moral distinctions between actions and omissions leading to a patient's death ended when consensus developed that withdrawing care is ethically equivalent to withholding care. Likewise, in general, there are no legal distinctions between withholding and withdrawing. Nonetheless, patients, families, and health care providers often perceive differences between them and their psychological effects.

The legal issue of whether artificial nutrition and hydration provided by an oral, nasal, or percutaneous feeding tube constitutes medical care was decided when the U.S. Supreme Court deemed it so in its 1990 decision on Nancy Cruzan. This decision established a constitutionally protected legal

right to refuse any medical care by competent adults or by appropriate surrogate decision makers acting in accord with the patient's previously expressed preferences or values.

Principle 3

Surrogate decision makers should decide whether to forgo life-sustaining therapy on behalf of patients who have lost decision-making capacity based on knowledge of what the patient would have wanted under similar circumstances. In the absence of such knowledge, decisions should be based on the patient's best interests.

Surrogate decision makers are commonly one or more members of the patient's immediate family. However, others may serve in this role under a number of circumstances. When a patient has legally designated someone as health care proxy by means of a durable power of attorney for health care, the designee must be the surrogate decision maker, even if he or she is not a member of the patient's family. When the patient has not arranged for a valid durable power of attorney but has otherwise identified someone as health care proxy, either in writing or verbally, his or her choice should be respected. Finally, when the patient has not designated a health care proxy or where state statutes do not specify a formal legal hierarchy that determines the order of selection of a surrogate, the presumption is that a close family member who knows the patient well should be the surrogate decision maker. In these circumstances, the patient's attending physician, as an advocate for protecting the patient's interests, has the responsibility for evaluating the appropriateness of a surrogate decision maker.

Legal Standards for Surrogate Decision Makers

Surrogate decision makers should use one of these two ethical and legal standards: (a) the *substituted judgment standard* and (b) the *best interests standard.*

Under the substituted judgment standard, the surrogate decision maker expresses what the patient would have preferred under the circumstances. The decision maker must have knowledge either about the preferences of the patient, as expressed orally or in writing in an advanced directive, e.g., a living will, or about the patient's values and life goals, from which valid inferences can be made.

Under the best interests standard, such knowledge is lacking, and the surrogate decision maker along with the caregivers must weigh the *benefits* of life-sustaining therapy against its *burdens.* The decision is based on the outcome of the balance. For example, the benefits of life, chance of survival, and chance of full recovery with a high quality of life are weighed against the burdens of pain, additional suffering, and poor eventual quality of life.

Principle 4

When in doubt about a patient's preferences, health care providers should err on the side of sustaining life.

Although the essence of Principle 4 is obvious, less obvious is a corollary to the principle: Health care providers who decide to sustain a patient's life should be willing to stop life-sustaining therapy if it is later determined that the patient would not have wanted it or that it was not in his or her best interests. Consistent with this principle is the concept of a "therapeutic trial of life support." Despite uncertainty about their effectiveness, life-sustaining therapies may be started in order to determine whether they will benefit the patient. Once therapy is under way, the decision to continue it or not can be made by an objective assessment, rather than a prediction, of its effectiveness.

For example, the question often arises whether a patient with acute respiratory failure complicating severe chronic obstructive pulmonary disease, once intubated and ventilated, can be successfully weaned from mechanical ventilation over a certain period of time that is acceptable to the patient. In many cases, the question can be resolved only by a time-limited therapeutic trial of assisted ventilation. In certain instances, when it can be agreed before the therapeutic trial, the ventilator can be withdrawn and the patient allowed to die if extubation or progress toward extubation is not made after an agreed-upon period. Such a therapeutic trial is preferable to not attempting potentially beneficial therapy because of uncertainty or the patient's fear that once such therapy is started, the ventilator would be continued indefinitely, even against his or her preferences.

Principle 5

Providing the patient or surrogate decision maker has been informed and consented, it is ethically appropriate to relieve pain and other suffering, such as dyspnea, even if doing so has the potential to hasten the patient's death

Giving medication to relieve pain and suffering that may hasten death as a side effect should not be confused with active euthanasia or assisted suicide. When acting in accord with Principle 5, the health care provider's intention should be to relieve pain and suffering. This follows from the principle of beneficence. In contrast, the intention when performing active euthanasia or assisted suicide is to *cause* the patient's death. Withdrawal of mechanical ventilation to allow patients to die from disease is ethically and legally distinct from active euthanasia or assisted suicide. However, in the past some authors have referred to such withdrawal as *passive euthanasia.* Since this term may be confused with active euthanasia, it should be avoided when referring to acts of withholding or withdrawing life support.

Principle 6

It is inappropriate to force physicians or other health care providers to comply with a patient's request to forgo life-sustaining therapy if compliance violates the health care provider's personal moral values. Under these circumstances, responsibility for care of the patient should be transferred to another provider who can respect the patient's request.

This principle affirms individual values and acknowledges the pluralistic nature of society, especially in the United States. Although the principle respects the right of the health care provider to act in accord with personal values, despite conflict with the patient's preferences, it continues to support the patient's autonomy. There may be difficulty in implementing this principle if the health care provider who is in conflict with the patient is uncooperative. For example, if the attending physician refuses to comply with the patient's or family's request to withdraw life support because of his or her personal moral values, the family may have to assert themselves in having that physician transfer the patient to another, more supportive, physician.

ETHICS RELATED TO FUTILE MEDICAL INTERVENTIONS

The issue of a patient's family demanding continuation of what health care providers judge as futile interventions remains controversial. While some suggest that there are limits to the respect for patient autonomy and that there is no ethical "right" to receive useless or futile interventions, others argue that the definition of medical futility is so subjective that use of the term, and decision making based upon it, are unjustified.

Principle 7

Health care professionals are not obligated to provide medical interventions that are judged as futile, even if requested by the patient or family. Futile life support may be limited without consent of the patient or surrogate decision maker.

Although Principle 7 lacks the strong consensus that supports the six preceding ethical principles, limiting life-sustaining therapy that has been judged futile has, in one form or another, already been incorporated into clinical practice. One may ask whether the term *futile life support* is inherently contradictory. If an intervention supports life, how can it be futile?

First, in response, one should make a distinction between *physiological futility* and *medical futility.* An intervention that is judged to be *physiologically futile* is one that is not expected to or does not achieve the relevant physiological function as an end point. For example, cardiopulmonary resuscitation (CPR) is judged to be physiologically futile at the point when health care providers decide to stop an unsuccessful resuscitation. The CPR has failed in its goal of restoring a spontaneous circulation. In the same sense, CPR may be regarded as physiologically futile in a patient with refractory septic shock who has a cardiac arrest after progressively worse hypotension despite use of maximal vasopressor therapy. Under these circumstances—a cardiac arrest occurring despite maximal medical therapy—the conclusion that CPR would have virtually no chance of being successful (beyond possibly a brief time period) appears reasonable. An attempt at cardiopulmonary resuscitation would prolong the patient's dying somewhat but could also do physical harm to the patient, e.g., by fracturing ribs, etc. Prolonging dying is not one of the goals of medicine and, under these circumstances, CPR would violate the principle of nonmaleficence. Arguably, some see forcing health care providers to perform CPR with virtually no prospect of success as violating the ethical integrity of the medical profession.

Although there is modest consensus about physiological futility, medical futility is more difficult to define. Some have suggested that an intervention can be judged to be medically futile if reasoning and experience indicate that the intervention would have a high likelihood of failing to result in "meaningful survival." In applying this definition, the key words are *high likelihood,* which acknowledges the uncertainties inherent in clinical decision making, and *meaningful survival.* Meaningful survival signifies that survival has a quality and duration that are of value to the particular individual. Importantly, *quality of life* refers to the *patient's* point of view, not that of the health care provider. As an extension of this definition, some organizations of critical care specialists have recommended that survival of patients with permanent loss of consciousness, such as those in a persistent vegetative state, should be regarded as meaningless. Using this criterion, a life-sustaining intervention for such patients can be judged to be medically futile and, therefore, not obligatory.

Because application of the concepts of physiological or medical futility as the basis for withholding or withdrawing life-sustaining intervention can be misapplied due to their subjective definitions, appropriate guidelines and safeguards for their application should be incorporated within a health care institution's written policies. This is especially important to ensure due process for patients and families. Furthermore, appropriate resources, such as institutional ethics committees or consulting bioethicists, should be available to provide consultations to clinicians and families. In contrast to the legacy of high-level, important court decisions affirming a patient's right to forgo life-sustaining therapy, case law on use of physiological or medical futility as the basis for withdrawal of life support is quite limited and, at present, inconclusive.

ETHICAL PRINCIPLES RELATED TO MICROALLOCATION OF ICU RESOURCES

Microallocation includes the process of admitting patients who are competing for a limited number of ICU beds or providing specific scarce resources to patients within the ICU—e.g., use of continuous renal replacement therapy or extracorporeal life support (ECLS). Microallocation encompasses concepts of both triage and rationing. *Triage* is the system of prioritizing patients according to severity of illness and, under some circumstances (e.g., in combat or disasters with mass casualties), according to the degree of benefit accrued to the patient by access to medical care. It entails consideration

of the impact of caring for one patient on the system's capacity to care for others. In the broad sense, *rationing* is an economic term that refers to the process of deciding among competing goals when resources are limited. In a narrow sense, rationing implies depriving some patients of beneficial care when not all can receive that care. One example is the use of waiting lists for solid organ transplants.

In contrast to the constantly inadequate number of solid organs for transplantation, ICU bed shortages often occur intermittently. Furthermore, in the face of *persistent* excess demand, ICU shortages can be addressed by spending more money to open more ICU beds, whereas the same does not solve the problem of scarcity of solid organs.

Compared to the obvious impact of an insufficient supply of solid organs on mortality, the impact on patient outcomes of situations when ICU demand exceeds ICU supply is unclear. This may be due to the presence of flexibility in ICU supply and demand compared to the circumstances of shortage of solid organs. Flexibility of *supply* arises from using "intermediate care" units for patients who do not necessarily need critical care but who still require monitoring and more care than provided on a general inpatient unit. There is also flexibility in *demand* since patients who normally would be admitted to an ICU postoperatively often can be held in postanesthesia care units. In response to severe ICU bed shortages, elective surgical cases may be canceled. Finally, emergency departments may be able to function for limited periods in a similar holding capacity in response to ICU bed shortages.

The following principles are derived from fundamental legal and ethical principles and can serve as guides to making microallocation decisions in the ICU despite lack of an explicit societal consensus in how to allocate care and expensive health care resources.

Principle 8

Each individual's life is equally valuable.

This principle affirms two fundamental concepts: (a) All individuals are equal; and (b) all human life is valuable. The principle reflects the egalitarian concept that all individuals are equal because of their same intrinsic worth, which in turn arises from their humanity and human dignity. On this basis, each individual should receive respect and equal treatment. According to this principle, access to ICU resources and other services should *not* be prioritized according to perceptions of relative social worth among individuals. Patients should not be regarded as more or less valuable to society by virtue of their social class, employment status, family status or ethnicity, etc.

The principle has its roots in legal principles derived from concepts of due process in the Constitution of the United States. Although there is no legal right to health care in general for citizens of the United States, there is a legal obligation for health care providers to administer care in emergency situations. Because care in the ICU is similar to emergency care from the perspective of the need to address urgent and often life-threatening medical needs, one could argue that for patients in need, ICU care is as much a right as emergency care. Although this remains an unresolved legal issue, external accrediting and state regulatory bodies hold health care institutions accountable to have resources available to meet the medical needs of their patients.

Principle 9

Vulnerable members of the community should be protected.

This principle reiterates Principle 8 that all members of the community should be treated as having equal value. However, Principle 9 goes beyond a simple sense of equality by highlighting that additional safeguards should be taken to ensure that society's vulnerable members are treated fairly.

One of these safeguards is protection against potential tyranny of the majority. For example, consider a policy in which the majority of subscribers of a health maintenance organization (HMO) decide to not fund beneficial critical care for premature infants or the elderly in order to make money available for other health care purposes. Such a policy would adversely affect these vulnerable groups, whether or not the majority's motives were judged to be altruistic (e.g., improving public health programs) or self-serving (e.g., providing free cosmetic surgery).

Historical justifications for this precaution reflect past events when society has restricted access to education, employment, or health care for certain vulnerable groups, such as the poor, the handicapped, or ethnic and racial minorities. In accord with John Rawls' principle of fair equality of opportunity, there is an egalitarian duty to provide extra (not equal) resources to those who are disabled or disadvantaged as a means of helping them function effectively in society. For example, education of handicapped children is supplemented by provision of additional resources. The supplementation provides the handicapped with a fair equality of opportunity to achieve a basic level of education. The same rationale justifies provision of additional health care resources, such as critical care, to patients in greater need rather than provision of each person with an equal amount, irrespective of need.

Current legal protections for certain vulnerable groups in the United States also reflect this principle. For example, as potential subjects in clinical research, children and other persons with absent or limited autonomy, such as the mentally retarded or prisoners, are accorded extra protection.

Principle 10

Access to intensive care should be based on the patient's medical need and the potential benefit of such care; judgments about whether a benefit is worthwhile should reflect not only the values of the patient and health care providers but also the values of the community.

This principle affirms that decisions to admit and care for patients in the ICU should be primarily based on *medical* appropriateness. In general, this principle holds that patients with the same degree of medical need should be treated

the same. However, the principle also recognizes that different medical interventions can be used for the same medical need and have a range of potential benefits from minimally (marginally) beneficial to clearly beneficial. On this basis, patients should receive critical care only when they have sufficient medical need and when critical care provides a sufficient degree of potential benefit, i.e., exceeds a certain threshold.

Evaluating the value of receiving critical care is a complicated process that incorporates three points of view: those of the health care provider, patient, and community. The health care provider's professional knowledge is required for assessing the patient's medical needs, deciding which interventions can meet those needs, and predicting the likelihood of success. In addition, although medical benefit denotes how well an intervention meets the patient's needs, only the patient can determine if the potential benefit of an intervention has sufficient personal value to justify receiving it. Finally, the community and health care institution—the parties ultimately paying for the resources—have a legitimate role in deciding whether the potential benefit of a certain intervention has sufficient value to society to make it worth the financial cost. For example, the question of whether a marginally beneficial therapy should be covered by a health care plan needs a societal perspective that extends beyond medical expertise and patient opinion. Denial of care because of very low potential benefit should reflect the community's values and priorities for using its resources.

Communities and their health care institutions may place different values on the same services. For example, one health care institution may decide that patients in states of permanent unconsciousness should be restricted from care in the ICU. Another may decide the opposite, holding that sanctity of life prevails above all other considerations. A health care system, its members, and its providers might decide not to provide critical care for all patients with irreversibly fatal diseases when death is imminent. In a financially closed system, such as one with full capitation or a global budget, money saved by such a decision could fund a comprehensive hospice home care program for the same category of patients. Involvement of health care providers in decision making provides a safeguard from the tyranny of the majority of the community, whereby vulnerable members are treated unfairly by denying reimbursement for clearly beneficial therapies.

Principle 11

Although health care providers have a primary obligation to benefit their patients, this duty has limits when it unfairly compromises the availability of resources for others.

The primary professional duty of health care providers is to promote their patients' best interests. This responsibility is derived from the principles of beneficence and fidelity and constitutes the core of the physician-patient relationship. Some have argued the physician-patient relationship bestows on the physician a *fiduciary-like responsibility* to his or her patients. Under this responsibility, physicians are obligated to put their patients' interests above their own and those of others when providing medical care. This obligation for physicians is needed because of marked inequalities of medical knowledge and experience between health care providers and patients. It also recognizes the patient's vulnerability and dependency on the health care provider due to sickness and disability.

In a closed system in which physicians put their patients' interests foremost without regard for limited resources, a situation arises that some have likened to the "tragedy of the commons." In this analogy, each herdsman is only motivated by self-interest and keeps adding cows to a common grazing area. Overgrazing eventually results in tragic consequences for all of the cows. Likewise, if health care providers keep spending limited health care resources on their own patients without regard for costs or availability of resources for other patients, the resources will be depleted eventually. The result is their unavailability for all. From these considerations arises the need for limits on the physician's duty. However, limitations cause an inherent tension for physicians between duty to patients and obligation to support a system whose availability of resources could be compromised by unchecked promotion of patient interests (e.g., by expending resources in the pursuit of minimal but expensive marginal benefits).

Even though health care providers should practice cost-effective medicine whenever possible—i.e., they should select the less costly of two therapies with equivalent effectiveness—in the absence of a closed system and explicit limits, providers are not obligated to withhold beneficial care from patients solely because of personal concerns over cost.

Allocation rules for the ICU should be made at the institutional level and not at the level of the individual practitioner. Individual physicians may have subjective biases about issues that constitute worthy bases for allocation decisions. Decision making on an institutional basis provides additional safeguards that the process is fair since institutional policy making is generally an explicit process that has built-in mechanisms for internal review and external scrutiny.

SPECIFIC ETHICAL QUESTIONS AND CONSIDERATIONS IN THE ICU

Principles 1 through 11 can be illustrated more fully when applied to a number of important ethical questions commonly arising in the ICU.

Can intubated patients in the ICU really express their preferences?

Although communication may be a difficult and slow process, selected patients receiving mechanical ventilation may be quite lucid, especially when not receiving sedation. At these times, it is not uncommon for health care professionals to communicate with the patient verbally and for the patient to write responses or questions. When the patient cannot write (e.g., due to neuromuscular weakness) more creative means of communication can be tried. Examples include

having the patient blink in response to yes or no questions and creating controlled leaks around the tracheal cuff to allow patients to phonate during the inspiratory phase of mechanical ventilation.

Should one assume that patients in the ICU are capable of valid decision making?

Under ordinary circumstances in medical practice, one should presume that adult patients have adequate decision-making capacity. In fact, the law presumes an adult to be competent until judged by a court to be legally incompetent. However, one can argue that a critically ill patient in an ICU generally lacks decision-making capacity. Many factors may compromise the decision-making capacity of a critically ill patient: effects of the underlying disease; use of sedatives, narcotics, and other mind-altering medications; sleep deprivation; pain; anxiety; disorientation; and fear. Adopting this point of view, health care providers should carefully assess the patient's decision-making capacity, relying on his or her communication, as discussed below.

What if the family or surrogate decision maker of a critically ill, incapacitated patient overrides the patient's previously known preferences regarding life-sustaining therapy?

In general, according to the principle of respect for patient autonomy, the patient's preferences should guide therapy, even if the patient's family or surrogate decision maker opposes these preferences. However, if the patient's surrogate has a valid durable power of attorney over the patient's health care decisions, the surrogate can legally exercise control over decisions—although it should be quite unusual for the person holding a durable power of attorney to ignore a patient's preferences. Regardless of the legal status of the surrogate, in the event of a conflict, the recommended first step for health care providers is discussion of differences directly with the surrogate. If needed, a request for informal or formal consultation from the hospital's ethics committee or bioethicist can be taken as the next step. In these circumstances, the principle of beneficence and the health care provider's fiduciary relationship with the patient obligate the health care provider to act as the patient's advocate. Only in rare instances should the conflict have to be resolved in a court of law.

What if health care providers do not agree with the patient's or surrogate's preferences regarding life support?

When health care providers disagree with patients or their surrogates regarding life support, physicians and nurses have little choice except to transfer care to other health care professionals. (This assumes, of course, that the decisions are made by an informed patient with adequate decision-making capacity or by a surrogate who has a valid durable power of attorney.) A classic example of this type of conflict is refusal of blood products on religious grounds by a Jehovah's Witness despite the presence of life-threatening gastrointestinal bleeding. In this case, health care providers must respect the patient's legal and ethical right to refuse the blood, even if such action results in the patient's death. When conflicting bioethical principles arise (Fig. 157-1), respect for patient autonomy overrides beneficence. Under different circumstances—e.g., if the patient is a child of a Jehovah's Witness and is a minor—health care providers can regularly obtain a court order to give blood products, despite the parents' opposition.

When preferences are expressed by a surrogate decision maker who lacks a valid durable power of attorney, the strength of the surrogate's directives is less compelling. If the patient's health care providers are concerned that the surrogate may not be acting in the patient's best interests, they should seek consultation with the ethics committee to resolve the conflict.

Is a "slow code" or "Hollywood code" ever ethically acceptable?

A "slow code" occurs when health care providers perform CPR with less than the usual intensity or speed; the intent of such an approach is to allow the patient to die. The premise is that resuscitating the patient is inappropriate. A "Hollywood code" carries the same meaning as "slow code" but includes the pretense that the code is genuine. The deception in both of these practices makes them ethically problematic and unacceptable. These practices may be employed in hospitals that do not have policies allowing DNR orders on the basis of physiological futility when CPR is considered extremely unlikely to be successful for patients. One way to discourage these types of codes is for institutions to support their physicians' authority to use their professional judgment in not providing inappropriate or ineffective interventions.

If CPR or another life-sustaining intervention is judged to be futile, what should health care providers do? Can they be forced to provide futile interventions?

When health care providers judge that CPR or other life support is futile, they should discuss this with the patient (if possible) or the patient's surrogate decision maker. Sometimes the surrogate or family agrees with the physician's judgment that limitation of life support is appropriate. Some families may even be thankful and relieved that the physician has taken responsibility for the decision to withhold or stop the intervention. If the surrogate opposes withholding CPR or other interventions that are judged futile, attempts to reach agreement through further discussion and consultation with the ethics committee should be made. If these efforts are unsuccessful, attempts should be made to transfer the patient to another physician in the same or another institution for provision of the particular intervention in question. However, patients for whom judgments of futility apply are often too unstable to be moved to another institution. Ultimately, if the patient cannot be transferred and if it is allowed by hospital policy, the physician should write a DNR order on the basis of futility and should inform the surrogate. If such DNR orders are not permitted by hospital policy and if the patient cannot be transferred to another hospital, the physician faces a limited number of alternatives: (a) acquiescence and provision of futile care; (b) resignation from the case by transferring care to another physician in the same institution; or (c) procurement of a court order to limit therapy on the basis of futility.

Is the current system of "first come, first served" regarding ICU admissions fair? Which patients should be discharged from a full ICU in order to make room for new patients?

Whether the admissions policy of an ICU is fair or unfair can be assessed by first considering the policy in relation to this basic principle of distributive justice: Equals should be treated equally and unequals treated unequally. If admission is granted solely on the basis of whether a patient's severity of illness meets a threshold, and if critical care can provide more than certain minimal threshold of potential benefit, the patient should be admitted to an available bed. This practice constitutes an example of "equals being treated equally," where the overriding criteria for equality or inequality are a sufficient degree of medical need and the potential for deriving benefit. If policies limit admissions to the ICU based solely on gender, race, ethnicity, or age—even if a patient meets thresholds for severity of illness and derivation of potential benefit—equals are being treated unequally and the decision is considered unfair.

If patients do not meet the thresholds for degree of illness or potential benefit, they should not be admitted, even if requested by the patient or his or her family. This scenario is an example of unequals (i.e., those with lower medical needs) being treated unequally (e.g., not being admitted to the ICU), where a sufficient degree of illness or potential benefit are the determinative criteria. These same considerations should govern not only decisions to admit patients to the ICU, but also decisions to continue care in the ICU.

What are the alternatives when a critically ill patient needs admission to a full ICU? Providers could refuse to admit the patient, irrespective of the relative degrees of illness among the new and old patients, assuming all existing ICU patients meet the criteria of sufficient medical need and derivation of potential benefit. This decision is consistent with the "first come, first served" rule. The waiting patient could be admitted to another ICU in the same hospital or stabilized and transferred to another hospital where an ICU bed is available. Alternatively, providers could transfer the least sick patient in the full ICU to another ICU in the same hospital or an intermediate care unit in order to make room for the new patient (assuming the new patient is clinically more in need than the transferred patient). Resources in the intermediate care unit might need to be increased temporarily to care for the transferred patient adequately. In addition, one could discharge the ICU patient with the poorest prognosis in order to make room for the new patient (assuming the new patient had a better prognosis than the one discharged). Unless differences in prognoses are striking, deciding on the relative benefits of critical care among patients is subject to bias and value judgments—a problematic issue from an ethics standpoint.

Currently available objective estimates of outcome in an ICU may improve decision making regarding resource allocation by decreasing subjectivity (see Chapter 156). However, these estimates can be misleading when used in this regard. The estimated risk of death assumes that the patient has received critical care; hence, a low predicted risk of death would not constitute firm grounds in *excluding* a patient from the ICU. It is clear that objective determination about who would do well in an intermediate care unit instead of an ICU would be useful in making these kinds of triage decisions. In addition, it is unclear how accurate the current generation of objective prognostic systems is in comparing relative risks of survival. For example, is a predicted mortality risk of 40 percent significantly different from a 50 percent risk? Finally, even if these systems predict mortality risks greater than 90 percent, it is unlikely that families of critically ill patients would accept a 5 or 10 percent chance of survival as too low to continue ICU care.

When should an individual patient's consumption of scarce or expensive resources be limited?

When a provided resource meets a patient's medical needs, the resource should be limited only if the patient is consuming a *disproportionate share;* that is, if continued consumption would threaten availability for others. For example, a patient who has persistent variceal hemorrhage, despite all possible therapeutic attempts, may require an almost continuous infusion of blood products to prevent death from exsanguination. When availability of the blood bank's supply of that type of blood product may be compromised, it is appropriate to stop transfusions. Some would argue that there is an *obligation* to do so. Such a decision by clinicians and appropriate consultants should be communicated to the family (since the patient is likely to be encephalopathic under these circumstances). However, deciding on the point at which a patient's share of a resource is disproportionate may be difficult.

With regard to consumption of limited or expensive resources, physicians face an ethical dilemma between two conflicting professional roles: (a) as patient advocate, keeping the patient alive in accord with the principles of beneficence and respect for autonomy; and (b) as a "wise steward" of a health care system's limited resources. Few guidelines exist that address the tension created by these dual roles. Although the limited resource in the example provided above was blood, the same argument could apply to health care costs. Money is as limited a resource as tangible medical products and interventions in a large health care system that is financially closed. In a closed system, money spent on behalf of one patient decreases funds available for other patients. One important future ethical challenge for health care providers in the ICU is integration of these roles as financial resources become even more constrained.

"DO NOT ATTEMPT RESUSCITATION" (DNAR) ORDERS IN THE INTENSIVE CARE UNIT

DNAR Orders and Terminology

End-of-life decisions have a prominent role in the management of patients in intensive care units. For critically ill patients, DNAR orders are common, and the majority of patients dying in intensive care units have DNAR orders at the time of their death. Clinicians practicing critical care must be familiar with the details of DNAR decision making. Because in-hospital resuscitations are much more likely to fail

than succeed, many hospitals have changed what was originally written as "Do Not Resuscitate" or DNR orders to the more realistic descriptor, "Do Not Attempt Resuscitation" or DNAR orders.

When to Discuss Withholding or Withdrawing Life-Sustaining Therapy

Ideally, a patient's primary care provider should have discussed the patient's preferences for withholding or withdrawing life support well before admission to an ICU. If done with medically informed foresight, the primary care provider should have discussed and clarified how use of life support fit into the patient's overall plan for medical care, in accord with the patient's life goals and values. At the time of this discussion, the patient should have been encouraged to prepare a written advance directive and designate a surrogate decision maker and preferably a durable power of attorney. Preferences for degrees of medical interventions under various specific scenarios that patients might reasonably encounter should have been discussed. For example, in the case of a patient with severe lung disease who has previously needed mechanical ventilation, what are the patient's preferences regarding re-intubation and duration of assisted ventilation? Does the patient want to be intubated again if clinically indicated? What should be done if the patient cannot be weaned after 1 week or after 2 or more weeks?

After a patient is admitted to an ICU, the patient, a family member, surrogate decision maker, or health care provider may initiate discussion about whether continued or new life support is appropriate. If the patient has an advance directive, the patient's ICU caregivers should explore its meaning and applicability to first clarify why the patient was admitted to the ICU. If the advance directive simply indicates that life support should be withdrawn when there is no reasonable hope for meaningful recovery (a common phrase in many living wills), one needs to understand how to interpret "reasonable" and "meaningful recovery" before being able to offer appropriate recommendations regarding continuing, withholding, or withdrawing life support.

However, if the patient lacks a written advance directive (which is the case in the vast majority of admissions), he or she may have talked to family or friends about preferences regarding life support (e.g., a preference "not to be kept alive by machines"). Alternatively, even if the patient has not expressed anything specifically about life support, family or close friends might agree about what the patient's preferences would be based on their knowledge of his or her life goals and values.

In circumstances in which a patient's prognosis is very poor and provision of CPR or other interventions would be futile or highly burdensome, the attending physician should initiate end-of-life discussions with the patient's family or surrogate decision maker as early as possible. In general, ICU attending physicians should meet with the patient's family within the first 48 hours of ICU admission specifically to discuss the patient's condition, prognosis, and what is known about the patient's preferences related to continuing or forgoing life support.

Assessment of a Patient's Decision-Making Capacity

Competency should be distinguished from *decision-making capacity.* An adult is legally competent until a court of law decides otherwise; children, as minors (unless emancipated by parenthood or marriage), lack legal competency. In contrast, decision-making *capacity* refers to a patient's functional ability, which is often determined by the patient's attending physician. Many legally competent patients lack adequate decision-making capacity when critically ill or heavily sedated. Conversely, a patient who is legally incompetent may retain some decision-making capacity, e.g., a teenager who has opinions about his or her medical care.

If a patient has adequate decision-making capacity in relation to a specific decision, then the patient should be able to demonstrate a set of abilities relating to comprehension, making comparisons, value judgments, and communication (Table 157-1). Adequate decision-making capacity in relation to a specific decision is generally present when the patient demonstrates all of the following: (a) comprehension; (b) comparative judgment; (c) communication; (d) appreciation of consequences; and (e) ability to make a choice. The patient should be able to understand information about his or her medical condition, its prognosis, and treatment alternatives, including having no treatment at all. The patient should also be able to judge and compare the medical alternatives and outcomes relative to personal values and life goals. Finally, the patient should be able to communicate preferences consistently. One should specify the context of the assessment for decision-making capacity, since in some cases patients may have adequate capacity for certain decisions but not for others.

The attending physician is responsible for assessing the patient's decision-making capacity. The process includes review of the patient's medical history, performance of mental status examinations, and consultation with the patient's

Table 157-1

Standards for Determining Decision-Making Capacity

Ability to communicate a choice
Ability to make a reasonable treatment choice
Ability to appreciate the decision and its consequences
Ability to rationally manipulate the information
Ability to understand the fundamental meaning of the decision

nurses and family. If doubt or conflict arises about the determination, additional information should be obtained, e.g., by requesting a psychiatric consultation.

Identification and Role of Surrogate Decision Makers

As is often the case, when a patient in the ICU lacks decision-making capacity, the physician commonly turns to a surrogate decision maker. The choice of proxy may be legally mandated in states that have established a legal hierarchy, e.g., spouse first, parents next, etc. Another legal mandate is an individual having a valid durable power of attorney for health care decisions. In the absence of a legal directive, if the patient has informally designated someone as surrogate decision maker, that choice should be followed with some exceptions. In most cases, the surrogate decision maker will be a close family member. An appropriate surrogate should be willing to serve in that role and to accept responsibility for making the patient's decisions, preferably based on knowledge of the patient's preferences, values, and life goals. This knowledge allows the surrogate to act on the basis of a substituted judgment, i.e., what the patient would have wanted under the circumstances.

In unusual cases, no individual who knows the patient or is willing to serve as a surrogate decision maker can be identified. In such circumstances, it is desirable to find a relatively neutral party (generally not a hospital employee) to act as surrogate—e.g., the chairperson of a hospital's ethics committee. If this is not possible, prior to their implementation, knowledgeable health care providers who are not involved in the case should review DNAR decisions. The aim of the review is to ensure that the process of determination of DNAR status is sound, i.e., the decision is based on a best interests standard or a futility judgment with appropriate due process.

Deciding on the DNAR Order

A DNAR order actually consists of much more than a proscription of CPR. In most hospitals, it also refers to withholding or withdrawing one or more life-sustaining therapies. For a patient in the ICU, these therapies may include antiarrhythmic drugs (chemical cardioversion), intubation, mechanical ventilation, dialysis, blood products, intravenous pressors, antibiotics, and parenteral and enteral nutrition.

How should limitation of certain treatments be decided? One approach is to define the goals of therapy that are applicable to the patient. Once these goals are established, one can decide which therapies are compatible with them. In some institutions, DNAR orders have been classified into three levels, each with a different goal of treatment (Table 157-2).

Table 157-2

Do Not Attempt Resuscitation (DNAR) Orders: Levels of Intervention and Associated

		Therapeutic Goals
Level	**Interventions**	**Goals of Therapy**
A	All therapies except cardiopulmonary resuscitation (CPR)	Patient is to receive all medically indicated therapies to preserve life and restore function, including those to *prevent* cardiac or respiratory arrest. However, if patient suffers cardiopulmonary arrest, *no* resuscitative attempts will be made unless specified in advance (e.g., only drug therapy permitted). Patient will not be intubated or mechanically ventilated. Restrictions may be temporarily suspended during general anesthesia or other invasive procedures if agreed upon previously. "No ICU transfer" may also be specified.
B	No additional therapy and no CPR	Therapy already under way to be continued as medically indicated, but in general, no additional treatment given except for patient comfort. Goal is maintenance of *status quo* while discussions evolve or prognosis becomes more certain. If cardiac or pulmonary arrest occurs, no resuscitative attempts to be made.
C	Palliative care only	Treatment limited to nursing care and therapy whose goal is comfort. Treatment for relief of pain, anxiety, or dyspnea may be used, even if the treatment worsens cardiac or respiratory function. All life-sustaining interventions, including artificially provided food and water, will be discontinued unless exceptions agreed upon, e.g., continued mechanical ventilation.

As a first step in the decision-making process, health care providers should meet with the patient's family or surrogate decision maker to inform them about the current medical situation, review the goals of therapy, and reassess the appropriateness of the level of current treatment in relation to the goals. The discussion should include the patient unless he or she lacks sufficient decision-making capacity. Attendance should include the attending physician, the patient's primary care physician (if applicable), consultants (when relevant for explanations and discussions of prognosis), house staff, and one or more ICU nurses and respiratory therapists caring for the patient. These meetings promote open communication among parties, help all to feel involved in the decision-making process, and facilitate understanding and acceptance of the results. "Family meetings," in which families have the opportunity to grieve while making DNAR decisions, have become common and a way of life in the practice of critical care medicine.

Carrying Out the DNAR Order

After deciding on the limits of therapy, the attending physician should document the meeting's discussion in the medical record and the justification for the DNAR order. The order should be written in a clearly identifiable location in the record as well as communicated orally to other health care providers. Details of DNAR policies vary among institutions. For example, in some states, the signature of a capable patient or surrogate decision maker may be required for a DNAR order. In the usual case, just prior to removal from assisted ventilation, bolus intravenous doses of opioids and benzodiazepines should be given pre-emptively to sedate the patient and control anxiety, pain, and dyspnea. After the desired level of sedation has been achieved, the patient is extubated and the dosage of opioids and sedatives is titrated to maintain patient comfort. A physician, nurse, or respiratory therapist may do this. If a staff member is uncomfortable with removal of life support, he or she should be given the option of not participating. Ultimately, the physician who writes the DNAR order must be prepared to extubate or remove the patient from the ventilator if necessary.

PROVIDING PALLIATIVE CARE TO ICU PATIENTS

Palliative care aims to restore or maintain quality of life and prevent needless physical or emotional suffering. Titrating opioids and sedatives to prevent the patient from suffering pain, dyspnea, or anxiety is one form of palliative care. Another is addressing the patient's and family's needs for relief of spiritual or existential suffering as well as bereavement care. It is a multidisciplinary process.

After removal from assisted ventilation, ICU patients may be legitimately kept in the ICU for palliative care. Although this may seem paradoxical to some, the patient's needs may demand an intense level of nursing and physician intervention to keep him or her comfortable, e.g., by frequent adjustments of the dose of opioid or sedative. Continued care in the ICU also has the advantage of providing continuity of care by the same physician and nursing team.

However, for patients whose needs for palliative care can be met by a less intense level of nursing and medical care, thought should be given to transferring that patient to another room outside of the ICU, e.g., in a step-down unit. This is especially important if medically needy patients require an ICU and there are no open ICU beds available. On the one hand, transfer of such patients should be given a higher priority if the demand for ICU beds is high and supply is tight, and if the patient's post-assisted ventilation course is estimated to be prolonged, i.e., longer than 1 to 2 days. Some hospitals have special palliative care units for such patients with specially trained nursing and medical staff and pleasant and private surroundings for the patient and his or her family.

On the other hand, transfer out of the ICU should be given lower priority if demand for ICU beds is modest and supply of open beds is good, and if the patient's course is anticipated to be measured in terms of hours. It makes little sense in such situations to transfer a patient out of an ICU bed for him or her to die during transport or several hours later in another unit.

Resolution of Conflicts

Good communication during the decision-making process, as a rule, prevents the occurrence of conflicts. However, if communication is poor among physicians and nurses, conflicts are common. Conflicts may also occur between the patient's family and the health care team. Conflicts may arise when one party favors forgoing life support and the other does not—for example, if the family wants full critical care continued despite pessimism about the patient's recovery on the part of the health care team. Alternatively, a family may wish to stop life support while the attending physician is reluctant to do so.

Resolution of conflicts begins with open communication among all parties. It may be helpful to consult with the hospital's ethics committee. Reviewing hospital policy, identifying legal myths or real limits, and getting all parties around the same table for discussion may resolve the conflict. Rarely should conflicts have to be referred for judicial review. If the situation reaches an impasse, it may be prudent to offer to transfer the patient to another attending physician in the same hospital or to another hospital rather than go to court.

CONCLUSION

In today's critical care environment, death in the ICU usually occurs after life-sustaining therapy is withheld or withdrawn. Many ethical considerations in the ICU arise from the frequency and complexity of this process. Health care providers

face ethical dilemmas in which decisions violate one or more ethical principles in order to respect an overriding ethical principle. Weighing ethical principles in limiting life support is supported by a broad ethical, legal, and professional consensus. As a general rule, the overriding principle is respect for patient autonomy, and hospital policies regarding DNAR orders should reflect this. Despite well-written policies, conflicts still occur, and other resources—e.g., ethics committees or consulting bioethicists—are frequently helpful in their resolution. Only in very rare cases should a conflict have to be resolved in court.

Residual volume (RV), L	1.4
Functional residual capacity (FRC), L	3.2
Total lung capacity (TLC), L	6.3
Residual volume/total lung capacity × 100 (RV/TLC), %	22
Mechanics of Breathing	
Forced vital capacity (FVC), L	4.9
Forced expiratory volume, first second (FEV_1), L	4.0
Maximum voluntary ventilation (MVV), L/min	170
Forced expiratory volume in 1 s/forced vital capacity × 100 (FEV_1/FVC), %	83
Forced expiratory volume in 3 s/forced vital capacity × 100 (FEV_3/FVC), %	97
Forced expiratory flow during middle half of FVC (FEF_{25-75}), L/s	4.7
Forced inspiratory flow at the middle of FIVC (FIF_{50}), L/s	5.0
Static compliance of the lungs (Cst, l), L/cm H_2O	0.2
Compliance of lungs and thoracic cage (CRS, respiratory system compliance) L/cm H_2O	0.1
Airway resistance at FRC (Raw), cm H_2O/L/s	1.5
Pulmonary resistance at FRC, cm H_2O/L/s	2.0
Airway conductance at FRC (G_{aw}), L/s/cm H_2O	0.66
Specific conductance (G_{aw}/V_1)	0.22
Maximum inspiratory pressure, mmHg	−75
Maximum expiratory pressure, mmHg	120
Distribution of Inspired Gas	
Single-breath N_2 test (ΔN_2 from 750 to 1250 ml in expired gas), % N_2	<1.5
Alveolar N_2 after 7 min of breathing O_2, % N_2	<2.5
Closing volume (CV), ml	400
CV/VC × 100, %	8
Closing capacity (CC), ml	1900
CC/TLC × 100, %	30
Slope of phase III in single-breath N_2 test, % N_2/L	<2
Gas Exchange	
O_2 consumption at rest (STPD), ml/min	240
CO_2 output at rest (STPD), ml/min	192
Respiratory exchange ratio (R), CO_2 output/O_2 uptake	0.8

ALVEOLAR GAS	
PA_{O_2}, mmHg	105
PA_{CO_2}, mmHg	40
ARTERIAL BLOOD	
Pa_{O_2}, mmHg	95
Sa_{O_2}, %	98
pH	7.41
Pa_{CO_2}, mmHg	40
Pa_{O_2}, while breathing 100% O_2, mmHg	640
Alveolar Ventilation	
Alveolar ventilation, L/min	4.2
Physiological dead space/tidal volume × 100 (V_D/V_T), %	<30
Alveolar-arterial oxygen-gradient, (A-a) P_{O_2}, mmHg	10
Diffusing Capacity	
Diffusing capacity at rest for CO, single-breath (D_{LCOsb}), ml CO/min/mmHg	29
Diffusing capacity per unit alveolar volume (D_L/V_A)	4.8
Control of Ventilation	
Ventilatory response to hypercapnia, L/min/per Δ Pa_{CO_2} mmHg	>0.5
Ventilatory response to hypoxia, L/min per ΔS_{O_2} (%)	>0.2
Arterial blood P_{O_2} during moderate exercise, mmHg	95
Pulmonary Hemodynamics	
Pulmonary blood flow (cardiac output), L/min	5.4
Pulmonary artery systolic/diastolic pressure, mmHg	25/8
Pulmonary capillary blood volume, ml	100
Pulmonary "capillary" (wedge) blood pressure, mmHg	<10

B

Terms and Symbols in Respiratory Physiology

GENERAL SYMBOLS

P	Partial pressure in blood or gas. P_{O_2} = partial pressure of O_2
$\bar{X}$	A bar over the symbol indicates a mean value. $\bar{P}$ = mean pressure, as distinct from instantaneous pressure
$\dot{X}$	A time derivative (rate) is indicated by a dot above the symbol $\dot{V}_{O_2}$ = oxygen consumption per minute, ml $\dot{V}_{CO_2}$ = CO_2 production per minute, ml
% X	Percent sign preceding a symbol indicates percentage of the predicted normal value
X/Y%	Percent sign following a symbol indicates a ratio function with the ratio expressed as a percentage. Both components of the ratio must be designated. $FEV_1/FVC, \% = 100 \times FEV_1/FVC$
XA, Xa	A small capital letter or a lower-case letter on the same line following a primary symbol is a qualifier to further define the primary symbol. Alternatively, subscript letters may be used. XA = X_A, Xa = X_a Additional qualifiers of the primary symbol may be identified as shown. $P_{E_{CO_2}}$ = Pressure of CO_2 in the expired air, mmHg

GAS PHASE SYMBOLS

Primary Symbols

V	Volume of gas
$\dot{V}$	Flow of gas
F	Fractional concentration of a gas

QUALIFYING SYMBOLS

I	Inspired V_I = inspired volume
E	Expired V_E = expired volume $\dot{V}_E$ = expired volume per minute
A	Alveolar V_A = alveolar volume $\dot{V}$ = alveolar ventilation per minute
T	Tidal V_T = tidal volume
D	Dead space V_D = volume of dead space $\dot{V}_D$ = dead-space ventilation per minute
B	Barometric P_B = barometric pressure
STPD	Standard conditions: temperature 0°C, pressure 760 mmHg, and dry (0 mmHg water vapor)
BTPS	Body conditions: body temperature and ambient pressure, saturated with water vapor at these conditions
ATPD	Ambient temperature and pressure, dry
ATPS	Ambient temperature and pressure, saturated with water vapor at these conditions
an	Anatomic
p	Physiological
f	Respiratory frequency, per minute
max	Maximum
t	Time

BLOOD PHASE SYMBOLS

Primary Symbols

Q	Volume of blood
$\dot{Q}$	Blood flow $\dot{Q}$ = cardiac output, L/min

C	Concentration in the blood phase C_{O_2} = concentration of oxygen in blood, ml of O_2 per 100 ml of blood
S	Saturation in the blood phase S_{O_2} = Saturation of hemoglobin with O_2, percent

Qualifying Symbols

a	Arterial Ca_{O_2} = concentration of O_2 in arterial blood, ml of O_2 per 100 ml of blood
c	Capillary Cc_{O_2} = concentration of O_2 in capillary blood, ml of O_2 per 100 ml of blood
c′	Pulmonary end-capillary Pc'_{O_2} = partial pressure of O_2 in end-capillary blood, mmHg
v	Venous Cv_{O_2} = concentration of O_2 in venous blood, ml of O_2 per 100 ml of blood
$\bar{v}$	Mixed venous $C\bar{v}_{O_2}$ = concentration of O_2 in mixed venous blood, ml of O_2 per 100 ml of blood

VENTILATION AND LUNG MECHANICS TESTS AND SYMBOLS

Static Lung Volumes*

Primary Compartments

RV	Residual volume. Volume of air remaining in the lungs after maximum expiration.
CV	Closing volume. Volume of air expired from the onset of airways closure to residual volume. May be expressed as a fraction of VC: CV/VC, %.
ERV	Expiratory reserve volume. Maximum volume of air expired from the resting end-expiratory level.
V_T	Tidal volume. Volume of air inspired or expired with each breath during quiet breathing. When tidal volume is used in gas-exchange formulations, this symbol is used.
IRV	Inspiratory reserve volume. Maximum volume of air inspired from the end-tidal inspiratory level.

* Expressed as BTPS.

Lung Capacities*

IC	Inspiratory capacity. The sum of IRV and TV.
IVC	Inspiratory vital capacity. Maximum volume of air inspired from the point of maximum expiration, i.e., from RV
VC	Vital capacity. Maximum volume of air expired from the point of maximum inspiration, i.e., from TLC
FRC	Functional residual capacity. Sum of RV and ERV. FRC is the volume of air remaining in the lungs at the resting end-expiratory position.
TLC	Total lung capacity. Volume of air in the lungs after maximum inspiration. Also, the sum of all volume compartments of the lungs.
RV/TLC,%	Residual volume to total lung capacity ratio, expressed as a percentage.
CC	Closing capacity. Closing volume plus residual volume, may be expressed as a percentage of TLC: CC/TLC, %.

Forced Respiratory Maneuvers During Spirometry†

FVC	Forced vital capacity. The maximum volume of air forcibly expired from total lung capacity.
FIVC	Forced inspiratory vital capacity. Maximum volume of air forcibly inspired starting from residual volume.
FEV*t*	Timed forced expiratory volume. Volume of air expired in a specified time in the course of the forced vital capacity maneuver. FEV_1 = volume of air expired during the first second of the FVC.
FEV*t*/FVC, %	Ratio of time forced expiratory volume to forced vital capacity, expressed as a percentage.
FEF*x*	Forced expiratory flow, related to some portion of the FVC curve. Modifiers refer to the amount of the FVC that has been expired at the time of measurement.
$FEF_{200-1200}$	Forced expiratory flow between 200 and 1200 ml of the FVC (formerly called the maximum expiratory flow rate).
FEF_{25-75}	Forced expiratory flow during middle half of the FVC (formerly called the maximum midexpiratory flow rate or MMEF).

* Combinations of volumes for practical purposes.
† All values at BTPS.

PEF	Peak expiratory flow. Highest value for expiratory flow.
$\dot{V}_{max_x}$	Maximum flow when x percent of the FVC has been expired. $\dot{V}_{max_{75}}$ = flow (instantaneous) when 75 percent of the FVC has been expired.
FIFx	Forced inspiratory flow. As in the case of the FEF, appropriate modifiers designate the volume at which flow is being measured. Unless otherwise specified, the volume qualifiers indicate the volume inspired from RV at the point of measurement. FIF_{25-75} = forced inspiratory flow during the middle half of the FIVC.
MVV	Maximum voluntary ventilation. Volume of air exhaled during maximum breathing efforts within a specified time period. If breathing frequency is set by the examiner, it is indicated by the qualifier. MVV_{60} = MVV at a breathing frequency of 60 per minute.
PImax	Maximum inspiratory pressure. The maximum pressure generated during an inspiratory effort.
PEmax	Maximum expiratory pressure. The maximum pressure generated during an expiratory effort.

Measurements Related to Ventilation

$\dot{V}_E$	Expired volume per minute (BTPS)
$\dot{V}_I$	Inspired volume per minute (BTPS)
$\dot{V}_{CO_2}$	Carbon dioxide production per minute (STPD)
$\dot{V}_{O_2}$	Oxygen consumption per minute (STPD)
R	Respiratory exchange ratio, the ratio of CO_2 output to O_2 intake in the lungs
$\dot{V}_A$	Alveolar ventilation per minute (BTPS)
$\dot{V}_D$	Ventilation per minute of the physiological dead space (BTPS) defined by the equation $\dot{V}_D = \dot{V}_E \frac{Pa_{CO_2} - P_{E_{CO_2}}}{Pa_{CO_2} - P_{I_{CO_2}}}$
V_D	Volume of the physiological dead space, calculated as $\dot{V}_D/f$.
V_D/V_T	Ratio of dead space to tidal volume. The fraction, usually expressed as a percentage, of each breath that does not contribute to CO_2 elimination.

Mechanics of Breathing*

Pressure Terms

Paw	Pressure at any point along the airways
Pao	Pressure at the airway opening
Ppl	Pleural pressure
P_A	Alveolar pressure
Pbs	Pressure at the body surface
Pes	Esophageal pressure: used to estimate Ppl
P_A–Pbs	Transthoracic pressure
P_A–Ppl	Transpulmonary pressure
Ppl–Pbs	Pressure difference across the chest wall
Paw–Ppl	Transbronchial pressure, estimated as difference between airway and pleural pressures.

Flow-Pressure Relationships†

R	General symbol for frictional resistance, defined as the ratio of pressure difference to flow.
Raw	Airway resistance, calculated from pressure difference between airway opening (Pa_o) and alveoli (P_A) divided by the airflow, $cmH_2O/L/s$.
R_L	Total pulmonary resistance, measured by relating flow-dependent transpulmonary pressure to airflow at the mouth.
Rti	Tissue resistance (viscous resistance of lung tissue), calculated as difference between R_L and Raw.
Rus	Resistance of the airways on the upstream (alveolar) side of the point in the airways where intraluminal pressure equals Ppl, i.e., equal pressure point. Measured during a forced expiration.
Rds	Resistance of the airways on the downstream (mouth) side of the point in the airways where intraluminal pressure equals Ppl, i.e., equal pressure point. Measured during a forced expiration.
Gaw	Airway conductance, reciprocal of Raw.
Gaw/V_L	Specific conductance, airway conductance, expressed per liter of lung volume at which Gaw is measured.

*All pressures expressed relative to ambient pressure unless otherwise specified.

†Unless otherwise specified, resistance measurements are assumed to be made at FRC.

Volume-Pressure Relationships

C — General symbol for compliance of the lungs, chest wall, or total respiratory system. Volume change per unit change in applied pressure. For the lungs, the applied pressure is the pressure difference across the lungs, or transpulmonary pressure, Pao–Ppl; for the chest wall, the applied pressure is the transthoracic pressure, Ppl–Pbs; for the entire respiratory system, the applied pressure is Pao–Pbs.

C_L — Lung compliance. Value for the volume change divided by the transpulmonary pressure.

Cw — Chest wall compliance. Value for the volume change divided by the transthoracic pressure.

Cdyn — Dynamic compliance. Value for compliance determined at time of zero gas flow at the mouth during uninterrupted breathing. The respiratory frequency appears as a qualifier. $Cdyn_{40}$ = dynamic compliance at a respiratory frequency of 40 per minute.

Cst — Static compliance, value for compliance determined on the basis of measurements made during a period of zero airflow.

C/V_L — Specific compliance. Compliance divided by the lung volume at which it is determined, usually FRC.

Pst — Static pulmonary pressure at a specified lung volume.
Pst_{TLC} = static recoil pressure of the lung measured at TLC (maximum recoil pressure)

DIFFUSING CAPACITY TESTS AND SYMBOLS

D_Lx — Diffusing capacity of the lung expressed as volume (STPD) of gas (x) uptake per minute per unit alveolar-capillary pressure difference for the gas used. A modifier can be used to designate the technique:

D_{LCO}/sB = Single-breath CO diffusing capacity

D_{LCO}/ss = Steady-state CO diffusing capacity

D_M — Diffusing capacity of the alveolar-capillary membrane (STPD).

θ — Reaction rate coefficient for red blood cells. Determined as the volume of gas (stpd) that will combine per minute with 1 unit volume of blood per unit of gas tension. If the specific gas is not stated, θ is assumed to refer to CO and is a function of existing O_2 tension.

V_C — Capillary blood volume. This should be Qc for consistency with other symbols, but Vc is entrenched in the literature. In the equation that follows for $1/D_L$, Vc represents the effective pulmonary capillary blood volume, i.e., capillary blood volume in intimate association with alveolar gas.

$1/D_L$ — Total resistance to diffusion, including resistance to diffusion of test gas across the alveolar-capillary membrane, through plasma in the capillary, and across the red blood cell membrane (1/Dm), the resistance to diffusion with the red cell arising from the chemical reaction of the test gas and hemoglobin ($1/\theta Vc$), according to the formulation

$$\frac{1}{D_L} = \frac{1}{D_M} + \frac{1}{\theta Vc}$$

D_L/V_A — Diffusing capacity per unit of alveolar volume. D_L is expressed STPD, and V_A is expressed in liters, BTPS.

BLOOD GAS SYMBOLS

Symbols for these values are readily composed by combining general symbols. Some examples include the following:

Pa_{CO_2} — Arterial CO_2 tension, mmHg

Sa_{O_2} — Arterial O_2 saturation, percent

CcO_2 — Oxygen content of pulmonary end-capillary blood, ml of O_2 per 100 ml of blood

$(A\text{-}a)Po_2$ — Alveolar-arterial difference in the partial pressure of O_2, mm Hg

$Ca_{O_2}–C\bar{v}_{O_2}$ — O_2 content difference between arterial and mixed venous blood (arteriovenous O_2 difference), ml of O_2 per 100 ml of blood

PULMONARY SHUNT SYMBOLS

$\dot{Q}_s$ — Flow of blood via shunts. This is usually determined as percent of cardiac output ($\dot{Q}$) while breathing 100% O_2, according to the equation

$$\frac{\dot{Q}_s}{\dot{Q}} = \frac{CcO_2 - CaO_2}{CcO_2 - C\bar{v}O_2} \times 100$$

where
CcO_2 = O_2 content of end-capillary blood
CaO_2 = O_2 content of arterial blood
$C\bar{v}o_2$ = O_2 content of mixed venous blood
